ABSTRACT

Electroweak measurements performed with data taken at the electron–positron collider LEP at CERN from 1995 to 2000 are reported. The combined data set considered in this report corresponds to a total luminosity of about 3 fb^{-1} collected by the four LEP experiments ALEPH, DELPHI, L3 and OPAL, at centre-of-mass energies ranging from 130 GeV to 209 GeV.

Combining the published results of the four LEP experiments, the measurements include total and differential cross-sections in photon-pair, fermion-pair and four-fermion production, the latter resulting from both double-resonant WW and ZZ production as well as singly resonant production. Total and differential cross-sections are measured precisely, providing a stringent test of the Standard Model at centre-of-mass energies never explored before in electron–positron collisions. Final-state interaction effects in four-fermion production, such as those arising from colour reconnection and Bose–Einstein correlations between the two W decay systems arising in WW production, are searched for and upper limits on the strength of possible effects are obtained. The data are used to determine fundamental properties of the W boson and the electroweak theory. Among others, the mass and width of the W boson, m_W and Γ_W , the branching fraction of W decays to hadrons, $B(W \rightarrow \text{had})$, and the trilinear gauge-boson self-couplings g_1^Z , κ_γ and λ_γ are determined to be:

$$m_W = 80.376 \pm 0.033 \text{ GeV}$$

$$\Gamma_W = 2.195 \pm 0.083 \text{ GeV}$$

$$B(W \rightarrow \text{had}) = 67.41 \pm 0.27\%$$

$$g_1^Z = 0.984^{+0.018}_{-0.020}$$

$$\kappa_\gamma = 0.982 \pm 0.042$$

$$\lambda_\gamma = -0.022 \pm 0.019.$$

Author Lists

The ALEPH, DELPHI, L3, OPAL collaborations have provided the inputs for the combined results presented in this Report. The LEP Electroweak Working Group has performed the combinations. The Working Group consists of members of the four LEP collaborations. The lists of authors from the collaborations follow.

The ALEPH Collaboration

1. Introduction

The electron-positron collider LEP at CERN increased its collision centre-of-mass energy, \sqrt{s} , from the Z pole (LEP-I) up to 209 GeV during its second running phase (LEP-II) from 1995 to 2000. The four LEP experiments ALEPH, DELPHI, L3 and OPAL collected a combined total integrated luminosity of about 3 fb^{-1} in the LEP-II centre-of-mass energy range above the Z pole, 130 GeV to 209 GeV. This large data set explores the new energy regime accessed by LEP-II with high precision, allowing new tests of the electroweak Standard Model of particle physics [1] (SM), and searches for new physics effects at higher mass scales.

Combinations of electroweak measurements performed in electron-positron collisions at Z -pole centre-of-mass energies, at LEP-I and the SLC, are reported in Ref. [2]. Here, the measurements in the electroweak sector of the SM at LEP-II centre-of-mass energies are discussed, including, where necessary, studies of strong-interaction effects. Photon-pair, fermion-pair and four-fermion production processes are analysed and the results are presented in the form of total and differential cross-sections. Final-state interactions between the decay products in W -boson pair production are investigated for signals of colour reconnection and Bose–Einstein correlations. Pair-production of W bosons yields measurements of the mass, total decay width and decay branching fractions of the W boson. Together with other reactions such as single- W , single- Z , $WW\gamma$, Z -pair, $Z\gamma$ and $Z\gamma\gamma$ production, the data sample allows stringent tests of the non-Abelian structure of the electroweak gauge group, by measuring triple and quartic electroweak gauge boson couplings.

1.1. LEP-II data

In a circular accelerator such as LEP, the energy loss of the beam particles due to synchrotron radiation increases with the fourth power of the Lorentz γ factor. In order to push the LEP centre-of-mass energy beyond the Z -pole, the warm copper RF cavities used at LEP-I were replaced by superconducting RF cavities to increase the available RF power. In parallel the LEP-II centre-of-mass energy increased in steps up to a maximum of 209 GeV, reached in 2000, the final year of LEP operation. The centre-of-mass energies and the corresponding integrated luminosities collected per experiment are reported in Table 1.1. For some of the analyses described in this report, the data have been combined in different slices of centre-of-mass energies. About 0.75 fb^{-1} of integrated luminosity was recorded by each LEP experiment, for a total of about 3 fb^{-1} .

Table 1.1

Centre-of-mass energies and integrated luminosities recorded by each experiment at LEP-II.

Year	Mean energy \sqrt{s} (GeV)	Luminosity (pb^{-1})
1995, 1997	130.3	6
	136.3	6
	140.2	1
1996	161.3	12
	172.1	12
1997	182.7	60
1998	188.6	180
1999	191.6	30
	195.5	90
	199.5	90
	201.8	40
2000	204.8	80
	206.5	130
	208.0	8
Total	130–209	745

**Fig. 1.1.** Cross-sections of electroweak SM processes. The dots with error bars show the measurements, while the continuous curves show the theoretical predictions based on the SM.

1.2. Standard-model processes

The various SM processes occurring at high centre-of-mass energies in electron–positron collisions and their cross-sections are shown as a function of the centre-of-mass energy in Fig. 1.1.

Photon-pair production

The photon-pair production process, $e^+e^- \rightarrow \gamma\gamma(\gamma)$, is dominated by QED interactions. The corresponding Feynman diagrams at Born level are shown in Fig. 1.2. Higher-order QED effects play a significant role but the weak interaction is negligible for the present data set. Therefore this reaction is different from the other processes discussed in this report as it provides a clean test of QED, independent of other parts of the SM.

Fig. 1.2. Feynman diagrams for the process $e^+e^- \rightarrow \gamma\gamma$ at the Born level.

Fig. 1.3. Feynman diagrams for the process $e^+e^- \rightarrow f\bar{f}$ at the Born level. For e^+e^- final states additional t -channel diagrams contribute.

Fig. 1.4. Feynman diagrams (CC03) for the process $e^+e^- \rightarrow W^+W^-$ at the Born level.

Fig. 1.5. Feynman diagrams (NC02) for the process $e^+e^- \rightarrow ZZ$ at the Born level.

Fermion-pair production

Pair-production of fermions proceeds mainly via s -channel exchange of a photon or a Z boson as shown in Fig. 1.3. For energies above the Z resonance, QED radiative corrections are very large, up to several 100% of the Born cross-section. This is caused by hard initial-state radiation of photons, which lowers the centre-of-mass energy, \sqrt{s} , of the hard interaction down to values $\sqrt{s'}$ close to the Z mass, called radiative return to the Z . In order to probe the hard interaction at the nominal energy scale \sqrt{s} , cuts are applied to remove the radiative return to the Z and only keep the high- Q^2 events. Further cuts remove non-resonant pair corrections arising from four-fermion production not included in the signal definition.

WW and ZZ production

One of the most important processes at LEP-II consists of pair production of on-shell W bosons as shown in Fig. 1.4. These events allow a determination of the mass and total decay width of the W boson. The non-Abelian nature of the electroweak gauge theory, leading to triple and quartic gauge-boson vertices such as those appearing in the two s -channel WW production diagrams, is studied and the gauge couplings are measured. Each W boson decays to a quark–antiquark pair, hadronising into jets, or to a lepton–neutrino pair, resulting in a four-fermion final state. The WW events are thus classified into fully hadronic, semileptonic and purely leptonic events. At higher centre-of-mass energies, four-fermion final states are also produced via Z -pair production, as shown in Fig. 1.5.

Final-state corrections arising from the interaction between the two W decay systems, such as colour reconnection and Bose–Einstein correlations, may lead to a cross-talk effect. Such an effect potentially spoils the assignment of decay products to decaying weak bosons in terms of four-momentum, with consequences in the measurement of the W -boson mass and width in the all-hadronic channel.

Radiative corrections to W -pair production are particularly interesting as they allow the study of quartic-gauge-boson vertices as shown in Fig. 1.6.

Fig. 1.6. Feynman diagrams for the process $e^+e^- \rightarrow WW\gamma$ and WWZ at the Born level involving quartic electroweak-gauge-boson vertices.

Fig. 1.7. Vector-boson fusion diagrams for the single $W/Z/\gamma$ process at the Born level.

Table 2.1

Simplified phase-space definition for the selection of $e^+e^- \rightarrow \gamma\gamma(\gamma)$ events. DELPHI does not select clusters in the range $[35^\circ, 42^\circ]$, $[88^\circ, 92^\circ]$ and $[138^\circ, 145^\circ]$. OPAL is sensitive to additional clusters up to $|\cos \theta_i| < 0.97$ ($i \geq 3$).

Experiment	Polar angles	Energies	Acollinearity
ALEPH	$ \cos \theta_i < 0.95$	$E_1, E_2 > 0.5 \cdot E_{\text{beam}}$	$\xi_{\text{acol}} < 20^\circ$
DELPHI	$25^\circ < \theta_i < 155^\circ$	$E_1, E_2 > 0.3 \cdot E_{\text{beam}}$	$\xi_{\text{acol}} < 50^\circ$
L3	$16^\circ < \theta_i < 164^\circ$	$E_1 + E_2 > E_{\text{beam}}$	$\xi_{\text{acol}} < 165^\circ$
OPAL	$ \cos \theta_i < 0.93$	$E_1, E_2 > p_z$	–

Four-fermion production

Besides the double-resonant WW and ZZ processes, single-resonant boson production channels such as those shown in Fig. 1.7, as well as non-resonant diagrams also contribute to four-fermion production. Selections are devised to separate the various four-fermion processes, in particular WW , ZZ , single- W and single- Z production. Single- W production is sensitive to the electromagnetic gauge couplings of the W boson, as the t -channel photon exchange diagram dominates over the t -channel Z exchange diagram at LEP-II energies. Bremsstrahlung diagrams with radiation of an on-shell Z boson off an initial- or final-state fermion leg in Bhabha scattering contribute to single- Z production in the form of Zee final states.

2. Photon-pair production

2.1. Introduction

The differential cross-section for the photon-pair production process $e^+e^- \rightarrow \gamma\gamma(\gamma)$ is presented here for centre-of-mass energies above 183 GeV. This process is one of the few channels at LEP energies with negligible contribution from the weak interaction. Therefore it provides a clean test of quantum electrodynamics, QED, at high energies. The combination is based on the publications [3–6].

Section 2.2 gives a short overview on the event selections of the four experiments as far as they are relevant for the determination of the theory uncertainty, which is described in Section 2.3. Also the expected cross-sections from QED and other models are given. In Section 2.4 the combination of the differential cross-section is presented. The total cross-section given in Section 2.5 is derived from the differential cross-section. The results are summarised in Section 2.6.

2.2. Event selection

The topology of this channel is very clean and the event selection, which is similar for all experiments, is based on the presence of at least two energetic clusters in the electromagnetic calorimeters (ECAL). A minimum energy of the two highest-energy ECAL clusters is required. Restrictions are made either on the acollinearity, ξ_{acol} , or on the missing longitudinal momentum, p_z . The cuts and the allowed range in polar angle, θ_i , of the observed clusters are listed in Table 2.1. The clusters are ordered by decreasing energy. In order to remove background, especially from Bhabha events, charged tracks are in general not allowed except when they can be associated to a photon conversion in one hemisphere.

Besides limited coverage of the ECAL, selection cuts to reject events with charged tracks are the main reason for a reduced signal efficiency. The effect of the different cuts depends strongly on the detector geometry. Therefore experimental systematic errors are considered uncorrelated between the experiments.

2.3. Theory

2.3.1. QED born cross-section

The differential cross-section for the QED process $e^+e^- \rightarrow \gamma\gamma$ in lowest order is known since a long time [7]:

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{Born}} = \frac{\alpha^2}{s} \left[\frac{1 + \beta^2 + \beta^2 \sin^2 \theta}{1 - \beta^2 \cos^2 \theta} - \frac{2\beta^4 \sin^4 \theta}{(1 - \beta^2 \cos^2 \theta)^2} \right], \quad (2.1)$$

where \sqrt{s} is the centre-of-mass energy. Since the emitted photons are real, with a vanishing invariant mass, the relevant scale for the fine-structure constant α is zero momentum transfer. In the following the relativistic limit for the velocity of the electron $\beta = p/E \rightarrow 1$ will be used. Since the final-state particles are identical the polar angle θ is defined such that $\cos \theta > 0$ to avoid double counting. This results in a full phase space of $\int d\Omega = 2\pi$.

Higher-order QED corrections are relevant but the lowest-order contribution involving weak couplings is negligible compared to the current experimental precision of about 1%. There is no resonance effect for this process at energies around the Z mass (LEP-I) since a spin-one vector or axial-vector particle cannot couple to two real photons. However, at the W -pair threshold there is a resonance-like effect, since the photons can be radiated off an on-shell W loop, with a dominating contribution from the triangle diagram with $WW\gamma\gamma$ coupling [8]. At such energies, corrections of up to 1.2% are expected for $\cos \theta = 0$. At the energies considered here the corrections are smaller, e.g., for a centre-of-mass energy of 200 GeV they are below 0.2% at all angles, and will be neglected.

2.3.2. Non-QED models

Various models predict deviations from the QED expectation. The simplest ansatz is the introduction of cut-off parameters Λ_{\pm} as used for Bhabha and Møller scattering [9,10]. With this formalism a short range exponential deviation is added to the Coulomb potential resulting in a differential cross-section of the form:

$$\left(\frac{d\sigma}{d\Omega}\right)_{\Lambda_{\pm}} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{Born}} \pm \frac{\alpha^2 s}{2\Lambda_{\pm}^4} (1 + \cos^2 \theta). \quad (2.2)$$

New effects can also be described by effective Lagrangian theory [11]. Here dimension-6 terms lead to anomalous $ee\gamma$ couplings. The resulting deviations in the differential cross-section are similar in form to those for cut-off parameters, but with a slightly different definition of the parameter: $\Lambda_6^4 = \frac{2}{\alpha} \Lambda_{\pm}^4$. Dimension 7 and 8 Lagrangians introduce $ee\gamma\gamma$ contact interactions and result in an angular-independent term added to the Born cross-section:

$$\left(\frac{d\sigma}{d\Omega}\right)_{\Lambda'} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{Born}} + \frac{s^2}{32\pi} \frac{1}{\Lambda'^6}. \quad (2.3)$$

The associated parameters are given by $\Lambda_7 = \Lambda'$ and $\Lambda_8^4 = m_e \Lambda'^3$ for dimension 7 and dimension 8 couplings, respectively.

Theories of quantum gravity in extra spatial dimensions might solve the hierarchy problem since gravitons would propagate in a compactified higher dimensional space, while other Standard Model (SM) particles are confined to the usual $3+1$ space-time dimensions [12]. While in these models the Planck mass M_D in $D = n+4$ dimensions is chosen to be at the electroweak scale, the usual Planck mass M_{Pl} in four dimensions would be $M_{Pl}^2 = R^n M_D^{n+2}$, where R is the compactification radius of the additional dimensions. Since gravitons couple to the energy-momentum tensor, their interaction with photons is as weak as that with fermions. However, the huge number of Kaluza-Klein excitation modes in the extra dimensions may give rise to observable effects. These effects depend on the scale $M_s (\sim M_D)$ which may be as low as $\mathcal{O}(\text{TeV})$. Model dependences are absorbed in the parameter λ which is expected to be of order 1. For this analysis it is assumed that $\lambda = \pm 1$. The expected differential cross-section is given by [13]:

$$\left(\frac{d\sigma}{d\Omega}\right)_{M_s} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{Born}} - \frac{\alpha s}{2\pi} \frac{\lambda}{M_s^4} (1 + \cos^2 \theta) + \frac{s^3}{16\pi^2} \frac{\lambda^2}{M_s^8} (1 - \cos^4 \theta), \quad \lambda = \pm 1. \quad (2.4)$$

Instead of an ordinary electron an excited electron e^* coupling to electron and photon could be exchanged in the t -channel of the process [10,14]. In the most general case $e^*e\gamma$ couplings would lead to a large anomalous magnetic moment of the electron on which strong experimental limits exist [15]. This effect can be prevented by a chiral magnetic coupling of the form:

$$\mathcal{L} = \frac{1}{2\Lambda} \bar{e}^* \sigma^{\mu\nu} \left[gf \frac{\tau}{2} W_{\mu\nu} + g' f' \frac{Y}{2} B_{\mu\nu} \right] e_L + \text{h.c.}, \quad (2.5)$$

where τ are the Pauli matrices and Y is the hypercharge. The model parameters are the compositeness scale Λ and the relative couplings f and f' to the gauge fields W and B with SM couplings g and g' . For the process $e^+e^- \rightarrow \gamma\gamma(\gamma)$, effects

Fig. 2.1. Radiative corrections for the four experiments: shown is the ratio of the full third-order RADCOR Monte-Carlo cross-section calculation with the phase-space cuts used by each experiment to the Born cross-section. The line labelled RADCOR is the ratio determined without any phase-space cuts.

vanish in the case of $f = -f'$. For $f_\gamma = -\frac{1}{2}(f + f')$ the following cross-section results [16]:

$$\left(\frac{d\sigma}{d\Omega}\right)_{e^*} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{Born}} + \frac{\alpha^2 f_\gamma^4}{16 \Lambda^4} s \sin^2 \theta \left[\frac{p^4}{(p^2 - M_{e^*}^2)^2} + \frac{q^4}{(q^2 - M_{e^*}^2)^2} \right] - \frac{\alpha^2 f_\gamma^2}{2s \Lambda^2} \left[\frac{p^4}{(p^2 - M_{e^*}^2)} + \frac{q^4}{(q^2 - M_{e^*}^2)} \right], \quad (2.6)$$

with $p^2 = -\frac{s}{2}(1 - \cos \theta)$ and $q^2 = -\frac{s}{2}(1 + \cos \theta)$. In the following it is assumed that $\Lambda = M_{e^*}$ unless stated otherwise.

2.3.3. Radiative corrections

Radiative corrections, i.e., the ratio of the next-to-leading order QED to Born level, are shown in Fig. 2.1. They are determined from Monte-Carlo simulations [17], implementing a full third-order calculation including electron-mass effects. In case the third photon is below an energy cut-off, only two back-to-back photons are generated. Fourth-order effects are not included. The event angle θ is calculated as:

$$\cos \theta = \left| \sin \left(\frac{\theta_1 - \theta_2}{2} \right) \right| / \sin \left(\frac{\theta_1 + \theta_2}{2} \right), \quad (2.7)$$

to minimise higher order effects, where $\theta_{1,2}$ are the polar angles of the two highest-energy photons.

The correction labelled RADCOR shown in Fig. 2.1 is determined from the angles $\theta_{1,2}$ of the two highest-energy photons generated without restriction on the angle. The radiative corrections depend on the selected phase space, which differs between the four experiments as listed in Table 2.1. For OPAL the radiative corrections are identical to the RADCOR distribution, apart from the edge effect, since events with a high energy photon having $|\cos \theta_i| > 0.93$ are rejected due to the cut on the longitudinal momentum. Radiative corrections for DELPHI are moderate and similar to OPAL due to the intermediate restriction on the acollinearity angle. L3 on the other hand has a very loose cut on the acollinearity angle. Thus events with only one hard photon in the accepted angle range $|\cos \theta_{2/1}| < 0.96$, the other hard photon having $0.96 < |\cos \theta_{1/2}| \simeq 1$, are selected. The event angle is calculated from the angle $\cos \theta_3$ of an observed soft photon leading to a smaller $\cos \theta$. Especially in the central region, where the cross-section is small, this leads to large corrections of up to 30%. ALEPH has a very tight cut on the acollinearity angle leading to a cross-section smaller than the Born cross-section in the central region.

2.3.4. Theory uncertainty

For the $\gamma\gamma(\gamma)$ channel, no detailed study of the theory uncertainty, i.e., the uncertainty of the third-order Monte-Carlo prediction, exists. For a QED process the higher-order effect can be estimated to be $10\% (\simeq \sqrt{\alpha})$ of the correction due to the highest calculated order. For each experiment the theory uncertainty is estimated as 10% of the radiative correction, with a minimum of 0.5%.

A Monte-Carlo study shows that despite different selections the overlap in the selected phase space is very high, for example, at $\cos \theta = 0.7$ where the third-order DELPHI cross-section is larger than the OPAL cross-section, all events in the phase space selected by OPAL are also in the phase space selected by DELPHI. This means that the common part of the correction is correlated between experiments.

Table 2.2

Combined differential cross-sections for $e^+e^- \rightarrow \gamma\gamma(\gamma)$. The first two numbers of each block are the centre-of-mass energy, \sqrt{s} , and the total luminosity, \mathcal{L} . The following rows list for each bin: weighted $\cos \theta$, total number of events N , correction C , theory error (theo), experimental systematic error (exp) and systematic uncorrelated error (unc). The errors are relative and given in %. The differential cross-section (in pb) is: $d\sigma/d\cos \theta(\cos \theta, \sqrt{s}) = N/C/B/\mathcal{L}$. The value listed for $\cos \theta'$ corresponds to $d\sigma/d\cos \theta(\cos \theta') \cdot B = \int_{\text{bin}} d\sigma/d\cos \theta d\cos \theta$.

For each $\cos \theta$ bin the theory error is calculated as the luminosity weighted average over the four experiments taking the correlation into account. The resulting error, listed in Tables 2.2 and 2.3, varies between 0.5% and 1.0%. The first $\cos \theta$ bin shows a larger error because DELPHI's analysis does not cover this region and thus the L3 measurements get a larger weight.

To determine limits on non-QED models these correlations are taken into account in the following way. Obviously the radiative corrections in neighbouring bins are due to the same effects and hence correlated. Forward and central region on the other hand are uncorrelated. A detailed correlation matrix describing this situation properly is difficult to implement with a log-likelihood fit while for a χ^2 fit the available statistics are too small. To keep the log-likelihood fits of the non-QED models simple, just two independent regions are defined: barrel ($\cos \theta < 0.75$) and endcap ($\cos \theta > 0.75$). Within each region the theory error is 100% correlated, whereas the two regions are treated as uncorrelated. This simplified treatment is possible, since the theory uncertainty is smaller than the experimental systematic and statistical uncertainties.

2.4. Combination of the differential cross-section

Apart from ALEPH at 183 GeV, all experiments provide the measured angular distributions in bins of $\cos \theta$, with a bin-width $B = 0.05$ for all bins except for the last one which has $B = 0.0113$. Only the $\cos \theta$ -range covered differs. Besides the centre-of-mass energy $\sqrt{s_k}$ and luminosity \mathcal{L}_k of each experiment k , the information includes the number of observed events N_k^{obs} , the number of expected events N_k^{QED} or equivalently the correction C_k with $N_k^{\text{QED}} = C_k \left(\frac{d\sigma}{d\cos \theta} \right)_{\text{Born}} \mathcal{L}_k B$, as well

Table 2.3

Combined differential cross-sections for $e^+e^- \rightarrow \gamma\gamma(\gamma)$. The first two numbers of each block are the centre-of-mass energy, \sqrt{s} , and the total luminosity, \mathcal{L} . The following rows list for each bin: weighted $\cos \theta$, total number of events N , correction C , theory error (theo), experimental systematic error (exp) and systematic uncorrelated error (unc). The errors are relative and given in %. The differential cross-section (in pb) is: $d\sigma/d\cos \theta(\cos \theta, \sqrt{s}) = N/C/B/\mathcal{L}$. The value listed for $\cos \theta'$ corresponds to $d\sigma/d\cos \theta(\cos \theta') \cdot B = \int_{\text{bin}} d\sigma/d\cos \theta \, d\cos \theta$.

as the experimental systematic error δ_k^{exp} . The experiment-dependent terms C_k correct for the different phase-space cuts reported in Table 2.1. All experiments assume an experimental systematic error which does not depend on $\cos \theta$ and hence is correlated between all bins. The OPAL experiment introduces an additional uncorrelated experimental error δ^{unc} for some bins. As explained above the experimental systematic error is uncorrelated between experiments. The resulting errors on the LEP combination are reported in Tables 2.2 and 2.3.

The effective centre-of-mass energy, \sqrt{s} , is determined as the luminosity weighted average, taking into account that the cross-section is proportional to $1/s$:

$$s = \mathcal{L} / \sum_k \frac{\mathcal{L}_k}{s_k}, \quad (2.8)$$

where $\mathcal{L} = \sum_k \mathcal{L}_k$. The average correction C at a given angle and energy is calculated as:

$$C = \sum_k \frac{d\sigma}{d\cos \theta}(\cos \theta_k, s_k) \mathcal{L}_k C_k / \frac{d\sigma}{d\cos \theta}(\cos \theta, s) \mathcal{L}. \quad (2.9)$$

Fig. 2.2. Combined differential cross-sections relative to the QED expectation. The error bars shown include the statistical and systematic experimental errors. The theory uncertainty is small, decreasing from 1.0% to 0.5% for increasing $|\cos\theta|$.

Fig. 2.3. The differential cross-section combined for all energies compared to the expectation from QED. The lower plot shows the ratio of measured and expected cross-section, with the band indicating the theory error.

Similarly the systematic errors are calculated, adding the contributions in quadrature. The results are given in [Tables 2.2 and 2.3](#). The combined differential cross-section in each bin, corrected to Born level, is then calculated as:

$$\frac{d\sigma}{d\cos\theta} = \frac{N}{CB\mathcal{L}} \quad (2.10)$$

where $N = \sum_k N_k^{\text{obs}}$. The ratio of the combined cross-section and the expected Born cross-section is shown in [Fig. 2.2](#). For illustration the differential cross-section combined for all energies is shown in [Fig. 2.3](#). On average, the cross-section is slightly below the QED expectation.

Fig. 2.4. The total cross-section as a function of energy for two regions in $\cos \theta$. The error includes statistical and systematic experimental error. The theory error is shown as the band on the QED prediction.

Table 2.4

The total cross-section (in pb) for $e^+e^- \rightarrow \gamma\gamma(\gamma)$. For the measured cross-sections (LEP) the statistical and systematic errors are given. The theory error of 0.45% (0.41%) for $\cos \theta < 0.90$ (0.9613) is quoted for the QED expectation.

\sqrt{s} (GeV)	$\cos \theta < 0.90$		$\cos \theta < 0.9613$	
	LEP	QED	LEP	QED
182.7	$8.26 \pm 0.26 \pm 0.08$	7.98 ± 0.04	$11.65 \pm 0.34 \pm 0.13$	11.57 ± 0.05
188.6	$7.38 \pm 0.12 \pm 0.06$	7.49 ± 0.03	$10.44 \pm 0.15 \pm 0.11$	10.86 ± 0.04
191.6	$7.07 \pm 0.28 \pm 0.06$	7.26 ± 0.03	$10.56 \pm 0.39 \pm 0.11$	10.52 ± 0.04
195.5	$7.12 \pm 0.17 \pm 0.06$	6.97 ± 0.03	$9.92 \pm 0.22 \pm 0.10$	10.10 ± 0.04
199.5	$6.38 \pm 0.16 \pm 0.06$	6.69 ± 0.03	$9.27 \pm 0.21 \pm 0.10$	9.70 ± 0.04
201.6	$6.84 \pm 0.24 \pm 0.06$	6.55 ± 0.03	$9.15 \pm 0.30 \pm 0.10$	9.50 ± 0.04
205.3	$6.13 \pm 0.15 \pm 0.05$	6.32 ± 0.03	$8.79 \pm 0.20 \pm 0.09$	9.16 ± 0.04
206.7	$6.03 \pm 0.13 \pm 0.06$	6.24 ± 0.03	$8.81 \pm 0.17 \pm 0.10$	9.04 ± 0.04

2.5. Combined total cross-section

The total cross-section is derived by integrating the combined differential cross-section. Since the coverage in the scattering angle varies between experiments, the total cross-section is given for two ranges, $\cos \theta < 0.9613$ and $\cos \theta < 0.90$. The latter range is covered by all four experiments. The results are shown in Fig. 2.4 and are summarised in Table 2.4. For the theory error the contributions in barrel and endcap are added in quadrature. The total cross-section (especially for $\cos \theta < 0.9613$) is dominated by the very forward region, where the cross-section is strongly increasing.

2.6. Interpretation

Limits on the parameters describing the non-QED models discussed in Section 2.3.2 are determined from log-likelihood fits to the combined differential cross-section. Where possible the fit parameters are chosen such that the likelihood function is approximately Gaussian. The results of the fits are given in Table 2.5. The values of the fit parameters are about 1.5 standard deviations below the expectation, reflecting the low cross-section in the central region.

Since no significant deviations with respect to the QED expectations are found – all the parameters are compatible with zero – 95% confidence level limits are obtained by renormalising the probability distribution of the fit parameter to the physically allowed region, $\epsilon \geq 0$ for each Λ^+ limit and $\epsilon \leq 0$ for Λ^- limits. For limits on the coupling of an excited electron f_γ/Λ a scan over the mass M_{e^*} is performed and presented in Fig. 2.5. The cross-section is nonlinear in the fit parameter only for M_{e^*} . The obtained negative log likelihood distribution is shown in Fig. 2.6 and the limit is determined at 1.92 units above the minimum.

2.7. Conclusion

The differential cross-section for the photon-pair production process $e^+e^- \rightarrow \gamma\gamma(\gamma)$ was measured and found in agreement with the expectation from QED. Limits on new physics were obtained for various models. They supersede by

3. Fermion-pair production

3.1. Introduction

The LEP-II data were taken at centre-of-mass energies, \sqrt{s} , increasing from 130 GeV to 209 GeV. These energies are well above the Z-pole and the cross-sections for $e^+e^- \rightarrow f\bar{f}$ are significantly smaller than those at the Z-pole. The four LEP experiments have made measurements of the $e^+e^- \rightarrow f\bar{f}$ process over this range of energies [19–22], and a combination of these data is discussed in this section.

Initial-state photon radiation is very important in analysing $e^+e^- \rightarrow f\bar{f}$. If an initial-state photon (or photons) is emitted then the effective e^+e^- centre-of-mass energy is reduced from \sqrt{s} to a lower value $\sqrt{s'}$. The rate of events at a given effective energy is given by the probability to emit photons times the cross-section of $e^+e^- \rightarrow f\bar{f}$ at the reduced centre-of-mass energy $\sqrt{s'}$. For the case when $\sqrt{s'} \simeq m_Z$, corresponding to a photon energy of $E_\gamma = (s - m_Z^2)/(2\sqrt{s})$, the rate becomes very large. This part, which is called radiative return to the Z, is thus important in both the event selection and the analysis of $e^+e^- \rightarrow f\bar{f}$. For the studies reported in this section only events with a small amount of initial state radiation, i.e., large $\sqrt{s'}/s$, are retained.

Fig. 2.6. Log likelihood difference $\Delta\text{Log } L = -\ln \mathcal{L} + \ln \mathcal{L}_{\text{max}}$ as a function of $M_{e^*}^{-4}$. The coupling is fixed at $f = f' = 1$. The value corresponding to $\Delta\text{Log } L = 1.92$ is $M_{e^*}^{-4} = 55.8 \text{ TeV}^{-4} \rightarrow M_{e^*} = 366 \text{ GeV}$.

Table 3.1

The nominal and actual average centre-of-mass energies for data collected during LEP-II operation in each year. The approximate average integrated luminosity analysed per experiment at each energy is also shown.

Year	Nominal energy (GeV)	Actual energy (GeV)	Luminosity (pb^{-1})
1995	130	130.1	3
	136	136.1	3
1996	161	161.3	10
	172	172.1	10
1997	130	130.1	2
	136	136.1	2
	183	182.7	50
1998	189	188.6	170
1999	192	191.6	30
	196	195.5	80
	200	199.5	80
	202	201.7	40
2000	205	204.9	80
	207	206.5	140

The cross-section for $e^+e^- \rightarrow e^+e^-$ is considerably larger than those of $e^+e^- \rightarrow \mu^+\mu^-$ and $e^+e^- \rightarrow \tau^+\tau^-$ because of the additional Feynman diagrams involving t -channel photon and Z exchange. The low angle $e^+e^- \rightarrow e^+e^-$ Bhabha scattering process is used to determine the luminosity.

In the years 1995 through 1999 LEP delivered luminosity at a number of distinct centre-of-mass energy points. In 2000 most of the luminosity was delivered close to two distinct energies, but there was also a significant fraction of the luminosity delivered in more or less a continuum of energies. To facilitate the combination of the fermion-pair measurements, the four LEP experiments divided the data collected in 2000 into two energy bins: from 202.5 to 205.5 GeV, and above 205.5 GeV. The nominal and actual centre-of-mass energies to which the LEP data are averaged for each year are given in Table 3.1.

A number of measurements of the process $e^+e^- \rightarrow f\bar{f}$ exist and are combined. The averages of cross-section and forward-backward asymmetry measurements are discussed in Section 3.2. In Section 3.3 the averages of the differential cross-section measurements, $\frac{d\sigma}{d\cos\theta}$, for the channels $e^+e^- \rightarrow \mu^+\mu^-$ and $e^+e^- \rightarrow \tau^+\tau^-$ are presented; similar averages for differential cross-sections for $e^+e^- \rightarrow e^+e^-$ are given in Section 3.4. In Section 3.5 the combined results are interpreted in terms of contact interactions, the exchange of Z' bosons, the exchange of leptoquarks or squarks and the exchange of gravitons in large-extra-dimensions scenarios. The results are summarised in Section 3.6.

The uncorrelated systematic errors on the input measurements have been separated from the statistical errors, allowing the decomposition of the errors on the averages into statistical and systematic components. Multiplicative corrections have

Fig. 3.1. Diagrams leading to the production of initial state non-singlet electron–positron pairs in $e^+e^- \rightarrow \mu^+\mu^-$, which are considered as signal in the common signal definition.

been used to correct measurements to the full solid angle or full s' region of the common signal definition. Additional errors have been included to account for uncertainties in these corrections.

Where comparisons with Standard Model (SM) predictions are performed, the predictions are calculated using ZFITTER [23] version 6.36 with the following input parameters:

$$m_Z = 91.1875 \text{ GeV} \quad (3.1)$$

$$m_t = 170.9 \text{ GeV} \quad (3.2)$$

$$m_H = 150 \text{ GeV} \quad (3.3)$$

$$\Delta\alpha_{\text{had}}^{(5)}(m_Z^2) = 0.02758 \quad (3.4)$$

$$\alpha_S(m_Z) = 0.118. \quad (3.5)$$

3.2. Averages for cross-sections and asymmetries

In this section the results of the combination of cross-sections and asymmetries are given. The individual experiments' analyses of cross-sections and forward–backward asymmetries are presented in a number of publications [24–27]. Cross-section results are combined for the $e^+e^- \rightarrow q\bar{q}$, $e^+e^- \rightarrow \mu^+\mu^-$ and $e^+e^- \rightarrow \tau^+\tau^-$ channels, forward–backward asymmetry measurements are combined for the $\mu^+\mu^-$ and $\tau^+\tau^-$ final states. Events are classified according to the effective centre-of-mass energy, $\sqrt{s'}$. The averages are made for the samples of events with high effective centre-of-mass energies.

Individual experiments study different $f\bar{f}$ signal definitions; corrections are applied to bring the measurements to the common signal definition²:

- $\sqrt{s'}$ is taken to be the mass of the s -channel propagator, with the $f\bar{f}$ signal being defined by the cut $\sqrt{s'}/s > 0.85$.
- ISR–FSR photon interference is subtracted to render the propagator mass unambiguous.
- Results are given for the full 4π angular acceptance.
- Initial state non-singlet diagrams [28], see for example Fig. 3.1, which lead to events containing additional fermion pairs are considered as part of the two-fermion signal. In such events, the additional fermion pairs are typically lost down the beampipe of the experiments, such that the visible event topologies are usually similar to difermion events with photons radiated from the initial state.

The corrections to the common signal definition were applied in two stages. First, for any measurement which used a restricted angular range or s' cut different from the default, a multiplicative correction was applied to the measurement, the associated errors, and the associated SM prediction to correct the acceptance to 4π and to the common s' cut. These corrections were calculated with ZFITTER for each centre-of-mass energy value. Although these corrections are sizeable, up to 14%, they are expected to be well modelled. In the second stage an additive correction was used to correct for any other differences in signal definition (e.g., use of a different s' definition, inclusion of interference between initial- and final-state radiation, treatment of four-fermion contribution) and centre-of-mass energy. The additive correction is simply the difference between the SM prediction calculated using the common signal definition, at the mean centre-of-mass energy of the measurements, and that provided by the experiment (corrected for acceptance where necessary).

