Introduction

Hydroxylated polymers can be regarded as powerful precursors in the preparation of new polymers through chemical modification, which can finally lead to properly functionalized macromolecules for specific applications. According to this approach, polymers like poly(vinyl alcohol) (PVA) and poly(glycidol) have been extensively used in order to get hydrogels, membranes, emulsifiers, stimuli-responsive materials, etc.

Polyamines can be prepared by ring opening polymerization of aziridines and azetidines, through a cationic mechanism, as only the three- and four-member rings contain enough ring strain to be polymerized. This polymerization reaction proceeds with the competition of many undesirable side reactions such as proton transfer termination, branching and macrocycle formation. Proton transfer termination can be avoided by using tertiary amines as monomers, but the other two undesirable reactions can be only reduced by means of an appropriate choice of the monomer structure and the polymerization conditions. For this reason, the polymerization of each aziridine and azetidine implies a deep optimization of the reaction conditions[1].

In this work we tackle the polymerization of a hydroxylated aziridine, 1-(2-hydroxyethyl)aziridine, which could lead to a suitable starting polymer in the preparation of more complex polyamines through its chemical modification. In particular, we are finally interested in the preparation of Side-Chain Liquid Crystalline polyamines (SCLCPs) by chemical modification with tapered groups.

Materials and Methods

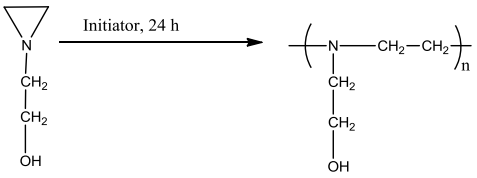
All reagents (1-(2-hydroxyethyl)aziridine (95%), boron trifluoride diethyl etherate (46,5% BF_3 basis), boron trifluoride ethylamine complex, lanthanum trifluoromethanesulfonate (99,9%), scandium trifluoromethanesulfonate (99%), methyl trifluoromethanesulfonate (98%), ethylamine (2.0 M solution in THF) trimethylsulfonium iodide (98%), triphenylcarbenium hexachloroantimonate, triethyloxonium tetrafluoroborate, benzylamine (99%)) were supplied by Fluka or Aldrich and used as received.

Solvents (acetonitrile, N,N-dimethylformamide) were purified according to the literature[2].

The obtained polymers were characterized by viscosity determination, Infra-red spectroscopy (IR), Differential Scanning Calorimetry (DSC), Thermogravimetric Analysis (TGA) and ^{1}H and ^{13}C NMR. By taking advantage of the extremely regular structure of the main chain, we also recorded the ^{15}N NMR which, in this case, allowed us to detect end groups and branching points and to exclude side reactions arising from the hydroxyl groups.

Results and Discusion

The polymerization of 1-(2-hydroxyethyl)aziridine was reported by Rivas et al.[3] in the early 90's by using $BF_3 \cdot Et_2O$ but, though the reported ^{1}H and ^{13}C NMR spectra showed the expected signals as prevailing, they also showed small signals which were not discussed by the authors and which arise from end groups, branching or macrocycle formation, as well as side reactions which involve the participation of the hydroxyl group. In this study we deepened the cationic polymerization of this monomer by using several initiators ($BF_3 \cdot Et_2O$, $BF_3 \cdot EtNH_2$, $La(OTf)_3$, Methyl triflate, etc.) in order to obtain polymers with a variety of molecular weights and backbone macrostructures, since these features can strongly affect the mesomorphic behaviour of side-chain liquid crystalline polymers to be subsequently synthesized.



Conclusions

Polymerization with boron trifluoride amine complex gave the best results as far as the obtainment of a polyamine with linear structure and a moderate molecular weight is concerned. The obtained polymers will be used for further preparation of Side-Chain Liquid Crystalline polyamines containing mesogenic groups, which can lead to supramolecular columnar mesophases; in such structures, the polymer backbone is expected to form a helical structure, which gives the ability to transport proton ions by the channel mechanism.

