Management of Toxicity Induced by Anti-EGFR Therapy in Metastatic Colorectal Cancer

Published online: 8 June 2013

Abstract Use of anti-epidermal growth factor receptor (anti-EGFR) agents has yielded significant advances in the treatment of patients with metastatic colorectal cancer. In fact these drugs, which include the monoclonal antibodies cetuximab and panitumumab, can be delivered both as a single agent and in combination with chemotherapy, achieving better survival and quality of life and in some cases also resectability of metastases. However, these agents can result in the development of toxicities that are usually different from those observed with chemotherapy alone. For the management of these adverse effects, proper knowledge is mandatory. Skin toxicity is the most frequent adverse effect. Other toxicities can be observed, such as hypomagnesemia, gastrointestinal toxicity, and thromboembolic events. Severe infusion reactions can be life-threatening. For these reasons a review of anti-EGFR-drug-related toxicity is useful for clinical practice.

Introduction

Colorectal cancer (CRC) is one of the leading causes of cancer-related deaths. In recent decades the integration of different therapeutic strategies, such as surgery, radiation therapy, and systemic therapy, has yielded improved overall survival and quality of life. Systemic therapy includes both chemotherapeutic regimens and targeted drugs. However, the introduction of new targeted drugs has resulted in the development of specific toxicities and a radically different tolerability profile compared with chemotherapy. Because cytotoxic agents are used for cancer therapy, all early-phase studies were designed to identify the maximum tolerated dose and the dose-limiting toxicities. These parameters are based on the close relationship between the dose and the toxicity frequency and magnitude. In contrast, the side effects caused by targeted drugs seem to be influenced by the dose, but a clear relationship has not been defined.

The anti-epidermal growth factor receptor (anti-EGFR) agents used in CRC treatment are the monoclonal antibodies cetuximab and panitumumab. For these drugs, the commonest side effects are related to the expression of EGFR in normal tissues. Skin, the gastrointestinal tract, and the kidney are all tissues where EGFR is normally expressed.

Since skin rash, diarrhea, and hypomagnesemia, which arise during anti-EGFR treatment, seem to be different from those induced by chemotherapy, this review gathers the most recent knowledge regarding this topic. Other side effects such as pulmonary and thromboembolic events are rare with these

agents, even though they are more associated with other EGFR inhibitors such as tyrosine kinase inhibitors, which are used in treatment of other malignancies. For each toxicity, we report a clinical description, the known pharmacological mechanisms, and the management. A summary of the biological mechanism of the anti-EGFR inhibitors is also included.

Skin Toxicity

Skin toxicity is the commonest side effect observed during the treatment with anti-EGFR agents. It includes several signs and symptoms, such as papulopustular rash, xerosis/fissures, pruritus, paronychia, hair changes, and mucositis. The incidence ranges from 30 % for mucositis to 80 % for skin rash (Fig. 1). Although less than 20 % of patients have severe symptoms [1], skin toxicity is visible, often causes physical and emotional discomfort, resulting in a significant impact on quality of life [2••], and may lead to dose reduction in 60 % of patients or discontinuation of treatment in 32 % of them [3], with subsequent worse clinical outcomes and an increase of management costs.

Pharmacological Mechanisms

The exact mechanism of skin toxicity related to EGFR inhibitors is not clearly understood. The coincident inhibition of receptor activity in tissue that depends on EGFR signaling for normal functions seems to play a critical role in rash development, resulting in impairment of keratinocyte growth and differentiation and increased apoptosis [4]. There is some evidence in the literature that these agents may alter the immune system. More recently, a preclinical model showed the role of tumor necrosis factor α (TNF-α) and interleukin-1 in the development of skin rash associated with EGFR inhibitors, and it suggested a possible therapeutic role for anti-TNF-α agents [5]. Several studies have aimed to identify histological and immunohistochemical features of the skin during therapy with EGFR inhibitors, showing decreased phosphorylated Akt/phosphatidylinositol 3-kinase pathway activation. This action has a key role in cell survival and keratinocyte differentiation [6] in both the epidermis and the dermis, and also upregulation of p27 in the epidermis of patients treated with cetuximab, probably leading to growth inhibition of basal keratinocytes [7]. Moreover, treatment with EGFR inhibitors induces early differentiation by upregulating the expression of terminal differentiation markers (keratin 1 and keratin 10) [8]. Another mechanism described during keratinocyte differentiation is the activation of signal transducer and activator of transcription 3 in the basal layer of the epidermis [9], but there are no data regarding the association between this finding and the skin toxicity caused by EGFR inhibitors. This could result in greater alterations in both the epidermis and follicles such as atrophy, which is seen in