Uncertainties derived from a comparison of ZFITTER with KK2f [29] are included; these are shown in Table 3.2. Additional errors are also included to account for those cases where the SM prediction provided by the experiment had used a version of ZFITTER other than the default one, or different parameters; these are shown in Table 3.3. The inclusion of these errors has a very small effect on the averages. The hadronic cross-sections change by less than 0.02%, the leptonic cross-sections by less than 0.1% and typically 0.05% and the lepton asymmetries by 0.001.

Theoretical uncertainties associated with the SM predictions for each of the measurements are not included during the averaging procedure, but must be included when assessing the compatibility of the data with theoretical predictions. The

Table 3.3

Errors applied to account for uncertainties on the ZFITTER predictions quoted by each experiment, depending on ZFITTER version and parameter settings used by each experiment. Values for cross-sections are given as a fraction of the corresponding cross-section; those for asymmetries are absolute.

Expt.	Energies	$\sigma(q\bar{q})$	$\sigma(\mu^+\mu^-)$	$\sigma(\tau^+\tau^-)$	$A_{FB}(\mu^+\mu^-)$	$A_{FB}(\tau^+\tau^-)$
ALEPH	130–183	0.002	0.005	0.005	0.001	0.001
	189–207	0.002	0.003	0.003	0.0006	0.0006
DELPHI	130–207	0.00015	0.00007	0.00007	0.00002	0.00002
L3	130–189	0.002	0.005	0.005	0.005	0.005
	192–207	0.002	0.003	0.003	0.002	0.002
OPAL	130–207	0.00005	0.00005	0.00005	–	–

theoretical uncertainties on the SM predictions amount to 0.26% on $\sigma(q\bar{q})$, 0.4% on $\sigma(\mu^+\mu^-)$ and $\sigma(\tau^+\tau^-)$, 2% on $\sigma(e^+e^-)$, and 0.004 on the leptonic forward–backward asymmetries [28].

The average is performed using the best linear unbiased estimator technique (BLUE) [30], which is equivalent to a χ^2 minimisation. All data from the nominal centre-of-mass energy points are averaged at the same time.

Particular care is taken to ensure that the correlations between the hadronic cross-sections are reasonably estimated. The errors are broken down into six categories, with the ensuing correlations accounted for in the combinations:

- The statistical uncertainty.
- The systematic uncertainty for the final state X which is fully correlated between energy points for that experiment.
- The systematic uncertainty for experiment Y which is fully correlated between different final states for this energy point.
- The systematic uncertainty for the final state X which is fully correlated between energy points and between different experiments.
- The systematic uncertainty which is fully correlated between energy points and between different experiments for all final states.
- The uncorrelated systematic uncertainty.

The measurements used in the combination are presented in [Appendix B.1](#), using this decomposition of the uncertainties. Uncertainties in the hadronic cross-sections arising from fragmentation models and modelling of ISR are treated as fully correlated between experiments. Despite some differences between the models used and the methods of evaluating the errors in the different experiments, there are significant common elements in the estimation of these sources of uncertainty.

[Table 3.4](#) gives the averaged cross-sections and forward–backward asymmetries for all energies. The χ^2/dof for the average of the LEP-II $f\bar{f}$ data is 163/180, corresponding to a χ^2 probability of 81%. Most correlations are rather small, with the largest components at any given pair of energies being those between the hadronic cross-sections. The other off-diagonal terms in the correlation matrix are smaller than 10%. The correlation matrix between the averaged hadronic cross-sections at different centre-of-mass energies is given in [Table 3.5](#).

[Figs. 3.2](#) and [3.3](#) show the LEP averaged cross-sections and asymmetries, respectively, as a function of the centre-of-mass energy, together with the SM predictions. There is good agreement between the SM expectations and the measurements of the individual experiments and the combined averages. The ratios of the measured cross-sections and asymmetries to the SM expectations, averaged over all energies and taking into account the correlations between the data points and the theoretical errors on the SM predictions, are given in [Table 3.6](#). It is concluded that there is no evidence in the results of the combinations of the cross-sections and lepton forward–backward asymmetries for physics beyond the SM in the process $e^+e^- \rightarrow f\bar{f}$, for $f = q, \mu$ or τ .

3.3. Differential cross-sections for muon- and tau-pair final states

The LEP experiments have measured the differential cross-section, $\frac{d\sigma}{d\cos\theta}$, for the $e^+e^- \rightarrow \mu^+\mu^-$ and $e^+e^- \rightarrow \tau^+\tau^-$ channels for samples of events with high effective centre-of-mass energy, $\sqrt{s'}/s > 0.85$. A combination of these results is made using the BLUE technique. For some bins the number of observed events is very small, so the statistical error associated with each measurement is taken as the expected statistical error on the differential cross-section, computed

Table 3.4

Combined LEP results for the $e^+e^- \rightarrow f\bar{f}$ cross-sections (in pb) and forward–backward asymmetries; in each case the first error is statistical and the second systematic. The SM predictions are from ZFITTER.

Table 3.6

Comparison of measurements to SM predictions for each channel. The second column gives the mean ratio of data to prediction; the third column gives the numbers of standard deviations of the ratio from unity.

Channel	Ratio	Deviation
$\sigma(q\bar{q})$	1.0092	+1.21
$\sigma(\mu^+\mu^-)$	0.9936	−0.45
$\sigma(\tau^+\tau^-)$	1.0005	+0.02
$A_{FB}(\mu^+\mu^-)$	0.9925	−0.35
$A_{FB}(\tau^+\tau^-)$	1.0246	+0.90

from the expected number of events in each bin for each experiment. Using a Monte-Carlo simulation it has been shown that this method provides a good approximation to the exact likelihood method based on Poisson statistics.

Fig. 3.2. Combined LEP results on the cross-sections for $q\bar{q}$, $\mu^+\mu^-$ and $\tau^+\tau^-$ final states, as a function of centre-of-mass energy. The expectations of the SM, computed with ZFITTER, are shown as curves. The lower plot shows the difference between the data and the SM.

Fig. 3.3. Combined LEP results on the forward-backward asymmetry for $\mu^+\mu^-$ and $\tau^+\tau^-$ final states as a function of centre-of-mass energy. The expectations of the SM computed with ZFITTER, are shown as curves. The lower plot shows differences between the data and the SM.

The combination includes data from 183 GeV to 207 GeV from DELPHI and OPAL, data at 189 GeV from L3 and data from 189 GeV to 207 GeV from ALEPH. Each experiment's data are binned in 10 bins of $\cos \theta$ at each energy, using their own signal definition. The polar scattering angle, θ , is the angle of the outgoing negative lepton with respect to the incoming

Table 3.7

The acceptances in $\cos \theta$ for which the experimental measurements at all energies are presented for combination, and the acceptance for the LEP average. For DELPHI the acceptance is shown for the different channels. For ALEPH, L3 and OPAL the acceptance is the same for muon and tau-lepton channels.

Experiment	$\cos \theta_{\min}$	$\cos \theta_{\max}$
ALEPH	−0.95	0.95
DELPHI ($e^+e^- \rightarrow \mu^+\mu^-$)	−0.97	0.97
DELPHI ($e^+e^- \rightarrow \tau^+\tau^-$)	−0.96	0.96
L3	−0.90	0.90
OPAL	−1.00	1.00
Average	−1.00	1.00

electron direction in the detector coordinate system. The outer acceptances of the most forward and most backward bins for which the experiments present their data are different. This was accounted for as part of the correction to a common signal definition. The ranges in $\cos \theta$ for the measurements of the individual experiments and the average are given in Table 3.7. The signal definition used corresponded to the definition given in Section 3.2.

Correlated systematic errors between different experiments, channels and energies, arising from uncertainties on the overall normalisation, are considered in the averaging procedure. All data from all energies are combined in a single fit to obtain averages at each centre-of-mass energy.

The results of the averages are reported in Tables 3.8 and 3.9 and shown in Figs. 3.4 and 3.5, with more details summarised in Appendix B.2. The correlations between bins in the average are less than 2% of the total error on the averages in each bin. The combination results in a χ^2 of 352.2 for 320 degrees of freedom, corresponding to a probability of 10.4%.

3.4. Differential cross-sections for electron–positron final states

The LEP experiments have measured the differential cross-section, $\frac{d\sigma}{d\cos\theta}$ for the process $e^+e^- \rightarrow e^+e^-$ with different acollinearity cuts [19–22]. The results are combined using a χ^2 fit to the measured differential cross-sections, using the experimental errors as given by the experiments. In contrast to the muon and tau-lepton channels, the higher statistics makes the use of expected errors, as discussed in Section 3.3, unnecessary here.

The combination includes data from 189 to 207 GeV, provided by ALEPH, DELPHI and OPAL. Each experiment's data are binned according to an agreed common definition, which takes into account the large forward peak of Bhabha scattering:

- 10 bins for $\cos \theta$ between 0.0 and 0.90 and
- 5 bins for $\cos \theta$ between −0.90 and 0.0

at each energy, where the polar scattering angle, θ , is the angle of the outgoing electron with respect to the incoming electron direction in the lab coordinate system. Apart from the common binning in $\cos \theta$, each experiment uses its own signal definition. The ranges in $\cos \theta$ covered by the individual experiments and the range used for the combination are given in Table 3.10. The signal definition used for the LEP average corresponds to an acollinearity cut of 10° .

Correlated systematic errors between different experiments, energies and bins at the same energy, arising from uncertainties on the overall normalisation, and from migration of events between forward and backward bins with the same absolute value of $\cos \theta$ due to uncertainties in the corrections for charge confusion, were considered in the averaging procedure.

An average for all energies between 189 and 207 GeV was performed. The results of the averages are reported in Tables 3.11 and 3.12 and shown in Figs. 3.6 and 3.7, with more details summarised in Appendix B.3. The χ^2/dof for the average is 199.4/189, corresponding to a probability of 28.8%.

The correlations between bins in the average are well below 5% of the total error on the averages in each bin for most of the cases, and around 10% for bins close to the edges of the acceptance. The agreement between the averaged data and the predictions from the Monte-Carlo generator BHWIDE [31] is good, with a χ^2 of 85 for 90 degrees of freedom, corresponding to a probability of 63%. In conclusion, the combined results for the $e^+e^- \rightarrow e^+e^-$ channel are compatible with the SM.

3.5. Interpretation

The combined cross-section and asymmetry results are interpreted in a variety of models. They are used to place limits on the mass of a possible additional heavy neutral boson, Z' , under different assumptions. Limits on contact interactions between leptons and between leptons and quarks are obtained. The former results are of particular interest since they are inaccessible to $p\bar{p}$, pp or ep colliders. Limits are also provided on the masses of leptoquarks. The $e^+e^- \rightarrow e^+e^-$ channel is used to constrain the scale of gravity in models with extra dimensions.

Table 3.8

Combined LEP results for the $e^+e^- \rightarrow \mu^+\mu^-$ differential cross-sections, in pb divided by $\Delta(\cos\theta)$. The combined statistical and systematic error is shown. The SM predictions are from ZFITTER.

3.5.1. Models with Z' bosons

The combined hadronic and leptonic cross-sections and the leptonic forward–backward asymmetries are used to fit the data to models including an additional, heavy, neutral boson, Z' .

New gauge bosons in the intermediate TeV scale are motivated by several theoretical approaches [32]. For instance, the breaking of Grand Unifying Theories (GUTs) based on $SO(10)$ or E_6 symmetries may leave one or several $U(1)$ remnants unbroken down to TeV energies, before the symmetry reduces to the SM symmetry. In the case of the E_6 model, one has the possible breaking pattern:

$$E_6 \rightarrow SO(10) \times U(1)_\psi \rightarrow SU(5) \times U(1)_\chi \times U(1)_\psi \rightarrow SM \times U(1)', \quad (3.6)$$

and the new Z' boson corresponding to the final $U(1)'$ remnant is a linear combination of the gauge bosons of the two $U(1)$ groups, $U(1)_\chi$ and $U(1)_\psi$, generated in the two-step symmetry breaking, $Z' = Z'_\chi \cos\beta + Z'_\psi \sin\beta$. The value $\beta = \arctan(-\sqrt{5/3})$ would correspond to a Z'_η originating from the direct breaking of E_6 to a rank-5 group in superstring inspired models. Other options are left–right (LR) models, based on the group $SU(2)_R \times SU(2)_L \times U(1)_{B-L}$ in which the new Z'_{LR} will couple to a linear combination of the right-handed and $B-L$ currents with a parameter:

$$\alpha_{LR}^2 = \frac{\sin^2\theta_W g_R^2}{\cos^2\theta_W g_L^2} - 1. \quad (3.7)$$

Below the resonance, new gauge bosons appear as deviations from the SM predictions due to $\gamma-Z'$ and $Z-Z'$ interference terms. Fits are made to the mass of a Z' , $M_{Z'}$, for Z' models varying the parameters β and α_{LR} including four special models referred to as χ , ψ , η and L–R [33] and the Sequential Standard Model (SSM) [34], which proposes the existence of a Z' with exactly the same coupling to fermions as the standard Z .

Table 3.9

Combined LEP results for the $e^+e^- \rightarrow \tau^+\tau^-$ differential cross-sections, in pb divided by $\Delta(\cos\theta)$. The combined statistical and systematic error is shown. The SM predictions are from ZFITTER.

Table 3.10

The acceptances for which experimental data are presented for the $e^+e^- \rightarrow e^+e^-$ channel and the acceptance for the LEP average.

Experiment	$\cos\theta_{\min}$	$\cos\theta_{\max}$
ALEPH ($\sqrt{s}/s > 0.85$)	−0.90	0.90
DELPHI (acol. < 20°)	−0.72	0.72
OPAL (acol. < 10°)	−0.90	0.90
Average (acol. < 10°)	−0.90	0.90

The LEP-II data alone do not significantly constrain the mixing angle between the Z and Z' fields, $\Theta_{ZZ'}$. However, results from a single experiment in which LEP-I data are used in the fit show that the mixing is consistent with zero (see for example Ref. [35], giving limits of 30 mrad or less depending on the model). Hence, for these fits $\Theta_{ZZ'}$ is fixed to zero. The calculation of Z' contributions is implemented in an extension of the ZFITTER program [36].

The predictions from the Z' models are fitted to the combined LEP-II cross-section and forward–backward asymmetry measurements. In this approach the absence of Z' bosons is equivalent to infinite Z' mass or zero coupling.

No significant evidence is found for the existence of a Z' boson in any of the models. In its absence, 95% confidence level lower limits on $M_{Z'}$ are obtained with a Bayesian method with the assumption of a flat prior in the physically allowed region. The lower limits on the Z' mass are summarised in Table 3.13 and shown in Fig. 3.8.

Table 3.11

Combined LEP results for the $e^+e^- \rightarrow e^+e^-$ differential cross-sections, in pb divided by $\Delta(\cos\theta)$, for \sqrt{s} between 189 GeV and 200 GeV. The combined statistical and systematic error is shown. The SM predictions are from BHWIDE.

Table 3.13

The 95% confidence level lower limits on the Z' mass in the χ , ψ , η , L-R and SSM models.

Model	χ	ψ	η	L-R	SSM
$M_{Z'}^{\text{limit}}$ (GeV)	785	500	500	825	1760

3.5.2. Contact interactions

The averaged differential cross-sections for electron-pairs, the averaged cross-sections and forward–backward asymmetries for muon-pairs and tau-lepton pairs, and the hadron cross-sections are used to search for contact interactions between leptons and between leptons and quarks.

Following Ref. [37], contact interactions are parametrised by an effective Lagrangian, \mathcal{L}_{eff} , which is added to the SM Lagrangian and has the form:

$$\mathcal{L}_{\text{eff}} = \frac{g^2}{(1 + \delta)A_{\pm}^2} \sum_{i,j=L,R} \eta_{ij} \bar{e}_i \gamma_{\mu} e_i \bar{f}_j \gamma^{\mu} f_j, \quad (3.8)$$

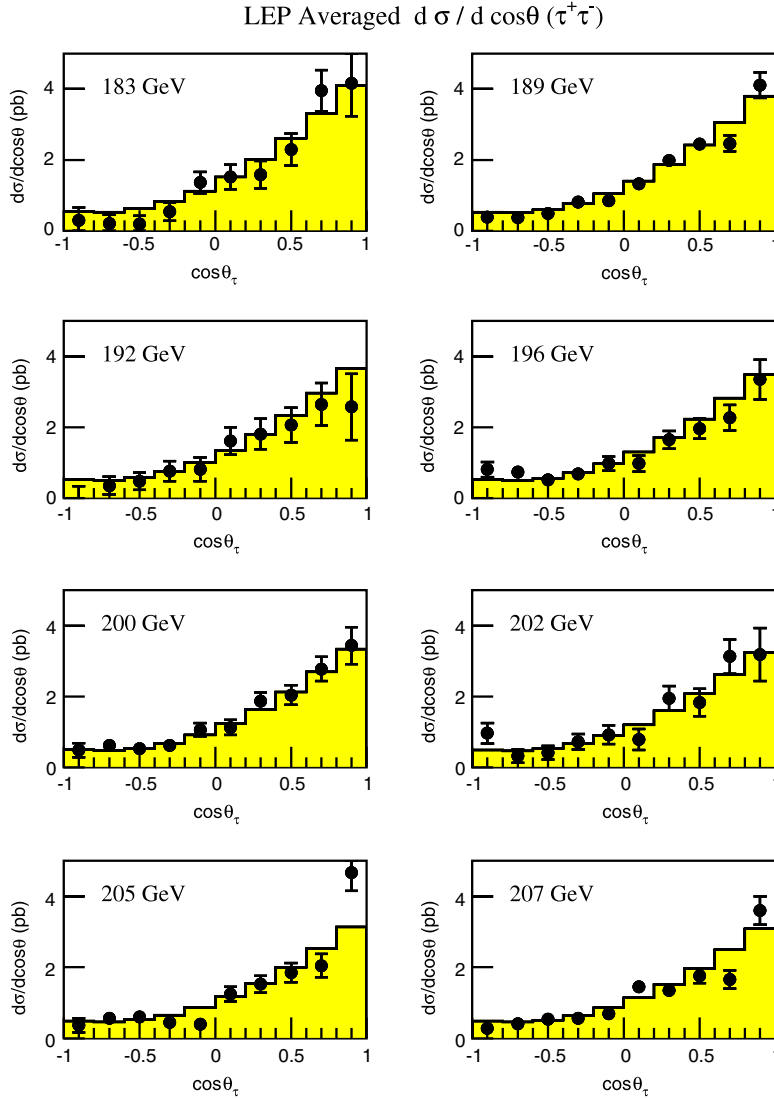

Fig. 3.5. LEP averaged differential cross-sections for $e^+e^- \rightarrow \tau^+\tau^-$ at energies of 183–207 GeV. The SM predictions, shown as solid histograms, are computed with ZFITTER.

where $g^2/4\pi$ is taken to be 1 by convention, $\delta = 1(0)$ for $f = e$ ($f \neq e$), $\eta_{ij} = \pm 1$ or 0, Λ_\pm is the scale of the contact interactions, e_i and f_j are left or right-handed spinors. By assuming different helicity coupling between the initial state and final state currents, a set of different models can be defined from this Lagrangian [38], with either constructive (+) or destructive (−) interference between the SM process and the contact interactions. The models and corresponding choices of η_{ij} are given in Table 3.14. The models LL, RR, VV, AA, LR, RL, V0, A0, A1 are considered here since these models lead to large deviations in the $e^+e^- \rightarrow \mu^+\mu^-$ and $e^+e^- \rightarrow \tau^+\tau^-$ channels. Potential deviations between SM predictions and measurements of the hadronic cross-section can be interpreted as new interactions occurring between electrons and a single quark flavour only, or as interaction between electrons and all quark flavours at the same time. In the former case the scale of the contact interaction is denoted by Λ_{uu} for a flavour of up type (u, c) and by Λ_{dd} for a flavour of down type (d, s, b), while for the latter the scale of the single contact interaction is denoted by Λ_{qq} .

For the purpose of fitting contact interaction models to the data, a new parameter $\varepsilon_\pm = 1/\Lambda_\pm^2$ is defined; $\varepsilon = 0$ in the limit that there are no contact interactions. This parameter is allowed to take both positive and negative values in the fits. Theoretical uncertainties on the SM predictions are taken from Ref. [28], see above.

The values of ε extracted for each model are all compatible with the SM expectation $\varepsilon = 0$ within at most two standard deviations. The fitted values of ε are converted into 95% confidence level lower limits on Λ_\pm . The limits are obtained with a Bayesian method with the assumption of a flat prior in the physically allowed region, $\varepsilon \geq 0$ for each Λ_+ limit and $\varepsilon \leq 0$ for Λ_- limits. The results are shown in Table 3.15 and illustrated in Fig. 3.9. The parameters Λ given in the last column of

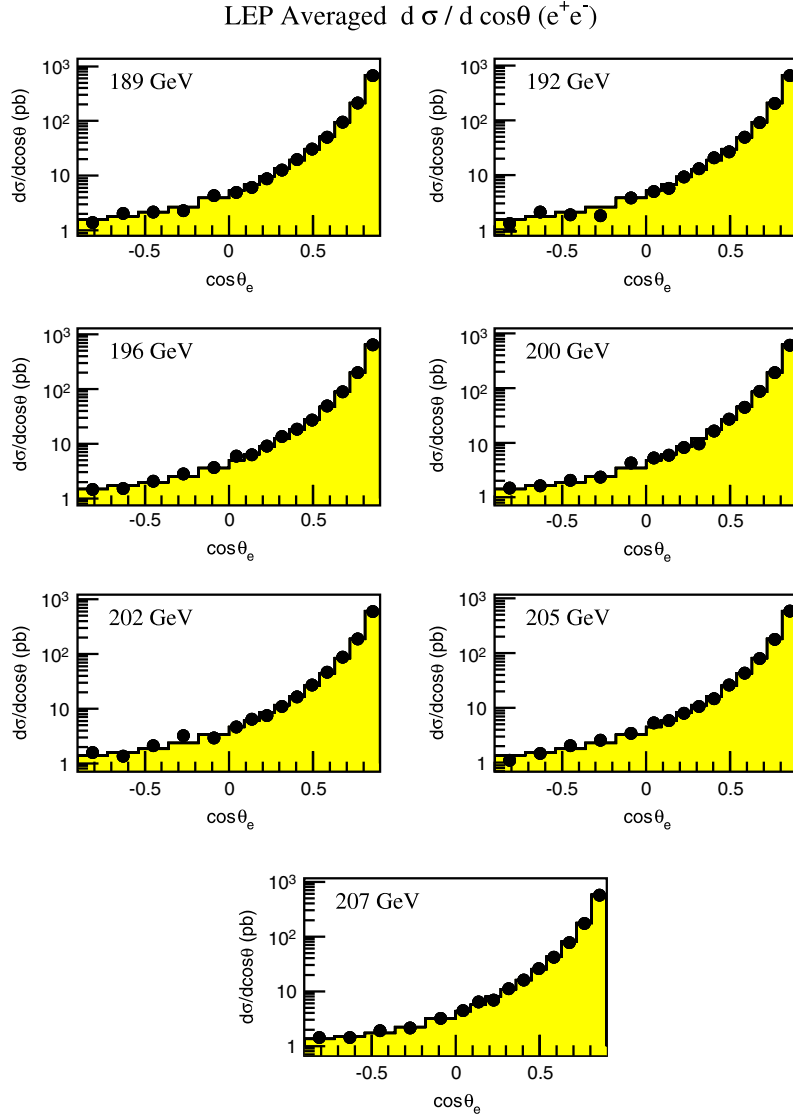

Fig. 3.6. LEP averaged differential cross-sections for $e^+e^- \rightarrow e^+e^-$ at energies of 189–207 GeV. The SM predictions, shown as solid histograms, are computed with BHWIDE.

Table 3.14

Choices of η_{ij} for different contact interaction models.

Model	η_{LL}	η_{RR}	η_{LR}	η_{RL}
LL^\pm	± 1	0	0	0
RR^\pm	0	± 1	0	0
VV^\pm	± 1	± 1	± 1	± 1
AA^\pm	± 1	± 1	∓ 1	∓ 1
LR^\pm	0	0	± 1	0
RL^\pm	0	0	0	± 1
$V0^\pm$	± 1	± 1	0	0
$A0^\pm$	0	0	± 1	± 1
$A1^\pm$	± 1	∓ 1	0	0

Table 3.15 are derived from the $\Lambda_{e^+e^-}$ values combined with the results on Λ from a combined fit to the $\mu^+\mu^-$ and $\tau^+\tau^-$ cross-sections and asymmetries.

The full correlation matrix of the differential cross-sections for electron pairs, obtained in the averaging procedure, is used in the fits. Some aspects of the combination of the LEP data on Bhabha scattering are discussed in Refs. [39–41]. For the

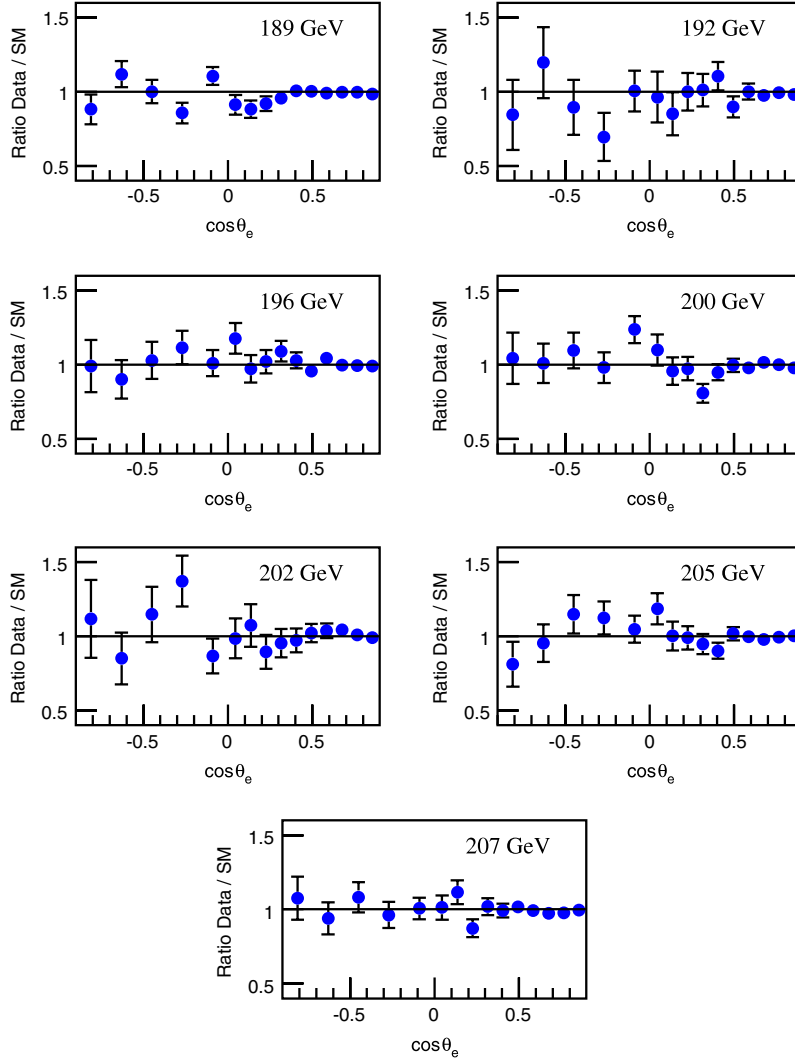

LEP Averaged $d\sigma/d\cos\theta(e^+e^-)$

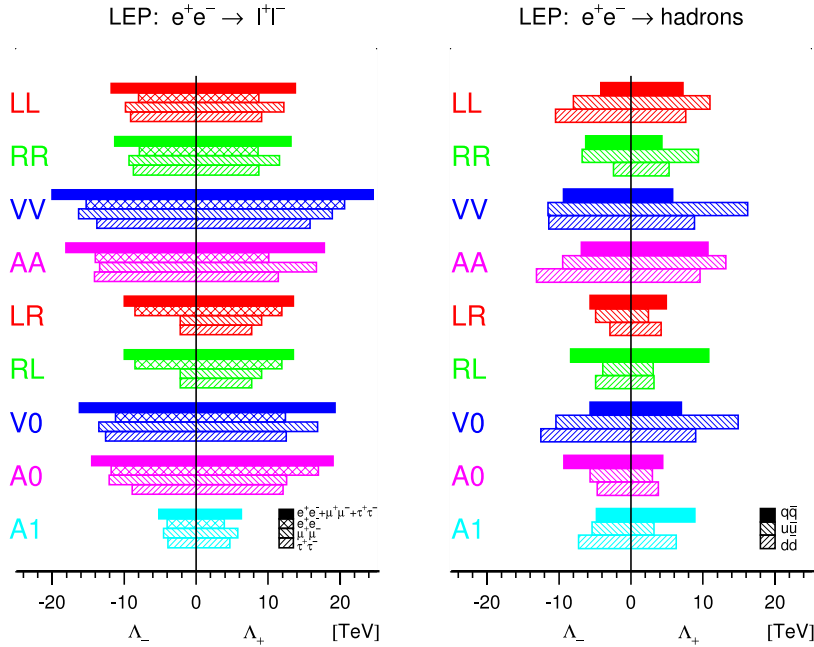

Fig. 3.9. The 95% confidence limits on Λ_\pm , for constructive (+) and destructive interference (−) with the SM, for the contact interaction models discussed in the text. Results are shown for $e^+e^- \rightarrow e^+e^-$, $e^+e^- \rightarrow \mu^+\mu^-$, and $e^+e^- \rightarrow \tau^+\tau^-$ as well as for $e^+e^- \rightarrow u\bar{u}$, $e^+e^- \rightarrow d\bar{d}$ and $e^+e^- \rightarrow q\bar{q}$. For $e^+e^- \rightarrow \ell^+\ell^-$, universality in the contact interactions between leptons is assumed.

VV model with positive interference and assuming electromagnetic coupling strength instead of $g^2/4\pi = 1$ [40], the scale Λ can be converted to an upper limit on the electron size:

$$r_e < 1.1 \cdot 10^{-19} \text{ m}. \quad (3.9)$$

Models with stronger couplings will make this upper limit even stronger.

Fig. 3.10. Ratio of the LEP averaged differential cross-section for $e^+e^- \rightarrow e^+e^-$ compared to the SM prediction. The effects expected from virtual graviton exchange are also shown.

3.5.3. Large extra dimensions

An approach to the solution of the hierarchy problem has been proposed in [42], which brings close the electroweak scale $m_{EW} \sim 1$ TeV and the Planck scale $M_{Pl} = \frac{1}{\sqrt{G_N}} \sim 10^{15}$ TeV. In this framework the effective 4 dimensional M_{Pl} is connected to a new $M_{Pl(4+n)}$ scale in a $(4 + n)$ dimensional theory:

$$M_{Pl}^2 \sim M_{Pl(4+n)}^{2+n} R^n, \quad (3.10)$$

where there are n extra compact spatial dimensions of radius R .

In the production of fermion- or boson-pairs in e^+e^- collisions this class of models can manifest itself through virtual effects due to the exchange of gravitons (Kaluza–Klein excitations). As discussed in [43–46], the exchange of spin-2 gravitons modifies in a unique way the differential cross-sections for fermion pairs, providing clear signatures. These models introduce an effective scale (ultraviolet cut-off). We will adopt the notation from [43] and call the gravitational mass scale M_s . The cut-off scale is supposed to be of the order of the fundamental gravity scale in $4 + n$ dimensions.

The parameter ε is defined as:

$$\varepsilon = \frac{\lambda}{M_s^4}, \quad (3.11)$$

where the coefficient λ is of order 1 and cannot be calculated explicitly without knowledge of the full quantum gravity theory. In the following analysis we will assume that $\lambda = \pm 1$ in order to study both the cases of positive and negative interference. To compute the deviations from the SM due to virtual graviton exchange we use the calculations [45,44].

A fit to the $e^+e^- \rightarrow e^+e^-$ differential cross-section is performed; this channel has by far the highest sensitivity. The fitted values of ε agree well with the SM expectation, and are used to derive limits on the gravitational mass scale M_s at 95% CL:

$$M_s > 1.09 \text{ TeV} \quad \text{for } \lambda = +1, \quad (3.12)$$

$$M_s > 1.25 \text{ TeV} \quad \text{for } \lambda = -1. \quad (3.13)$$

An example of the analysis is shown in Fig. 3.10.

The interference of virtual graviton exchange amplitudes with both t -channel and s -channel Bhabha scattering amplitudes makes this the most sensitive search channel at LEP. The results obtained here would not be strictly valid if the luminosity measurements of the LEP experiments, based on the very same process, is also be affected by graviton exchange.

Table 3.16

The 95% confidence level lower limits on the LQ mass assuming $g_{L,R} = \sqrt{4\pi\alpha}$. For $\tilde{S}_{1/2}(L)$ no limit can be set because the contribution from this leptoquark type to the hadronic cross-section is not observable with the precision of the measurements.

LQ type	m_{LQ}^{\min} (GeV)	LQ type	m_{LQ}^{\min} (GeV)
$S_0(L) \rightarrow eu$	646	$V_{1/2}(L) \rightarrow ed$	348
$S_0(R) \rightarrow eu$	516	$V_{1/2}(R) \rightarrow eu, ed$	238
$\tilde{S}_0(R) \rightarrow ed$	256	$\tilde{V}_{1/2}(L) \rightarrow eu$	186
$S_1(L) \rightarrow eu, ed$	429	$V_0(L) \rightarrow e\bar{d}$	897
$S_{1/2}(L) \rightarrow e\bar{u}$	228	$V_0(R) \rightarrow e\bar{d}$	482
$S_{1/2}(R) \rightarrow e\bar{u}, e\bar{d}$	285	$\tilde{V}_0(R) \rightarrow e\bar{u}$	577
$\tilde{S}_{1/2}(L) \rightarrow e\bar{d}$	–	$V_1(L) \rightarrow e\bar{u}, e\bar{d}$	765

However, as shown in [39], the effect on the cross-section in the luminosity angular range is so small that it can safely be neglected in this analysis.

3.5.4. Leptoquarks

Leptoquarks (LQ) mediate quark–lepton transitions. They carry fermion numbers, $F = L + 3B$. Following the notations in Refs. [47,48], scalar leptoquarks, S_l , and vector leptoquarks, V_l , are indicated based on spin and isospin l . Isomultiplets with different hypercharges are denoted by an additional tilde. It is assumed that leptoquark couplings to quark–lepton pairs are flavour-diagonal and preserve baryon- and lepton-number. The couplings refer to g_L , g_R , according to the chirality of the lepton. In the process $e^+e^- \rightarrow q\bar{q}$ leptoquarks can be exchanged in u - or t -channel, with $F = 0$ or $|F| = 2$.

For convenience, one type of leptoquarks is assumed to be much lighter than the others. Further, experimental constraints on the product $g_L g_R$ allow separate studies of $g_L \neq 0$ or $g_R \neq 0$.

Assuming a coupling of electromagnetic strength, $g = \sqrt{4\pi\alpha}$, where α is the fine structure constant, limits on the masses of leptoquarks coupling to electrons and the first generation of quarks are derived with a Bayesian method with the assumption of a flat prior in the physically allowed region from comparisons of the theoretical predictions for the total hadronic cross-section to the LEP-II averaged measurements.

The 95% confidence level lower limits on masses m_{LQ} are summarised in Table 3.16.

3.6. Summary

A combination of the LEP-II $e^+e^- \rightarrow f\bar{f}$ cross-sections (for hadron, muon and tau-lepton final states) and forward–backward asymmetries (for muon and tau-lepton final states) from LEP running at energies from 130 to 209 GeV is made. The results from the four LEP experiments are in good agreement with each other. The averages for all energies are shown in Table 3.4. The use of the combined fermion-pair results in an S-Matrix analysis is discussed in Appendix A. Differential cross-sections, $\frac{d\sigma}{d\cos\theta}$, for $e^+e^- \rightarrow \mu^+\mu^-$, $e^+e^- \rightarrow \tau^+\tau^-$ and $e^+e^- \rightarrow e^+e^-$ are also combined. Results are shown in Figs. 3.4–3.6. All results are in good agreement with the predictions of the SM.

The averaged cross-section, forward–backward asymmetry and differential cross-section results are interpreted in a variety of models. The LEP-II averaged cross-sections and lepton asymmetries are used to obtain lower limits on the mass of a possible Z' boson in different models. Limits range from 500 to 1760 GeV depending on the model. Limits on the scale of contact interactions between leptons and between electrons and quarks are determined. A full set of limits are reported in Table 3.15. Limits on the scale of gravity in models with extra dimensions ranging from 1.09 to 1.25 TeV are obtained. Limits on the masses of leptoquarks are derived from the hadronic cross-sections. The limits range from 186 to 897 GeV depending on the type of leptoquark.

4. Final-state interconnection effects

At LEP-II, Final-State Interconnection (FSI) effects may exist when two colourless W or Z bosons decay hadronically, close in space–time to one another. Two phenomena are considered: Colour Reconnection (CR) and Bose–Einstein Correlations (BEC). The former is expected to appear as a consequence of the strong interaction described by non-perturbative QCD, while the latter is due to the quantum mechanical properties of those particles in the hadronic final state which follow Bose statistics. Both were observed in other physical systems [49,50]. An additional motivation for the study of FSI effects is that they introduce potentially large systematic uncertainties in the measurement of the mass of the W boson using fully hadronic W -pair decays. The studies described here allow a better understanding of CR and BEC at LEP-II and, by constraining models and their parameters, impose limits on their quantitative effect in the W -boson mass measurement.

4.1. Colour reconnection

4.1.1. Introduction

In $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events, the products of the two colour singlet W decays have in general a significant space–time overlap, because the separation of their decay vertices, $\tau_W \sim 1/\Gamma_W \approx 0.1$ fm, is small compared to characteristic hadronic distance scales of ~ 1 fm. Colour reconnection, also known as colour rearrangement (CR), was first introduced in [51] and refers to a reorganisation of the colour flow between the decay products of the two W bosons. A precedent for such effects is set by colour suppressed B meson decays, e.g. $B \rightarrow J/\psi K$, where there is “cross-talk” between the two original colour singlets, $\bar{c} + s$ and $c + \text{spectator}$ [51,52].

QCD interference effects between the colour singlets in W^+W^- decays during the perturbative phase are expected to be small, affecting the W mass by $\sim (\frac{\alpha_s}{\pi N_{\text{colours}}})^2 \Gamma_W \sim \mathcal{O}(1 \text{ MeV})$ [52]. In contrast, non-perturbative effects involving soft gluons with energies less than Γ_W may be significant, with effects on m_W of $\sim \mathcal{O}(10 \text{ MeV})$. To estimate the impact of this phenomenon, a variety of phenomenological models have been developed [52–57]. These models differ mainly in the detailed mechanism of CR and hadronisation, and in the fraction of reconnected events.

Some of the models can also be tested at the Z peak in three-jet events. The analyses [58–60] showed that the ARIADNE model type 1 [53], and similar the Rathsman/GAL model [57] with default parameter settings, is not consistent with the data. Colour rearrangement in W -pair events could, however, also be caused by additional reconnection mechanisms. The combination presented here concentrates on the SK1 model [52] in which the probability for reconnection to occur in an event is given by $p_{\text{reco}} = 1 - \exp(-\mathcal{L}k_l)$. The quantity \mathcal{L} is the space–time overlap integral between the colour flux tubes that are stretched between quarks and gluons originating from the perturbative phase of the two hadronic W decays, and k_l is an adjustable parameter of the SK1 model, thus allowing to vary the fraction of reconnected events in the Monte-Carlo simulation. Fig. 4.1 shows the reconnection probability, p_{reco} as a function of the model parameter k_l , for an SK1 Monte-Carlo event sample generated at a centre-of-mass energy of 189 GeV, and used by all LEP experiments as part of the combination procedure. By varying k_l , the SK1 model results can be compared to other models which have a fixed reconnection probability, such as the ARIADNE model type 2 [53] and HERWIG [54]. In the context of W mass measurements, it is observed [61–64] that all models behave similarly when adjusted to the same reconnection fraction. The HERWIG CR model assumes a reconnection probability of 1/9 counting the possible colour rearrangements, while the ARIADNE-2 reconnection probability is about 22% at a centre-of-mass energy of 189 GeV.

Many observables have been studied in the search for an experimental signature of colour reconnection. The inclusive properties of events such as the mean charged particle multiplicity, distributions of thrust, rapidity, transverse momentum and $\ln(1/x_p)$, where x_p is the scaled particle momentum, are found to have limited sensitivity [65,66]. The effects of CR are predicted to be numerically larger in these observables when only higher mass hadrons such as kaons and protons are considered [67]. However, experimental investigations [66] find no significant gain in sensitivity due to the low production rate of such particles in W decays.

Eventually, two methods were developed which yield a sensitive handle on CR effects in hadronic W decays: the so-called “particle-flow” method [68,69], and the influence of CR on the W -boson mass reconstructed as a function of the particle momentum threshold and when applying different jet algorithms. These two are described in the following and their combined results are presented.

4.1.2. Particle-flow measurements

In the analogy with the “string effect” analysis in 3-jet $e^+e^- \rightarrow q\bar{q}g$ events [70], the particle-flow method has been investigated by the DELPHI, L3 and OPAL collaborations [71,72,65]. In these analyses, pairs of jets in $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events are associated with the decay of a W , after which four jet–jet regions are chosen: two corresponding to jets sharing the same W parent (intra- W), and two in which the parents differ (inter- W). As there is a two-fold ambiguity in the assignment of inter- W regions, the configuration having the smaller sum of inter- W angles is chosen.

Particles are projected onto the planes defined by these jet pairs and the particle density constructed as a function of ϕ , the projected angle relative to one jet in each plane. To account for the variation in the opening angles, ϕ_0 , of the jet–jet pairs defining each plane, the particle densities in ϕ are constructed as functions of normalised angles, $\phi_r = \phi/\phi_0$, by a simple rescaling of the projected angles for each particle, event by event. Particles having projected angles ϕ smaller than ϕ_0 in at least one of the four planes are considered further. This gives particle densities, $\frac{1}{N_{\text{event}}} \frac{dn}{d\phi_r}$, in four regions with ϕ_r in the range from 0 to 1, and where n and N_{event} are the number of particles and events, respectively.

As the particle density reflects the colour flow in an event, CR models predict a change in the relative particle densities between inter- W and intra- W regions. On average, colour reconnection is expected to affect the particle densities of both inter- W regions in the same way and so they are added together, as are the two intra- W regions. The observable used to quantify such changes, R_N , is defined:

$$R_N = \frac{\frac{1}{N_{\text{event}}} \int_{0.2}^{0.8} \frac{dn}{d\phi_r} (\text{intra-}W) d\phi_r}{\frac{1}{N_{\text{event}}} \int_{0.2}^{0.8} \frac{dn}{d\phi_r} (\text{inter-}W) d\phi_r}. \quad (4.1)$$

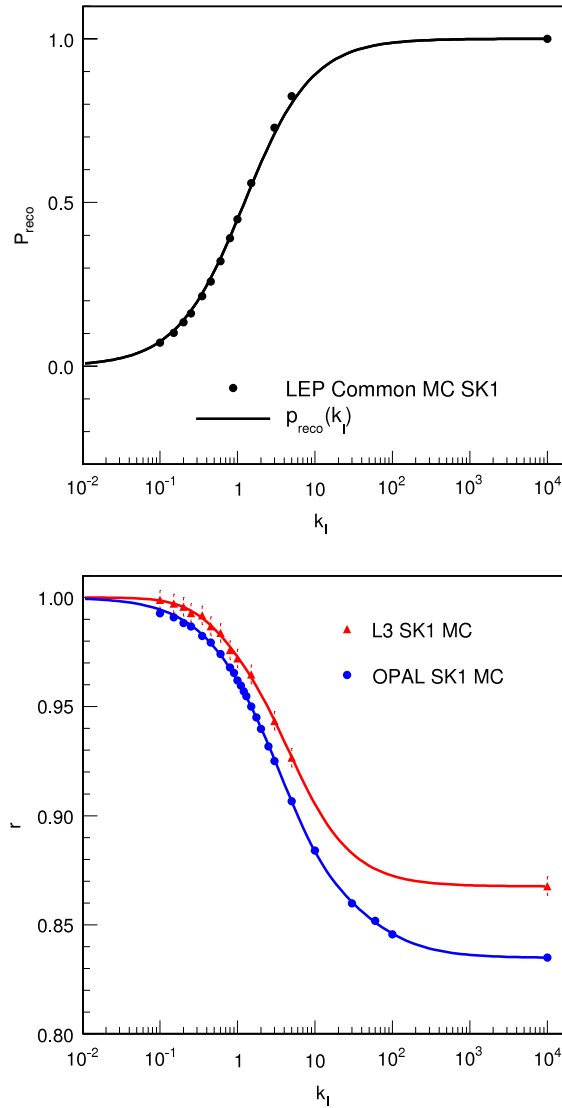

Fig. 4.1. Top: Reconnection probability as a function of the SK1 model parameter, k_l , together with an approximate curve $p_{\text{reco}}(k_l)$ to guide the eye. Bottom: Monte-Carlo calculation and parametrisation of the particle-flow ratio, $r(k_l)$, for L3 and OPAL, shown as triangles and circles, respectively.

As the effects of CR are expected to be enhanced for low momentum particles far from the jet axes, the range of integration excludes jet cores ($\phi_r \approx 0$ and $\phi_r \approx 1$). The precise upper and lower limits are optimised by model studies of predicted sensitivity.

The DELPHI, L3 and OPAL experiments have developed their own variation on this analysis, differing primarily in the selection of $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events. In DELPHI [71] and L3 [72], events are selected in a very particular configuration (“topological selection”) by imposing restrictions on the jet–jet angles and on the jet-resolution parameter for the three-to four-jet transition (Durham [73] or Luclus [74] schemes). This leads to more planar events than those in an inclusive $W^+W^- \rightarrow q\bar{q}q\bar{q}$ sample and the association between jet pairs and W bosons is given by the relative angular separation of the jets. The overall efficiency for selecting signal events ranges between 12% and 22% with purities of 70%–85%. The efficiency to assign the correct jets to the parent W ’s amounts to 70%–91%. Data samples with small signal efficiency typically have the highest purity and best efficiency for correct jet assignment. The OPAL [65] event selection is based on their W mass analysis. Assignment of pairs of jets to W ’s follows the procedure used in measuring m_W , using a multivariate algorithm [64] with an overall efficiency for selecting $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events of 40%, a signal purity of 86%, and an efficiency for correctly assigning jets to parent W ’s of 90%, albeit with a less planar topology and hence a more complicated colour flow.

The data are corrected bin-by-bin for background contamination in the inter- W and intra- W regions separately. The possibility of CR effects existing in background processes is neglected because the background is dominated by $e^+e^- \rightarrow q\bar{q}$ events and the $ZZ \rightarrow q\bar{q}q\bar{q}$ background, in which CR effects may also be present, is at the level of 2% only.

Table 4.1

Particle-flow measurements compared to Monte-Carlo predictions for the SK1 CR model and different hadronisation models, together with systematic uncertainties, provided by L3 and OPAL for the CR combination.

R_N	Experiment	
	L3	OPAL
Data	0.8436 ± 0.0217	1.2426 ± 0.0248
JETSET	0.8622 ± 0.0037	1.2910 ± 0.0028
SK1 (100%)	0.7482 ± 0.0033	1.0780 ± 0.0028
HERWIG	0.8822 ± 0.0038	1.3110 ± 0.0029
ARIADNE	0.8754 ± 0.0037	1.2860 ± 0.0028
Systematics	L3	OPAL
Intra-W BEC	0.0017	0.0017
$e^+e^- \rightarrow q\bar{q}$ shape	0.0086	0.0104
$\sigma(e^+e^- \rightarrow q\bar{q})$	0.0071	0.0024
$ZZ \rightarrow q\bar{q}q\bar{q}$ shape	0.0020	0.0018
$\sigma(ZZ \rightarrow q\bar{q}q\bar{q})$	0.0020	0.0009
Detector effects	0.0016	0.0142
E_{cm} dependence	0.0020	0.0005

The measured values of R_N are compared after they have been normalised using a common sample of Monte-Carlo events, processed using the detector simulation and particle-flow analysis of each experiment. The ratio, r , is constructed:

$$r = \frac{R_N^{\text{data}}}{R_N^{\text{no-CR}}}, \quad (4.2)$$

where R_N^{data} and $R_N^{\text{no-CR}}$ are the values of R_N measured by each experiment in data and in a common sample of events simulated without CR. In the absence of CR, all experiments should find r consistent with unity. The default no-CR sample used for this normalisation consists of $e^+e^- \rightarrow W^+W^-$ events produced using the KORALW [75] event generator and hadronised using the JETSET [76] model.

The common Monte-Carlo samples used in the combination are only available at a single centre-of-mass energy, E_{cm} , of 188.6 GeV. The R_N are however measured at each centre-of-mass energy separately, in both real data and Monte-Carlo simulations. The predicted variation of R_N with centre-of-mass energy is determined by each experiment using its own samples of simulated $e^+e^- \rightarrow W^+W^-$ events, with hadronisation performed using the no-CR JETSET model. The evolutions of R_N are parametrised by second order polynomial functions in E_{cm} and are detailed in Refs. [71,72,65]. The R_N measured in data are subsequently extrapolated by each experiment to the reference energy of 188.6 GeV.

Input from a particle-flow measurement is provided by L3 and OPAL in terms of measured R_N and corresponding ΔR_N for different systematic variations of the analysis or different Monte Carlo modelling [72,65]. They are shown in Table 4.1. DELPHI provides their results in terms of likelihood functions, which are discussed below. Systematic uncertainties due to Bose–Einstein correlations are limited to the level which is compatible with the LEP measurement of BEC (see Section 4.2). Scale uncertainties on the main background processes $e^+e^- \rightarrow q\bar{q}$ and $ZZ \rightarrow q\bar{q}q\bar{q}$, and hadronisation uncertainties, which are derived from the spread of R_N for the JETSET, ARIADNE and HERWIG hadronisation models are also taken into account. For these uncertainties the smallest of each systematic uncertainty of L3 and OPAL is taken as correlated, the remaining part as uncorrelated. Detector effects and the extrapolation to a single centre-of-mass energy, as well as the uncertainty of the 4-jet background shape of $e^+e^- \rightarrow q\bar{q}$ events with multi-gluon emission, are assumed to be uncorrelated.

The scaled measurements of L3 and OPAL, $r_1^{\text{data}} = r_L^{\text{data}}$ and $r_2^{\text{data}} = r_O^{\text{data}}$, are combined by minimising a χ^2 function which depends on the model parameter k_i through the model dependence of $r_i(k_i)$:

$$\chi_r^2(k_i, c_1, c_2) = \sum_{i,j=1,2} \left\{ (r_i^{\text{data}} - r_i(k_i) + c_i \delta_{i,r}) (C_r^{-1})_{ij} \cdot (r_j^{\text{data}} - r_j(k_i) + c_j \delta_{j,r}) \right\} + \sum_{m,n=1,2} c_m (C_c^{-1})_{mn} c_n. \quad (4.3)$$

The covariance matrix, C_r , is constructed from only the uncorrelated uncertainties and is actually diagonal. Correlated uncertainties are introduced by varying each measurement r_i^{data} with an additive term $c_i \delta_{i,r}$, where $\delta_{i,r}$ is the correlated part of the uncertainty on r_i^{data} , and c_i are auxiliary variables. The second term in the χ_r^2 function introduces correlations between the auxiliary variables, so that the systematic uncertainties $\delta_{i,r}$ also become effectively correlated. This procedure is equivalent to the so-called profile likelihood method with correlated nuisance parameters, see, e.g., [77] and references therein. The correlation matrix $(C_c^{-1})_{mn}$ is constructed such that the uncertainty and central value of k_i is exactly identical to the result obtained with a classical and full covariance matrix C_r . The best agreement is found for a correlation coefficient of 0.50 between the auxiliary parameters. This more complicated prescription is used to combine this result with other CR inputs, which are provided in terms of likelihood functions.

To be able to vary k_l continuously in the minimisation, the SK1 model predictions of $r_i(k_l)$ are described by a parametrised, phenomenological function:

$$r_i(k_l) = 1 + a_{i,1} \frac{k_l}{k_l + b_i} + a_{i,2} \left(\frac{k_l}{k_l + b_i} \right)^2 + a_{i,3} \left(\frac{k_l}{k_l + b_i} \right)^4 + \frac{a_{i,4}}{(1 + k_l)} - a_{i,4}. \quad (4.4)$$

By construction, $r_i(k_l)$ is equal to 1 in the limit $k_l \rightarrow 0$, i.e., when no CR effects are present. The parameters, $a_{i,j}$ and b_i ($i = 1, 2, j = 1, \dots, 4$), of the function are adjusted to fit the $r_i(k_l)$ dependence determined in the SK1 Monte-Carlo simulation by L3 and OPAL, which are shown in Table D.1 of Appendix D. The terms $\frac{k_l}{k_l + b_i}$ are motivated by the approximate description of the functional shape of the reconnection probability, $p_{\text{reco}}(k_l)$.

With this parameter set, the function and the Monte-Carlo simulations agree within less than one statistical standard deviation, as shown in Fig. 4.1. The best fitting parameter values are listed in Table D.2.

The DELPHI experiment also performed a particle-flow analysis [71]. The result is represented in terms of two likelihood functions, $L_{p\text{-flow},D,\text{full}}(k_l)$ and $L_{p\text{-flow},D,\text{uncorr}}(k_l)$, where the former contains all systematic uncertainties and the latter only uncorrelated systematic uncertainties. These likelihoods are transformed into $\Delta\chi^2(k_l) = -2 \log L(k_l)$ values, which are smoothed by cubic splines and then used in the combination. To treat correlations with other inputs properly, a systematic variation, $\delta_{p\text{-flow},D}(k_l)$, of k_l is introduced such that the full $\Delta\chi^2_{p\text{-flow},D,\text{full}}(k_l)$ can be reproduced in the following way from the uncorrelated $\Delta\chi^2_{p\text{-flow},D,\text{uncorr}}(k_l)$ using an auxiliary variable c_3 :

$$\Delta\chi^2_{p\text{-flow},D,\text{corr}}(k_l) = \min_{c_3} \left\{ \Delta\chi^2_{p\text{-flow},D,\text{uncorr}}(k_l + c_3 \delta_{p\text{-flow},D}(k_l)) + c_3^2 \right\}. \quad (4.5)$$

The combined minimisation of $\Delta\chi^2_{p\text{-flow},D,\text{corr}}(k_l, c_3)$ with respect to k_l and c_3 is equivalent to a minimisation of $\Delta\chi^2_{p\text{-flow},D,\text{full}}(k_l)$ with respect to k_l only. The best agreement between the full description and this procedure is obtained for $\delta_{p\text{-flow},D}(k_l) = 0.246 + (0.754)^2 k_l$, which is shown in Fig. 4.2. The advantage of this method is again the possibility to correlate c_3 with systematic uncertainties from other CR inputs.

4.1.3. Determination of CR effects using W mass estimators

A second very sensitive observable for CR is the variation of the reconstructed W -boson mass in fully hadronic events when applying different particle momentum thresholds and jet algorithms at event reconstruction. As pointed out before, CR influences mostly the particle-flow between jets and hence the low momentum component of the hadronic jets. Thus, estimators of m_W in which the jet-defining parameters are chosen to enhance or reduce the weight given to such low momentum particles allow an observable to be constructed which is sensitive to the presence or absence of CR. To measure the effect of CR, the mass difference, Δm_W , of two estimators is determined in data and compared to the mass difference predicted by a certain CR model. Since only mass differences are used to measure CR, the correlation with the actual W mass measurement is small, in the order of 10% [61,71,64].

The ALEPH experiment studied the dependence of m_W as a function of a momentum threshold, p_{cut} , of the jet particles and of the cone radius R of the jets, which were constructed using the Durham-PE algorithm [73]. The p_{cut} thresholds were varied between 1 GeV and 3 GeV and the radius between 0.4 rad and 1.0 rad. DELPHI compared the m_W value from the standard W mass analysis with alternative estimators applying a cone cut at $R = 0.5$ rad and a particle momentum cut at 2 GeV, applying again the Durham jet clustering algorithm [73] in combination with an iterative cone algorithm in order to estimate the direction of the modified jets. OPAL found that their optimal CR sensitivity is for the comparison between an analysis with a particle momentum cut at 2.5 GeV and an alternative one in which the jet particles are weighted according to a factor p^κ , with $\kappa = -0.5$. The Durham jet clustering algorithm [73] is used to calculate the modified jet directions.

The ALEPH, DELPHI and OPAL inputs are provided in terms of $\Delta\chi^2$ curves with complete systematic uncertainties and with only the uncorrelated part, $\Delta\chi^2_{\Delta m_W,i,\text{full}}(k_l)$ and $\Delta\chi^2_{\Delta m_W,i,\text{uncorr}}(k_l)$, respectively. Cubic splines are used to interpolate between the provided data points. Correlations are again not taken directly from the input function, $\Delta\chi^2_{\Delta m_W,i,\text{full}}(k_l)$, but are introduced by varying k_l with additional uncertainties $\pm \delta(k_l)$ using auxiliary variables c_i :

$$\Delta\chi^2_{\Delta m_W,A,\text{corr}}(k_l) = \min_{c_4} \left\{ \Delta\chi^2_{\Delta m_W,A,\text{uncorr}}(k_l + c_4 \delta_{\Delta m_W,A}(k_l)) + c_4^2 \right\}, \quad (4.6)$$

$$\Delta\chi^2_{\Delta m_W,D,\text{corr}}(k_l) = \min_{c_5} \left\{ \Delta\chi^2_{\Delta m_W,D,\text{uncorr}}(k_l + c_5 \delta_{\Delta m_W,D}(k_l)) + c_5^2 \right\}, \quad (4.7)$$

$$\Delta\chi^2_{\Delta m_W,O,\text{corr}}(k_l) = \min_{c_6} \left\{ \Delta\chi^2_{\Delta m_W,O,\text{uncorr}}(k_l + c_6 \delta_{\Delta m_W,O}(k_l)) + c_6^2 \right\}. \quad (4.8)$$

The parametrisations of $\delta_{\Delta m_W,i}(k_l)$ follow step-wise linear functions and are listed in Appendix D. The original input of ALEPH, DELPHI and OPAL is shown in Fig. 4.2 and compared to the $\Delta\chi^2_{\Delta m_W,i,\text{corr}}(k_l)$ functions using the prescription described above. Good agreement is observed.

The main correlated systematic uncertainties which are taken into account are from comparisons of hadronisation models, background scale and shape uncertainties, as well as Bose–Einstein correlations. Detector effects and corrections

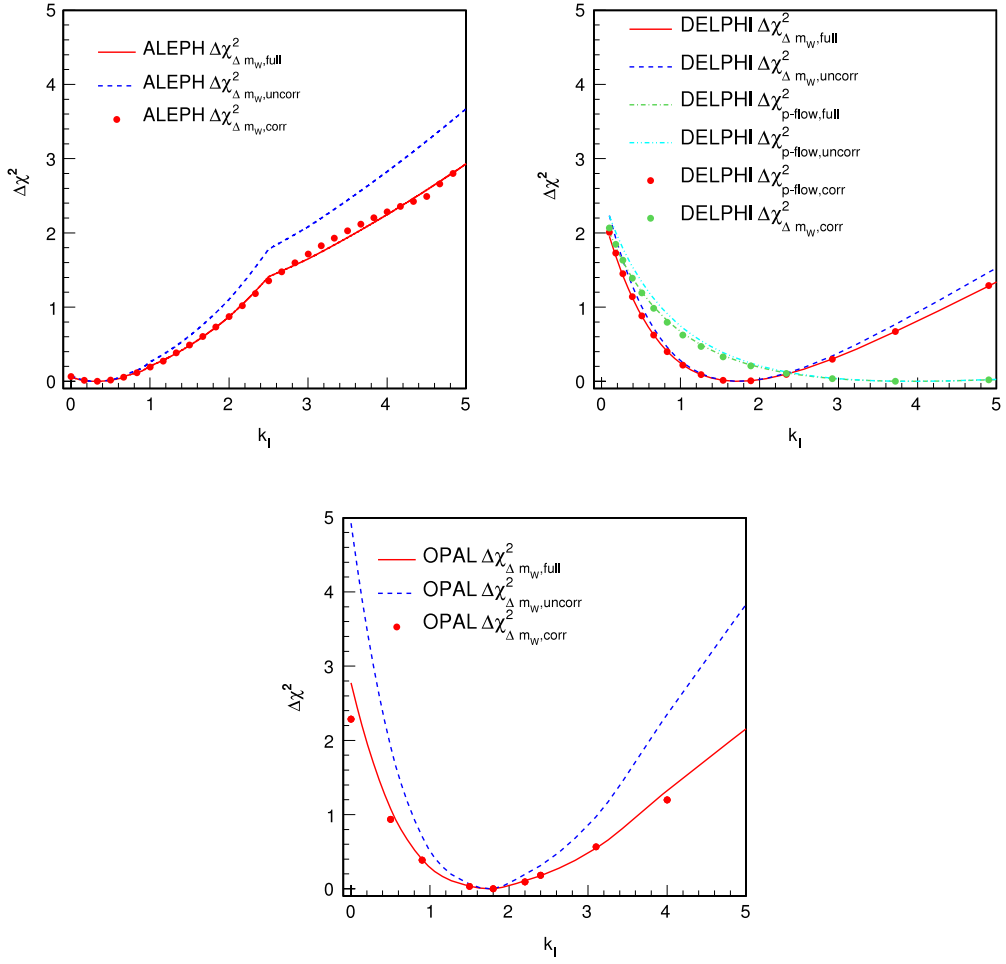

Fig. 4.2. Comparison of $\Delta\chi^2$ distributions for CR measurements from particle-flow and mass estimator differences, Δm_W , by the ALEPH, DELPHI and OPAL experiments. Distributions are shown when all uncertainties (continuous lines) and only uncorrelated uncertainties (dashed lines) are taken into account. The full-uncertainty curves are compared to the $\Delta\chi^2$ distribution when the variation of the parametrised uncertainty $\delta(k_l)$ is used to introduce the correlated part of the systematic uncertainties (circles).

of the 4-jet background are taken as uncorrelated. The original ALEPH analysis [61] does not consider uncertainties due to the BEC effect. Therefore, the corresponding $\delta_{\Delta m_W,A}(k_l)$ values are scaled up by 11%, which is derived from an additional dedicated systematic study.

4.1.4. Combination of LEP CR measurements

The LEP measurements of CR using the particle-flow method and the mass estimator differences are combined using the following total $\Delta\chi^2$ function:

$$\begin{aligned}
 \Delta\chi^2(k_l, c_1, \dots, c_6) = & \sum_{i,j=1,2} \left\{ (r_i^{\text{data}} - r_i(k_l) + c_i \delta_{i,r}) (C_r^{-1})_{ij} (r_j^{\text{data}} - r_j(k_l) + c_j \delta_{j,r}) \right\} \\
 & + \Delta\chi_{p\text{-flow},D,\text{uncorr}}^2(k_l + c_3 \delta_{p\text{-flow},D}(k_l)) + \Delta\chi_{\Delta m_W,A,\text{uncorr}}^2(k_l + c_4 \delta_{\Delta m_W,A}(k_l)) \\
 & + \Delta\chi_{\Delta m_W,D,\text{uncorr}}^2(k_l + c_5 \delta_{\Delta m_W,D}(k_l)) + \Delta\chi_{\Delta m_W,O,\text{uncorr}}^2(k_l + c_6 \delta_{\Delta m_W,O}(k_l)) \\
 & + \sum_{m,n=1}^6 c_m (C_c^{-1})_{mn} c_n,
 \end{aligned} \tag{4.9}$$

which is constructed from the ingredients presented above. It is minimised with respect to k_l and the auxiliary parameters c_1, \dots, c_6 , which are correlated through the covariance matrix C_c . In the LEP combination, the correlation coefficients are set to 0.5, motivated by the full covariance matrix of the R_N measurements, where the correlated systematic uncertainties are reduced to only the common part in each pair of measurements.

Fig. 4.3. Individual and LEP combined $\Delta\chi^2$ curves for the measurement of the CR parameter k_l in the SK1 model.

As a cross-check, the CR measurements of each collaboration are combined, and the best k_l values as well as their uncertainties are extracted using the procedure described above. All results of the individual experiments [61,71,72,64] could be adequately reproduced, with small deviations being attributed to known systematic effects covered by the assigned uncertainties. More details can be found in the [Appendix D](#).

The $\Delta\chi^2$ curves obtained for each experiment are shown in [Fig. 4.3](#), together with the LEP result. Combining all LEP data yields:

$$k_l = 1.26^{+0.84}_{-0.64}. \quad (4.10)$$

This result corresponds to a preferred reconnection probability of 51% at a centre-of-mass energy of 189 GeV in the SK1 model. Absence of CR cannot be excluded, but is disfavoured by LEP at more than two standard deviations.

4.1.5. Summary

A combination of the LEP particle-flow and W -mass estimator results is presented, using the entire LEP-II data sample. The data exclude with 6.9 standard deviations an extreme version of the SK-I model in which colour reconnection has been forced to occur in essentially all events. The combination procedure has been generalised to the SK-I model as a function of its reconnection probability. The combined data are described best by the model in which 51% of events at 189 GeV are reconnected, corresponding to $k_l = 1.26$. The LEP data disfavour the no-CR hypothesis at 99.5% confidence level, deviating from it by 2.8 standard deviations. The 68% confidence level range for k_l is determined to be $0.62 \leq k_l \leq 2.10$.

4.2. Bose–Einstein correlations

4.2.1. Introduction

The LEP experiments have studied the strength of particle correlations between two hadronic systems obtained from W -pair decays occurring close in space–time at LEP-II. The work presented in this section is focused on so-called Bose–Einstein correlations (BEC), *i.e.*, the enhanced probability of production of pairs (multiplets) of identical mesons close together in phase space. The effect is readily observed in particle physics, in particular in hadronic decays of the Z boson, and is qualitatively understood as a result of quantum-mechanical interference originating from the symmetry of the amplitude of the particle production process under exchange of identical mesons.

The presence of correlations between hadrons coming from the decay of a W -pair, in particular those between hadrons originating from different W bosons, can affect the direct reconstruction of the mass of the initial W bosons. The measurement of the strength of these correlations can be used to constrain the corresponding systematic uncertainty in the W mass measurement.

4.2.2. Methods

The principal method [78], called “mixing method”, used in the measurement is based on the direct comparison of 2-particle spectra from genuine hadronic W -pair events, $WW \rightarrow q\bar{q}q\bar{q}$, and from mixed WW events. The latter are constructed by mixing the hadronic sides of two semileptonic W -pair events, $WW \rightarrow q\bar{q}\ell\nu$, first used in [79]. Such a reference sample has the advantage of reproducing the correlations between particles belonging to the same W boson, while the particles from different W bosons are uncorrelated by construction.

This method gives a model-independent estimate of the interplay between the two hadronic systems, for which BEC and also colour reconnection are considered as dominant sources. The possibility of establishing the strength of inter- W correlations in a model-independent way is rather unique; most correlations do carry an inherent model dependence on the reference sample. In the present measurement, the model dependence is limited to the background subtraction.

4.2.3. Distributions

The two-particle correlations are evaluated using two-particle densities defined in terms of the 4-momentum transfer $Q = \sqrt{-(p_1 - p_2)^2}$, where p_1, p_2 are the 4-momenta of the two particles:

$$\rho_2(Q) = \frac{1}{N_{ev}} \frac{dn_{pairs}}{dQ}. \quad (4.11)$$

Here n_{pairs} stands for the number of like-sign (unlike-sign) 2-particle permutations.³ In the case of two stochastically independent hadronically decaying W bosons the two-particle inclusive density is given by:

$$\rho_2^{WW} = \rho_2^{W^+} + \rho_2^{W^-} + 2\rho_2^{\text{mix}}, \quad (4.12)$$

where ρ_2^{mix} can be expressed via the single-particle inclusive density $\rho_1(p)$ as:

$$\rho_2^{\text{mix}}(Q) = \int d^4p_1 d^4p_2 \rho^{W^+}(p_1) \rho^{W^-}(p_2) \delta(Q^2 + (p_1 - p_2)^2) \delta(p_1^2 - m_\pi^2) \delta(p_2^2 - m_\pi^2). \quad (4.13)$$

Assuming further that:

$$\rho_2^{W^+}(Q) = \rho_2^{W^-}(Q) = \rho_2^W(Q), \quad (4.14)$$

one obtains for the case of two stochastically independent hadronically decaying W bosons:

$$\rho_2^{WW}(Q) = 2\rho_2^W(Q) + 2\rho_2^{\text{mix}}(Q). \quad (4.15)$$

In the mixing method, ρ_2^{mix} is obtained by combining two hadronic W systems from two different semileptonic W -pair events. The direct search for inter- W BEC is done using the difference of 2-particle densities:

$$\Delta\rho(Q) = \rho_2^{WW}(Q) - 2\rho_2^W(Q) - 2\rho_2^{\text{mix}}(Q), \quad (4.16)$$

or, alternatively, their ratio:

$$D(Q) = \frac{\rho_2^{WW}(Q)}{2\rho_2^W(Q) + 2\rho_2^{\text{mix}}(Q)} = 1 + \frac{\Delta\rho(Q)}{2\rho_2^W(Q) + 2\rho_2^{\text{mix}}(Q)}. \quad (4.17)$$

Given the definition of the genuine inter- W correlations function $\delta_l(Q)$ [80], it can be shown that

$$\delta_l(Q) = \frac{\Delta\rho(Q)}{2\rho_2^{\text{mix}}(Q)}. \quad (4.18)$$

To disentangle the BEC effects from other possible correlation sources (such as energy-momentum conservation or colour reconnection), which are supposed to be the same for like-sign and unlike-sign charge pairs, the double difference:

$$\delta\rho(Q) = \Delta\rho^{\text{like-sign}}(Q) - \Delta\rho^{\text{unlike-sign}}(Q), \quad (4.19)$$

or the double ratio,

$$d(Q) = D^{\text{like-sign}}(Q)/D^{\text{unlike-sign}}(Q), \quad (4.20)$$

is analysed.

The event mixing procedure may introduce artificial distortions, or may not fully account for some detector effects or for correlations other than BEC. Most of these possible effects are treated in the Monte-Carlo simulation without inter- W BEC. Therefore they are reduced by using the double ratio or the double difference:

$$D'(Q) = \frac{D(Q)_{\text{data}}}{D(Q)_{\text{MC, nointer}}}, \quad \Delta\rho'(Q) = \Delta\rho(Q)_{\text{data}} - \Delta\rho(Q)_{\text{MC, nointer}}, \quad (4.21)$$

where $D(Q)_{\text{MC, nointer}}$ and $\Delta\rho(Q)_{\text{MC, nointer}}$ are derived from a MC without inter- W BEC.

³ For historical reasons, the number of particle permutations rather than combinations is used in formulas, leading to a factor 2 in front of ρ_2^{mix} in Eq. (4.12). The experimental statistical errors are, however, based on the number of particle pairs, i.e., 2-particle combinations.

Table 4.2

The centre-of-mass energies, luminosities and the number of events used for the different measurements.

	\sqrt{s} (GeV)	Luminosity (pb^{-1})	Number of events	
			$WW \rightarrow q\bar{q}q\bar{q}$	$WW \rightarrow q\bar{q}\ell\nu$
ALEPH	183–209	683	6155	4849
DELPHI	189–209	550	3252	2567
L3	189–209	629	5100	3800
OPAL	183–209	680	4470	4533
ALEPH R*	172–189	242	2021	–

In addition to the mixing method, ALEPH [81] also uses the double ratio of like-sign pairs ($N_{\pi^{++},--}(Q)$) and unlike-sign pairs $N_{\pi^{+-}}(Q)$ corrected with Monte-Carlo simulations without BEC effects:

$$R^*(Q) = \left(\frac{N_{\pi^{++},--}(Q)}{N_{\pi^{+-}}(Q)} \right)^{\text{data}} \bigg/ \left(\frac{N_{\pi^{++},--}(Q)}{N_{\pi^{+-}}(Q)} \right)^{\text{MC}}_{\text{noBE}}. \quad (4.22)$$

In analyses based on $\Delta\rho(Q)$, $\delta\rho(Q)$ or $\delta_l(Q)$, a deviation from zero indicates the presence of inter- W correlations, whereas for studies of $D(Q)$, $D'(Q)$ or $d(Q)$, the corresponding signature is a deviation from unity. For $R^*(Q)$, a difference between data and the Monte-Carlo prediction excluding inter- W BEC is studied.