Fig. 1 Examples of cutaneous toxicities: in the clockwise direction, overgrowth of eyelashes, paronychia, skin lesions on the back, and facial rash

87.5 % of patients treated with cetuximab and in 50 % of patients treated with panitumumab, but also dyskeratosis, dysmaturation, and suppurative folliculitis are quite frequent, whereas dermal inflammatory infiltrate is less frequent with cetuximab than with panitumumab. This is probably due to the lower levels of CD68, CD54, and CD4 seen in these patients [10•]. In addition, EGFR inhibitors induce lower expression of cytoskeletal proteins—vinculin and α_1-actinin—reducing migration and invasion [11], whereas in keratinocytes they increase chemokine expression by upregulating extracellular-signal-regulated kinases 1 and 2. This process, resulting in enhanced skin inflammation [12], is probably not mediated by the arachidonic acid/prostaglandin pathway, with recruitment of leukocytes that release enzymes, causing apoptosis and tissue damage, which is responsible for clinical cutaneous manifestations. These clinical findings are also know as PRIDE (papulopustules and or paronychia, regulatory abnormalities of hair growth, itching, and dryness due to EGFR inhibitors) [13].

Clinical Aspects

Clinical signs and symptoms may be divided into three categories depending on their target: inflammation of the pilosebaceous follicle, represented by skin rash associated with EGFR inhibitors, which occurs at an early stage and is frequent; alteration of the skin barrier, which is primarily responsible for xerosis, fissures, and pruritus, which are frequent and delayed; and lesions of the skin appendages (paronychia, pyogenic granuloma, hair changes), which are delayed and less frequent [14•].

Skin rash is the commonest dermatological toxicity, and affects 85 % of patients treated with cetuximab [15] and 90 % of patients treated with panitumumab [16]. It usually develops early during the first week or first month of therapy. Thereafter, it tends to improve spontaneously despite continued treatment. It is often confined to seborrheic areas (rich in sebaceous glands): the mid-facial region, excluding the periocular region and the upper trunk (typically V-shaped), often extending to retroauricular areas, the scalp, the nape of the neck, shoulders, and even the pubis. In some patients it may involve the extremities [17, 18]. Clinically, it is characterized by a monomorphic papulopustular eruption which consists of erythematous follicular papules that evolve into pustules, sometimes coalescent, thus forming inflammatory plaques, which may become infected, usually with *Staphylococcus aureus*, and form yellow crusts [7]. However, evolution from pustules to crust formation is not necessarily a sign of infection, but corresponds to the drying out of the exudates on the surface of the epidermis. Comedones and hyperseborrhea do not occur [19]. Histological analysis reveals a superficial inflammatory cell infiltrate around the follicular infundibulum. Later, an influx of neutrophils causes the rupture of the follicle and the epithelial lining [20]. This histological picture corresponds to superficial aseptic neutrophilic suppurative folliculitis associated with atrophy of the stratum corneum. The pustular appearance and the clinical and histological differences suggest that this rash is not acne. So terms such as "acneiform" and "acne-like" should be avoided.

Skin xerosis is present in up to 35 % of patients receiving EGFR inhibitor therapy. Unlike skin rash, it generally has a late onset after around 30–60 days or more but persists throughout treatment with EGFR inhibitors. It manifests itself in the form of dry, squamous skin, often accompanying or following papulopustular rash. The xerosis may evolve to chronic asteatotic eczema (in one third of cases), and may be associated with painful fissures at the fingertips, palms, or knuckles and on the soles, which may become infected. Some patients experience dryness of the vagina and perineum, causing discomfort [17]. In physiopathological terms, skin xerosis seems to be linked to the abnormal differentiation of keratinocytes, which is associated with a reduction in the synthesis of loricrin—a protein located in the corneocyte envelope and which plays a key role in maintaining the integrity of the skin barrier [21].