4.2.4. Results

The four LEP experiments have published results applying the mixing method to the full LEP-II data sample. As examples, the distributions of $\Delta\rho'$ measured by ALEPH [82], δ_l measured by DELPHI [83], D and D' measured by L3 [84] and D measured by OPAL [85] are shown in Figs. 4.4–4.7, respectively. In addition ALEPH have published results using R^* [81]. The centre-of-mass energies, luminosities and the number of events used for the different measurements are listed in Table 4.2.

A simple combination procedure is available through a χ^2 average of the numerical results of each experiment [81–85] with respect to a specific BEC model under study, here based on comparisons with various tuned versions of the LUBOEI model [76,86]. The tuning is performed by adjusting the parameters of the model to reproduce correlations in samples of Z and semileptonic W decays, and applying identical parameters to the modelling of inter- W correlations (so-called “fullBE” scenario). In this way the tuning of each experiment takes into account detector systematic uncertainties in the track measurements.

An important advantage of the combination procedure used here is that it allows the combination of results obtained using different analyses. The combination procedure assumes a linear dependence of the observed size of BEC on various estimators used to analyse the different distributions. It is also verified that there is a linear dependence between the measured W mass shift and the values of these estimators [63]. The estimators are: the integral of the $\Delta\rho(Q)$ distribution (ALEPH, L3, OPAL); the parameter Λ when fitting the function $N(1 + \delta Q)(1 + \Lambda \exp(-k^2 Q^2))$ to the $D'(Q)$ distribution, with N fixed to unity (L3), or δ fixed to zero and k fixed to the value obtained from a fit to the full BEC sample (ALEPH); the parameter Λ when fitting the function $N(1 + \delta Q)(1 + \Lambda \exp(-Q/R))$ to the $D(Q)$, $D'(Q)$ and d distributions, with R fixed to the value obtained from a fit to the full BEC sample (OPAL); the parameter Λ when fitting the function $\Lambda \exp(-RQ)(1 + \epsilon RQ) + \delta(1 + \frac{\rho_2^W}{\rho_2^{\text{mix}}})$ to the δ_l distribution, with R and ϵ fixed to the value obtained from a fit to the full BEC sample (DELPHI); and finally the integral of the term describing the BEC part, $\int \lambda \exp(-\sigma^2 Q^2)$, when fitting the function $\kappa(1 + \epsilon Q)(1 + \lambda \exp(-\sigma^2 Q^2))$ to the $R^*(Q)$ distribution (ALEPH).

The size of the correlations for like-sign pairs of particles measured in terms of these estimators is compared with the values expected in the model with and without inter- W correlations in Table 4.3. Table 4.4 summarises the normalised fractions of the model seen.

For the combination of the above measurements one has to take into account correlations between them. Correlations between results of the same experiment are strong and are not available. Varying these correlations and combining the three ALEPH measurements, for example, one obtains normalised fractions of the model seen very close to those of the most precise measurement. Therefore, for simplicity, the combination of the most precise measurements of each experiment is made here: D' from ALEPH, δ_l from DELPHI, D' from L3 and D from OPAL. In this combination only the uncertainties in the understanding of the background contribution in the data are treated as correlated between experiments (denoted as “corr. syst.” in Table 4.3). The combination via a fit using MINUIT gives:

$$\frac{\text{data} - \text{model}(\text{noBE})}{\text{model}(\text{fullBE}) - \text{model}(\text{noBE})} = 0.17 \pm 0.095(\text{stat.}) \pm 0.085(\text{sys.}) = 0.17 \pm 0.13, \quad (4.23)$$

where “noBE” includes correlations between decay products of each W , but not the ones between decay products of different W s and “fullBE” includes all the correlations. A $\chi^2/\text{dof} = 3.5/3$ of the fit is observed. The measurements and their average are shown in Fig. 4.8. The measurements used in the combination are marked with an arrow. The results of LEP experiments are in good agreement.

Table 4.3

An overview of the results from different measurements described in Section 4.2.3: the difference between the measured correlations and the model without inter- W correlations (data–noBE), the corresponding statistical (stat.) and total systematic (syst.) errors, the correlated systematic error contribution (corr. syst.), and the difference between “fullBE” and “noBE” scenario. The measurements used in the combination are highlighted.

Analysis	Data–noBE	stat.	syst.	corr. syst.	fullBE–noBE	Ref.

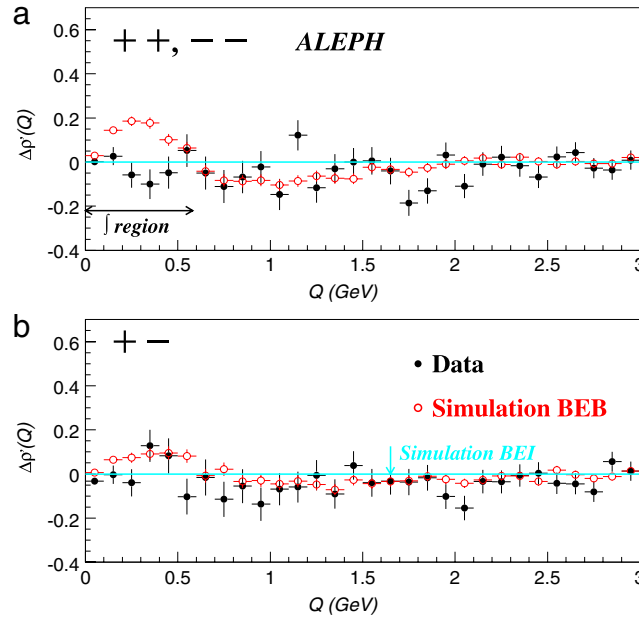

Fig. 4.4. Distribution of the quantity $\Delta\rho'$ for like- and unlike-sign pairs as a function of Q as measured by the ALEPH collaboration [82]. BEI stands for the case in which Bose–Einstein correlations do not occur between decay products of different W bosons, and BEB if they do.

4.2.5. Conclusions

The LUBOEI model of BEC between pions from different W bosons is disfavoured. The 68% confidence level (CL) upper limit on these correlations is $0.17 + 0.13 = 0.30$. This result can be translated into a 68% CL upper limit on the shift of the W mass measurements due to the BEC between particles from different W s, Δm_W , assuming a linear dependence of Δm_W on the size of the correlation. For the specific BE model investigated, LUBOEI, a shift of -35 MeV in the W mass is obtained at full BEC strength. The W mass analysis techniques applied are, however, optimised to reduce colour reconnection effects

Fig. 4.5. Distributions of the quantity δ_l for like-sign pairs as a function of Q as measured by the DELPHI collaboration [83]. The solid line shows the fit results. BEI stands for the case in which Bose–Einstein correlations do not occur between decay products of different W bosons, and BEA if they do.

on m_W which also has the effect of reducing the mass shift due to BEC. A combination of the reduced shifts reported by the LEP experiments [87–90] gives a shift of -23 MeV in the W mass at full BEC strength. Thus the 68% CL upper limit on the magnitude of the mass shift within the LUBOEI model is: $|\Delta m_W| = 0.30 \times 23 \text{ MeV} = 7 \text{ MeV}$.

5. Boson-pair and four-fermion processes

5.1. Introduction and signal definitions

Cross-section measurements at LEP-II are essential because they allow many direct and indirect tests of the Standard Model (SM). W -pair production and decay, certainly the most interesting manifestation of four-fermion production, is directly related to fundamental parameters of the model, such as the W -boson mass at the production threshold energy and to the non-Abelian gauge structure of the theory. The W -decay branching fractions and the value of $|V_{cs}|$ can be directly extracted from a cross-section measurement. A broader investigation of four-fermion production in several regions of phase space also brings additional information on the boson–fermion coupling structure, on the effect of radiative corrections and on the possible presence of new physics.

This chapter summarises the combination of final results of the four LEP experiments on four-fermion production cross-sections. The signals, with the exception of WW and ZZ , are defined on the basis of their final states together with cuts to enhance certain regions of phase space. For WW and ZZ , a diagrammatic definition is used for the sake of simplicity, even though this corresponds to a non gauge invariant definition. In what follows we will use terms such as “singly resonant” or “doubly resonant”, indicating regions of the phase space rather than a process itself.

The most interesting regions of the four-fermion phase space that are measured at LEP and for which a combination is performed, are summarised as:

- **WW** : defined as the CC03 component of the four-fermion processes, involving s -channel γ and Z exchange and t -channel ν exchange (see Fig. 1.4).
- **ZZ** : in analogy with the definition of W -pair production, Z -pair production is defined as the subset of NC02 Feynman diagrams having two resonant Z bosons (see Fig. 1.5).
- **$Z\gamma^*$** : defined for final states with two fermion–antifermion pairs, at least one being leptonic (electrons or muons). To properly consider only singly resonant regions, it is required that one and only one of the invariant masses of the couples satisfies: $|m_{ff'} - m_Z| < 2\Gamma_Z$, where $m_{ff'}$ is the invariant mass of the two same-flavour fermions. In case of four identical leptons all oppositely charged couples have to be considered. Moreover the following final state dependent phase-space cuts have been introduced:

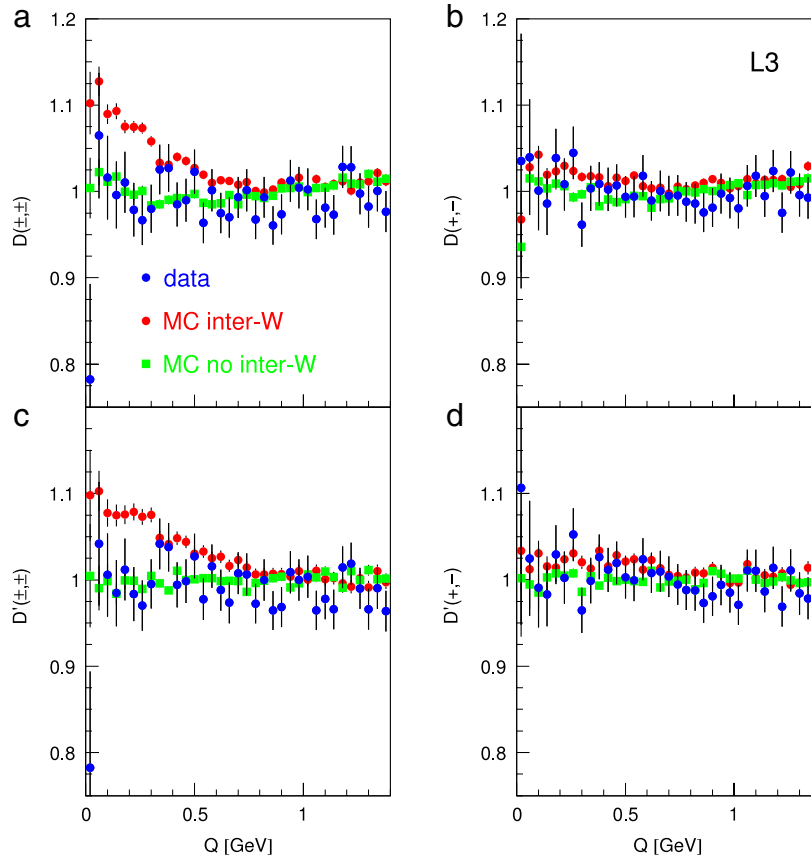

Fig. 4.6. Distributions of the quantity D and D' for like- and unlike-sign pairs as a function of Q as measured by the L3 collaboration [84].

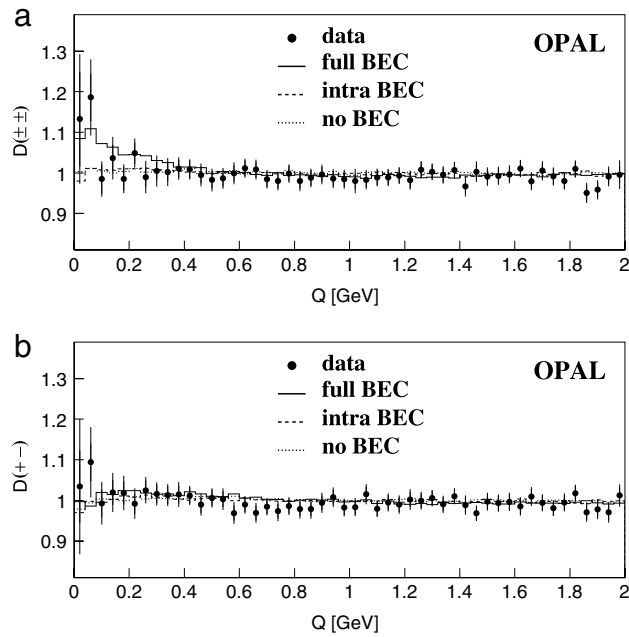

Fig. 4.7. Distribution of the quantity D for like- and unlike-sign pairs as a function of Q as measured by the OPAL collaboration [85].

Fig. 4.8. Measured BEC expressed as the relative fraction of the model with inter- W correlations. The arrows indicate the measurements used in the combination. The LEP combination is shown at the bottom.

- $eeqq, \mu\mu qq$: $|\cos\theta_\ell| < 0.95, m_{\ell\ell} > 5 \text{ GeV}, m_{qq} > 10 \text{ GeV}, \ell = e, \mu$
- $\nu\nu qq$: $m_{qq} > 10 \text{ GeV}$
- $\nu\nu\ell\ell$: $m_{\ell\ell} > 10 \text{ GeV}, m_{\ell\nu} > 90 \text{ GeV}$ or $m_{\ell\nu} < 70 \text{ GeV}, \ell = e, \mu$
- $\ell_1\ell_1\ell_2\ell_2$: $|\cos\theta_{\ell_1\ell_2}| < 0.95, m_{\ell_1\ell_1} > 5 \text{ GeV}, m_{\ell_2\ell_2} > 5 \text{ GeV}, \ell = e, \mu$.
- **Wev**: considered as the complete t -channel subset of Feynman diagrams contributing to $e\nu\ell\bar{f}'$ final states, with additional cuts to exclude the regions of phase space dominated by multiperipheral diagrams, where the cross-section calculation is affected by large uncertainties. The phase space cuts are (charge conjugation is implicit): $m_{q\bar{q}} > 45 \text{ GeV}$ for the $e\nu q\bar{q}$ final states, $E_\ell > 20 \text{ GeV}$ for the $e\nu l\nu$ final states with $\ell = \mu$ or τ , and finally $|\cos\theta_{e-}| > 0.95, |\cos\theta_{e+}| < 0.95$ and $E_{e+} > 20 \text{ GeV}$ for the $e\nu e\nu$ final states (see Fig. 1.7).
- **Zee**: defined considering only the $eeq\bar{q}$ and $ee\mu\mu$ final states. The following phase space cuts are applied to enhance the signal: $m_{q\bar{q}}(m_{\mu\mu}) > 60 \text{ GeV}$, and in addition: $\theta_{e-} < 12^\circ, 12^\circ < \theta_{e+} < 120^\circ$ and $E_{e+} > 3 \text{ GeV}$ when the positron is visible, or $\theta_{e+} > 168^\circ, 60^\circ < \theta_{e-} < 168^\circ$ and $E_{e-} > 3 \text{ GeV}$ when the electron is visible. This definition assumes the electron direction to be $+z$ and the positron direction to be $-z$.
- **WW γ** : it is defined as the part of the $e^+e^- \rightarrow W^+W^-\gamma$ process compatible with charged currents, i.e., including the final states $udud\gamma, cscs\gamma, udcs\gamma, udlv\gamma, cslv\gamma, \ell v\ell v\gamma$, assuming a diagonal CKM matrix. The following phase-space cuts are applied to enhance the signal: $E_\gamma > 5 \text{ GeV}, |\cos\theta_\gamma| < 0.95, \cos\theta_{\gamma f} < 0.9$, the invariant mass of the W -decay fermion pairs between $m_W - 2\Gamma_W$ and $m_W + 2\Gamma_W$ (see Fig. 1.6).

The cross-sections are determined from a fit to the number of observed events in data, knowing the signal efficiencies corresponding to the above signal definitions, and the expected accepted backgrounds, from Monte-Carlo simulations.

The LEP cross-section combination is performed in a fit to the $N = N_{\text{exp}} \times N_{\sqrt{s}}$ experimental inputs, where N_{exp} identifies the number of LEP experiments providing input for the measurement and $N_{\sqrt{s}}$ is the number of energy points provided. The method used is the Best Linear Unbiased Estimate method (BLUE) described in [30]. In the fits, inter-experiment and inter-energy correlations of the systematic errors are taken into account, dividing the sources according to their correlation and assuming for each either 0% or 100% correlation strength for simplicity. After building the appropriate $N \times N$ correlation matrix for the measurements, the χ^2 minimisation fit is performed by matrix algebra and is cross-checked with the use of Minuit [91].

The numbers shown here represent the combination of cross-section values and derived quantities such as branching fractions or differential distributions. For each measurement, the collaborations provided input in agreement with the conventions used to define the signal and to split the systematic uncertainties: small differences may therefore appear between the values quoted here and those published by the experiments. The combinations are performed for the whole LEP-II period, that includes data from e^+e^- collisions from $\sqrt{s} = 183 \text{ GeV}$ up to $\sqrt{s} = 207 \text{ GeV}$. The energy binning chosen and the corresponding average integrated luminosity per experiment at each energy point are shown in Table 5.1; they result from a combination of the luminosity in the hadronic and leptonic channels, therefore small changes from the values published by individual experiments may be present.

The structure of this chapter is as follows: in Section 5.2 the W -pair production is described and the combined results on cross-sections, W branching fractions, $|V_{cs}|$ and W polar-angle distributions are presented. Sections 5.3 and 5.4 concern

Monte-Carlo statistics	No	No

neutral current boson production and present combined results on ZZ and $Z\gamma^*$ cross-sections, respectively. The combination of single boson production cross-sections is reported in Section 5.5. All the presented results are compared to recent theoretical predictions, many of which were developed in the framework of the LEP-II Monte-Carlo workshop [92].

5.2. W -pair production

The signal definition has been given in Section 5.1. W -pair production is investigated via all possible final states arising in the decay of the two W bosons. According to the different decays, three topologically different final states can arise: the fully hadronic, where both W bosons decay into quarks, characterised by high multiplicity of the final state; the mixed hadronic–leptonic, also called semileptonic, with the presence of an isolated and energetic lepton and hadronic decay products of the second W ; and the fully leptonic, with the production of two acoplanar leptons. The SM branching fractions for these final states are, respectively, 0.456, 0.349, and 0.105 [23]. There are ten experimentally distinguishable final states: $q\bar{q}q\bar{q}$, $q\bar{q}\mu^+\nu$, $q\bar{q}e^+\nu$, $q\bar{q}\tau^+\nu$, $\mu^+\nu\tau^-\nu$, $e^+\nu\tau^-\nu$, $\tau^+\nu\tau^-\nu$, $\mu^+\nu e^-\nu$, $\mu^+\nu\mu^-\nu$, $e^+\nu e^-\nu$. Charge conjugation is assumed everywhere.

Event selections are generally based on Neural Network approaches to separate the signals from the major backgrounds, which arise mainly from $q\bar{q}(\gamma)$ events in the fully hadronic final state, while four-fermion backgrounds are also important in the other channels. Typical selection efficiencies range from 80% to 90% in the fully hadronic channel, from 70% to 90% in the various semileptonic channels and about 70% in the fully leptonic ones. The purest channels (95%) are the semileptonic ones with electrons or muons in the final state. Details on the event selections and experimental performances can be found in [93–96].

5.2.1. Total cross-section measurement

From the number of WW selected events in data, knowing the expected background and the efficiency on the signal, the production cross-section is extracted through likelihood fits. Cross-sections are then combined, accounting for the correlation of the systematic errors as shown in Table 5.2. The inputs used for the combinations are given in Table E.1, with the details on the composition of the systematic error in terms of correlated components shown in Table E.2. For this analysis, the SM W -decay branching fractions are assumed; see Section 5.2.2 for the measurement of these branching fractions.

The measured statistical errors are used for the combination; after building the full 32×32 covariance matrix for the measurements, the χ^2 minimisation fit is performed by matrix algebra, as described in Ref. [30], and is cross-checked using Minuit [91].

The results from each experiment for the W -pair production cross-section are shown in Table 5.3, together with the LEP combination at each energy. All measurements assume SM values for the W decay branching fractions. The combined LEP cross-sections at the eight energies are all positively correlated, see Table E.3, with correlations ranging from 6% to 19%.

Fig. 5.1 shows the combined LEP W -pair cross-section measured as a function of the centre-of-mass energy. The experimental results are compared with the theoretical calculations from YFSWW [97,98] and RACOONWW [99] between

Table 5.3

W -pair production cross-section from the four LEP experiments and combined values at all recorded centre-of-mass energies. The measurements above 175 GeV have been combined in a single fit, taking into account inter-experiment as well as inter-energy correlations of systematic errors, with a χ^2/dof of 26.6/24. The fit at 161.3 GeV (172.1 GeV) has a χ^2/dof of 1.3/3 (0.22/3).

\sqrt{s} (GeV)	WW Cross-section (pb)				
	ALEPH	DELPHI	L3	OPAL	LEP
161.3	4.23 ± 0.75	$3.61^{+0.99}_{-0.87}$	$2.89^{+0.82}_{-0.71}$	$3.62^{+0.94}_{-0.84}$	3.69 ± 0.45
172.1	11.7 ± 1.3	11.4 ± 1.4	12.3 ± 1.4	12.3 ± 1.3	12.0 ± 0.7
182.7	15.86 ± 0.63	16.07 ± 0.70	16.53 ± 0.72	15.45 ± 0.62	15.92 ± 0.34
188.6	15.78 ± 0.36	16.09 ± 0.42	16.17 ± 0.41	16.24 ± 0.37	16.05 ± 0.21
191.6	17.10 ± 0.90	16.64 ± 1.00	16.11 ± 0.92	15.93 ± 0.86	16.42 ± 0.47
195.5	16.60 ± 0.54	17.04 ± 0.60	16.22 ± 0.57	18.27 ± 0.58	16.99 ± 0.29
199.5	16.93 ± 0.52	17.39 ± 0.57	16.49 ± 0.58	16.29 ± 0.55	16.77 ± 0.29
201.6	16.63 ± 0.71	17.37 ± 0.82	16.01 ± 0.84	18.01 ± 0.82	16.98 ± 0.40
204.9	16.84 ± 0.54	17.56 ± 0.59	17.00 ± 0.60	16.05 ± 0.53	16.81 ± 0.29
206.6	17.42 ± 0.43	16.35 ± 0.47	17.33 ± 0.47	17.64 ± 0.44	17.20 ± 0.24

155 and 215 GeV using $m_W = 80.35$ GeV. The two programs have been extensively compared and agree at a level better than 0.5% at the LEP-II energies [92]. The calculations above 170 GeV, based for the two programs on the so-called leading-pole (LPA) or double-pole (DPA) approximations [92], have theoretical uncertainties decreasing from 0.7% at 170 GeV to about 0.4% at centre-of-mass energies larger than 200 GeV,⁴ while in the threshold region, where the programs use an improved Born approximation, a larger theoretical uncertainty of 2% is assigned. This theoretical uncertainty is represented by the blue band in the figure. The cross-sections are sensitive to the W -boson mass, such that an error of 50 MeV on the W mass would translate into additional errors of 0.1% (3.0%) on the cross-section predictions at 200 GeV (161 GeV), respectively. All results, up to the highest centre-of-mass energies, are in agreement with the two theoretical predictions considered and listed in Table E.4. In the lower part of the figure, the data are also compared with hypothetical predictions for which W -pair production happens in absence of one or two of the CC03 diagrams. The need for the diagram with a ZWW vertex is a spectacular confirmation of the non-Abelian nature of the electroweak SM.

The agreement between the measured W -pair cross-section, $\sigma_{WW}^{\text{meas}}$, and its expectation according to a given theoretical model, $\sigma_{WW}^{\text{theo}}$, can be expressed quantitatively in terms of their ratio:

$$\mathcal{R}_{WW} = \frac{\sigma_{WW}^{\text{meas}}}{\sigma_{WW}^{\text{theo}}}, \quad (5.1)$$

averaged over the measurements performed by the four experiments at different energies in the LEP-II region. The above procedure has been used to compare the measurements at the eight energies between 183 GeV and 207 GeV with the predictions of GENTLE [100], KORALW [101,98], YFSWW [97,98] and RACONWW [99]. The measurements at 161 GeV and 172 GeV have not been used in the combination because they were performed using data samples of low statistics and because of the high sensitivity of the cross-section to the value of the W mass at these energies.

The combination of the ratio \mathcal{R}_{WW} is performed using as input from the four experiments the 32 cross-sections measured at each of the eight energies. These are then converted into 32 ratios by dividing them by the theoretical predictions listed in Table E.4. The full 32×32 covariance matrix for the ratios is built taking into account the same sources of systematic errors used for the combination of the W -pair cross-sections at these energies.

The small statistical errors on the theoretical predictions at the various energies, taken as fully correlated for the four experiments and uncorrelated between different energies, are also translated into errors on the individual measurements of \mathcal{R}_{WW} . The theoretical errors on the predictions, due to the physical and technical precision of the generators used, are not propagated to the individual ratios but are used when comparing the combined values of \mathcal{R}_{WW} to unity. For each of the four models considered, two fits are performed: in the first, eight values of \mathcal{R}_{WW} at the different energies are extracted, averaged over the four experiments; in the second, only one value of \mathcal{R}_{WW} is determined, representing the global agreement of measured and predicted cross-sections over the whole energy range.

The results of the fits to \mathcal{R}_{WW} for YFSWW and RACONWW are given in Table 5.4, with more details given in Table E.5. As already qualitatively noted from Fig. 5.1, the LEP measurements of the W -pair cross-section above threshold are in very good agreement with the predictions and can test the theory at the level of better than 1%. In contrast, the predictions from GENTLE and KORALW are about 3% too high with respect to the measurements due to the lack of LPA/DPA corrections; the equivalent values of \mathcal{R}_{WW} in those cases are, respectively, 0.970 ± 0.008 and 0.976 ± 0.008 . The results of the fits for YFSWW and RACONWW are also shown in Fig. 5.2, where relative errors of 0.5% on the cross-section predictions have been assumed. For simplicity the energy dependence of the theory error on the W -pair cross-section has been neglected in

⁴ The theoretical uncertainty $\Delta\sigma/\sigma$ on the W -pair production cross-section calculated in the LPA/DPA above 170 GeV can be parametrised as $\Delta\sigma/\sigma = (0.4 \oplus 0.072 \cdot t_1 \cdot t_2)\%$, where $t_1 = (200 - 2 \cdot m_W)/(\sqrt{s} - 2 \cdot m_W)$ and $t_2 = (1 - (\frac{2 \cdot m_W}{200})^2)/(1 - (\frac{2 \cdot m_W}{\sqrt{s}})^2)$.

Fig. 5.1. Measurements of the W -pair production cross-section, compared to the predictions of RACOONWW [99] and YFSWW [97,98]. The shaded area represents the uncertainty on the theoretical predictions, estimated as $\pm 2\%$ for $\sqrt{s} < 170$ GeV and ranging from 0.7% to 0.4% above 170 GeV. The W mass is fixed at 80.35 GeV; its uncertainty is expected to give a significant contribution only at threshold energies.

the figure. The main differences between the predictions of YFSWW/RACOONWW and GENTLE/KORALW arise from non-leading $\mathcal{O}(\alpha)$ electroweak radiative corrections to the W -pair production process and non-factorisable corrections, which are included (in the LPA/DPA leading-pole/double-pole approximation [92]) in both YFSWW and RACOONWW, but not in GENTLE and KORALW. The data clearly prefer the computations which more precisely include $\mathcal{O}(\alpha)$ radiative corrections.

5.2.2. Derived quantities

From the cross-sections of the individual WW decay channels, each experiment determined the values of the W branching fractions, with and without the assumption of lepton universality.⁵ In the fit with lepton universality, the branching fraction to hadrons is determined from that to leptons by constraining the sum to unity. In building the full 12×12 covariance matrix, the same correlations of the systematic errors as used for the cross-section measurements are assumed. The detailed inputs to LEP and the correlation matrices are reported in Table E.6.

The results from each experiment are reported in Table 5.5 together with the LEP combination and shown in Fig. 5.3. The results of the fit which does not assume lepton universality show a negative correlation of 20.1% (12.2%) between the

⁵ In what follows any effects from lepton masses on W partial widths are neglected given their small size.

Table 5.4

Ratios of LEP combined W -pair cross-section measurements to the expectations according to YFSWW [97,98] and RACOONWW [99]. For each of the two models, two fits are performed, one to the LEP combined values of \mathcal{R}_{WW} at the eight energies between 183 GeV and 207 GeV, and another to the LEP combined average of \mathcal{R}_{WW} over all energies. The results of the fits are given in the table together with the resulting χ^2/dof . The fits take into account inter-experiment as well as inter-energy correlations of systematic errors.

\sqrt{s} (GeV)	$\mathcal{R}_{WW}^{\text{YFSWW}}$	$\mathcal{R}_{WW}^{\text{RACOONWW}}$

OPAL	10.71 ± 0.27	10.78 ± 0.26	11.14 ± 0.31	67.41 ± 0.44
LEP	10.71 ± 0.16	10.63 ± 0.15	11.38 ± 0.21	67.41 ± 0.27
χ^2/dof	6.3/9			15.4/11

$W \rightarrow \tau\bar{\nu}_\tau$ and $W \rightarrow e\bar{\nu}_e$ ($W \rightarrow \mu\bar{\nu}_\mu$) branching fractions, while between the electron and muon decay channels there is a positive correlation of 13.5%.

From the results on the leptonic branching fractions an excess of the branching fraction $W \rightarrow \tau\bar{\nu}_\tau$ with respect to the other leptons is evident. The excess can be quantified by the pair-wise ratios of the branching fractions, which represent a

Fig. 5.3. Leptonic and hadronic W branching fractions, as measured by the experiments, and the LEP combined values according to the procedures described in the text.

test of lepton universality in the decay of on-shell W bosons:

$$\mathcal{B}(W \rightarrow \mu \bar{\nu}_\mu) / \mathcal{B}(W \rightarrow e \bar{\nu}_e) = 0.993 \pm 0.019, \quad (5.2)$$

$$\mathcal{B}(W \rightarrow \tau \bar{\nu}_\tau) / \mathcal{B}(W \rightarrow e \bar{\nu}_e) = 1.063 \pm 0.027, \quad (5.3)$$

$$\mathcal{B}(W \rightarrow \tau \bar{\nu}_\tau) / \mathcal{B}(W \rightarrow \mu \bar{\nu}_\mu) = 1.070 \pm 0.026. \quad (5.4)$$

The branching fraction of W into taus with respect to that into electrons and muons differs by more than two standard deviations, where the correlations have been taken into account. The branching fractions of W into electrons and into muons agree well. Assuming only partial lepton universality the ratio between the tau fractions and the average of electrons and muons can also be computed:

$$2\mathcal{B}(W \rightarrow \tau \bar{\nu}_\tau) / (\mathcal{B}(W \rightarrow e \bar{\nu}_e) + \mathcal{B}(W \rightarrow \mu \bar{\nu}_\mu)) = 1.066 \pm 0.025 \quad (5.5)$$

resulting in an agreement at the level of 2.6 standard deviations only, with all correlations included.

If overall lepton universality is assumed (in the massless assumption), the hadronic branching fraction is determined to be $67.41 \pm 0.18(\text{stat.}) \pm 0.20(\text{syst.})\%$, while the leptonic branching fraction is $10.86 \pm 0.06(\text{stat.}) \pm 0.07(\text{syst.})\%$. These results are consistent with the SM expectations of 67.51% and 10.83% [23], respectively. The systematic error receives equal contributions from the correlated and uncorrelated sources.

Within the SM, the branching fractions of the W boson depend on the six matrix elements $|V_{qq'}|$ of the Cabibbo–Kobayashi–Maskawa (CKM) quark mixing matrix not involving the top quark. In terms of these matrix elements, the leptonic branching fraction of the W boson $\mathcal{B}(W \rightarrow \ell \bar{\nu}_\ell)$ is given by

$$\frac{1}{\mathcal{B}(W \rightarrow \ell \bar{\nu}_\ell)} = 3 \left\{ 1 + \left[1 + \frac{\alpha_s(M_W^2)}{\pi} \right] \sum_{\substack{i=(u,c), \\ j=(d,s,b)}} |V_{ij}|^2 \right\}, \quad (5.6)$$

where $\alpha_s(M_W^2)$ is the strong coupling constant and fermion mass effects are negligible. Taking $\alpha_s(M_W^2) = 0.119 \pm 0.002$ [102], and using the experimental knowledge of the sum $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 + |V_{cd}|^2 + |V_{cb}|^2 = 1.0544 \pm 0.0051$ [102], the above result can be interpreted as a measurement of $|V_{cs}|$ which is the least well determined of these matrix elements:

$$|V_{cs}| = 0.969 \pm 0.013.$$

The error includes a contribution of 0.0006 from the uncertainty on α_s and a 0.003 contribution from the uncertainties on the other CKM matrix elements, the largest of which is that on $|V_{cd}|$. These uncertainties are negligible in the error of this determination of $|V_{cs}|$, which is dominated by the experimental error of 0.013 arising from the measurement of the W branching fractions.

5.2.3. W angular distribution

In addition to measuring the total W^+W^- cross-section, the LEP experiments produce results for the differential cross-section, $d\sigma_{WW}/d\cos\theta_W$, where θ_W is the polar angle of the produced W^- with respect to the e^- beam direction. The LEP combination of these measurements will allow future theoretical models which predict deviations in this distribution to be tested against the LEP data in a direct and, as far as possible, model-independent manner. To reconstruct the $\cos\theta_W$ distribution it is necessary to identify the charges of the decaying W bosons. This can only be performed without significant ambiguity when one of W -boson decays via $W \rightarrow e\nu$ or $W \rightarrow \mu\nu$, in which case the lepton provides the charge tag. Consequently, the combination of the differential cross-section measurements is performed for the $q\bar{q}e\nu$ and $q\bar{q}\mu\nu$ channels combined. Selected $q\bar{q}\tau\nu$ events are not considered due to the larger backgrounds and difficulties in determining the tau lepton charge in the case where not all charged decay products are detected.

The measured $q\bar{q}e\nu$ and $q\bar{q}\mu\nu$ differential cross-sections are corrected to correspond to the CC03 set of diagrams with the additional constraint that the charged lepton is more than 20° away from the e^+e^- beam direction, $|\theta_{\ell\pm}| > 20^\circ$. This angular requirement corresponds approximately to the experimental acceptance of the four LEP experiments and also greatly reduces the difference between the full $4f$ cross-section and the CC03 cross-section by reducing the contribution of t -channel diagrams in the $q\bar{q}e\nu$ final state.⁶ The angle $\cos\theta_W$ is reconstructed from the four-momenta of the fermions from the W^- decay using the ECALO5 photon recombination scheme [92], a prescription for combining photons to a close-by charged fermion.

The LEP combination is performed in ten bins of $\cos\theta_W$. Because the differential cross-section distribution evolves with \sqrt{s} , reflecting the changing relative s - and t -channel contributions, the LEP data are divided into four \sqrt{s} ranges: 180 GeV–184 GeV, 184 GeV–194 GeV, 194 GeV–204 GeV, and 204 GeV–210 GeV. It has been verified for each \sqrt{s} range that the differences in the differential cross-sections at the mean value of \sqrt{s} compared to the luminosity-weighted sum of the differential cross-sections reflecting the actual distribution of the data across \sqrt{s} are negligible compared to the statistical errors.

The experimental resolution in LEP on the reconstructed values of $\cos\theta_W$ is typically 0.15–0.20. When simulating W -pair production, a significant migration between generated and reconstructed bins of $\cos\theta_W$ is observed. The effects of bin-to-bin migration are not explicitly unfolded, instead each experiment obtains the cross-section in the i th bin of the differential distribution, σ_i , from

$$\sigma_i = \frac{N_i - b_i}{\epsilon_i \mathcal{L}}, \quad (5.7)$$

where:

N_i is the observed number of $q\bar{q}e\nu/q\bar{q}\mu\nu$ events reconstructed in the i th bin of the $\cos\theta_W$ distribution.

b_i is the expected number of background events in bin i . The contribution from four-fermion background is treated as in each of the experiments' W^+W^- cross-section analyses.

ϵ_i is the Monte-Carlo efficiency in bin i , defined as $\epsilon_i = S_i/G_i$ where S_i is the number of selected CC03 MC $q\bar{q}\ell\nu_\ell$ events reconstructed in bin i and G_i is the number of MC CC03 $q\bar{q}e\nu/q\bar{q}\mu\nu$ events with generated $\cos\theta_W$ (calculated using the ECALO5 recombination scheme) lying in the i th bin ($|\theta_{\ell\pm}| > 20^\circ$). Selected $q\bar{q}\tau\nu$ events are included in the numerator of the efficiency.

This bin-by-bin efficiency correction method has the advantages of simplicity and that the resulting σ_i are uncorrelated. The main disadvantage of this procedure is that bin-by-bin migrations between generated and reconstructed $\cos\theta_W$ are corrected purely on the basis of the SM expectation and may potentially be biased. The validity of the simple correction procedure was tested by considering a range of deviations from the SM. Specifically, the SM $\cos\theta_W$ distribution was reweighted, in turn, by factors of $1 + 0.1(\cos\theta_W - 1)$, $1 - 0.2\cos^2\theta_W$, $1 + 0.2\cos^2\theta_W$ and $1 - 0.4\cos^8\theta_W$, and data samples generated corresponding to the combined LEP luminosity. These reweighting functions represent deviations which are large compared to the statistics of the combined LEP measurements. The bin-by-bin correction method was found to result in good χ^2 distributions when the extracted $\cos\theta_W$ distributions were compared with the underlying generated distribution (e.g. the worst case gave a mean χ^2 of 11.3 for the 10 degrees of freedom corresponding to the ten $\cos\theta_W$ bins), and no significant bias was found in these tests.

For the LEP combination the systematic uncertainties on measured differential cross-sections are broken down into two terms: uncertainties which are fully correlated between bins and experiments and errors which are correlated between bins but uncorrelated between experiments. This procedure reflects the fact that the dominant systematic errors affect the overall normalisation of the measured distributions rather than the shape.

The detailed inputs provided by the four LEP experiments are reported in Tables E.7–E.10. Table 5.6 presents the combined LEP results. In the table the bin-by-bin error breakdown is also reported. The result is also shown in Fig. 5.4, where the combined data are superimposed on the four-fermion theory predictions calculated with Kandy [98] and RACOONWW [99],

⁶ With this requirement the difference between the total four-fermion (CC20 [92]) and double-resonant (CC03) $q\bar{q}e\nu$ cross-section is approximately 3.5%, as opposed to 24.0% without the lepton angle requirement. For the $q\bar{q}\mu\nu$ channel the difference between the total four-fermion (CC10 [92]) and double-resonant (CC03) cross-section is less than 1% in both cases.

Table 5.6

Combined W^- differential angular cross-section in the 10 angular bins for the four chosen energy intervals. For each energy range, the sum of the measured integrated luminosities and the luminosity-weighted centre-of-mass energy is reported. The results per angular bin in each of the energy interval are then presented: σ_i indicates the average of $d[\sigma_{WW}(BR_{e\nu} + BR_{\mu\nu})]/d\cos\theta_{W^-}$ in the i th bin of $\cos\theta_{W^-}$, with a bin width of 0.2. For each bin, the values of the total, statistical and systematic errors are reported. All values are given in pb.

which are indistinguishable on the plot scale. The agreement of data and calculations is generally very good, with an apparent under-fluctuation of data with respect to the central values of the theory predictions in the last bin of the 194 GeV–204 GeV energy range.

5.3. Z -pair production

The signal definition has been given in Section 5.1. Z -pair production shows several similarities to W -pair production. The different final states depend on the decay of the heavy bosons: it is possible to have four quarks, two quarks and two leptons or four leptons in the final state. The signatures are very clean and the main background is represented by WW production.

The approaches used by the experiments for the selection are based on Neural Network techniques. The final states studied involve both the hadronic and leptonic decays of the Z boson, where invisible decays are included when accompanied by a charged decay. The selection efficiencies depend significantly on the final state, ranging from 25% to 60%, with purities from 30% to 70% [103–106]. The main backgrounds include four-fermion production, di-leptonic and QCD final states.

The LEP combination is performed applying the same technique as used for the WW cross-section measurement. The symmetrised expected statistical error of each analysis is used, to avoid biases due to the limited number of selected events. The detailed inputs from the experiments are reported in Table E.11. The results of the individual experiments are summarised in Table 5.7, together with the LEP averages. The composition of the systematic error in terms of correlated components is shown in Table E.12. The cross-sections used for the combination are determined by the experiments using the frequentist approach, without assuming any prior for the value of the cross-section itself.

The measurements are shown in Fig. 5.5 as a function of the LEP centre-of-mass energy, where they are compared to the YFSZZ [107] and ZZTO [108] predictions as listed in Table E.13. Both these calculations have an estimated uncertainty of 2% [92]. The data do not show any significant deviation from the theoretical expectations.

In analogy with the W -pair cross-section, a value for \mathcal{R}_{ZZ} can also be determined: its definition and the procedure of the combination follows those described for \mathcal{R}_{WW} . The data are compared with the YFSZZ and ZZTO predictions; Table 5.8, with more details given in Table E.14, reports the combined values of \mathcal{R}_{ZZ} at each energy and combined, and Fig. 5.6 shows them in comparison to unity, where the $\pm 2\%$ error on the theoretical ZZ cross-section is shown as a yellow band. The experimental accuracy on the combined value of \mathcal{R}_{ZZ} is about 5%.

5.4. $Z\gamma^*$ production

The signal definition has been given in Section 5.1. The study of these final states is also relevant for the measurement of neutral gauge couplings. The LEP collaborations did not provide a complete analysis of all possible $Z\gamma^*$ final states. While ALEPH and OPAL did not present any results on $Z\gamma^*$, DELPHI provided results for the $\nu\nu q\bar{q}$, $\ell\ell q\bar{q}$, $\ell\ell\ell\ell$ and $q\bar{q}q\bar{q}$

LEP (ADLO)

Fig. 5.4. LEP combined $d[\sigma_{WW}(BR_{e\nu} + BR_{\mu\nu})]/d\cos\theta_{W^-}$ distributions for the four chosen energy intervals. The combined values (points) are superimposed on the four-fermion predictions from KandY and RACONWW.

Table 5.7

Z-pair production cross-sections from the four LEP experiments and combined values for the eight centre-of-mass energies between 183 GeV and 207 GeV. The χ^2/dof of the combined fit is 14.5/24.

206.6	$1.05^{+0.22}_{-0.21}$	$0.96^{+0.16}_{-0.15}$	$1.09^{+0.18}_{-0.17}$	$0.97^{+0.20}_{-0.19}$	1.00 ± 0.09

final states [109], and L3 provided results for the $\nu\nu qq$, $\ell\ell qq$, $\ell\ell\nu\nu$, and $\ell\ell\ell\ell$ channels [110], where $\ell = e, \mu$. Final states containing τ leptons were not studied. The combination reported here has been performed using data from the final states provided by both DELPHI and L3, namely $\nu\nu qq$, $\mu\mu qq$ and $ee qq$.

To increase the statistics the cross-sections were determined using the full data sample at an average LEP-II centre-of-mass energy. Table 5.9 presents the measured cross-sections, where the expected statistical errors were used for the combination. As noted in Section 5.1, the $Z\gamma^*$ signal has been defined by mass and angular cuts specific to each of the contributing channels, and the comparison of the combined LEP cross-section with the theoretical prediction, calculated with `g4f` [111] and shown in the last section of Table 5.9, has been made by imposing the same cuts on each of the experimental and simulated samples included in the combination. The results agree well with the expectations.

Fig. 5.5. Measurements of the Z-pair production cross-section, compared to the predictions of YFSZZ [107] and ZZTO [108]. The shaded area represents the $\pm 2\%$ uncertainty on the predictions.

Table 5.8

Ratios of LEP combined Z-pair cross-section measurements to the expectations according to ZZTO [108] and YFSZZ [107]. The results of the combined fits are given together with the resulting χ^2/dof . Both fits take into account inter-experiment as well as inter-energy correlations of systematic errors.

$\sqrt{s}(\text{GeV})$	$\mathcal{R}_{ZZ}^{\text{ZZTO}}$	$\mathcal{R}_{ZZ}^{\text{YFSZZ}}$

Average	0.966 ± 0.052	0.960 ± 0.052
χ^2/dof	17.4/31	17.4/31

5.5. Single-boson production

The study of singly resonant final states finds its motivations in the comparison with SM calculations in a delicate region of the 4- f phase space, where the treatment of ISR or fermion loop corrections can induce large corrections, up to several percent, to the total cross-section. These processes are also very sensitive to the value of α_{QED} . Moreover, single W production also brings information on possible anomalous $WW\gamma$ couplings.

Single boson production at LEP is mostly realised via t -channel processes, where either the incident electron or positron maintains its direction, escaping undetected along the beam and thus generating missing momentum along the z axis. Single W and single Z production then proceed dominantly via the vector boson fusion process illustrated in Fig. 1.7 or via Bremsstrahlung processes. In the case of single W production in the $W \rightarrow e\bar{\nu}_e$ final state, the W is detected either by its hadronic decay producing two jets, or by its leptonic decay producing a single charged lepton; single Z production in the $Z \rightarrow e^+e^-$ final state is identified from an electron recoiling against two fermions (quarks or leptons) coming from the Z decay.

The selection of these events is particularly difficult because of the relatively low cross-section of the signal and because of the presence of large backgrounds in these phase space regions. Particularly large backgrounds arise from radiative $q\bar{q}$ production or $\gamma\gamma$ scattering. The analyses, mostly based on sequential cuts on kinematic variables, have an efficiency which depends on the considered final state and ranges typically from 35% to 60% [112–116]. These references describe results on

Fig. 5.6. Ratios of LEP combined Z-pair cross-section measurements to the expectations according to ZZTO [108] and YFSZZ [107]. The yellow bands represent constant relative errors of 2% on the two cross-section predictions.

Table 5.9

$Z\gamma^*$ measurements by the experiments and combined LEP measurements. The columns show, respectively, the channel, the luminosity-weighted centre-of-mass energy, the luminosity, the measured cross-section, the measured statistical error, the systematic contribution uncorrelated between experiments, the systematic contribution correlated between experiments and the expected statistical error from the simulation. For the LEP combination the full systematic error and the total error are given and the last column presents the theory expectation with `grc4f` [111].

single-boson production using selection criteria which are specific to the individual experiments. The results shown below are derived from a common selection procedure using the criteria listed in Section 5.1.

5.5.1. W cross-section measurement

The signal definition has been given in Section 5.1. The LEP combination of the single- W production cross-section is performed using the expected statistical errors, given the limited statistical precision of the single measurements. The correlation of the systematic errors in energy and among experiments is properly taken into account. The hadronic and the total single- W cross-sections are combined independently, as the former is less contaminated by $\gamma\gamma$ interaction contributions. The details on the input measurements are summarised in Tables E.15 and E.16.

The hadronic single- W results and combinations are reported in Table 5.10 and Fig. 5.7. The total single- W results, for all decay modes and combinations are listed in Table 5.11 and Fig. 5.8. In the two figures, the measurements are compared with the expected values from WPHACT [117] and `grc4f` [111], listed in Table E.17. In Fig. 5.7, the predictions of WTO [118], which includes fermion-loop corrections for the hadronic final states, have also been included. As discussed more in detail in [92], the theoretical predictions are scaled upward to correct for the implementation of QED radiative corrections at the wrong energy scale s . The full correction of 4%, derived from comparison with the theoretical predictions from SWAP [119], is conservatively taken as a systematic error. This uncertainty dominates the $\pm 5\%$ theoretical error currently assigned to

Table 5.10

Single- W hadronic production cross-section from the LEP experiments and combined values for the eight energies between 183 and 207 GeV, in the hadronic decay channel of the W boson. The χ^2/dof of the combined fit is 13.2/16.

Average	1.058 ± 0.078	1.090 ± 0.080
χ^2/dof	12.1/23	12.1/23

The agreement can also be appreciated in Table 5.12, where the values of the ratio between measured and expected cross-section values according to the computations of grc4f and WPHACT are reported, with additional details listed in Table E.18. The combination is performed accounting for the energy and experiment correlations of the systematic sources. The results are also presented in Fig. 5.9.

5.5.2. Zee cross-section measurement

The signal definition has been given in Section 5.1. The combination of results is performed with the same technique used for the other channels. The results include the hadronic and the leptonic channels and all the centre-of-mass energies from 183 to 209 GeV from the ALEPH [112], DELPHI [113] and L3 [120] Collaborations. The OPAL results [121] are not included in the combination as they were not provided according to the common signal definition.

Tables 5.13 and 5.14, with details summarised in Table E.19, present the inputs from the experiments and the corresponding LEP combinations in the muon and hadronic channel, respectively. The $ee\mu\mu$ cross-section is already combined in energy by the individual experiments to increase the statistics of the data. The combination takes into account the correlation of the energy and experimental systematic errors. The results in the hadronic channel are compared with the predictions of WPHACT and grc4f, listed in Table E.20, in Fig. 5.10 as a function of the centre-of-mass energy.

The same data are expressed as ratios of the measured to the predicted cross-section, listed in Table 5.15, with details on the decomposition of the systematic error reported in Table E.21, and shown in Fig. 5.11. The accuracy of the combined ratio is about 7% with three experiments contributing to the average.

Fig. 5.9. Ratios of LEP combined total single- W cross-section measurements to the expectations according to `gxc4f` [111] and `WPHACT` [117]. The yellow bands represent constant relative errors of 5% on the two cross-section predictions.

5.6. $WW\gamma$ production

The signal definition has been given in Section 5.1. The study of photon production in association with a W -boson pair is important for testing the sector of quartic gauge couplings. In order to increase the statistical accuracy, the LEP combination is performed in energy intervals rather than at each energy point; they are defined according to the LEP-II running periods where more statistics were accumulated. The luminosity-weighted centre-of-mass energy per interval is determined in each experiment and then combined to obtain the corresponding value for each energy interval. Table 5.16 reports those energies and the cross-sections measured by the experiments that are used in this combination [122–124], together with the combined LEP values.

Fig. 5.12 shows the combined data points compared with the cross-section calculated with `EEWWG` [125] and `RACONWW`. The `RACONWW` prediction is shown in the figure without any theory error band.

Fig. 5.10. Measurements of the single-Z hadronic production cross-section, compared to the predictions of WPHACT [117] and grc4f [111]. The shaded area represents the $\pm 5\%$ uncertainty on the predictions.

Table 5.15

5.7. Summary

This chapter has summarised the final LEP results in terms of four-fermion cross-sections and derived quantities. The WW cross-section has been measured precisely at LEP-II energies. The measurements clearly favour those theoretical predictions which properly include $O(\alpha)$ electroweak corrections, thus showing that the SM can be tested at the loop level at LEP-II.

In general the results are in good agreement with the SM predictions, both in the charged current and in the neutral current sector. A small anomaly in the W decay branching fractions, favouring W decays into $\tau\nu_\tau$ compared to the other lepton families, is observed in the data. This excess is above two standard deviations in the measured branching fractions into both $e\nu_e$ and $\mu\nu_\mu$.

Fig. 5.11. Ratios of LEP combined single-Z hadronic cross-section measurements to the expectations according to grc4f [111] and WPHACT [117]. The yellow bands represent constant relative errors of 5% on the two cross-section predictions.

Fig. 5.12. Measurements of the $WW\gamma$ production cross-section, compared to the predictions of EEWWG [125] and RACOONWW [99]. The shaded area in the EEWWG curve represents the $\pm 5\%$ uncertainty on the predictions.

6. Electroweak gauge boson self couplings

6.1. Introduction

The measurement of gauge boson couplings and the search for possible anomalous contributions due to the effects of new physics beyond the Standard Model (SM) are among the principal physics aims at LEP-II [126]. Combined results on triple gauge boson couplings are presented here.

The W -pair production process, $e^+e^- \rightarrow W^+W^-$, involves the charged triple gauge boson vertices between the W^+W^- and the Z or photon shown in Fig. 1.4. During LEP-II operation, about 10,000 W -pair events were collected by each experiment. Single W ($e\nu W$) and single photon ($\nu\bar{\nu}\gamma$) production at LEP are also sensitive to the $WW\gamma$ vertex, see Fig. 1.7. Results from these channels are also included in the combination for some experiments; the individual references should be consulted for details. The Monte-Carlo calculations, RacoowWW [99] and YFSWW [97,98], incorporate an improved treatment of $O(\alpha_{em})$ corrections to WW production. The corrections affect the measurements of the charged TGCs in W -pair

production. Results including these $O(\alpha_{em})$ corrections have been submitted from all four LEP collaborations ALEPH [127], DELPHI [128], L3 [129] and OPAL [130].

At centre-of-mass energies exceeding twice the Z boson mass, pair production of Z bosons is kinematically allowed. Here, one searches for the possible existence of triple vertices involving only neutral electroweak gauge bosons. Such vertices could also contribute to $Z\gamma$ production. In contrast to triple gauge boson vertices with two charged gauge bosons, purely neutral gauge boson vertices do not occur at tree level in the SM of electroweak interactions.

The expected total and differential cross-sections of these processes depend on the values of the triple gauge couplings, allowing their measurements by comparing Monte-Carlo simulations to the data. In contrast to the analysis of electroweak gauge boson self-couplings performed at hadron colliders, no form-factor term scaling the bare couplings is applied in the analysis of the LEP data.

6.1.1. Charged triple gauge boson couplings

The parametrisation of the charged triple gauge boson vertices is described in Refs. [126,131–133]. The most general Lorentz invariant Lagrangian which describes the triple gauge boson interaction has fourteen independent complex couplings, seven describing the $WW\gamma$ vertex and seven describing the WWZ vertex. Assuming electromagnetic gauge invariance as well as C and P conservation, the number of independent TGCs reduces to five. A common set is $\{g_1^Z, \kappa_\gamma, \kappa_Z, \lambda_\gamma, \lambda_Z\}$, with SM values of $g_1^Z = \kappa_\gamma = \kappa_Z = 1$ and $\lambda_\gamma = \lambda_Z = 0$. The parameters proposed in [126] and used by the LEP experiments are g_1^Z, κ_γ and λ_γ with the gauge constraints:

$$\kappa_Z = g_1^Z - (\kappa_\gamma - 1) \tan^2 \theta_W, \quad (6.1)$$

$$\lambda_Z = \lambda_\gamma, \quad (6.2)$$

where θ_W is the weak mixing angle. In an effective Lagrangian approach, all three of the remaining independent couplings, g_1^Z, κ_γ and λ_γ , receive contributions from operators of dimension six or greater. The couplings are considered as real, with the imaginary parts fixed to zero. Note that the measured coupling values themselves and not their deviation from the SM values are quoted. LEP combinations are made in single-parameter fits, in each case setting the other TGCs to their SM value.

The coupling g_1^Z describes the overall strength of the WWZ coupling. The photonic couplings κ_γ and λ_γ are related to the magnetic and electric properties of the W boson. One can write the lowest order terms for a multipole expansion describing the $W-\gamma$ interaction as a function of κ_γ and λ_γ . For the magnetic dipole moment, μ_W , and the electric quadrupole moment, q_W , one obtains:

$$\mu_W = \frac{e}{2m_W} (1 + \kappa_\gamma + \lambda_\gamma), \quad (6.3)$$

$$q_W = -\frac{e}{m_W^2} (\kappa_\gamma - \lambda_\gamma). \quad (6.4)$$

The inclusion of $O(\alpha_{em})$ corrections in the Monte-Carlo calculations has a considerable effect on the charged TGC measurement. Both the total cross-section and the differential distributions are affected. The cross-section is reduced by 1%–2% depending on the energy. For the differential distributions, the effects are naturally more complex. The polar W^- production angle carries most of the information on the TGC parameters; its shape is modified to be more forwardly peaked. In a fit to data, the $O(\alpha_{em})$ effect manifests itself as a negative shift of the obtained TGC values with a magnitude of typically -0.015 for λ_γ and g_1^Z and -0.04 for κ_γ .

6.1.2. Neutral triple gauge boson couplings

There are two classes of Lorentz invariant structures associated with neutral TGC vertices which preserve $U(1)_{em}$ and Bose symmetry, as described in [132,134].

The first class refers to anomalous $Z\gamma\gamma^*$ and $Z\gamma Z^*$ couplings which are accessible at LEP in the process $e^+e^- \rightarrow Z\gamma$. The parametrisation contains eight couplings: h_i^V with $i = 1, \dots, 4$ and $V = \gamma, Z$. The superscript $V = \gamma$ refers to $Z\gamma\gamma^*$ couplings and superscript $V = Z$ refers to $Z\gamma Z^*$ couplings. The photon and the Z boson in the final state are considered as on-shell particles, while the third boson at the vertex, the s -channel internal propagator, is off shell. The couplings h_1^V and h_2^V are CP-odd while h_3^V and h_4^V are CP-even.

The second class refers to anomalous $ZZ\gamma^*$ and ZZZ^* couplings which are accessible at LEP-II in the process $e^+e^- \rightarrow ZZ$. This anomalous vertex is parametrised in terms of four couplings: f_i^V with $i = 4, 5$ and $V = \gamma, Z$. The superscript $V = \gamma$ refers to $ZZ\gamma^*$ couplings and the superscript $V = Z$ refers to ZZZ^* couplings. Both Z bosons in the final state are assumed to be on-shell, while the third boson at the triple vertex, the s -channel internal propagator, is off-shell. The couplings f_4^V are CP-odd whereas f_5^V are CP-even.

In an effective Lagrangian approach, the couplings $h_1^V, h_3^V, f_4^V, f_5^V$ receive contributions from operators of dimension six or greater, while the lowest-dimension operators contributing to h_2^V and h_4^V have dimension eight. Note that the h_i^V and the f_i^V couplings are independent of each other. They are assumed to be real and they vanish at tree level in the SM. Results on neutral gauge boson couplings are reported for single- and two-parameter fits.

Table 6.1

The systematic uncertainties considered correlated between the LEP experiments in the charged TGC combination and their effect on the combined fit results for the charged TGC parameters.

Source	g_1^Z	κ_γ	λ_γ
σ_{WW} prediction	0.003	0.018	0.002
σ_W prediction	–	0.003	0.001
Hadronisation	0.003	0.005	0.004
Bose–Einstein Correlation	0.002	0.003	0.002
Colour Reconnection	0.003	0.005	0.002
$O(\alpha_{em})$ correction	0.002	0.014	0.002

6.2. Combination procedure

The combination is based on the individual likelihood functions from the four LEP experiments. Each experiment provides the negative log likelihood, $\log \mathcal{L}$, as a function of the coupling parameters to be combined. The single-parameter analyses are performed fixing all other parameters to their SM values. For the charged TGCs, the gauge constraints listed in Section 6.1.1 are always enforced. Either the $\log \mathcal{L}$ curves were available in numerical form or they have been treated as parabolic according to the respective publication. Details of the individual measurements entering the combination are summarised below.

The $\log \mathcal{L}$ functions from each experiment include statistical as well as those systematic uncertainties which are considered as uncorrelated between experiments. In all combinations, the individual $\log \mathcal{L}$ functions are combined. It is necessary to use the $\log \mathcal{L}$ functions directly in the combination, since in some cases they are not parabolic, and hence it is not possible to properly combine the results by simply taking weighted averages of the measurements.

The main contributions to the systematic uncertainties that are uncorrelated between experiments arise from detector effects, background in the selected signal samples, limited Monte-Carlo statistics and the fitting method. Their importance varies for each experiment and the individual references should be consulted for details.

In the neutral TGC sector, the main correlated systematic uncertainties arise from the theoretical cross-section prediction in ZZ and $Z\gamma$ -production, about 2% for ZZ and about 1% (2%) in the $q\bar{q}\gamma$ ($\nu\bar{\nu}\gamma$) channel. The effect of a correlated treatment has been estimated in earlier measurements to be negligible. Hence this and all other correlated sources of systematic errors, such as those arising from the LEP beam energy, are for simplicity treated as uncorrelated. The combination is performed by adding the $\log \mathcal{L}$ curves of the individual experiments.

In the charged TGC sector, systematic uncertainties considered correlated between the experiments are summarised in Table 6.1: the theoretical cross-section prediction, σ , which is 0.5% for W -pair production and 5% for single W production, hadronisation effects (HAD), the final state interactions, namely Bose–Einstein correlations (BEC) and colour reconnection (CR), and the uncertainty in the radiative corrections themselves (LPA). The latter was the dominant systematic error in previous combinations, where we used a conservative estimate, namely the full effect from applying the $O(\alpha_{em})$ corrections. Analyses on the subject are available from several LEP experiments, based on comparisons of fully simulated events using two different leading-pole approximation schemes (LPA-A and LPA-B, [135] and references therein). In addition, the availability of comparisons of the generators incorporating $O(\alpha_{em})$ corrections, RacoonWW and YFSWW [99,97,98], makes it possible to perform a more realistic estimation of this effect and its uncertainty. In general, the TGC shift measured in the comparison of the two generators is found to be larger than the effect from the different LPA schemes. This improved estimation, while still being conservative, reduces the systematic uncertainty from $O(\alpha_{em})$ corrections by about a third for g_1^Z and λ_γ and roughly halves it for κ_γ , compared to the full $O(\alpha_{em})$ correction. The application of this reduced systematic error renders the charged TGC measurements statistics dominated. In case of the charged TGCs, the systematic uncertainties considered correlated between the experiments amount to 32% of the combined statistical and uncorrelated uncertainties for λ_γ and g_1^Z , while for κ_γ they amount to 57%, indicating again that the measurements of λ_γ , g_1^Z and κ_γ are limited by data statistics.

The combination procedure [136] used for the charged TGCs allows the combination of statistical and correlated systematic uncertainties, independently of the analysis method chosen by the individual experiments. The combination uses the likelihood curves and correlated systematic errors submitted by each of the four experiments. The procedure is based on the introduction of an additional free parameter to take into account the systematic uncertainties, which are treated as shifts on the fitted TGC value, and are assumed to have a Gaussian distribution. A simultaneous minimisation of both parameters, TGC and systematic error, is performed.

In detail, the combination proceeds in the following way: the set of measurements from the LEP experiments ALEPH, DELPHI, OPAL and L3 is given with statistical and uncorrelated systematic uncertainties in terms of likelihood curves: $-\log \mathcal{L}_{stat}^A(x)$, $-\log \mathcal{L}_{stat}^D(x)$, $-\log \mathcal{L}_{stat}^L(x)$ and $-\log \mathcal{L}_{stat}^O(x)$, respectively, where x is the coupling parameter in question. Also given are the shifts for each of the five totally correlated sources of uncertainty mentioned above; each source S leads to systematic errors σ_A^S , σ_D^S , σ_L^S and σ_O^S .

Additional parameters Δ^S are included in order to take into account a Gaussian distribution for each of the systematic uncertainties. The procedure then consists in minimising the function:

$$-\log \mathcal{L}_{total} = \sum_{E=A,D,L,O} \log \mathcal{L}_{stat}^E \left(x - \sum_S (\sigma_E^S \Delta^S) \right) + \sum_S \frac{(\Delta^S)^2}{2} \quad (6.5)$$

where x and Δ_S are the free parameters, and the sums run over the four experiments E and the correlated systematic errors S discussed above and listed in Table 6.1. The resulting uncertainty on x takes into account all sources of uncertainty, yielding a measurement of the coupling with the error representing statistical and systematic sources. The projection of the minima of the log-likelihood as a function of x gives the combined log-likelihood curve including statistical and systematic uncertainties. The advantage over the scaling method used previously is that it treats systematic uncertainties that are correlated between the experiments correctly, while not forcing the averaging of these systematic uncertainties into one global LEP systematic uncertainties scaling factor. In other words, the (statistical) precision of each experiment gets reduced by its own correlated systematic errors, instead of an averaged LEP systematic error. The method has been cross-checked against the scaling method, and was found to give comparable results. The inclusion of the systematic uncertainties leads to small differences, as expected by the improved treatment of correlated systematic errors. A similar behaviour is seen in Monte-Carlo comparisons of these two combination methods [137]. Furthermore, it was shown that the minimisation-based combination method used for the charged TGCs agrees with the method based on optimal observables, where systematic effects are included directly in the mean values of the optimal observables (see [137]), for any realistic ratio of statistical to systematic uncertainties. Further details on the combination method can be found in [136].

In the following, single-parameter fits are presented for the TGC parameters g_1^Z , κ_γ , λ_γ , h_i^V and f_i^V , while results from two-parameter fits are also given for (f_4^V, f_4^Z) and (f_5^V, f_5^Z) . For results quoted in numerical form, the one standard deviation uncertainties (68% confidence level) are obtained by taking the coupling values for which $\Delta \log \mathcal{L} = +0.5$ above the minimum. The 95% confidence level (C.L.) limits are given by the coupling values for which $\Delta \log \mathcal{L} = +1.92$ above the minimum. For multi-parameter analyses, the two dimensional 68% C.L. contour curves for any pair of couplings are obtained by requiring $\Delta \log \mathcal{L} = +1.15$, while for the 95% C.L. contour curves $\Delta \log \mathcal{L} = +3.0$ is required. Since the results on the different parameters and parameter sets are obtained from the same data sets, they cannot themselves be combined when looking at models establishing additional relations between these couplings.

6.3. Measurements

The combined results presented here are obtained from charged and neutral electroweak gauge boson coupling measurements as discussed above. The individual references should be consulted for details about the data samples used.

The charged TGC analyses of ALEPH, DELPHI, L3 and OPAL use data collected at LEP-II with centre-of-mass energies up to 209 GeV. These analyses use different channels, typically the semileptonic and fully hadronic W -pair decays [127–130,138–140]. The full data set is analysed by all four experiments. Anomalous TGCs affect both the total production cross-section and the shape of the differential cross-section as a function of the polar W^- production angle. The relative contributions of each helicity state of the W bosons are also changed, which in turn affects the distributions of their decay products. The analyses presented by each experiment make use of different combinations of each of these quantities. In general, however, all analyses use at least the expected variations of the total production cross-section and the W^- production angle. Results from $e\nu W$ and $\nu\bar{\nu}\gamma$ production are included by some experiments. Single- W production is particularly sensitive to κ_γ , thus providing information complementary to that from W -pair production.

The h -coupling analyses of ALEPH, DELPHI and L3 use data collected at LEP-II with centre-of-mass energies of up to 209 GeV. The OPAL measurements use the data at 189 GeV only. The results of the f -couplings are obtained from the whole data set above the ZZ -production threshold by all experiments. The experiments already pre-combine different processes and final states for each of the couplings. All analyses use measurements of the total cross-sections of $Z\gamma$ and ZZ production and the differential distributions in the determination of the h_i^V couplings [141–144] and the f_i^V couplings [141,142,145,146], while DELPHI also includes $Z\gamma^*$ data in the determination of both sets of couplings.

6.4. Results

We present results from the four LEP experiments on the various electroweak gauge boson couplings, and their combination. The results quoted for each individual experiment are calculated using the methods described in Section 6.2. Therefore they may differ slightly from those reported in the individual references, as the experiments in general use other methods to combine the data from different channels and to include systematic uncertainties. In particular for the charged couplings, experiments using a combination method based on optimal observables (ALEPH, OPAL) obtain results with small differences compared to the values given by our combination technique. These small differences have been studied in Monte-Carlo tests and are well understood [137]. For the h -coupling results from OPAL and DELPHI, a slightly modified estimate of the systematic uncertainty due to the theoretical cross-section prediction is responsible for slightly different limits compared to the published results.

Table 6.2

The measured central values and one standard deviation errors obtained by the four LEP experiments for the charged TGC parameters. In each case the parameter listed is varied while the remaining two are fixed to their SM values (also shown). Both statistical and systematic errors are included. The values given here differ slightly from the ones quoted in the individual contributions from the four LEP experiments, as a different combination method is used. See text in Section 6.2 for details.

Parameter	ALEPH	DELPHI	L3	OPAL	SM
g_1^Z	$0.996^{+0.030}_{-0.028}$	$0.975^{+0.035}_{-0.032}$	$0.965^{+0.038}_{-0.037}$	$0.985^{+0.035}_{-0.034}$	1
κ_γ	$0.983^{+0.060}_{-0.060}$	$1.022^{+0.082}_{-0.084}$	$1.020^{+0.075}_{-0.069}$	$0.899^{+0.090}_{-0.084}$	1
λ_γ	$-0.014^{+0.029}_{-0.029}$	$0.001^{+0.036}_{-0.035}$	$-0.023^{+0.042}_{-0.039}$	$-0.061^{+0.037}_{-0.036}$	0

Table 6.3

The combined results for the 68% C.L. errors and 95% C.L. intervals obtained for the charged TGC parameters from the four LEP experiments. In each case the parameter listed is varied while the other two are fixed to their SM values (also shown). Both statistical and systematic errors are included.

Parameter	68% C.L.	95% C.L.	SM
g_1^Z	$+0.984^{+0.018}_{-0.020}$	[0.946, 1.021]	1
κ_γ	$+0.982^{+0.042}_{-0.042}$	[0.901, 1.066]	1
λ_γ	$-0.022^{+0.019}_{-0.019}$	[-0.059, 0.017]	0

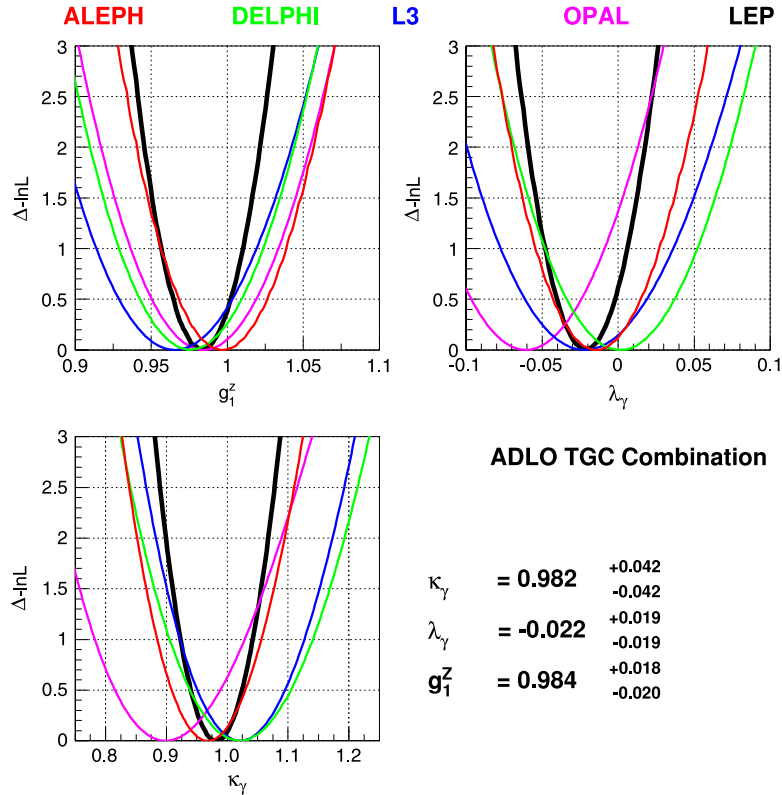

Fig. 6.1. The log \mathcal{L} curves of the four experiments (thin lines) and the LEP combined curve (black line) for the three charged TGCs g_1^Z , κ_γ and λ_γ . In each case, the minimal log \mathcal{L} value is subtracted.