Pruritus occurs in about half of all patients treated with EGFR inhibitors, having a relatively strong impact on their health-related quality of life. Generally, it is associated with papulopustular rash, but can also occur without rash, as a consequence of dry skin [22]. Pruritus caused by the chronicity of xerosis can also continue by an increase in the number of dermal mast cells—histamine-releasing cells—identified during EGFR inhibitor treatment [23].

Nail and periungual toxicity occur in 10-20 % of patients in general after 2 months or more of EGFR inhibitor therapy and consist mainly of nail fold inflammation (paronychia) characterized by a red, warm, painful border around the nail, sometimes associated with serous discharge. Periungual pyogenic granuloma-like lesions may complicate paronychia, leading to pain and functional limitations. Also onycholysis or onychodystrophy may result as a consequence of nail matrix inflammation [22]. This clinical presentation may be aggravated by infection due to *S. aureus*, Gram-negative bacilli, or more rarely, *Candida albicans*. It must be suspected if the patient experiences intense, pulsatile pain and a buildup of pressure and if crusts appear [24]. The other ungual anomalies reported refer to the stoppage or slowing of nail growth, fine, fragile, or brittle nails, and onycholysis (detachment of the ungual bed of a distolateral origin) [13].

Hair changes usually occur 2-5 months after the start of treatment. They occur in approximately 50 % of patients treated with EGFR inhibitors, and may include trichomegaly and hypertrichosis of eyelashes, often presenting as facial hirsutism, and also the texture of the facial and scalp hair can change and become wavy, fine, and brittle. Slower growth and alopecia are regularly observed. They generally resolve spontaneously after discontinuation of therapy [17].

Finally, the commonest oral complication is mucositis, presenting as broad areas of erythema or aphthous-like stomatitis [25], whereas severe mucositis and other oral side effects are infrequent.

Management of Skin Toxicity

Although skin toxicity is the most frequent side effect and impacts a very large number of patients with CRC treated with EGFR inhibitors, there are only a few controlled studies in the literature to guide best practice for management. Mostly they are based on the experience of clinicians, case reports, and nonrandomized studies with a small sample size. In the absence of definitive evidence from randomized trials, the Multinational Association of Supportive Care in Cancer (MASCC) has recently reviewed pertinent studies in the literature using established criteria in order to develop first-generation recommendations for dermatological toxicities associated with EGFR inhibitors [22]. An group of Italian experts has presented recommendations for the management of each type of skin toxicity during treatment with cetuximab, on the basis of a review of literature, to improve compliance and outcomes of patients treated with EGFR inhibitors [26].

The reactive treatment of skin rash depends on toxicity severity, evaluated by version 4.0 of the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events (CTCAE) scale, which is the reference severity scale used in clinical trials to classify cutaneous side effects related to EGFR inhibitors. For grade 1 (characterized by papulopustules or symptom-free erythema), no specific treatment is recommended, whereas grade 2 (characterized by eruption with papules or pustules covering less than 50 % of the body surface, with symptoms that do not interfere with daily activities) can be treated with topical antibiotherapy (clindamycin 1 % gel, erythromycin 3 % gel, or metronidazole 1 % gel) two times a day until it improves to grade 1, and for the pustule-prevalent type, orally administered tetracycline (minocycline 100 mg/day, doxycycline 100 mg/day) can be used for 4 weeks. For grade 3 toxicity (characterized by eruption with papules or pustules covering more than 50 % of the body surface, with symptoms that interfere with daily activities) it is recommended to interrupt treatment for less than 21 days and if no improvement occurs to discontinue therapy. Moreover, topical treatment as for grade 2 should be used together with systemic treatment with orally administered tetracycline for 4 weeks and oral corticosteroids (prednisone 0.5 mg/kg) for up to 10 days. For nonresponsive and grade 4 patients (generalized rash or severe symptoms that require emergency treatment), systemic treatment with an oral retinoid (isotretinoin 0.3-0.5 mg/kg), intravenous corticosteroids, intravenous antibiotics (amoxicillin/clavulanic acid, gentamicin), intravenous antihistamines, and hydration or hospitalization can be considered. However, a new classification system specifically for side effects related to EGFR inhibitors has been put forward by a group of experts, the MASCC, and is based on the severity of local involvement of folliculitis and not on the degree of extension [27]. A recent prospective study comparing this classification system (MESTT) with version 4.0 of CTCAE has shown that the correlation is excellent for rash, pruritus, xerosis, onycholysis, and alopecia, but there is an increase in toxicity grade with the MESTT classification for paronychia [28•]. Although the MESTT classification seems to be more precise, it is also more difficult to put into daily practice. Moreover, it has still to be validated. In contrast, even though it is not yet sufficiently appropriate for assessing the skin toxicity of EGFR inhibitors, version 4.0 of CTCAE has already been validated and is widely used in current practice.