6.4.1. Charged triple gauge boson couplings

The individual analyses and results of the experiments for the charged couplings are described in [127,128,138–140,130]. The results of single-parameter fits from each experiment are shown in Table 6.2, where the errors include both statistical and systematic effects. The individual log \mathcal{L} curves and their sum are shown in Fig. 6.1. The results of the combination are given in Table 6.3. A list of the systematic errors treated as fully correlated between the LEP experiments, and their shift on the combined fit result were given in Table 6.1. The combined results agree well with the SM expectation.

Table 6.4

The 95% C.L. intervals ($\Delta \log \mathcal{L} = 1.92$) in the neutral TGC parameters h_i^V measured by the DELPHI, L3 and OPAL, and the LEP combined values. In each case the parameter listed is varied while the remaining ones are fixed to their SM values ($h_i^V = 0$). Both statistical and systematic uncertainties are included. DELPHI did not interpret its measurements in terms of neutral gauge couplings of dimension 8 operators, hence does not enter in the combination for $h_{2/4}^V$.

Parameter	DELPHI	L3	OPAL	LEP
h_1^V	[−0.14, 0.14]	[−0.06, 0.06]	[−0.11, 0.11]	[−0.05, 0.05]
h_2^V		[−0.05, 0.02]	[−0.08, 0.08]	[−0.04, 0.02]
h_3^V	[−0.05, 0.04]	[−0.06, 0.00]	[−0.16, −0.01]	[−0.05, −0.00]
h_4^V		[−0.00, 0.04]	[0.01, 0.13]	[0.01, 0.05]
h_1^Z	[−0.23, 0.23]	[−0.15, 0.14]	[−0.19, 0.19]	[−0.12, 0.11]
h_2^Z		[−0.09, 0.08]	[−0.13, 0.13]	[−0.07, 0.07]
h_3^Z	[−0.30, 0.16]	[−0.22, 0.11]	[−0.27, 0.12]	[−0.19, 0.06]
h_4^Z		[−0.07, 0.15]	[−0.08, 0.17]	[−0.04, 0.13]

Fig. 6.2. The log \mathcal{L} curves of DELPHI, L3, and OPAL experiments and the LEP combined curve for the four neutral TGCs h_i^V , $i = 1, 2, 3, 4$. In each case, the minimal value is subtracted. Note, DELPHI did not interpret its measurements in terms of neutral gauge couplings of dimension 8 operators, hence does not enter in the combination for $h_{2/4}^V$.

6.4.2. Neutral triple gauge boson couplings

The individual analyses and results of the experiments for the h -couplings are described in [142–144]. The results from DELPHI, L3 and OPAL, and the LEP combination, are shown in Table 6.4, where the errors include both statistical and systematic uncertainties. The individual log \mathcal{L} curves and their sum are shown in Figs. 6.2 and 6.3. The results agree with the SM expectation.

The individual analyses and results of the experiments for the f -couplings are described in [141,142,145,146]. The single-parameter results for each experiment and the LEP combination are shown in Table 6.5, where the errors include both statistical and systematic uncertainties. The individual log \mathcal{L} curves and their sum are shown in Fig. 6.4. Three experiments, ALEPH, L3 and OPAL, contributed data to two-parameter fits to the TGC pairs (f_4^V, f_4^Z) and (f_5^V, f_5^Z) . The two-parameter results including the LEP combination are shown in Table 6.6, where the errors include both statistical and systematic uncertainties. The 68% C.L. and 95% C.L. contour curves resulting from the combinations of the two-dimensional likelihood curves are shown in Figs. 6.5 and 6.6. The couplings agree with the SM expectation.

Fig. 6.3. The $\log \mathcal{L}$ curves of the DELPHI, L3, OPAL experiments and the LEP combined curve for the four neutral TGCs h_i^Z , $i = 1, 2, 3, 4$. In each case, the minimal value is subtracted. Note, DELPHI did not interpret its measurements in terms of neutral gauge couplings of dimension 8 operators, hence does not enter in the combination for $h_{2/4}^Z$.

Table 6.5

The 95% C.L. intervals ($\Delta \log \mathcal{L} = 1.92$) in the neutral TGC parameters f_i^V measured by ALEPH, DELPHI, L3 and OPAL, and the LEP combined values. In each case the parameter listed is varied while the remaining ones are fixed to their SM values ($f_i^V = 0$). Both statistical and systematic uncertainties are included.

Parameter	ALEPH	DELPHI	L3	OPAL	LEP
f_4^Y	[−0.32, 0.33]	[−0.23, 0.25]	[−0.28, 0.28]	[−0.32, 0.33]	[−0.17, 0.19]
f_4^Z	[−0.53, 0.54]	[−0.40, 0.42]	[−0.48, 0.46]	[−0.45, 0.58]	[−0.28, 0.32]
f_5^Y	[−0.73, 0.74]	[−0.52, 0.48]	[−0.39, 0.47]	[−0.71, 0.59]	[−0.35, 0.32]
f_5^Z	[−1.18, 1.19]	[−0.38, 0.62]	[−0.35, 1.03]	[−0.94, 0.25]	[−0.34, 0.35]

Table 6.6

The 95% C.L. intervals ($\Delta \log \mathcal{L} = 1.92$) in the neutral TGC parameters f_i^V in two-parameter fits measured by ALEPH, L3 and OPAL, and the LEP combined values. In each case the two parameters listed are varied while the remaining ones are fixed to their SM values ($f_i^V = 0$). Both statistical and systematic uncertainties are included. Since the shape of the log-likelihood is not parabolic, there is some ambiguity in the definition of the correlation coefficients and the values quoted here are approximate.

Parameter	ALEPH	L3	OPAL	LEP	Correlations	
f_4^Y	[−0.29, 0.25]	[−0.28, 0.28]	[−0.32, 0.33]	[−0.20, 0.18]	1.00	−0.33
f_4^Z	[−0.43, 0.44]	[−0.48, 0.46]	[−0.47, 0.58]	[−0.29, 0.32]	−0.33	1.00
f_5^Y	[−0.59, 0.57]	[−0.53, 0.62]	[−0.67, 0.62]	[−0.40, 0.38]	1.00	−0.20
f_5^Z	[−0.90, 0.78]	[−0.47, 1.39]	[−0.95, 0.33]	[−0.56, 0.36]	−0.20	1.00

6.5. Summary and conclusions

Combinations of charged and neutral triple gauge boson couplings were made, based on results from the four LEP experiments ALEPH, DELPHI, L3 and OPAL. No deviation from the SM prediction is seen for any of the electroweak gauge boson couplings studied. While the existence of charged TGCs was experimentally verified already early on by the measurement of the total WW cross-section, see also Section 5, their values have now been measured with an accuracy

Fig. 6.4. The log \mathcal{L} curves of the four experiments, and the LEP combined curve for the four neutral TGCs f_i^V , $V = \gamma, Z$, $i = 4, 5$. In each case, the minimal value is subtracted.

Fig. 6.5. Contour curves of 68% C.L. and 95% C.L. in the plane of the neutral TGC parameters (f_4^γ, f_4^Z) showing the LEP combined result to which ALEPH, L3 and OPAL contributed.

of 0.02 to 0.04, and found to be in agreement with the SM expectation. As an example, these data allow the Kaluza–Klein theory [147], in which $\kappa_\gamma = -2$, to be excluded [148]. No evidence of the existence of neutral TGCs are found, limiting their magnitude to less than 0.05 to 0.35 depending on coupling.

Fig. 6.6. Contour curves of 68% C.L. and 95% C.L. in the plane of the neutral TGC parameters (f_5^γ, f_5^Z) showing the LEP combined result to which ALEPH, L3 and OPAL contributed.

7. Mass and width of the W boson

7.1. Introduction

The mass of the W boson is a fundamental parameter in particle physics. Together with the Z -boson mass, it sets the energy scale of electroweak symmetry breaking. Both masses are closely related to the weak mixing angle. At LEP, the W -boson mass is determined by measuring the cross-section of W -boson pairs at the production threshold, from the leptonic decay spectrum of the W boson, and by directly reconstructing W boson decays. The latter method is the more precise one. It also allows a determination of the total decay width of the W boson. Direct measurements of W -boson mass and width are also performed at the Tevatron $p\bar{p}$ collider [149–152].

7.2. Determination of the W mass at the W -pair production threshold

The SM cross-section of the reaction $e^+e^- \rightarrow W^+W^-$ shows a typical threshold behaviour close to a centre-of-mass energy that corresponds to twice the W mass. In the threshold region the cross-section rises in proportion to the velocity of the W bosons produced, which is approximately given by $\beta = \sqrt{1 - 4m_W^2/s}$, neglecting radiative corrections and finite width effects. Thus, a measurement of the production cross-section at a given centre-of-mass energy is directly related to the W boson mass. The intrinsic precision of this method is similar to the direct-reconstruction method, described below. However, since LEP predominantly operated at higher centre-of-mass energies in order to search for new physics as well as to make precise electroweak measurements, the data collected at threshold energies corresponds to only 3% of the full data set (see Table 1.1).

Using Monte-Carlo simulations, the centre-of-mass energy where the cross-section is most sensitive to m_W was determined to be $\sqrt{s} = 161$ GeV, but data at 172–183 GeV were also analysed to extract m_W from the measured cross-section. Each LEP experiment compared the measured cross-sections at each centre-of-mass energy to the m_W dependent SM prediction calculated using the GENTLE program [100]. The results of the four LEP experiments combined for the different centre-of-mass energies [153,88,154,155] are shown in Table 7.1. Owing to the dependence of the theory cross-section on the mass for a given centre-of-mass energy, both the extracted mass and its uncertainty decrease with increasing measured cross-sections.

Systematic uncertainties from hadronisation and fragmentation effects in hadronically decaying W bosons, radiative corrections, final-state interactions are all negligible compared to the statistical uncertainty of the measurement. Combining all LEP W -pair threshold data yields:

$$m_W(\text{threshold}) = 80.42 \pm 0.20 \pm 0.03(E_{\text{LEP}}) \text{ GeV}, \quad (7.1)$$

where the uncertainty due to the LEP centre-of-mass energy [156] is given separately. The treatment of systematic uncertainties is further detailed below.

Table 7.1

W mass measurements from the W^+W^- threshold cross-section at $\sqrt{s} = 161\text{--}183$ GeV [153,88,154,155]. The uncertainties include statistical and systematic contributions.

Threshold analysis	
Experiment	m_W (GeV)
ALEPH	80.20 ± 0.34
DELPHI	$80.45^{+0.45}_{-0.41}$
L3	$80.78^{+0.48}_{-0.42}$
OPAL	$80.40^{+0.46}_{-0.43}$

7.3. Measurement of mass and width by direct reconstruction

7.3.1. Mass reconstruction

The mass and total decay width of the W boson is determined with high precision by reconstructing directly the decay products of the two W bosons, mainly in the fully hadronic, $W^+W^- \rightarrow q\bar{q}q\bar{q}$, and semi-leptonic, $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$, decay channels.

The $W^+W^- \rightarrow \ell\nu_\ell\ell\nu_\ell$ decay also contains information on m_W when analysing the leptonic energy spectrum or reconstructing an approximated mass of the decaying W bosons, as performed by the OPAL collaboration [157]. However, the intrinsic statistical precision dominates the total uncertainty and OPAL determines a value of:

$$m_W(\ell\nu_\ell\ell\nu_\ell) = 80.41 \pm 0.41(\text{stat.}) \pm 0.13(\text{syst.}) \text{ GeV}, \quad (7.2)$$

analysing data at centre-of-mass energies between 183 GeV and 209 GeV. It is interesting to compare this result with those from the other decay channels, since systematic uncertainties from hadronic W decays are absent. Within the given precision it agrees well with the W mass measurements in $W^+W^- \rightarrow q\bar{q}q\bar{q}$ and $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ events discussed below. For the purpose of the LEP combination, OPAL combines the measurements in the fully leptonic channel at each run period with the semi-leptonic results.

The $W^+W^- \rightarrow q\bar{q}q\bar{q}$ decays are reconstructed from hadronic jets observed in the final state, formed from measured particle tracks and energy depositions in the calorimeters. Different jet clustering algorithms are applied, e.g., the Durham [73], Diclus [158], and Cambridge [159] algorithms. Depending on the choice of clustering parameters, additional gluon radiation may be resolved, so that not only pairs of jets, but also five-jet topologies are reconstructed. Similarly, initial-state photon radiation (ISR) and final-state photon radiation (FSR) may be detected by a calorimetric cluster consistent with an electromagnetic shower shape and without a matched track in a given angular cone around the photon candidate. Such reconstruction methods improve the detailed knowledge of the event kinematics and therefore the resolution in the reconstructed masses of the decaying W bosons. The correct reconstruction of the fully hadronic final state is further complicated by combinatorial ambiguities to pair the reconstructed jets to the W decays. In case of four jets there are three possible combinations. For five-jet topologies this number increases to 15. The ambiguity is treated differently by the four LEP experiments. ALEPH selects only one combination in their analyses, using a pairing probability that is based on the CC03 matrix element evaluated for the reconstructed jets [87]. The other experiments use a W -mass estimator which combines all pairings that have a high probability to be correct [88–90]. The pairings are weighted accordingly in the combined mass likelihood. In this way, a maximum of information is retained for the subsequent mass extraction method. For DELPHI, the weights are based on the polar angle of the reconstructed W boson, the sum of jet charges of each jet combination and the transverse momentum of the gluon jet in five-jet events [88]. L3 exploits the probability of a kinematic fit [89], while OPAL uses a neural network trained with the above-mentioned variables and the reconstructed mass differences of the W bosons [90]. The fully hadronic data samples are furthermore separated into 4-jet and 5-jet sub-samples (L3), or all possible jet configurations, also with different clustering schemes, and properly weighted in the final m_W and Γ_W analysis.

Semi-leptonic W -pair decays, $W^+W^- \rightarrow q\bar{q}e\nu_e$, $W^+W^- \rightarrow q\bar{q}\mu\nu_\mu$ and $W^+W^- \rightarrow q\bar{q}\tau\nu_\tau$, are reconstructed as a pair of hadronic jets, possibly with a third jet from gluon radiation, and an isolated electron, muon or tau lepton. Photons from initial state radiation are detected in about 5% of the events and excluded from the jet clustering. The mass of the hadronically decaying W is determined directly from the jet system. In the leptonic $W \rightarrow e\nu_e$ and $W \rightarrow \mu\nu_\mu$ decays, the missing momentum vector is calculated applying total momentum conservation and is assigned to the momentum of the neutrino. The masses of both W decays can thus be reconstructed. In case of the $q\bar{q}\tau\nu_\tau$ final state, only the hadronically decaying W contains useable W -mass information due to the presence of a second neutrino from the tau decay.

7.3.2. Kinematic fitting

The di-jet mass resolution is mainly determined by the precision of jet energy measurements. The jet energy is carried by charged particles ($\sim 62\%$ on average), photons ($\sim 27\%$) and neutral hadrons ($\sim 10\%$), which are measured using the tracking and calorimetric devices of the detectors. Even with the help of sophisticated energy-flow algorithms which combine tracks and calorimetric clusters in order to reduce effects of double counting of particles, the best jet energy resolutions achieved

are typically $\Delta E/E \approx 60\text{--}80\%/ \sqrt{E/\text{GeV}}$. The corresponding di-jet mass resolution for W -boson decays is in the order of 8–9 GeV.

The mass resolution is substantially improved by imposing the constraint that the total energy in the event should equal the known LEP centre-of-mass energy [156], or that the energy of each W boson should be equal to the LEP beam energy. In practice, this is most commonly implemented by means of a kinematic fit. In such a fit, the measured parameters of the jets and leptons are adjusted, taking account of their measurement uncertainties in such a way as to satisfy the constraints of energy and momentum conservation. In case of hadronic jets, the jet three-momenta are varied while keeping the jet velocity constant, as systematic effects cancel in the ratio of jet momentum and jet energy. For leptons, the energy for electrons and momentum for muons, together with the polar and azimuthal angles, are considered in the fit. The lepton masses are set to their nominal values. For $q\bar{q}\tau\nu_\tau$ final states, an energy rescaling of the hadronic system to the beam energy is practically equivalent to a kinematic fit, due to the lack of further kinematic constraints.

In the $q\bar{q}q\bar{q}$ case, the improved kinematic reconstruction is referred to as a 4C fit, because there are four energy and momentum constraints. In the $q\bar{q}e\nu$ and $q\bar{q}\mu\nu_\mu$ channels it is referred to as a 1C or one constraint fit, because the three momentum components of the neutrino have to be determined, eliminating three of the constraints. It is often useful to impose the additional constraint that the masses of the two W bosons are equal, leading to a 5C or 2C fit, in which case the kinematic fit provides a single estimate of the average W mass in each event. Although the equal-mass assumption is not fulfilled in an individual event, it is valid on average. Since the intrinsic total width of the W is much smaller than the mass resolution, the equal-mass assumption further improves the mass resolution. The corresponding probabilities of fits in terms of a χ^2 variable are used to reject background and to resolve combinatorial ambiguities in the $q\bar{q}q\bar{q}$ channel.

The resolution on the W -boson mass varies slightly from experiment to experiment. Typical values,⁷ after use of kinematic fitting, are 2.5 GeV for the $W^+W^- \rightarrow q\bar{q}e\nu_e$ and $W^+W^- \rightarrow q\bar{q}\mu\nu_\mu$ channels, 3.1 GeV for the $W^+W^- \rightarrow q\bar{q}\tau\nu_\tau$ channel and 1.5 GeV for the $W^+W^- \rightarrow q\bar{q}q\bar{q}$ channel, at $\sqrt{s} = 189$ GeV. These resolutions increase to 2.9 GeV, 3.4 GeV and 1.7 GeV, respectively, at $\sqrt{s} = 207$ GeV.

The use of a kinematic fit or an equivalent kinematic constraint implies that the scale of the W mass measurement is directly linked to the knowledge of the LEP beam energy. Checks on the determination of the LEP energy are discussed in Appendix C. It should also be emphasised that the kinematic fit technique neglects the effects of initial-state radiation (ISR) if it is not measured directly in the detector. The average energy radiated in ISR in $e^+e^- \rightarrow W^+W^-$ events is 2.2 GeV at $\sqrt{s} = 189$ GeV, rising to ~ 3.5 GeV at $\sqrt{s} = 207$ GeV, which is substantially smaller than the intrinsic resolution of the jet energies and hence of the W mass, and therefore cannot be resolved by kinematic fitting. Any remaining bias due to unmeasured ISR photons is taken into account in the W mass and width extraction methods based on MC simulations of radiative effects.

7.3.3. Techniques for determining the W -boson mass and width

In the direct reconstruction method, the mass of the W boson is obtained by comparing data to simulated $e^+e^- \rightarrow W^+W^-$ event samples generated with known values of m_W and Γ_W , in order to obtain those which describe the data best. These Monte-Carlo samples are of large statistics, typically 10^6 events. Since the generation of event samples for all possible parameter values is very computing time intensive, different methods are used to perform the m_W and Γ_W extraction in a more efficient, but still precise way.

The Monte-Carlo simulation programs used to generate the signal process, KandY [98], RACONWW [99], and WPHACT [117], include all relevant diagrams leading to the same 4-fermion final state and full $O(\alpha)$ electroweak radiative corrections. Real ISR photons are calculated in $O(\alpha^3)$, and FSR photons to higher order leading-log approximation. The underlying mass and width of the W boson are defined using a relativistic Breit-Wigner propagator with s -dependent width which is also the convention adopted to quote the measured values. Tau decays are simulated using the TAUOLA [160] package. The fragmentation and hadronisation of quark and gluon jets is described by the JETSET [76], HERWIG [54], and ARIADNE [161] programs, which are compared to estimate the corresponding systematic uncertainties. The default fragmentation parameters exclude any FSI effects from Bose–Einstein correlations (BEC) or colour reconnection (CR). For the latter, a dedicated procedure is developed to suppress mass biases in the $W^+W^- \rightarrow q\bar{q}q\bar{q}$ channel, which is detailed below.

The background, mainly from $e^+e^- \rightarrow q\bar{q}(\gamma)$ with additional gluon radiation and pair production of Z bosons, amounts to 2%–15% in the $q\bar{q}\ell\nu_\ell$ channels, depending on the selected W^+W^- final state, and about 30% in the $q\bar{q}q\bar{q}$ channel. The background is simulated using Monte-Carlo programs which include radiative corrections with higher order ISR and FSR. Dedicated control samples of 2-fermion and 4-fermion events are studied by the LEP experiments to ensure the agreement of the Monte-Carlo simulations with data, concerning jet and lepton resolutions, event shape variables, and detector response. Any remaining differences are taken into account as systematic uncertainties.

The methods that are applied to extract the W mass and width results are based on unbinned maximum likelihood fits to the measured data. Different procedures are employed to construct the likelihood functions and to describe their

⁷ The resolutions quoted here are estimated from the distributions of the difference between the fitted W mass and the average of the two true W masses in each event. These resolution functions are not Gaussian, and the values quoted represent RMS values computed in a range ± 10 GeV around zero. In order to estimate the intrinsic mass resolution, events with significant ISR are excluded, and Monte-Carlo information is used to identify the correct jet-pairings in the $q\bar{q}q\bar{q}$ channel.

dependence on the underlying m_W and Γ_W values. For the final results, ALEPH and L3 apply a reweighting method, while OPAL and DELPHI use a convolution technique. The OPAL collaboration also performs fits of an analytical description of the Breit-Wigner resonance curves and background shapes to data, in order to access systematic uncertainties of the mass and width extraction method. Since the W -boson width, Γ_W , depends on the mass m_W , the SM dependence of Γ_W on m_W is assumed when performing the fit to the data to determine m_W . In fits for Γ_W , both m_W and Γ_W are varied independently. The m_W values obtained in the two-parameter fits are consistent within the given uncertainty with the one-parameter fit for m_W only. The methods used are described in the following.

Monte-Carlo reweighting. In the reweighting method, a multi-dimensional probability density is calculated using different mass estimators. These estimators are the masses from the 5C and 4C kinematic fit in the $q\bar{q}q\bar{q}$ channel, and those of the 2C and 1C fit for $q\bar{q}e\nu_e$ and $q\bar{q}\mu\nu_\mu$ events. To further improve the sensitivity, ALEPH also includes the uncertainty on the 5C and 2C masses. The $q\bar{q}\tau\nu_\tau$ sample contributes only with the rescaled hadronic mass. The probability densities are determined from distributions of the corresponding multi-differential cross-sections, including m_W and Γ_W dependent signal predictions and background contributions. This is done either using binned distributions or a local sampling of the phase-space density determined from Monte-Carlo simulations. Since the signal Monte-Carlo sample is generated with pre-defined underlying W mass and width values, the m_W and Γ_W dependence is introduced by reweighting of Monte-Carlo events. Each signal event is given a weight according to the ratio of the absolute values of the matrix element squared for the $e^+e^- \rightarrow W^+W^- \rightarrow f\bar{f}f\bar{f}(\gamma)$ process, calculated for the m_W and Γ_W values that are to be determined and for the nominal m_W and Γ_W used in the simulation. The total likelihood functions of the different data samples are maximised with respect to m_W and Γ_W . This method is applied for the final ALEPH and L3 results, and by the OPAL collaboration to evaluate systematic uncertainties of the extraction method.

Convolution method. In this method, a probability density function is computed for each event, giving the probability that this event, with a set of reconstructed mass estimators $m_{i,\text{rec}}$ ($i = 1, \dots, n$), originated from a sample with true W mass and width, m_W and Γ_W , of the following schematic form:

$$P_s(m_W, \Gamma_W, m_{i,\text{rec}}) = S(m_W, \Gamma_W, m_i, s') \otimes \text{ISR}(s', s) \otimes R(m_i, m_{i,\text{rec}}). \quad (7.3)$$

In this expression, $S(m_W, \Gamma_W, m_i, s')$ is the true distribution of the mass estimators, folded with the radiator function $\text{ISR}(s', s)$ and the detector resolution function, $R(m, m_{\text{rec}})$, which is determined from Monte-Carlo simulations and describes the probability that an event of true mass estimator m_i would be reconstructed with mass estimators $m_{i,\text{rec}}$. The likelihood for the data is then constructed as the product of $f_s P_s(m_W, \Gamma_W, m_{i,\text{rec}}) + f_b P_b(m_{i,\text{rec}})$ over all events, where f_s and f_b are the probabilities that the event originates from signal and background processes, respectively, and $P_b(m_{i,\text{rec}})$ is a parametrisation of the background distribution. The parameters of interest, m_W and Γ_W , are estimated by maximising the total likelihood. In this approach, the resolution function may take account of the uncertainties in the reconstructed mass, which are likely to vary from event to event, and thus better measured events are given greater weight. This procedure is used for the final OPAL and DELPHI results.

7.3.4. Combination procedure

The maximum likelihood fits are performed for each of the data sets at the different centre-of-mass energies and for each W -pair decay channel separately. Table 7.2 shows the final results on m_W obtained by the four LEP experiments with the direct reconstruction method in the $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ final states. For the LEP combination, each experiment individually combines the results of the three $q\bar{q}\ell\nu_\ell$ channels. The OPAL collaboration also includes the $\ell\nu_\ell\ell\nu_\ell$ measurements in these results. Input to the combination procedure are thus the m_W and Γ_W central values and uncertainties from the four LEP experiments in the $q\bar{q}q\bar{q}$ (4q) and $q\bar{q}\ell\nu_\ell + \ell\nu_\ell\ell\nu_\ell$ (non-4q) final states for five centre-of-mass energy bins corresponding to the five years of data taking. These inputs combine the data collected in 1996 at 172 GeV, in 1997 at 183 GeV, in 1998 at 189 GeV, in 1999 at 192–202 GeV, and in 2000 at 205–209 GeV.

The combination of the measurements is performed and the evaluation of the components of the total measurement uncertainty is assessed using the Best Linear Unbiased Estimate (BLUE) technique [30]. In this way, statistical and systematic uncertainties of each measurement are properly taken into account, including correlations between them. The LEP combination procedure as described here is also applied to combine the measurements of each LEP experiment for comparison with the combined measurement published by each experiment in Table 7.2. The observed differences are mainly due to a different assessment of FSI uncertainties, which affects the fully hadronic channel, as discussed below. The changes of the semi-leptonic results are due to systematic uncertainties correlated between the $q\bar{q}q\bar{q}$ and $q\bar{q}\ell\nu_\ell$ channels.

7.3.5. Overview of systematic uncertainties

There are several sources of systematic uncertainties affecting the measurements of m_W and Γ_W . Table 7.3 summarises the systematic and statistical uncertainties on the W mass and width measurements evaluated for the combined LEP data using the direct reconstruction method. For the W mass determination, the uncertainties are also given separately for the $q\bar{q}\ell\nu_\ell$ and $q\bar{q}q\bar{q}$ final states, and for their combination. The main contributions are discussed in the following.

Table 7.2

W mass measurements from direct reconstruction ($\sqrt{s} = 172\text{--}209$ GeV). Results are given for the semi-leptonic, fully-hadronic channels and the combined value. The top part of the table shows the results as published by the experiments [87–90], using their individual evaluations of FSI effects; these results are final. The bottom part of the table shows the results of the experiments when propagating the common LEP estimates of FSI effects to the mass, which also affects the $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ results through correlations due to other systematic uncertainties. The $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ results from the OPAL collaboration include mass information from the $W^+W^- \rightarrow \ell\nu_\ell\ell\nu_\ell$ channel.

Table 7.3

Error decomposition for the combined LEP W mass and width results using the direct reconstruction method. Information from cross-section measurements at the W -pair production threshold are not included in the W -mass uncertainties. Detector effects include uncertainties in the jet and lepton energy scales and resolution. The ‘Other’ category refers to errors, all of which are uncorrelated between experiments, arising from: simulation statistics, background estimation, four-fermion treatment, fitting method and event selection. The error decomposition in the $q\bar{q}\ell\nu_\ell$ and $q\bar{q}q\bar{q}$ channels refers to the independent fits to the results from the two channels separately. Large correlated uncertainties, mainly from FSI, lead to a reduced weight of measurements contributing to the average result and thus an increased statistical uncertainty both in the $q\bar{q}q\bar{q}$ channel and for the LEP combination.

LEP centre-of-mass energy. Since the LEP centre-of-mass energy is used as a constraint in order to improve the W mass resolution, uncertainties in the centre-of-mass energy translate directly into uncertainties on m_W . These can approximately be obtained by scaling the LEP centre-of-mass energy uncertainties with the ratio $m_W/(\sqrt{s}/2)$. The W width is less affected. At W -pair threshold energies, the calibration of the LEP centre-of-mass energy yields precisions of 25–27 MeV, and at energies between 182.7 GeV up to 201.6 GeV the uncertainty is 20–24 MeV. Since in the last LEP runs in the year 2000 horizontal corrector magnets were used to spread the magnetic field over a larger bending section in order to eventually increase the LEP beam energy to its absolute maximum, the related additional systematic effects reduced the centre-of-mass energy precision to 37–42 MeV.

A cross-check of the LEP energy determination is performed by analysing $e^+e^- \rightarrow Z + \gamma \rightarrow f\bar{f} + \gamma$ events with hard ISR photons, mostly emitted at small polar angles with respect to the beam directions. In these events with a so-called radiative return to the Z , the mass of the 2-fermion system is calculated from the fermion production angles only, assuming energy–momentum conservation. The mass spectrum exhibits a peak around the Z mass value. Comparing the Z mass, $m_Z^{f\bar{f}}$, determined from this spectrum with the precise value of m_Z measured at Z pole energies [2] is equivalent to a test of the

Table 7.4

Correlation between the LEP centre-of-mass energy measurements in the six run periods [156].

\sqrt{s} (GeV)	LEP energy correlations					
	161	172	183	189	192–202	205–209
161	1.00	1.00	0.57	0.56	0.58	0.36

192–202	0.58	0.58	0.95	0.94	1.00	0.55
205–209	0.36	0.37	0.53	0.53	0.55	1.00

LEP centre-of-mass energy (see [Appendix C](#) for further details):

$$\Delta\sqrt{s} = \sqrt{s} - \sqrt{s}_{\text{LEP}} = \sqrt{s} \frac{m_Z^{\text{f}\bar{\text{f}}} - m_Z}{m_Z}, \quad (7.4)$$

with the nominal value of \sqrt{s}_{LEP} [156] provided by the LEP energy working group. When combining all available LEP data [87,162–164] with Z decays to hadrons, and to electron, muon, and tau pairs, the difference is found to be

$$\Delta\sqrt{s} = -54 \pm 54 \text{ MeV}, \quad (7.5)$$

in good agreement with no shift with respect to the more precise standard LEP energy calibration.

The properly calibrated LEP centre-of-mass energy is used in the W mass and width analysis on event-by-event basis. Uncertainties on m_W and Γ_W are determined by detailed Monte-Carlo studies, and also the effect of the LEP energy spread is taken into account. When combining the LEP W mass and width results the correlations between the LEP energy uncertainties at the different energies are properly included. They are derived from the LEP energy model [156] and listed in [Table 7.4](#). The overall LEP energy uncertainty is 9 MeV on m_W and 5 MeV on Γ_W .

Detector effects. The effects of detector performance as well as of identification and reconstruction efficiencies for final state leptons, jets and photons are studied in dedicated control data samples. Energy and momentum calibration, as well as detector alignment and angular measurements, very important for the mass reconstructed, were studied [87–90]. Since Monte-Carlo samples are compared to data to extract m_W and Γ_W , all effects are modelled in detail in the simulation and remaining differences to data result in corresponding systematic uncertainties. The LEP experiments provide separate uncertainties for lepton and jet measurements. These are considered uncorrelated between measurements from different experiments, but correlated for m_W and Γ_W measurements from the same experiment at different LEP energy points. The total systematic uncertainty from detector effects is 10 MeV and 8 MeV on m_W in the $q\bar{q}\ell\nu_\ell$ and $q\bar{q}q\bar{q}$ channels. The W width systematic uncertainties due to finite precision in modelling jet and lepton measurements is 23 MeV, combining all final states.

Fragmentation and hadronisation. Since the m_W and Γ_W extraction methods rely on the comparison of Monte-Carlo simulations to data the modelling of the fragmentation and hadronisation process subsequent to the $W \rightarrow q\bar{q}$ decay is essential. The calibration of the reconstructed jets is very sensitive to the fractions of the different final state hadrons inside the jets. Furthermore, the jet reconstruction usually cannot resolve each individual hadron, so that the same particle masses are assumed (usually the pion mass) when tracks and clusters are combined to form quark and gluon jets. To assess systematic uncertainties due to fragmentation and hadronisation, different Monte-Carlo models are compared, whose parameters are adjusted to describe high-statistic data samples of $Z \rightarrow q\bar{q}$ decays at the Z pole. These Z decays are depleted in b -quarks, to resemble the hadronic decays of W bosons. The systematic uncertainty is derived from the relative shifts in W mass and width values determined in Monte-Carlo samples using the JETSET/PYTHIA [76], HERWIG [165], and ARIADNE [161] fragmentation models. In addition, the fraction of certain hadrons, like kaons and protons, is directly measured in $W \rightarrow q\bar{q}$ decays and compared to the fragmentation models. The measurement uncertainties on these fractions are also taken into account in the fragmentation and hadronisation systematic uncertainties for the m_W and Γ_W determination.

Since all four LEP experiments study the same fragmentation models, the systematic uncertainty is taken as fully correlated for all measurements of the W mass and width. Eventually, the systematic effect on m_W is estimated to be 13 MeV and 19 MeV in the $q\bar{q}\ell\nu_\ell$ and $q\bar{q}q\bar{q}$ final states. In the W width determination, the corresponding systematic uncertainties contribute with 40 MeV to the combined W width measurement.

Colour reconnection. A particular systematic uncertainty arises in the $W^+W^- \rightarrow q\bar{q}q\bar{q}$ channel, where the two W bosons decay close in phase space so that FSI effects may play a significant role. Indeed, colour reconnection (CR) effects leads to shifts of the extracted W mass up to about 100 MeV [87–90] if nominal jet reconstruction is applied and data are compared to Monte-Carlo models with and without colour reconnection. These large shifts are observed even if the measured constraints on the reconnection parameters, which are discussed in [Section 4](#), are applied. The LEP collaborations therefore developed new techniques in the $q\bar{q}q\bar{q}$ channel. It is observed that colour reconnection effects on m_W as implemented in the

ARIADNE [53], SK [52], and HERWIG [54] models are reduced when the jet reconstruction is modified. This is achieved by either rejecting particles inside jets with energies or momenta lower than a given threshold or by reweighting their energies and momenta to suppress soft particles, which are mainly in the inter-jet and reconnection-sensitive region. The four LEP experiments applied thresholds and weights which are optimised individually for the colour reconnection constraints of the SK-I model [52] which are measured by each experiment separately. In the optimisation process the overall uncertainty on m_W is minimised, again individually, trading a reduced statistical precision due to a modified jet reconstruction for an improved FSI systematic uncertainty. For the LEP combined analysis, the threshold values and weights of each experiment are however not always optimal when the LEP combined upper limit on the SK-I parameter, $k_I < 2.10$, is used as reference for the CR uncertainty in the LEP m_W combination. Although this reduces the relative weight of some m_W measurements in the LEP combination, a further optimisation is not performed.

For the final LEP combination, the central value of the W mass is determined using Monte-Carlo samples without colour reconnection. The systematic uncertainties are evaluated from the mass differences observed when data is compared to the SK-I model with $k_I = 2.10$. The systematic uncertainties are evaluated at each centre-of-mass energy independently since the colour reconnection effects are energy dependent. The systematic uncertainties are taken as symmetric in the combination procedure and correlated between all measurements in the $q\bar{q}q\bar{q}$ channel at the different centre-of-mass energies and by the four LEP experiments. They contribute 35 MeV to the total uncertainty in the fully hadronic final state.

When the W width is extracted, the optimisation of the jet reconstruction is not applied by the LEP collaborations, and the standard jet measurement is used. The reason is the relatively large statistical uncertainty of the W width measurement, which does not require a modification of the standard $q\bar{q}q\bar{q}$ analysis. The corresponding CR uncertainty is evaluated using the LEP upper limit on the SK-I parameter, $k_I < 2.10$, like in the W mass determination, and corresponds to 27 MeV on the combined width result.

Bose–Einstein correlations. A further source of uncertainty connected with FSI in the $W^+W^- \rightarrow q\bar{q}q\bar{q}$ channel is the possibility of Bose–Einstein correlations (BEC) between identical mesons in the decay of different W bosons. The measurement of these correlations is discussed in detail in Section 4. For the final LEP results, Bose–Einstein correlations between particles from inside each hadronically decaying W are implemented in the Monte-Carlo simulation according to the BE_{32} model [76], which describes $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ data well. However, the combined analysis of LEP data yields an upper limit on the strength of Bose–Einstein correlations between mesons from different W bosons of 30% of the full correlation in the BE_{32} model. The systematic effect on the W mass and width in the $W^+W^- \rightarrow q\bar{q}q\bar{q}$ channel is effectively reduced by the modified jet reconstruction algorithms, which were originally introduced for controlling systematic uncertainties from CR. Therefore, the uncertainties due to Bose–Einstein correlations on the W mass in $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events is 7 MeV, while it is just 3 MeV on the combined width result.

Initial state radiation and $\mathcal{O}(\alpha)$ effects. Photon radiation influences the reconstructed W mass spectra. The Monte-Carlo programs used to extract m_W and Γ_W , Kandy, RACONWW and WPHACT, include ISR effects in the YFS exponentiation scheme to $\mathcal{O}(\alpha^3)$, full $\mathcal{O}(\alpha)$ electroweak corrections, including interference between ISR, FSR and photon radiation of the W boson, as well as screened Coulomb corrections. These describe Coulomb interactions between the W bosons, which are potentially large but screened due to the limited lifetime of the W bosons. Higher-order leading-log FSR corrections are included using PHOTOS for leptons and PYTHIA for quarks. ISR effects on m_W are estimated by comparing the $\mathcal{O}(\alpha^3)$ with the $\mathcal{O}(\alpha^2)$ calculation, yielding small shifts of about 1 MeV [166]. The effect of Coulomb screening are estimated by taking half of the difference between Monte-Carlo samples with screened Coulomb effect and without any Coulomb effect, which amounts to about 7 MeV. To evaluate the uncertainty on the non-leading $\mathcal{O}(\alpha)$ electroweak corrections, a direct comparison of the RACONWW and the Kandy generators is performed. The observed differences are in the order of 10 MeV for $q\bar{q}\ell\nu_\ell$ and 5 MeV for $q\bar{q}q\bar{q}$. Some systematic studies overlap, however, and the experiments apply different strategies to assess them. The total LEP uncertainty on the W mass due to radiative corrections is 8 MeV in the semi-leptonic channel and 5 MeV in the fully hadronic channel. Full correlation between all data sets is assumed. In case of the W width, the corresponding uncertainties amount to 6 MeV when combining all final states.

Other sources of systematic uncertainties. The contribution of background to the selected W -pair samples arises mainly from 4-fermion and hadronic 2-fermion events. All LEP experiments study the event shapes of the different background contributions using control samples to best describe the data. The systematic effect of the background on m_W and Γ_W are derived by varying the overall scale on the production cross-sections of the background processes, mainly $e^+e^- \rightarrow q\bar{q}(\gamma, g)$ and $e^+e^- \rightarrow ZZ$, within the measured uncertainty. Effects on the mass spectrum which do not scale with the overall production rate are studied by varying, for example, the slope of the background spectra.

In addition, uncertainties due to limited Monte-Carlo statistics, from the mass and width extraction techniques, and due to the event selection are considered. Early analyses at LEP-II used Monte-Carlo simulations based on CC03 matrix elements to simulate W^+W^- production. In this case, systematic biases of the W mass and width may arise because four-fermion diagrams are neglected which might interfere with W -pair production.

All these categories of systematic uncertainties are taken as uncorrelated in the LEP combination and contribute on the mass with 3 MeV in the semi-leptonic channel and 10 MeV in the fully hadronic channel, and 12 MeV on Γ_W .

Fig. 7.1. The measurements of the W -boson mass obtained by the four LEP collaborations (as published) together with the LEP combined result. The combined value includes correlations between experiments, between different energy points, and between the $q\bar{q}\ell\nu_\ell$ and $q\bar{q}q\bar{q}$ channels. A revised estimation of systematic uncertainties due to colour reconnection and Bose–Einstein correlations is applied to the input of the individual measurements to the LEP combined results in order to take the direct determination of FSI parameters into account.

7.4. LEP combined W -boson mass

The combined LEP W mass from direct reconstruction data alone is:

$$m_W(\text{direct}) = 80.375 \pm 0.025(\text{stat.}) \pm 0.022(\text{syst.}) \text{ GeV}, \quad (7.6)$$

with a total uncertainty of 34 MeV. The combination has a χ^2/dof of 47.7/37, corresponding to a probability of 11.1%. The weight of the fully-hadronic channel in the combination amounts to just 22% due to significant FSI systematic uncertainties.

The largest contribution to the systematic error originates from hadronisation uncertainties, which are fully correlated between all measurements. In the absence of any systematic effects the current LEP statistical precision on m_W would be 22 MeV. The statistical error contribution in the LEP combination is larger than this, 25 MeV, due to the reduced weight of the fully-hadronic channel, mainly due to FSI systematic uncertainties.

When the threshold measurements (Section 7.2) are combined with the precise results obtained from direct reconstruction one achieves a W mass measurement of:

$$m_W = 80.376 \pm 0.025(\text{stat.}) \pm 0.022(\text{syst.}) \text{ GeV}, \quad (7.7)$$

with a slightly improved total uncertainty of 33 MeV. The combination has a χ^2/dof of 48.9/41, corresponding to a probability of 18.5%. The LEP energy uncertainty is the only correlated systematic error source between the threshold and direct reconstruction measurements. The threshold measurements have a weight of only 2% in the combined fit. This LEP combined result is compared with the final results of the four LEP experiments in Fig. 7.1.

7.5. Consistency checks

The masses from the two channels with all uncertainties and correlations included are:

$$m_W(W^+W^- \rightarrow q\bar{q}\ell\nu_\ell) = 80.372 \pm 0.030(\text{stat.}) \pm 0.021(\text{syst.}) \text{ GeV}, \quad (7.8)$$

$$m_W(W^+W^- \rightarrow q\bar{q}q\bar{q}) = 80.387 \pm 0.040(\text{stat.}) \pm 0.044(\text{syst.}) \text{ GeV}. \quad (7.9)$$

The two results are correlated with a correlation coefficient of 0.20. These results and the correlation between them can be used to combine the two measurements or to form the mass difference. The LEP combined results from the two channels are compared with those quoted by the individual experiments in Fig. 7.2. When combining the m_W measurements in the $q\bar{q}\ell\nu_\ell$ and $q\bar{q}q\bar{q}$ channels separately and neglecting any correlations between these final states, results consistent within 2 MeV with the correlated averages above are obtained.

The difference between the combined W -boson mass measurements obtained from the fully-hadronic and semi-leptonic channels, $\Delta m_W(q\bar{q}q\bar{q} - q\bar{q}\ell\nu_\ell)$ is also determined. Since Δm_W is primarily of interest as a check of the possible effects of final state interactions, the uncertainties from Bose–Einstein correlation and colour reconnection are set to zero in its determination. A fit imposing otherwise the same correlations as those for the results given in the previous sections yields:

$$\Delta m_W(q\bar{q}q\bar{q} - q\bar{q}\ell\nu_\ell) = -12 \pm 45 \text{ MeV}. \quad (7.10)$$

Fig. 7.2. The W mass measurements in the $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ channels (top), and the $W^+W^- \rightarrow q\bar{q}q\bar{q}$ channel (bottom) obtained by the four LEP collaborations (as published) compared to the combined value. Correlations between experiments and between measurements at different energy points are properly taken into account. The combined non-4q and 4q results are correlated since they are obtained from a fit to both channels taking into account inter-channel correlations. For the LEP combination, the assessment of systematic uncertainties due to colour reconnection and Bose–Einstein correlations for the individual measurements of the four experiments is revised with respect to the direct LEP measurements of FSI.

Note that this mass difference has a different value and opposite sign compared to the difference between the $q\bar{q}q\bar{q}$ and $q\bar{q}\ell\nu_\ell$ mass values presented above, because the BEC and CR uncertainties are not included in its determination. A significant non-zero value for Δm_W could indicate that such Bose–Einstein correlation or colour reconnection effects are biasing the value of m_W determined from $W^+W^- \rightarrow q\bar{q}q\bar{q}$ events. The consistency of the mass difference with zero shows that such FSI effects are well suppressed by the modified jet reconstruction in the fully hadronic channel.

7.6. LEP combined W -boson width

The method of direct reconstruction is also well suited to the direct measurement of the total decay width of the W boson. The published results of the four LEP experiments are shown in Table 7.5 and in Fig. 7.3.

For the LEP combination, each experiment provided a W width measurement for both $W^+W^- \rightarrow q\bar{q}\ell\nu_\ell$ and $W^+W^- \rightarrow q\bar{q}q\bar{q}$ channels for each of the data taking periods that were analysed, and using the same error categories as for the mass. The BEC and CR uncertainties supplied by the experiments were based on studies of phenomenological models of these effects, using the same estimates of such FSI effects as for the mass and propagating them to the width. Note that the W width results of the experiments do not use the techniques introduced to reduce sensitivity to FSI effects used for the mass analysis. A simultaneous fit to the results of the four LEP collaborations is performed in the same way as for the m_W measurement.

Table 7.5

W width measurements ($\sqrt{s} = 172\text{--}209$ GeV) from the individual experiments. The column labelled “published” shows the results as published by the experiments, using their individual evaluations of FSI effects. The column labelled “LEP combination” shows the results of the experiments when propagating the LEP measurements of FSI effects to the W width.

Experiment	Published Γ_W (GeV)	LEP combination Γ_W (GeV)
ALEPH	2.14 ± 0.11	2.14 ± 0.11
DELPHI	2.40 ± 0.17	2.39 ± 0.17
L3	2.18 ± 0.14	2.24 ± 0.15
OPAL	2.00 ± 0.14	2.00 ± 0.14

Fig. 7.3. The measurements of the W -boson width obtained by the four LEP collaborations (as published) together with the LEP combined result. The combined value includes correlations between experiments, between different energy points, and between the $q\bar{q}\ell\nu_\ell$ and $q\bar{q}q\bar{q}$ channels. A revised estimation of systematic uncertainties due to colour reconnection and Bose–Einstein correlations is applied to the input of the individual measurements to the LEP combined results in order to take the direct determination of FSI parameters into account.

Correlated systematic uncertainties are taken into account and the combination yields:

$$\Gamma_W = 2.195 \pm 0.063(\text{stat.}) \pm 0.055(\text{syst.}) \text{ GeV}, \quad (7.11)$$

for a total error of 83 MeV. The combination has a χ^2/dof of 37.4/33, corresponding to a probability of 27.3%.

7.7. Summary

The final results of the four LEP experiments on the mass and width of the W boson are combined taking into account correlated systematic uncertainties, with the result:

$$m_W = 80.376 \pm 0.033 \text{ GeV}, \quad (7.12)$$

$$\Gamma_W = 2.195 \pm 0.083 \text{ GeV}. \quad (7.13)$$

The correlations between mass and width are found to be less than 5% and thus negligible. These values correspond to the theoretical definition of a W -boson propagator with s -dependent width. The results of the mass and width determined by the LEP collaborations are in good agreement with the measurements at hadron colliders [149–152]. Updated constraints on SM parameters using the mass and width results are presented in [Appendix F](#).

8. Summary and conclusions

The four LEP experiments ALEPH, DELPHI, L3 and OPAL performed measurements in electron–positron collisions at centre-of-mass energies above the mass of the Z boson, ranging from 130 GeV, crossing the W -pair production threshold at 160 GeV, up to 209 GeV. Based on about 0.75 fb^{-1} of luminosity collected by each experiment, yielding a total of 3 fb^{-1} , many precision measurements are summarised in this report.

The combinations of precise electroweak results yield stringent constraints on the Standard Model (SM) and its free parameters, for example:

$$m_W = 80.376 \pm 0.033 \text{ GeV}$$

$$\Gamma_W = 2.195 \pm 0.083 \text{ GeV}$$

$$B(W \rightarrow \text{had}) = 67.41 \pm 0.27\%$$

$$g_1^Z = 0.984_{-0.020}^{+0.018}$$

$$\kappa_\gamma = 0.982 \pm 0.042$$

$$\lambda_\gamma = -0.022 \pm 0.019.$$

The results, together with measurements performed in electron–positron collisions at the Z-pole and in hadron collider experiments, test the SM with unprecedented precision at the highest interaction energies. The measurements agree well with the SM predictions.

Overall, the SM is verified to be a good theory up to the 200 GeV scale, see also the studies presented in [Appendix F](#). The data impose very tight constraints on any new physics beyond the SM, and are well compatible with a 125–126 GeV SM Higgs boson [167]. Any extended theory must be consistent with the SM or one or more Higgs doublet models such as super-symmetry.

Acknowledgements

We would like to thank the CERN accelerator divisions for the efficient operation of the LEP accelerator, the precise information on the beam energy scale and their close cooperation with the four experiments. We would also like to thank members of the SLD, CDF, DØ, NuTeV and E-158 collaborations for making results available to us and for useful discussions concerning their combination. Finally, the results and their interpretation within the SM would not have been possible without the close collaboration of many theorists.

Appendix A. S-Matrix

A.1. Introduction

The S-Matrix ansatz provides a coherent way of describing the measurements of the cross-section and forward–backward asymmetries in s -channel $e^+e^- \rightarrow f\bar{f}$ processes at centre-of-mass energies around the Z resonance and the measurements at centre-of-mass energies from 130 GeV to 209 GeV from the LEP-II program. This chapter describes the combination of results from the full LEP-I data sets of the four LEP experiments, to obtain a LEP combined result on the parameters of the S-Matrix ansatz describing the Z lineshape.

The standard description of the measurements at the Z resonance [2] makes use of nine parameters (m_Z , Γ_Z , σ_{had}^0 , R_ℓ^0 , $A_{\text{FB}}^{0,\ell}$, for $\ell = e, \mu, \tau$) which are reduced to five in case lepton universality is assumed. The S-Matrix formalism utilises an extra three parameters (assuming lepton universality) or seven parameters (not assuming lepton universality). The additional parameters describe the contributions to the cross-sections and forward–backward asymmetries of the interference between the exchange of a Z and a photon. The Z-pole data alone cannot tightly constrain these interference terms, in particular the interference term for cross-sections, since their contributions are small around the Z resonance and change sign at the pole. Owing to strong correlations between the size of the hadronic cross-section interference term and the mass of the Z, this leads to a larger error on the extracted mass of the Z compared to the standard five and nine parameter analyses where the hadronic interference term is fixed to the value predicted in the Standard Model (SM). However, using the LEP-II data leads to a significant improvement in the constraints on the interference terms and a corresponding reduction in the uncertainty on the mass of the Z, expected to result in a measurement of m_Z which is almost as precise but without having to constrain the γ/Z interference to the SM prediction.

The LEP combination is a two-step procedure: first a combination of the LEP-I based results, and then including the LEP-II data. For the LEP-I data, an average of the individual experiments' results on the S-Matrix parameters is made. Such a combination at parameter level, similar to the method used to combine the Z lineshape results in terms of the five and nine parameters [2], is presented here. To include the LEP-II data, a fit of the S-Matrix parameters to the combined LEP-II measurements of cross-sections and asymmetries as presented in Section 3 is envisaged, including in the χ^2 the LEP-I based combination of S-Matrix parameters with uncertainties and correlations as additional constraints.⁸

In [Appendix A.2](#) the parameters of the S-Matrix ansatz are explained in detail. In [Appendix A.3](#) the average of the LEP-I data is described, preparing for the inclusion of the LEP-II measurements in the future. The results are discussed in [Appendix A.4](#) while the detailed combination tables are listed in [Appendix A.5](#).

⁸ Based on preliminary LEP measurements, Ref. [168] contains a partial LEP-I+LEP-II combination along these lines, which shows the vast improvement made possible by including the LEP-II measurements.

A.2. The S-Matrix ansatz

The S-Matrix ansatz [169] is a rigorous approach to describe the cross-sections and forward–backward asymmetries in s -channel e^+e^- annihilations under the basic assumption that the processes can be parametrised as the exchange of a massless and a massive vector boson, in which the couplings of the bosons including their interference are treated as free and independent parameters. In this model, the cross-sections are parametrised as follows:

$$\sigma_{tot,f}^0(s) = \frac{4}{3}\pi\alpha^2 \left[\frac{g_f^{\text{tot}}}{s} + \frac{j_f^{\text{tot}}(s - \bar{m}_Z^2) + r_f^{\text{tot}}s}{(s - \bar{m}_Z^2)^2 + \bar{m}_Z^2\bar{\Gamma}_Z^2} \right] \quad \text{with } f = had, e, \mu, \tau, \quad (\text{A.1})$$

while the forward–backward asymmetries are given by:

$$A_{fb,f}^0(s) = \pi\alpha^2 \left[\frac{g_f^{\text{fb}}}{s} + \frac{j_f^{\text{fb}}(s - \bar{m}_Z^2) + r_f^{\text{fb}}s}{(s - \bar{m}_Z^2)^2 + \bar{m}_Z^2\bar{\Gamma}_Z^2} \right] / \sigma_{tot,f}^0(s), \quad (\text{A.2})$$

where \sqrt{s} is the centre-of-mass energy. The parameters r_f and j_f scale the Z exchange and the γ/Z interference contributions to the total cross-section and forward–backward asymmetries. The contribution g_f of the pure γ exchange is fixed to the value predicted by QED. Neither the hadronic charge asymmetry nor the flavour-tagged quark forward–backward asymmetries are considered here, which leaves 16 S-Matrix parameters to describe the LEP data: the mass and total width of the Z resonance, and 14 r_f and j_f parameters. Applying the constraint of neutral-current lepton universality reduces the number of parameters from 16 to 8.

In the SM the Z exchange term, the γ/Z interference term and the photon exchange term are given in terms of the fermion charges and their effective vector and axial-vector couplings to the Z by:

$$r_f^{\text{tot}} = \kappa^2 [g_{Ae}^2 + g_{Ve}^2] [g_{Af}^2 + g_{Vf}^2] - 2\kappa g_{Ve} g_{Vf} C_{Im} \quad (\text{A.3})$$

$$j_f^{\text{tot}} = 2\kappa g_{Ve} g_{Vf} (C_{Re} + C_{Im}) \quad (\text{A.4})$$

$$g_f^{\text{tot}} = Q_e^2 Q_f^2 |F_A(m_Z)|^2 \quad (\text{A.5})$$

$$r_f^{\text{fb}} = 4\kappa^2 g_{Ae} g_{Ve} g_{Af} g_{Vf} - 2\kappa g_{Ae} g_{Af} C_{Im} \quad (\text{A.6})$$

$$j_f^{\text{fb}} = 2\kappa g_{Ae} g_{Af} (C_{Re} + C_{Im}) \quad (\text{A.7})$$

$$g_f^{\text{fb}} = 0, \quad (\text{A.8})$$

with the following definitions:

$$\kappa = \frac{G_F m_Z^2}{2\sqrt{2}\pi\alpha} \approx 1.50 \quad (\text{A.9})$$

$$C_{Im} = \frac{\Gamma_Z}{m_Z} Q_e Q_f \text{Im} \{F_A(m_Z)\} \quad (\text{A.10})$$

$$C_{Re} = Q_e Q_f \text{Re} \{F_A(m_Z)\} \quad (\text{A.11})$$

$$F_A(m_Z) = \frac{\alpha(m_Z)}{\alpha}, \quad (\text{A.12})$$

where $\alpha(m_Z)$ is the complex fine-structure constant, and $\alpha \equiv \alpha(0)$. The expressions of the S-Matrix parameters in terms of the effective vector and axial-vector couplings given above neglect the imaginary parts of the effective couplings. The photonic virtual and bremsstrahlung corrections are included through the convolution of Eqs. (A.1) and (A.2) with the same radiator functions as used in the five and nine parameter Z -lineshape fits [2].

In the S-Matrix framework, the parameters mass (\bar{m}_Z) and total width ($\bar{\Gamma}_Z$) of the Z boson are defined in terms of a relativistic Breit-Wigner with s -independent width. These definitions are related to the usual definitions of the mass m_Z and width Γ_Z of a Breit-Wigner resonance with s -dependent width, used in [2], as follows:

$$m_Z \equiv \bar{m}_Z \sqrt{1 + \bar{\Gamma}_Z^2 / \bar{m}_Z^2} \approx \bar{m}_Z + 34.20 \text{ MeV}, \quad (\text{A.13})$$

$$\Gamma_Z \equiv \bar{\Gamma}_Z \sqrt{1 + \bar{\Gamma}_Z^2 / \bar{m}_Z^2} \approx \bar{\Gamma}_Z + 0.94 \text{ MeV}. \quad (\text{A.14})$$

The predictions of the S-Matrix ansatz for cross-sections and asymmetries are calculated using SMATASY [170], which in turn uses ZFITTER [23] to calculate the QED convolution of the electroweak kernel. In case of the e^+e^- final state, t -channel and s/t interference contributions are added to the s -channel ansatz [2].

A.3. LEP-I combination

The LEP experiments have determined the 16 S-Matrix parameters using their full LEP-I data set [171–174]. These results are averaged using the BLUE technique [30]. Sources of systematic uncertainty correlated between the experiments have been investigated using techniques described in Ref. [2] and are accounted for in the averaging procedure.

The main problem in the combination is the proper treatment of the common systematic uncertainties. The LEP experiments provide their results in terms of the standard S-Matrix parametrisation. This parameter set is not well suited for the determination of common systematic uncertainties since common errors such as the theory error for luminosity affect many parameters. Using a transformed parameter set, which is defined as similar as possible to the standard LEP nine parameter set, facilitates the study of common systematic errors as well as cross checks with the LEP nine-parameter combination [2]. The experiments' results are transformed to this parameter set, combined, and the final results transformed back to the standard S-Matrix parameter set. The transformed S-Matrix parameters are defined as follows:

$$S_{\text{had}} \equiv \frac{r_{\text{had}}^{\text{tot}}}{\Gamma_Z^2} \quad (\text{A.15})$$

$$R_e^{\text{smx}} \equiv \frac{r_{\text{had}}^{\text{tot}}}{r_e^{\text{tot}}} \quad (\text{A.16})$$

$$R_\mu^{\text{smx}} \equiv \frac{r_{\text{had}}^{\text{tot}}}{r_\mu^{\text{tot}}} \quad (\text{A.17})$$

$$R_\tau^{\text{smx}} \equiv \frac{r_{\text{had}}^{\text{tot}}}{r_\tau^{\text{tot}}} \quad (\text{A.18})$$

$$A_{FB}^{\text{smx},e} \equiv \frac{3}{4} \frac{r_e^{\text{fb}}}{r_e^{\text{tot}}} \quad (\text{A.19})$$

$$A_{FB}^{\text{smx},\mu} \equiv \frac{3}{4} \frac{r_\mu^{\text{fb}}}{r_\mu^{\text{tot}}} \quad (\text{A.20})$$

$$A_{FB}^{\text{smx},\tau} \equiv \frac{3}{4} \frac{r_\tau^{\text{fb}}}{r_\tau^{\text{tot}}} \quad (\text{A.21})$$

Table A.1 gives the input of the four LEP experiments for the 16 transformed S-Matrix parameters. The corresponding correlation matrices are given in Tables A.8–A.11.

Table A.2 shows the common systematic uncertainty of the transformed S-Matrix parameters due to the uncertainties in the LEP centre-of-mass energy. The parameters m_Z and $J_{\text{had}}^{\text{tot}}$ are the most sensitive of all 16 S-Matrix parameters to the inclusion of the LEP-II data, and are also the most interesting ones in comparison to the five and nine parameter fits. For these parameters the most significant source of systematic error correlated between experiments arises from the uncertainty on

χ^2/dof	$59.96 / 48$

the e^+e^- centre-of-mass energy. These errors amount to ± 3.2 MeV on m_Z and ± 0.16 on $j_{\text{had}}^{\text{tot}}$, with a correlation coefficient of -0.86 . Table A.3 specifies the common uncertainties due to theoretical uncertainties in the calculation of the t -channel contributions for Bhabha scattering. In this case the determination of the common error was complicated by the fact that the experiments choose different procedures for the t -channel correction, which yield different common errors. We used the common t -channel errors as determined by ALEPH [2] as basis for the combination since these result in the smallest common errors. As a cross-check the combination was repeated with common t -channel errors based on OPAL's analysis which yields the largest common errors. The effect on the combined result is small, the shift of central values is below 20% of its uncertainty. In this parametrisation, the luminosity theory uncertainty affects only the parameter S_{had} . The uncertainties are 0.061% for ALEPH, DELPHI and L3, and 0.054% for OPAL.

The result of the LEP-I combination in terms of the transformed S-Matrix parameters is listed in Table A.4, Table A.5 shows the corresponding correlation matrix. Transforming this result back to the standard S-Matrix parameter set, the combination is reported in Tables A.6 and A.7. The χ^2/dof for the average of all 16 parameters is $59.8/48$, corresponding to a probability of 12%.

A.4. Discussion

In the LEP-I combination the measured values of the Z boson mass $m_Z = 91.1929 \pm 0.0059$ GeV agrees well with the results of the standard nine parameter fit, 91.1876 ± 0.0021 GeV, albeit with a significantly larger error, resulting from the correlation with the large uncertainty on $j_{\text{had}}^{\text{tot}}$. This uncertainty is the dominant source of uncertainty on m_Z in the S-Matrix fits. The measured value of $j_{\text{had}}^{\text{tot}} = -0.10 \pm 0.33$ also agrees with the prediction of the SM, $0.2201^{+0.0032}_{-0.0137}$.

A.5. S-Matrix combination tables

See Tables A.8–A.11.

Appendix B. Two-fermion combination details

B.1. Input measurements

In this section, the experimental measurements of total cross-sections and forward–backward asymmetries as used in the combination are reported. For each result, the ZFITTER prediction, followed by the measured value and the six error

B.2. Differential cross-section for muon- and tau-pair final states

The following lists show for each centre-of-mass energy point (rounded in GeV) the LEP-combined differential lepton-pair cross-sections (DC) for $\mu^+\mu^-$ (MM) and $\tau^+\tau^-$ (TT) final states in 10 $\cos\theta$ -bins (1–10) of constant width 0.2, comparing the LEP average value and its total error with the SM prediction. Also shown is the overall χ^2/dof and the bin-by-bin χ^2/dof contribution. The overall matrix of correlation coefficients and inverse covariance matrix are available at the LEPEWWG web site: <http://www.cern.ch/LEPEWWG/2>.

Total χ^2/NDF = 352.156/320

183_DC_MM_1	average =	0.197 +- 0.183	SM=	0.547	χ^2/NDF =	0.688/1
183_DC_MM_2	average =	0.589 +- 0.163	SM=	0.534	χ^2/NDF =	0.717/1
183_DC_MM_3	average =	0.807 +- 0.174	SM=	0.627	χ^2/NDF =	2.204/1
183_DC_MM_4	average =	1.033 +- 0.197	SM=	0.823	χ^2/NDF =	0.211/1
183_DC_MM_5	average =	1.178 +- 0.236	SM=	1.121	χ^2/NDF =	0.014/1

B.3. Differential cross-section for electron–positron final states

The following lists show for each centre-of-mass energy point (rounded in GeV) the LEP-combined differential cross-sections (DC) for e^+e^- (EE) final states in 15 $\cos\theta$ -bins (1–15 with bin boundaries as defined in Tables 3.11 and 3.12), comparing the LEP average value and its total error with the SM prediction. Also shown is the overall χ^2/dof and the bin-by-bin χ^2/dof contribution. The overall matrix of correlation coefficients and inverse covariance matrix are available at the LEPEWWG web site: <http://www.cern.ch/LEPEWWG/2>.

Appendix C. Determination of the LEP centre-of-mass energy using radiative-return events

The LEP collaborations performed measurements of radiative Z boson production, $e^+e^- \rightarrow Z + \gamma \rightarrow f\bar{f} + \gamma$, at centre-of-mass energies well above the Z peak, $\sqrt{s} = 161\text{--}209$ GeV [87,162–164]. Events with pairs of electrons, muons, taus, and hadronic jets were selected. The presence of hard ISR photons, mostly emitted at small polar angles with respect to the beam directions and recoiling against the di-fermion system, led to typical event topologies with acollinear fermions measured in

Fig. C.1. Examples of reconstructed two-fermion mass spectra in the $Z + \gamma \rightarrow \mu^+\mu^- + \gamma$ channel (left) and in the hadronic channel (right), as measured by OPAL and by L3, respectively [164]. The data collected at different centre-of-mass energies is combined and compared to Monte-Carlo predictions using the nominal Z bosons mass [2]. The Z resonance peak is clearly visible.

the detector. Due to the photon emission, the mass of the two-fermion system, $\sqrt{s'}$, is reduced to values less than \sqrt{s} . The spectrum of $\sqrt{s'}$ exhibits a resonance peak around the Z boson mass and allows a determination of m_Z . The determination of $\sqrt{s'}$ furthermore involves the knowledge of the e^+e^- centre-of-mass mass energy, because in the kinematic reconstruction of the $Z + \gamma \rightarrow f\bar{f} + \gamma$ events, energy-momentum conservation is imposed. Thus, a measurement of the Z boson mass in radiative-return events, $m_Z^{f\bar{f}}$, is equivalent to determining the average \sqrt{s} of each analysed data set. Fig. C.1 shows two examples of the two-fermion mass spectra measured by the LEP experiments.

The ISR photons are either detected as isolated energy depositions in the calorimeters compatible with an electromagnetic shower or as missing momentum pointing along the beam directions. Typically, the energy of the calorimeter shower is required to be larger than 30–60 GeV. For hadronic final states, a kinematic fit is applied to the event imposing energy and momentum conservation. In case the ISR photons are not observed in the detector, the sum of the photon momenta is assumed to either point along only one beam direction or along both beam axes. In the kinematic fit, usually both possibilities are tested and the one obtaining the best fit results is eventually chosen. In this way, the mass of the two-fermion system is reconstructed with optimised precision. In leptonic final states, $\sqrt{s'}$ is determined using the well-measured polar angles of the leptons, according to the following equation:

$$\sqrt{s'} = \sqrt{1 - \frac{2E_{\text{ISR}}}{\sqrt{s}}}, \quad \text{with} \quad (C.1)$$

$$E_{\text{ISR}} = \sqrt{s} \frac{|\sin(\theta_1 + \theta_2)|}{\sin \theta_1 + \sin \theta_2 + |\sin(\theta_1 + \theta_2)|}. \quad (C.2)$$

The leptonic polar angles θ_1 and θ_2 are determined either relative to the beam axis if no photon is measured in the detector, or relative to the direction of the measured ISR photon.

After correcting for remaining background, the mass of the Z boson is extracted either by applying a Monte-Carlo event reweighting based on the corresponding matrix element of the signal process or by fitting an analytical function describing the signal spectrum to the data. The measured Z mass, $m_Z^{f\bar{f}}$, is then compared to the Z mass determined in precision measurements at Z -pole energies [2], $m_Z = 91.1875 \pm 0.0021$ GeV. The comparison is converted into a difference in terms of the centre-of-mass energy, $\Delta\sqrt{s}$, between \sqrt{s} derived from radiative return events and the nominal centre-of-mass energy, \sqrt{s}_{LEP} , determined by the precise LEP energy calibration [156]:

$$\Delta\sqrt{s} = \sqrt{s} - \sqrt{s}_{\text{LEP}} = \sqrt{s} \frac{m_Z^{f\bar{f}} - m_Z}{m_Z}. \quad (C.3)$$

This observable is eventually used to combine the results of the four LEP experiments.

Various sources of systematic uncertainties are studied and possible correlations between them are taken into account in the combination procedure. The dominant uncertainty is due to the modelling of the fragmentation process in hadronic Z decays. An uncertainty of 22 MeV on $\Delta\sqrt{s}$ is derived from a comparison of different fragmentation models implemented in the PYTHIA [76], HERWIG [165], and ARIADNE [161] software packages. The Monte-Carlo predictions of the $e^+e^- \rightarrow f\bar{f} + \gamma$ process are calculated using the KK v4.02 [29] Monte-Carlo generator. Theoretical uncertainties in the description of ISR and FSR and missing higher order corrections are estimated by reweighting events applying different orders of α in the prediction and comparing it to the $\mathcal{O}(\alpha^2)$ calculations in the Coherent Exclusive Exponentiation scheme. Furthermore, the effect of neglecting the interference between ISR and FSR was studied. The total systematic uncertainties due to modelling of ISR and

Table C.1

Systematic and statistical uncertainties on the measurement of the LEP centre-of-mass energy shift, $\Delta\sqrt{s}$.

Source	Uncertainty on $\Delta\sqrt{s}$ (MeV)
Fragmentation	22
ISR/FSR modelling	7
Four fermion background	6
Z mass	1
LEP parameters	3
Total correlated	23
Monte-Carlo statistics	7
Detector bias and resolution	28
Total uncorrelated	29
Total systematics	37
Total statistical	40
Total	54

Table C.2

Combined results of ALEPH, DELPHI, L3, and OPAL on the determination of the LEP centre-of-mass energy shift, $\Delta\sqrt{s}$, with respect to the nominal value of \sqrt{s} . The results are shown for the leptonic and hadronic final states, as well as for the different data taking periods, together with the LEP combined value. Statistical and systematic uncertainties are given separately.

Data set	$\Delta\sqrt{s}$ (MeV)
$e^+e^- \rightarrow \text{hadrons} + \gamma$	$-88 \pm 40 \pm 56$
$e^+e^- \rightarrow \ell^+\ell^- + \gamma$	$-10 \pm 80 \pm 26$
$\sqrt{s} = 183 \text{ GeV}$	$70 \pm 98 \pm 50$
$\sqrt{s} = 189 \text{ GeV}$	$-86 \pm 60 \pm 46$
$\sqrt{s} = 192\text{--}202 \text{ GeV}$	$-66 \pm 62 \pm 44$
$\sqrt{s} = 205\text{--}209 \text{ GeV}$	$-140 \pm 70 \pm 52$
All LEP data	$-54 \pm 40 \pm 36$

FSR amounts to 7 MeV. The uncertainty due to the prediction of the four-fermion background using measured cross-sections as input is estimated to be 6 MeV. The operational parameters of the LEP collider may also influence the reconstruction of the two-fermion mass. In particular, the effects of beam energy spread and a possible asymmetry in beam energy were studied and found to influence $\Delta\sqrt{s}$ by less than 3 MeV. The uncertainty on the nominal Z boson mass contributes with less than 1 MeV. All these sources of systematic uncertainties are assumed to be fully correlated between experiments.

Each experiment determined the influence of detector alignment, bias in angular measurements, uncertainty of energy and momentum scale and resolution in great detail. Control samples were selected in data to measure the various detector and resolution effects. These uncertainties are treated as uncorrelated between experiments. Uncertainties from limited Monte-Carlo statistics also contribute. If sources of systematic uncertainties affect data from different data taking periods or different channels similarly also the corresponding correlations are taken into account. A summary of the different sources of systematic uncertainties is listed in Table C.1. The uncertainties due to Monte-Carlo statistics and detector bias and resolution are uncorrelated between experiments. Details of the systematic effects due to detector bias and resolution combine several individual sources of uncertainty and are discussed in the publications by the experiments [87,162–164]. The total statistical and systematic uncertainties on the LEP average for $\Delta\sqrt{s}$ are 40 MeV and 36 MeV, respectively.

When combining all available LEP data [87,162–164] with Z decays to hadrons, and to electron, muon, and tau pairs, the difference is found to be:

$$\Delta\sqrt{s} = -54 \pm 54 \text{ MeV}, \quad (\text{C.4})$$

in good agreement with no shift with respect to the more precise standard LEP energy calibration. There is also no significant shift observed when analysing the leptonic and hadronic decay channels separately. Furthermore, there is no significant dependence on the LEP beam energy, respectively data taking periods, as illustrated in Fig. C.2 and Table C.2.