Interesting data have been presented on the beneficial effect of a vitamin K_1 cream in prevention and treatment of skin rash induced by EGFR inhibitors. A reduction of the severity of skin rash related to EGFR inhibitors to grade 1 in 2.3 weeks [29], a lower incidence of skin rash of all grades, and the absence of severe forms when vitamin K_1 cream was used for prophylaxis were reported [30]. All published reports are, however, based on studies without a control group.

In the prophylactic treatment, 1 % hydrocortisone combined with moisturizer sunscreen and 100 mg minocycline twice daily for the first 6 weeks or 100 mg doxycycline twice daily for the first 8 weeks are recommended. This is supported by randomized phase III trials which demonstrated a significant decrease of skin rash severity [31, 32]. A recent phase II randomized trial [33•] comparing preemptive skin toxicity therapy with reactive treatment in 115 patients with CRC treated with panitumumab combined with irinotecan or irinotecan plus infusional 5-fluorouracil/leucovorin (FOLFIRI) has shown a significant reduction of approximately 50 % in the incidence of toxicities greater than grade 2 in favor of the preemptive group versus the reactive group [29 % vs 62 %; hazard ratio (HR) 0.3]. This preemptive strategy had no impact on the efficacy of the antitumoral treatment. There were no significant differences in overall response rate, disease control rate, and median progression-free survival (PFS) (4.7 months vs 4.1 months; HR 1). On the basis of the high frequency of skin rash and the early development during treatment with EGFR inhibitors, preventive/prophylactic management can be recommended [22].

No randomized trials studying the prevention or treatment of skin xerosis are in progress. Preventive strategies are important, including the use of tepid water, bath oils, or mild moisturizing soaps without fragrances for bathing. It is also important to avoid alcohol-containing lotions and direct sun exposure [34]. Moderate xerosis may be treated using moisturizing and emollient creams which contain urea, colloid oatmeal, or ammonium lactate and lactic acid for scaly areas. For severe xerosis, topical steroid creams may be necessary

[35, 36]. If there are fissures, thick moisturizing or zinc oxide creams may be applied. Steroid tape and hydrocolloid dressing are recommended for painful erythematous areas [37].

Even though there are no clinical trials in the literature evaluating treatment of pruritus induced by EGFR inhibitors, current guidelines recommend nonsedating second-generation antihistamines as a first approach, and an antiepilectic agent such as pregabalin or gabapentin as second-line treatment. Recent evidence has shown the efficacy of aprepitant in reducing erlotinib-induced pruritus [38], but no evidence exists for other EGFR inhibitors.

Paronychia is a difficult side effect to treat and mostly occurs after several months of treatment. There are no randomized trials investigating treatment of paronychia. Recommendations are based on experience, expert opinion, and case reports. It is very important to minimize periungual trauma (wearing comfortable shoes and avoiding aggressive pedicure), decrease inflammation, and prevent superinfection (use of topical corticosteroids and an anti-inflammatory dose of tetracycline is recommended) [39–46].

In the management of hirsutism, topically administered eflornithine cream has been studied in a randomized clinical trial. It was well tolerated and resulted in a significant improvement of quality of life [47]. Minoxidil has been found to be effective in treating nonscarring alopecia. Topically administered hydrocortisone (0.2 %), steroid shampoo, and class 1 steroid lotions [19] and mild shampoo followed by antibiotic spray have recently been reported to be effective in prevention and management aimed at reducing inflammation in scarring alopecia [48] .

Finally, the management of mucositis induced by EGFR inhibitors is based on the MASCC guidelines. These recommend assessing the oral mucosa prior to and during treatment. Mucositis-associated pain is aggressively treated with topical and systemic analgesics and sometimes opioids. Moreover, minocycline and doxycycline may be indicated for management of oral aphthous lesions [49]. Specific treatment is needed if specific oral infections such as candidiasis, herpes virus reactivation, and mucositis are diagnosed.

In conclusion, skin toxicity is a common adverse effect of EGFR-targeted agents. Current data indicate that both the onset and the intensity of rash are related to drug exposure, although the cause of rash remains unclear. Skin toxicity does not affect all patients and there is a high level of interpatient variability. This could be due to the methods used to assess and categorize rash. Susceptibility to both rash and the pharmacological effects of EGFR-targeted agents could be linked to polymorphic variations in the *EGFR* gene [1].

Relationship Between Skin Rash and Efficacy

Several studies have investigated the relationship between rash and clinical outcome with both cetuximab and panitumumab. Patients with metastatic CRC who developed skin rash during treatment with EGFR inhibitors had a better outcome than those who had grade 0 rash. Particularly, Saltz et al. [50] reported that 19.25 % of patients treated with cetuximab in combination with irinotecan had no rash and a median survival of 4.1 months, compared with 6.2 months for those with grade 1 rash, 10.5 months for those with grade 2 rash, and 14.9 months for those with grade 3 rash (no rash vs grade 3 rash, $p<0.0001$). Similar results were observed in patients treated with cetuximab alone [51]. In a randomized phase II trial of cetuximab plus irinotecan versus chemotherapy alone, 9.4 % of patients receiving the experimental treatment developed grade 3 rash, compared with 5.2 % of patients in the control arm. In addition, a higher response rate and median survival was associated with the severity of rash [52]. The EVEREST trial is based on this evidence, and showed a strong association between skin rash and clinical outcome in patients with metastatic CRC receiving cetuximab treatment (and also the reported relationship between rash severity and drug dose exposure) [1, 24, 38, 53]. The EVEREST trial investigated the effect of cetuximab dose escalation in those who developed no or mild skin reaction after 21 days of treatment with irinotecan plus cetuximab at a standard dose. Dose escalation was associated with higher intensity of rash of grade higher than 2 (59 % vs 38 %), and higher disease control rate (70 % vs 58 %) for K-Ras wild-type patients compared with the standard dose. This effect suggests that cetuximab dose escalation improves the efficacy of therapy in patients with no or minimal skin rash [54]. Also for panitumumab a significant relationship between skin rash severity and clinical outcome has been reported. Skin rash was observed in about 90 % of patients with metastatic CRC treated with panitumumab compared with 9 % of patients in the best support group [16]. Among patients in the panitumumab arm, 86 % of responders had a maximum skin rash severity of grade 2–4, and the remaining 14 % of responders had a grade 1 rash. PFS and overall survival were better for patients with grade 2–4 rash than for patients with grade 1 rash (PFS HR 0.62; overall survival HR 0.59). A subsequent trial which considered the K-Ras mutation status of patients confirmed the association between skin rash severity as measured by both the CTCAE grading system and dermatology life quality index scores and PFS, overall survival, disease-related symptoms, and health-related quality of life only for K-Ras wild-type patients treated with panitumumab, and not for the mutant K-Ras group [55]. Although skin rash is a marker of clinical benefit in patients with metastatic CRC treated with EGFR inhibitors, its use as a predictor factor of response in clinical practice has several limitations: it was not possible to select patients who may derive greater benefit from EGFR inhibitor therapy prior to the treatment; moreover, only a subgroup of patients who developed skin rash during EGFR treatment derived a significant survival benefit from therapy, probably because the amount of drug required to cause rash is

less than that required to induce tumor inhibition [56]. Finally, a direct relationship between EGFR blockade and skin rash development could not be the only possible explanation for this clinical association. For example, EGFR polymorphisms might increase the genetic susceptibility of some patients to develop rash and tumor response independently as described by Perea et al. [57]. Skin rash could be considered a factor correlated with a better prognosis rather than a predictor of response. It might be that the occurrence of rash reflects a patient's ability to develop an inflammatory reaction in response to damage caused by EGFR inhibitors in the skin, irrespective of the effect of EGFR inhibition in the tumor. Therefore, since our understanding of cause of rash remains limited, more studies on this are required.