Appendix D. Tests of the colour-reconnection combination procedure

Here we report on the tests of the LEP combination procedure used to combine the measurements of the LEP experiments on colour-reconnection (CR). It is shown that the LEP combination procedure is able to reproduce the combination of each experiment separately.

Fig. C.2. Difference between the energy determined in Z-return events and the nominal LEP centre-of-mass energy, $\Delta\sqrt{s}$, for the different experiments and final states (top), and for the data taking periods with energies well above the W -pair threshold (bottom). The individual measurements as well as the LEP combined values take systematic uncertainties and their correlations into account.

For each measurement, the dependence of the measured observable on the model parameter k_I is determined based on Monte-Carlo simulations. For the particle-flow based measurements, the results are reported in Table D.1. The corresponding parameter values for the phenomenological function shown in Eq. (4.4) are listed in Table D.2. The parametrisations of $\delta_{\Delta m_{W,i}}(k_I)$ which are used to introduce systematic uncertainties for the likelihood functions of the CR measurements from Δm_W by ALEPH, DELPHI, and OPAL are given by:

$$\delta_{\Delta m_{W,A}}(k_I) = \begin{cases} 0.416408 + (0.624184)^2 \cdot k_I, & k_I \in [0.0, 1.3) \\ 1.227847 + (0.251441)^2 \cdot (k_I - 1.3), & k_I \in [1.3, 2.5) \\ 1.529576 + (0.750313)^2 \cdot (k_I - 2.5), & k_I \in [2.5, 4.5) \\ 3.030202 + (0.279341)^2 \cdot (k_I - 4.5), & k_I \in [4.5, 6.0) \\ 3.449214 + (0.600389)^2 \cdot (k_I - 6.0), & k_I \in [6.0, \infty) \end{cases} \quad (D.1)$$

$$\delta_{\Delta m_{W,D}}(k_I) = 0.233054 + (0.486925)^2 \cdot k_I \quad (D.2)$$

$$\delta_{\Delta m_{W,O}}(k_I) = 0.666308 + (0.483630)^2 \cdot k_I. \quad (D.3)$$

A graphical comparison of the original input and the parametrised $\Delta\chi^2$ distributions is displayed in Fig. 4.2 and shows good agreement.

The ALEPH input is available as a set of $\Delta\chi^2(k_I)$ values including systematic uncertainties, which can be evaluated directly. The result is shown in Fig. D.1 and the numerical analysis yields:

$$k_I = 0.33^{+1.82}_{-0.33}. \quad (D.4)$$

Table D.1

Monte-Carlo predictions for the particle-flow parameter $R_N(k_I)$ provided for the SK1 model by L3 and OPAL.

k_I	$R_N(k_I)$ for SK1 Model

100.00	–	1.0918 ± 0.0028
10000.00	0.7482 ± 0.0033	1.0780 ± 0.0028

Table D.2

Parameter sets used for the functional description of the particle-flow input provided for the SK1 model by L3 and OPAL.

Experiment	a_1	a_2	a_3	a_4	b
L3	–12.1076	2.03107	–0.23384	–10.1780	1.18954
OPAL	–0.26969	0.20543	–0.06698	0.03388	10.8576

By construction, this agrees well with the original ALEPH result [61]. However, the ALEPH input does not include BEC systematic uncertainties. To incorporate also this effect, the correlated part of the systematic uncertainties is increased by 11%. This value is derived from a dedicated study, not included in the ALEPH publication. The final result using only ALEPH data and including BEC uncertainties is

$$k_I = 0.34^{+1.86}_{-0.34}. \quad (\text{D.5})$$

The 68% upper limit is about 3% higher compared to the original ALEPH input.

DELPHI provides $\Delta\chi^2(k_I)$ inputs from their ΔM_W and particle-flow analyses. In the DELPHI publication, both curves are simply added neglecting correlations, yielding [71]:

$$k_I = 2.2^{+2.5}_{-1.3}. \quad (\text{D.6})$$

As a cross-check, the same combination strategy is applied, i.e., assuming no correlations. When using a total $\chi^2(k_I)$ of:

$$\chi^2(k_I, c) = \Delta\chi^2_{\Delta M_W, D, \text{full}}(k_I) + \Delta\chi^2_{p\text{-flow}, D, \text{full}}(k_I), \quad (\text{D.7})$$

the following result is obtained:

$$k_I = 2.17^{+2.55}_{-1.33}, \quad (\text{D.8})$$

which is consistent with the combination performed by DELPHI. The LEP combination procedure allows a more refined treatment of correlations. Using a correlation coefficient of 0.50 between the measurements, motivated by the full covariance matrix for the particle-flow combination, the fit obtains:

$$k_I = 2.12^{+2.61}_{-1.33}. \quad (\text{D.9})$$

This corresponds to a 5% increase of the positive uncertainty and a small shift of the minimum. The result is shown in Fig. D.1.

The L3 input is provided in terms of $r(k_I)$ derived from Monte-Carlo simulations and the measured r_{data} together with measurement uncertainties. The fit results in:

$$k_I = 0.76^{+1.89}_{-1.22}, \quad (\text{D.10})$$

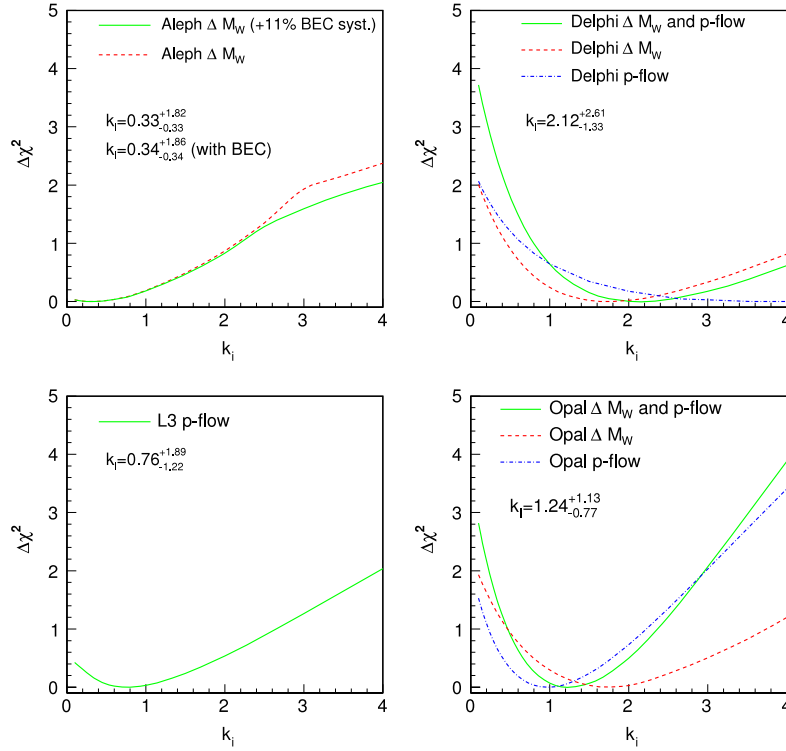

Fig. D.1. LEP input to the CR measurement in terms of $\Delta\chi^2$ curves. The input data provided by the ALEPH experiment are shown as a dashed line and are compared to the data used in the LEP combination, where additional BEC systematic uncertainties are taken into account. The DELPHI and OPAL results from the analysis of the W -mass shift, Δm_W , and from the measurement of particle-flow are shown as dashed and dotted lines, respectively. The solid line represents the combined results taking correlations into account. The L3 experiment provided input from the particle-flow measurement, also shown as a solid line.

and the corresponding $\Delta\chi^2$ curve is shown in Fig. D.1. The result obtained is different from the L3 paper on CR [72], where a value of $k_l = 0.08^{+1.02}_{-0.08}$ is derived. This is due to the difference between the non-CR reference Monte-Carlo simulation used by L3 and the common LEP Monte-Carlo sample used in this combination. These Monte-Carlo samples were generated with different fragmentation and hadronisation parameters; the former was tuned to describe L3 data best. The difference in the k_l result is fully compatible with the systematic uncertainty assigned to hadronisation and fragmentation effects.

OPAL measures k_l in W -mass shift and particle-flow analyses. As for DELPHI, a correlation coefficient of 0.50 is assumed between the correlated uncertainties in both inputs. Both $\Delta\chi^2$ curves and their combination are shown in Fig. D.1. The combined fit yields

$$k_l = 1.24^{+1.13}_{-0.77}. \quad (\text{D.11})$$

The 68% C.L. upper limit of 2.37 is in good agreement with the OPAL result $k_l < 2.3$ at 68% C.L. [64]. OPAL presents the results in terms of $p_{\text{reco}} = 0.43^{+0.15}_{-0.20}$ which translates into $k_l \approx 1.3^{+1.1}_{-0.8}$, using the conversion from p_{reco} to k_l based on OPAL's Monte-Carlo simulation. Using only information from ΔM_W , the fit obtains $k_l = 1.75^{+1.99}_{-1.28}$, also agreeing well with the OPAL publication: $k_l = 1.7^{+2.0}_{-1.2}$.

In summary, the LEP combination procedure reproduces well the results obtained by each collaboration, with the observed differences explained by known systematic effects.

Appendix E. Detailed inputs and results of LEP four-fermion averages

Tables E.1–E.21 give the details of the inputs and of the results for the calculation of LEP averages of the measured four-fermion cross-sections and the corresponding ratios of measured cross-sections to the theoretical predictions. For both inputs and results, whenever relevant, the breakdown of the errors into their various components is given in the tables.

For each measurement, the collaborations have privately provided unpublished information which is necessary for the combination of the LEP results, such as the expected statistical error or the split of the total systematic uncertainty into correlated and uncorrelated components. Where necessary, minor re-arrangements with respect to published results across error categories have been applied.

Table E.1

W -pair production cross-section (in pb) for different centre-of-mass energies from the four LEP experiments. The first column contains the centre-of-mass energy and the second the measurements. Observed statistical uncertainties are used in the fit and are listed in the third column; when asymmetric errors are quoted by the collaborations, the positive error is listed in the table and used in the fit. The fourth, fifth and sixth columns contain the components of the systematic errors, as subdivided by the collaborations into LEP-correlated energy-correlated (LCEC), LEP-uncorrelated energy-uncorrelated (LUEU), LEP-uncorrelated energy-correlated (LUEC). The total systematic error is given in the seventh column, the total error in the eighth.

206.6	17.145 ± 0.006	17.087 ± 0.009

Table E.5

Ratios of LEP combined W -pair cross-section measurements to the expectations of the considered theoretical models, for different centre-of-mass energies and for all energies combined. The first column contains the centre-of-mass energy, the second the combined ratios, the third the statistical errors. The fourth, fifth, sixth and seventh columns contain the sources of systematic errors that are considered as LEP-correlated energy-uncorrelated (LCEU), LEP-correlated energy-correlated (LCEC), LEP-uncorrelated energy-uncorrelated (LUEU), LEP-uncorrelated energy-correlated (LUEC). The total error is given in the eighth column. The only LCEU systematic sources considered are the statistical errors on the cross-section theoretical predictions, while the LCEC, LUEU and LUEC sources are those coming from the corresponding errors on the cross-section measurements. For the LEP averages, the χ^2/dof of the fit is also given in the ninth column.

\sqrt{s} (GeV)	\mathcal{R}_{WW}	$\Delta \mathcal{R}_{WW}^{\text{stat}}$	(LCEU) $\Delta \mathcal{R}_{WW}^{\text{syst}}$	(LCEC) $\Delta \mathcal{R}_{WW}^{\text{syst}}$	(LUEU) $\Delta \mathcal{R}_{WW}^{\text{syst}}$	(LUEC) $\Delta \mathcal{R}_{WW}^{\text{syst}}$	$\Delta \mathcal{R}_{WW}$	χ^2/dof

Table E.6

W branching fraction measurements (in %). The first column contains the decay channel, the second the measurements, the third the statistical uncertainty. The fourth and fifth column list the uncorrelated and correlated components of the systematic errors, as provided by the collaborations. The total systematic error is given in the sixth column and the total error in the seventh. Correlation matrices for the three leptonic branching fractions are given in the last column.

Table E.7

W^- differential angular cross-section in the 10 angular bins for the four chosen energy intervals for the ALEPH experiment. For each energy range, the measured integrated luminosity and the luminosity-weighted centre-of-mass energy is reported. The results per angular bin in each energy interval are then presented: σ_i indicates the average of $d[\sigma_{WW}(BR_{e\nu} + BR_{\mu\nu})]/d\cos\theta_{W^-}$ in the i th bin of $\cos\theta_{W^-}$ with width 0.2. The values in each bin of the measured and expected statistical error and of the systematic errors, LEP uncorrelated and correlated, are reported as well. All values are expressed in pb.

Appendix F. Constraints on the standard model

F.1. Introduction

The experimental measurements used here to place constraints on the Standard Model (SM) consist of three groups: (i) the final Z -pole results measured in electron–positron collisions by the ALEPH, DELPHI, L3, OPAL and SLD experiments, as combined in Ref. [2]; (ii) the mass and width of the W boson measured at LEP-II and described earlier in this report; and (iii) the measurements of the mass of the top quark and the mass and width of the W boson at the Tevatron collider.

The measurements allow checks of the validity of the SM and, within its framework, to infer valuable information about its fundamental parameters. The accuracy of the Z -boson and W -boson measurements makes them sensitive to the mass

Table E.9

W^- differential angular cross-section in the 10 angular bins for the four chosen energy intervals for the L3 experiment. For each energy range, the measured integrated luminosity and the luminosity-weighted centre-of-mass energy is reported. The results per angular bin in each energy interval are then presented: σ_i indicates the average of $d[\sigma_{WW}(BR_{e\nu} + BR_{\mu\nu})]/d\cos\theta_{W^-}$ in the i th bin of $\cos\theta_{W^-}$ with width 0.2. The values in each bin of the measured and expected statistical error and of the systematic errors, LEP uncorrelated and correlated, are reported as well. All values are expressed in pb.

Table E.10

W^- differential angular cross-section in the 10 angular bins for the four chosen energy intervals for the OPAL experiment. For each energy range, the measured integrated luminosity and the luminosity-weighted centre-of-mass energy is reported. The results per angular bin in each energy interval are then presented: σ_i indicates the average of $d[\sigma_{WW}(BR_{e\nu} + BR_{\mu\nu})]/d\cos\theta_{W^-}$ in the i th bin of $\cos\theta_{W^-}$ with width 0.2. The values in each bin of the measured and expected statistical error and of the systematic errors, LEP uncorrelated and correlated, are reported as well. All values are expressed in pb.

Table E.11

Z-pair production cross-section (in pb) at different energies from the four LEP experiments. The first column contains the LEP centre-of-mass energy, the second the measurements and the third the statistical uncertainty. The fourth, the fifth and the sixth columns list the different components of the systematic errors as defined in Table E.5. The total error is given in the seventh column, and the eighth column lists the symmetrised expected statistical error for each of the four experiments.

Table E.13

Z-pair cross-section predictions (in pb) interpolated at the data centre-of-mass energies, according to the YFSZZ [107] and ZZTO [108] predictions. The numbers in brackets are the errors on the last digit and arise from the numerical integration of the cross-section only.

\sqrt{s} (GeV)	ZZ cross-section (pb)	
	$\sigma_{ZZ}^{\text{YFSZZ}}$	$\sigma_{ZZ}^{\text{ZZTO}}$
182.7	0.254[1]	0.25425[2]
188.6	0.655[2]	0.64823[1]
191.6	0.782[2]	0.77670[1]
195.5	0.897[3]	0.89622[1]
199.5	0.981[2]	0.97765[1]
201.6	1.015[1]	1.00937[1]
204.9	1.050[1]	1.04335[1]
206.6	1.066[1]	1.05535[1]

of the top quark m_t , and to the mass of the Higgs boson m_H through electroweak loop corrections. While the leading m_t dependence is quadratic, the leading m_H dependence is logarithmic. Therefore, the inferred constraints on m_t are much stronger than those on m_H .

In a first step, the predictions for the mass and width of the W boson based on measurements performed at lower Z-pole centre-of-mass energies (LEP-I, SLC, etc.) [2] are compared to the direct measurements performed at LEP-II and the Tevatron. The comparison between prediction and direct measurement is also performed for the mass of the top quark. Finally, all measurements are used to infer constraints on the Higgs boson of the minimal SM.

This analysis updates our previous analysis [2]. Similar analyses of this type are presented in Refs. [102,175], obtaining equivalent results when accounting for the different sets of measurements considered.

F.2. Measurements

The measured quantities considered here are summarised in Table F.1. The predictions of these observables are also shown in this table, derived from the results of the SM fit to the combined high- Q^2 measurements described in the last

Table E.14

Ratios of LEP combined Z-pair cross-section measurements to the expectations, for different centre-of-mass energies and for all energies combined. The first column contains the centre-of-mass energy, the second the combined ratios, the third the statistical errors. The fourth to seventh columns contain the sources of systematic errors as defined in Table E.5. The total error is given in the eighth column. The only LCEU systematic sources considered are the statistical errors on the cross-section theoretical predictions, while the LCEC, LUEU and LUEC sources are those coming from the corresponding errors on the cross-section measurements. For the LEP averages, the χ^2/dof of the fit is also given in the ninth column.

Table E.15

Single- W hadronic production cross-section (in pb) at different energies. The first column contains the LEP centre-of-mass energy, and the second the measurements. The third column reports the statistical error, and the fourth to the sixth columns list the different systematic uncertainties. The labels LCEC, LUEU and LUEC are defined in Table E.5. The seventh column contains the total error and the eighth lists the symmetrised expected statistical error for the three LEP measurements, and, for the LEP combined value, the χ^2/dof of the fit.

column of Table F.2. The measurements obtained at the Z pole by the LEP and SLC experiments ALEPH, DELPHI, L3, OPAL and SLD and their combinations, reported in parts (a), (b) and (c) of Table F.1, are final and published [2].

The measurements of the W-boson mass published by CDF [176,151] and D0 [177,152], and on the W-boson width published by CDF [178,149] and D0 [179,150] are combined by the Tevatron Electroweak Working Group, based on a detailed treatment of correlated systematic uncertainties, with the result: $m_W = 80.387 \pm 0.016$ GeV [180] and $\Gamma_W = 2.050 \pm 0.058$ GeV [181]. Combining these Tevatron results with the final LEP-II results presented in Section 7 of this report, $m_W = 80.376 \pm 0.033$ GeV and $\Gamma_W = 2.195 \pm 0.083$ GeV, the resulting world averages are:

$$m_W = 80.385 \pm 0.015 \text{ GeV} \quad (\text{F.1})$$

$$\Gamma_W = 2.085 \pm 0.042 \text{ GeV}, \quad (\text{F.2})$$

and are used in the following.

For the mass of the top quark, m_t , the published results from CDF [182] and D0 [183] are combined by the Tevatron Electroweak Working Group with the result: $m_t = 173.2 \pm 0.9$ GeV [184].

In addition to these high- Q^2 results, the following results measured in low- Q^2 interactions and reported in Table F.3 are considered: (i) the measurements of atomic parity violation in caesium [185], with the numerical result [186] based on a revised analysis of QED radiative corrections applied to the raw measurement; (ii) the result of the E-158 collaboration on the electroweak mixing angle⁹ measured in Møller scattering [187]; and (iii) the final result of the NuTeV collaboration on neutrino–nucleon neutral to charged current cross-section ratios [188].

Using neutrino–nucleon data with an average $Q^2 \simeq 20$ GeV², the NuTeV collaboration has extracted the left- and right-handed couplings combinations $g_{\nu\text{Lud}}^2 = 4g_{Lv}^2(g_{Lu}^2 + g_{Ld}^2) = [1/2 - \sin^2\theta_{\text{eff}} + (5/9)\sin^4\theta_{\text{eff}}]\rho_v\rho_{ud}$ and $g_{\nu\text{Rud}}^2 = 4g_{Lv}^2(g_{Ru}^2 + g_{Rd}^2) = (5/9)\sin^4\theta_{\text{eff}}\rho_v\rho_{ud}$, with the ρ parameters for example defined in [189]. The NuTeV results for the effective couplings are: $g_{\nu\text{Lud}}^2 = 0.30005 \pm 0.00137$ and $g_{\nu\text{Rud}}^2 = 0.03076 \pm 0.00110$, with a correlation of -0.017 . While the result on $g_{\nu\text{Rud}}$ agrees with the SM expectation, the result on $g_{\nu\text{Lud}}$, relatively measured nearly eight times more precisely than $g_{\nu\text{Rud}}$, shows a deficit with respect to the expectation at the level of 2.9 standard deviations [188]. A recent study finds that EMC-like isovector effects are able to explain this difference [190].

An important quantity in electroweak analyses is given by the running electromagnetic fine-structure constant, $\alpha(m_Z^2)$. The uncertainty in $\alpha(m_Z^2)$ arises from the contribution of light quarks to the photon vacuum polarisation, $\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$:

$$\alpha(m_Z^2) = \frac{\alpha(0)}{1 - \Delta\alpha_\ell(m_Z^2) - \Delta\alpha_{\text{had}}^{(5)}(m_Z^2) - \Delta\alpha_{\text{top}}(m_Z^2)}, \quad (\text{F.3})$$

where $\alpha(0) = 1/137.036$. The top contribution, $-0.00007(1)$, depends on the mass of the top quark. The leptonic contribution is calculated to third order [191] to be 0.03150, with negligible uncertainty. For the hadronic contribution

⁹ E-158 quotes in the \overline{MS} scheme, evolved to $Q^2 = m_Z^2$. We add 0.00029 to the quoted value in order to obtain the effective electroweak mixing angle [102].

Table E.16

Single- W total production cross-section (in pb) at different energies. The first column contains the LEP centre-of-mass energy, and the second the measurements. The third column reports the statistical error, and the fourth to the sixth columns list the different systematic uncertainties. The labels LCEC, LUEU and LUEC are defined in Table E.5. The seventh column contains the total error and the eighth lists the symmetrised expected statistical error for the three LEP measurements, and, for the LEP combined values, the χ^2/dof of the fit.

Table E.18

Ratios of LEP combined total single- W cross-section measurements to the expectations, for different centre-of-mass energies and for all energies combined. The first column contains the centre-of-mass energy, the second the combined ratios, the third the statistical errors. The fourth to seventh columns contain the sources of systematic errors, as defined in Table E.5. The total error is given in the eighth column. The only LCEU systematic sources considered are the statistical errors on the cross-section theoretical predictions, while the LCEC, LUEU and LUEC sources are those arising from the corresponding errors on the cross-section measurements.

206.6	0.61752[4]	0.60819[4]

$\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$, we use the new result 0.02750 ± 0.00033 [192] listed in the first row of Table F.1, which takes into account recent results on electron–positron annihilations into hadrons at low centre-of-mass energies measured by the BES, CMD-2, KLOE and BABAR collaborations. The reduced uncertainty of 0.00033 still causes an error of 0.00012 on the SM prediction of $\sin^2 \theta_{\text{eff}}^{\text{lept}}$ and of 0.08 on the fitted value of $\log(m_H)$, while the $\alpha_s(m_Z^2)$ values presented here are stable against a variation of $\alpha(m_Z^2)$ in the interval quoted. Several evaluations of $\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$ exist which are more theory driven [193,194], resulting in a much reduced uncertainty. To show the effect of the $\alpha(m_Z^2)$ uncertainty on the results, we also use the most recent of these evaluations, 0.02757 ± 0.00010 [194].

An additional input parameter, not shown in Table F.1, is the Fermi constant G_F , determined from the μ lifetime: $G_F = 1.16637(1) \cdot 10^{-5} \text{ GeV}^{-2}$ [195]. New measurements of G_F yield values which are in good agreement [196]. The relative error of G_F is comparable to that of m_Z ; both uncertainties have negligible effects on the fit results.

F.3. Theoretical uncertainties

Detailed studies of the theoretical uncertainties in the SM predictions due to missing higher-order electroweak corrections and their interplay with QCD corrections had been carried out by the working group on ‘Precision calculations for the Z resonance’ [189], and later in Refs. [197] and [198]. Theoretical uncertainties are evaluated by comparing different but, within our present knowledge, equivalent treatments of aspects such as resummation techniques, momentum transfer scales for vertex corrections and factorisation schemes. The effects of these theoretical uncertainties are reduced by the inclusion of higher-order corrections [199,200] in the electroweak libraries TOPAZ0 [201] and ZFITTER [23].

Table E.21

Ratios of LEP combined single-Z hadronic cross-section measurements to the expectations, for different centre-of-mass energies and for all energies combined. The first column contains the centre-of-mass energy, the second the combined ratios, the third the statistical errors. The fourth to seventh columns contain the sources of systematic errors as defined in Table E.5. The total error is given in the eighth column. The only LCEU systematic sources considered are the statistical errors on the cross-section theoretical predictions, while the LCEC, LUEU and LUEC sources are those arising from the corresponding errors on the cross-section measurements. For the LEP averages, the χ^2/dof of the fit is also given in the ninth column.

Table F.1

Summary of high- Q^2 measurements included in the combined analysis of SM parameters. Section (a) summarises LEP-I averages, section (b) SLD results (\mathcal{A}_ℓ includes A_{LR} and the polarised lepton asymmetries), section (c) the LEP-I and SLD heavy flavour results, and section (d) electroweak measurements from LEP-II and the Tevatron. The total errors in column 2 include the systematic errors listed in column 3; the determination of the systematic part of each error is approximate. The SM results in column 4 and the pulls (difference between measurement and fit in units of the total measurement error) in column 5 are derived from the SM fit to all high- Q^2 data, see Table F.2 column 4.

		Measurement with total error	Systematic error	Standard-model fit	Pull

Table F.3

Summary of measurements performed in low- Q^2 reactions: atomic parity violation, e^-e^- Møller scattering and neutrino–nucleon scattering. The SM results and the pulls (difference between measurement and fit in units of the total measurement error) are derived from the SM fit including all high- Q^2 data (Table F.2, column 4) with the Higgs mass treated as a free parameter.

	Measurement with total error	Standard-model high- Q^2 fit	Pull
APV [186]			
$Q_W(\text{Cs})$	-72.74 ± 0.46	-72.909 ± 0.025	0.4
Møller [187]			
$\sin^2 \theta_{\text{MS}}(m_Z)$	0.2330 ± 0.0015	0.23110 ± 0.00011	1.3
νN [188]			
g_{VLud}^2	0.30005 ± 0.00137	0.30397 ± 0.00013	2.9
g_{VRud}^2	0.03076 ± 0.00110	0.03011 ± 0.00002	0.6

The use of the higher-order QCD corrections [200] increases the value of $\alpha_S(m_Z^2)$ by 0.001, as expected. The effect of missing higher-order QCD corrections on $\alpha_S(m_Z^2)$ dominates missing higher-order electroweak corrections and uncertainties in the interplay of electroweak and QCD corrections. A discussion of theoretical uncertainties in the determination of α_S can be found in Refs. [189,202], with a more recent analysis in Ref. [203] where the theoretical uncertainty is estimated to be about 0.001 for the analyses presented in the following.

The complete (fermionic and bosonic) two-loop corrections for the calculation of m_W [204], and the complete fermionic two-loop corrections for the calculation of $\sin^2 \theta_{\text{eff}}^{\text{lept}}$ [205] have been calculated. Including three-loop top-quark contributions to the ρ parameter in the limit of large m_t [206], efficient routines for evaluating these corrections have been implemented since version 6.40 in the semi-analytical program ZFITTER. The remaining theoretical uncertainties are estimated to be 4 MeV on m_W and 0.000049 on $\sin^2 \theta_{\text{eff}}^{\text{lept}}$. The latter uncertainty dominates the theoretical uncertainty in the SM fits and the extraction of constraints on the mass of the Higgs boson presented below. For a consistent treatment, the complete two-loop calculation for the partial Z decay widths should be calculated.

Fig. F.1. The comparison of the indirect constraints on m_W and m_t based on LEP-I/SLD data (dashed contour) and the direct measurements from the LEP-II/Tevatron experiments (solid contour). In both cases the 68% CL contours are plotted. Also shown is the SM relationship for the masses as a function of the Higgs mass in the region favoured by theory (< 1000 GeV) and allowed by direct searches (dark green bands). The arrow labelled $\Delta\alpha$ shows the variation of this relation if $\alpha(m_Z^2)$ is changed by plus/minus one standard deviation. This variation gives an additional uncertainty to the SM band shown in the figure. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. F.2. The 68% confidence level contour in m_W and m_H for the fit to all data except the direct measurement of m_W , indicated by the shaded horizontal band of ± 1 sigma width. The vertical bands show the 95% CL exclusion ranges on m_H from the direct searches.

The theoretical uncertainties discussed above are not included in the results presented in Tables F.2 and F.3. At present the impact of theoretical uncertainties on the determination of SM parameters from the precise electroweak measurements is small compared to the error due to the uncertainty in the value of $\alpha(m_Z^2)$, which is included in the results.

F.4. Standard-model analyses

Strong coupling constant

Of the measurements listed in Table F.1, R_ℓ^0 is the one most sensitive to QCD corrections. For $m_Z = 91.1875$ GeV and imposing $m_t = 173.2 \pm 0.9$ GeV [184] as a constraint, $\alpha_s = 0.1223 \pm 0.0038$ is obtained. Alternatively, $\sigma_{\text{lep}}^0 \equiv$

Fig. F.3. The 68% confidence level contour in m_t and m_H for the fit to all data except the direct measurement of m_t , indicated by the shaded horizontal band of ± 1 sigma width. The vertical bands show the 95% CL exclusion ranges on m_H from the direct searches.

Fig. F.4. $\Delta\chi^2 = \chi^2 - \chi^2_{\min}$ vs. m_H curve. The line is the result of the fit using all high- Q^2 data (last column of Table F.2); the band represents an estimate of the theoretical error due to missing higher order corrections. The vertical bands show the 95% CL exclusion ranges on m_H from the direct searches. The dashed curve is the result obtained using the evaluation of $\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$ from Ref. [194]. The dotted curve corresponds to a fit including also the low- Q^2 data from Table F.3.

$\sigma_{\text{had}}^0/R_\ell^0 = 2.0003 \pm 0.0027$ nb [2], which has higher sensitivity to QCD corrections and less dependence on m_H , yields: $\alpha_S = 0.1179 \pm 0.0030$. The central values obtained increase by 0.0013 and 0.0010, respectively, when changing m_H from 100 GeV to 300 GeV. These results on α_S , as well as those reported in the next section, are in good agreement with both independent measurements of α_S and the world average $\alpha_S(m_Z^2) = 0.1184 \pm 0.0007$ [207].

Electroweak analyses

In the following, several different SM analyses as reported in Table F.2 are discussed. The χ^2 minimisation is performed with the program MINUIT [91], and the predictions are calculated with ZFITTER 6.43 as a function of the five SM input parameters $\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$, $\alpha_S(m_Z^2)$, m_Z , m_t and $\log_{10}(m_H/\text{GeV})$ which are varied simultaneously in the fits; see [2] for details on the fit procedure. The somewhat large χ^2/dof for all of these fits is caused by the large dispersion in the values of the

Fig. F.5. Constraints on the mass of the Higgs boson from each observable. The Higgs-boson mass and its 68% CL uncertainty is obtained from a five-parameter SM fit to the observable, constraining $\Delta\alpha_{\text{had}}^{(5)}(m_Z^2) = 0.02750 \pm 0.00033$, $\alpha_s(m_Z^2) = 0.118 \pm 0.003$, $m_Z = 91.1875 \pm 0.0021$ GeV and $m_t = 173.2 \pm 0.9$ GeV. Because of these four common constraints the resulting Higgs-boson mass values are highly correlated. The shaded band denotes the overall constraint on the mass of the Higgs boson derived from all observables including the above four SM parameters as reported in the last column of Table F.2. Results are only shown for observables whose measurement accuracy allows to constrain the Higgs-boson mass on the scale of the figure.

leptonic effective electroweak mixing angle measured through the various asymmetries at LEP-I and SLD [2]. Following [2] for the analyses presented here, this dispersion is interpreted as a fluctuation in one or more of the input measurements, and thus we neither modify nor exclude any of them. A further significant increase in χ^2/dof is observed when the low- Q^2 NuTeV results are included in the analysis.

To test the agreement between the Z-pole data [2] (LEP-I and SLD) and the SM, a fit to these data is performed. This fit differs from the corresponding analysis reported in Ref. [2] in that the new result for $\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$ [192], reported in Table F.1, is used. The result is shown in Table F.2, column 1. The indirect constraints on m_W and m_t are shown in Fig. F.1, compared with the direct measurements. Also shown are the SM predictions for Higgs masses between 114 and 1000 GeV. The indirect and direct results on m_W and m_t are in good agreement. In both cases, a low value of the Higgs-boson mass is preferred.

For the fit shown in column 2 of Table F.2, the direct measurement of m_t from the Tevatron experiments is included, in order to obtain the best indirect determination of m_W . The result is also shown in Fig. F.2. The indirect determination of the W-boson mass, 80.363 ± 0.020 GeV, is in good agreement with the direct measurements at LEP-II and the Tevatron, $m_W = 80.385 \pm 0.015$ GeV. For the fit shown in column 3 of Table F.2 and Fig. F.3, the direct m_W and Γ_W measurements from LEP-II and the Tevatron are included instead of the direct m_t measurement, in order to obtain the constraint $m_t = 178_{-8}^{+11}$ GeV, in good agreement with the much more precise direct measurement of $m_t = 173.2 \pm 0.9$ GeV.

The best constraints on m_H are obtained when all high- Q^2 measurements are used in the fit. The results of this fit are shown in column 4 of Table F.2. The predictions of this fit for observables measured in high- Q^2 and low- Q^2 reactions are listed in Tables F.1 and F.3, respectively. In Fig. F.4 the observed value of $\Delta\chi^2 \equiv \chi^2 - \chi_{\text{min}}^2$ as a function of m_H is plotted for this fit including all high- Q^2 results. The solid curve is the result using ZFITTER, and corresponds to the last column of

Table F.2. The shaded band represents the uncertainty due to uncalculated higher-order corrections, as estimated by ZFITTER. Also shown is the result (dashed curve) obtained when using $\Delta\alpha_{\text{had}}^{(5)}(m_Z^2)$ of Ref. [194].

The 95% one-sided confidence level upper limit on m_H (taking the band into account) is 152 GeV. When the 95% C.L. lower limit on m_H of 114.4 GeV obtained from direct searches at LEP-II [208] is included, the upper limit increases from 152 GeV to 171 GeV.

Given the direct measurements of the other four SM input parameters, each observable is equivalent to a constraint on the mass of the SM Higgs boson. These constraints are compared in Fig. F.5. For very low Higgs-masses, the constraints are qualitative only as the effects of real Higgs-strahlung, neither included in the experimental analyses nor in the SM calculations of expectations, may become sizeable [209]. Besides the measurement of the W mass, the most sensitive measurements are the asymmetries, i.e., $\sin^2 \theta_{\text{eff}}^{\text{lept}}$. A reduced uncertainty for the value of $\alpha(m_Z^2)$ would therefore result in an improved constraint on $\log m_H$ and thus m_H , as already shown in Fig. F.4.

Direct searches for the Higgs boson of the SM are currently performed at the Tevatron and the LHC. In summer 2012, the combined Higgs-boson analyses of the Tevatron experiments CDF and D0 excluded the mass ranges of 100–103 GeV and 147–180 GeV and reported evidence for a new particle with a combined significance of about three standard deviations [210]. At the same time, using both 2011 and some 2012 data, the LHC collaborations ATLAS and CMS excluded the mass regions of 110–122 GeV and 128–600 GeV and both reported independently the observation of a new particle in Higgs-boson searches with a significance of five or more standard deviations [167]. The electroweak precision data are well compatible with the hypothesis that the new particle, observed with a mass in the range of 125–126 GeV, is the Higgs boson of the SM, as is also evident from Figs. F.1 to F.5. If the new particle is not the Higgs boson of the SM, the results of electroweak fits such as those presented here may be unreliable because in that case the new particle is not considered in the calculation of electroweak radiative corrections.

The KORALWcross-sections at 155–215 GeV have been kindly provided by the authors. They have actually been computed using YFSWW[97,98], switching off non-leading $\mathcal{O}(\alpha)$ radiative corrections and the screening of the Coulomb correction, to reproduce the calculation from KORALW.