Hypomagnesemia

Hypomagnesemia is a frequent adverse event (often ignored in many studies) reported during treatment with EGFR inhibitors, both with cetuximab (Erbitux®; ImClone Systems, New York, NY, USA) and with panitumumab [58]. It has not been described with small molecules targeting the EGFR pathway, such as gefitinib and erlotinib. It can be considered as an antibody-specific phenomenon. Schrag et al. [59] first reported on a patient with cetuximab-induced hypomagnesemia associated with significant clinical symptoms as fatigue and paresthesias. A recent meta-analysis [60] revealed that 36.5 % of patients treated with cetuximab for various cancers had hypomagnesemia of any grade, and 5.6 % had grade 3–4 hypomagnesemia. A similar result can be observed in the meta-analysis of Petrelli et al. [61], which included only prospective randomized phase III trials comparing cetuximab or panitumumab with standard chemotherapy or best supportive care. It showed a significantly higher risk of developing hypomagnesemia in the population treated with EGFR inhibitors (relative risk 5.83). Finally, the meta-analysis of Nie et al. [62] also reported a significantly higher incidence of severe hypomagnesemia (grade 3–4) in patients with metastatic CRC treated with the EGFR inhibitors cetuximab and panitumumab compared with standard chemotherapy (27.2 % vs 5.6 %; odds ratio 6.73).

Pharmacological Mechanism

The mechanism behind this toxicity has been described by Groenestege et al. [63]. EGFR inhibitors are strongly expressed in the kidney, particularly in the ascending limb of the loop of Henle, where 70 % of filtered magnesium is reabsorbed. EGFR blockade may interfere with magnesium transport, provoking renal wasting. The blockade of EGFR in the nephron would reversibly impair the function of the protein TRPM6, a member of the transient receptor potential family of the cation channels localized along the apical membrane of the loop of Henle and the distal convoluted tubule (where EGFR is overexpressed). This is involved in active transport of extracellular magnesium [64, 65]. Furthermore, Tejpar at al. [66] showed using 24-h urine analysis and intravenous magnesium load test efficacy that patients treated with monoclonal antibody EGFR inhibitors had defects in renal magnesium reabsorption. However, there is no direct evidence to support this hypothesis. The effects of EGFR blockade on magnesium absorption from the gut (where EGFR and TRPM6 are expressed) cannot be excluded. The same hypothesis of "renal tubular damage" was previously used to explain the phenomenon of "hypomagnesemic hypocalcemia," which was subsequently attributed to parathyroid hormone unresponsiveness in the presence of low serum magnesium levels [67]. According to this hypothesis, hypocalcemia is a secondary effect of low serum magnesium levels via peripheral blockade of parathyroid hormone. Correction of hypomagnesemia would restore parathyroid hormone responsiveness, resulting in a restoration of the equilibrium [68]. Finally, a homolog of TRPM6 protein, TRPM7, has recently been associated not only with magnesium homeostasis, but also with CRC pathogenesis and tumor growth [69]. This might explain a possible linkage between hypomagnesemia related to EGFR inhibitors and tumor progression, which needs to be explored in further studies.

Clinical Aspects

Hypomagnesemia may be divided into different clinical severity classes according to CTCAE version 4.0. The hypomagnesemia observed during treatment with EGFR inhibitors is mostly grade 1–2. Patients are often completely asymptomatic or have minimal symptoms such as fatigue. High-grade hypomagnesemia (grade 3, magnesium concentration between 0.7 and 0.9 mg/dl; grade 4, magnesium concentration below 0.7 mg/dl) has been reported in 10–15 % of patients treated with cetuximab, and in 3–6 % of patients treated with panitumumab [16]. The respective risk seems to be associated with the duration of treatment (6 %, 23 %, and 47 % in patients receiving cetuximab treatment for less than 3 months, for 3-6 months, and for more than 6 months, respectively) [68]. Severe hypomagnesemia is generally associated with nonspecific symptoms such as irritability, paresthesias, somnolence, confusion, temporospatial disorientation, and severe fatigue. These symptoms could easily be attributed to the underlying tumor or to previous/concomitant chemotherapy [70]. Magnesium is an important component of GTPase and a cofactor for Na/K-ATPase, adenylyl cyclase, and kinases. As a result, severe hypomagnesemia can induce cardiac arhythmia, coronary artery vasospasm, and sudden death. Appropriate and aggressive replacement of magnesium is recommended [71].

Management

Treatment of severe hypomagnesemia consists of intravenous supplementation of magnesium at doses of 6–10 g $MgSO_4$ daily or two to three times a week. Oral supplementation is mostly insufficient. Magnesium supplementation also results in normalization of serum calcium levels. Discontinuation of EGFR inhibitor therapy led to the resolution of hypomagnesemia in all cases [68]. However, in all patients receiving EGFR inhibitor treatment, magnesium levels should be monitored every 4-8 weeks until 4-8 weeks after the last therapy.

Relationship Between Toxicity and Efficacy

Some trials explored the relationship between hypomagnesemia related to EGFR inhibitors and the clinical efficacy of therapy, showing conflicting results. A recent retrospective analysis [72] of 68 patients with metastatic CRC treated with cetuximab and irinotecan showed a higher response rate, a longer time to progression, and longer overall survival in 25 patients, with more than 20 % decrease in magnesium levels compared with those patients with minor decrease of serum magnesium levels during treatment (response rate 64 % vs 25.6 %, $p=0.04$; time to progression 6 months vs 3.6 months, $p=0.0001$; overall survival 10.7 months vs 8.9 months, $p=0.021$). A similar result was observed in a subsequent trial [73••] with 143 patients with K-Ras wild-type metastatic CRC receiving the same therapy (irinotecan and cetuximab). Patients with an early decrease of magnesium levels of more than 50 % compared with the basal level had a higher tumor response (55.8 % vs 16.7 %, $P<0.0001$), a longer time to progression (6.3 months vs 3.6 months, $P<0.0001$), and a longer median overall survival (11.0 months vs 8.1 months, $P=0.002$). However, another retrospective analysis [74], exploring the association between hypomagnesemia and outcome in the NCIC Clinical Trials Group/Australasian Gastro-Intestinal Trials Group CO.17 clinical trial, showed that higher grade of hypomagnesemia and greater percent reduction in magnesium concentration at day 28 predict worse survival in patients treated with cetuximab in both the K-Ras wild-type population and the mutant population. We have to conclude that the results are conflicting.

Gastrointestinal Toxicity

Gastrointestinal toxicity is frequent during EGFR inhibitor therapy, including nausea and vomiting, abdominal pain, constipation, and diarrhea. Mostly, mild to moderate grades are reported; in 2-3 % of patients it can be severe. A significantly higher incidence of severe diarrhea (about 15-17 % of patients) has been reported when cetuximab or panitumumab is given in combination with chemotherapy, particularly the irinotecan regimen (Crystal trial [75], 15 % vs 10.5 %; and Peeters trial [76], 14 % vs 10 %), even though the same incidence of grade 3–4 diarrhea was observed with the addition of panitumumab to the combination of leucovorin, 5-fluorouracil, and oxaliplatin [77••]. Finally, a recent meta-analysis [62] showed a significant increase of grade 3–4 adverse events with EGFR inhibitors plus chemotherapy compared with chemotherapy alone in patients with metastatic CRC, including severe diarrhea (62.3 % vs 55.7 %; odds ratio 1.36). At present, the exact mechanism behind this toxicity is not clearly understood. It seems to be associated with blockade of EGFR activity in the gastrointestinal tract. EGFR is overexpressed and plays an important role in cell proliferation and differentiation. It also regulates cation channels involved in active transport of extracellular ions and intestinal secretions. Furthermore, the STEPP trial [33•], which explored the impact of preemptive treatment with doxycycline in patients with metastatic CRC, showed a significant reduction of both skin and nonskin toxicity (such as diarrhea and dehydration) in the preemptive group compared with the reactive control group, suggesting that diarrhea induced by the combination of EGFR inhibitors and chemotherapy has an inflammatory or infectious component that is potentially improved with the use of doxycycline, the only systemic agent administered. However, further studies are needed to evaluate the use of doxycycline for treatment of diarrhea induced by the combination of EGFR inhibitors and chemotherapy. Management of severe diarrhea should be aggressive, including use of loperamide or diphenoxylate, rehydration, and electrolyte replacement. Sometimes hospitalization is required.

Infusion Reaction

Even though infusion reaction is not a frequent side effect observed during EGFR inhibitor therapy, it is considered the most life-threatening side effect. Infusion reactions of any grade have been reported in about 10 % of patients treated with cetuximab and in 4 % of patients treated with panitumumab. Severe reactions (grade 3–4, NCI Common Toxicity Criteria, version 2) occurred in 4 % of patients treated with cetuximab and in less than 1 % of patients treated with panitumumab. In contrast to panitumumab therapy, cetuximab therapy requires premedication prior to infusion. Most severe reactions with cetuximab usually occur a few minutes after the first infusion, but 33 % may be observed after the second dose, and rarely with subsequent therapies. The physiopathological mechanism underlying a severe infusion reaction seems to be associated with IgE-

mediated anaphylaxis, which would affect patients who had IgE antibodies prior to treatment, as shown by Chung et al. [78]. In this trial, IgE antibodies against cetuximab were detected in blood samples of 68 % of patients who had infusion reaction, compared with 2 % of those without reaction ($p<0.001$). Moreover, IgE antibodies were discovered to be specific for α-1,3-galactose, expressed on the Fab portion of cetuximab heavy chain. So subsequent reexposure to the antigen would cross-link the Fab portion of IgE molecules, activating the mast cells or basophils and triggering the release of clinical mediators. A phase III trial of panitumumab showed that neutralizing antibodies were detected in only 1.4 % of patients who had an infusion reaction. The role of these in the pathogenesis of reactions and the effective mechanism behind this have yet to be understood. The management of mild-to-moderate infusion reaction consists of prompt interruption of infusion and antihistamine administration. After remission of clinical symptoms, the treatment can be continued at 50 % of the standard rate. Premedication with antihistamines and steroids is mandatory prior to the first cetuximab therapy, and is strongly recommended prior to subsequent therapies. It seems to reduce the cetuximab-related infusion reactions as shown by Siena et al. [79•]. No premedication is recommended prior to panitumumab therapy. Finally, Nielsen et al. [80] described two patients with grade 2 reaction who were rechallenged with cetuximab. Antihistamines and steroids prior to the next therapy were given without reaction. There are also limited data on rechallenge with an alternative EGFR inhibitor. Rechallenge with panitumumab without any premedication in patients who during infusion developed hypersensitivity reactions to cetuximab (11 cases) and vice versa (two cases) [81] showed no evidence of acute reaction [82, 83].

Pulmonary Toxicity

Adverse pulmonary reactions related to EGFR inhibitors are rare. As discussed already, these drugs can trigger a hypersensitivity reaction during drug infusion. In the case of respiratory symptoms, anaphylactic reactions have been observed with rapid onset of airway obstruction (bronchospasms, stridor, hoarseness). The use of premedication is useful in preventing these episodes. Severe reactions require immediate interruption of infusion and use of bronchodilators, antihistamines, and corticosteroids. The incidence of severe infusion reactions is approximately 3 % with cetuximab and 0.1 % with panitumumab [84].

Another clinical entity described with the use of cetuximab is bronchiolitis [85]. Pulmonary fibrosis has been rarely associated with cetuximab and panitumumab [86].

Conclusions

EGFR inhibition is one of the most important strategies for the treatment of patients with metastatic CRC. The introduction of the monoclonal antibodies cetuximab and panitumumab both as a single agent and in combination with chemotherapy has resulted in improvement of clinical outcomes in this setting. These advantages often include improvement in quality of life, but this effect could be compromised by toxicities related to EGFR inhibitors.

Skin toxicity is the most frequent side effect observed. It seems to be related to the expression of EGFR in the skin tissue. Some strategies are known to prevent and manage its onset. It does not usually require interruption of treatment except for severe manifestations with complications. However, proper management is essential to avoid delay or suspension of treatment and impairment of quality of life. Some studies have highlighted a positive relationship between skin rash and clinical outcomes.

Hypomagnesemia is related to the effect of EGFR function on magnesium reabsorption in the kidney. Its management consists of magnesium supplementation only in severe cases.

Gastrointestinal toxicity, such as diarrhea, and thromboembolic events can be a consequence of chemotherapy alone. In the treatment regimens including the combination of chemotherapy and the anti-EGFR monoclonal antibodies, a synergism has been recognized for this toxicity.

Finally, infusion reactions are rare events, but can be lethal. Cetuximab seems to be more associated with these events than panitumumab. An IgE-mediated anaphylaxis could explain this phenomenon. Management needs to be immediate since the onset is usually sudden. The opportunity of rechallenge after these events is under discussion.

Only in a few cases does the anti-EGFR-drug-related toxicity lead to withholding of treatment. Rarely, it leads to other severe complications. For this reason, proper management of these toxicities is mandatory to achieve full delivery of planned treatment and to not compromise quality of life.