Homeotropic Alignments of Nematic Liquid Crystals on Polar Substrates

Young Ju Kim, Mongryong Lee, and Kigook Song

Materials Research Center for Information Display, Kyung Hee University, Korea

ksong@khu.ac.kr

Introduction

The alignment of a liquid crystal molecule on a substrate depends on various interactions between liquid crystal and substrate, such as dispersion forces, dipolar interactions, steric interactions, and physical interactions due to distortion of orientation field of liquid crystals. These forces act oppositely sometimes and which interaction is dominant depends on the prevailing circumstances. Among those interactions, dispersion force (van der Waals force) is regarded as a long-range interaction and other interactions are regarded as short-range interactions which never go beyond a few tens of angstrom. In the present study, homeotropic alignment mechanisms of nematic liquid crystals on polar substrates were investigated. The relations between homeotropic alignment of liquid crystals and polarity of substrates were studied using polarized optical microscopy, conoscope, and FTIR spectroscopy.

Results and Discussion

Both positive LC (E7 Merck, $\Delta\varepsilon$=13.8) which is a mixture of cyano group liquid crystals and negative LC (LC-242 BASF, $\Delta\varepsilon\approx$-1.8) show homogeneous (planar) alignment on a glass substrate without any treatment. After glass substrates were treated with oxygen plasma, however, positive E7 were still aligned homogeneously whereas homeotropic (vertical) alignment was introduced for negative LC-242. After the plasma treatment, polarizability of the glass substrate along the surface increases by forming hydroxyl groups. In order to get more overlap areas in long-range van der Waals interactions between polarizability of liquid crystal molecules and that of the glass surface, positive E7 molecules (longitudinal dipole moment) prefer to align along the planar direction whereas vertical alignments are observed for negative LC-242 molecules whose polarizability direction is perpendicular to the molecular axis (transverse dipole moment).

As shown in Figure 1, FTIR absorption intensity of C≡N stretching mode (2226 cm^{-1}) of E7 decreases by changing its phase from isotropic to LC phase at 59°C. On untreated glass substrates, the C≡N stretching intensity of E7 becomes a maximum at near transition temperature (58.2°C). However, the peak intensity abruptly decreases and exhibits a minimum at near the transition temperature for E7 on a plasma treated substrate. These findings suggest the orientation changes of the LC director upon the phase change in which E7 momentarily shows homeotropic orientations. These results are good agreement with POM observations.

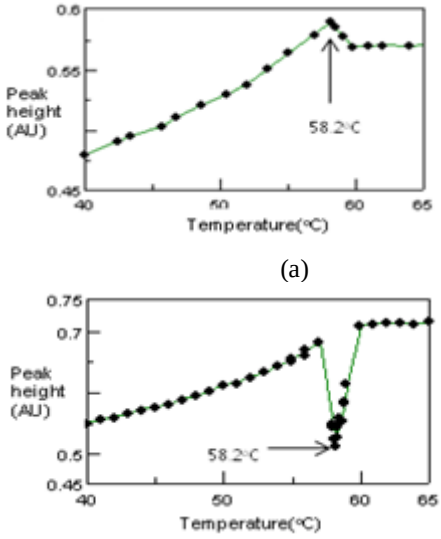

Figure 1. FTIR intensity of C≡N stretching mode (2226 cm^{-1}) of E7 with temperature. (a) for LC on untreated glass substrate, (b) for LC on plasma treated substrate.

Two competing temperature dependent forces are involved in determining the LC director orientation; one that prefers the homogeneous and the other homeotropic orientations. The long range van der Waals forces play an important role in deciding the orientation of LC director in a nematic temperature region, while the short range dipolar interaction becomes more important as the substrate becomes more polar with increased plasma treatments. At the transition temperature, highly polar nitrile group of E7 makes the long molecular axis aligned vertically by strong dipolar interaction with polar substrates. The orientation changes from vertical to planar alignments as further decreasing temperature can be explained by increasing van der Waals interaction due to increase dielectric anisotropy of liquid crystals.

Conclusions

The homeotropic alignment mechanisms for nematic liquid crystals were studied on polar substrates. The homogenous alignment was obtained for positive nematic liquid crystals while the homeotropic alignment for negative liquid crystals. These studies provide experimental evidences showing that there is competing forces to determine orientation of liquid crystals, and alignment can be controlled by adjusting substrate polarity.

Surface properties of silica modified by silane with polybutadiene oligomer tail

Introduction

Chemical modification of surface of oxide powders by covalent attachment of organosilanes is a versatile technique to tune surface properties, on the grounds of different requirements and specific applications. In the polymer field such a modification plays an important role in promoting adhesion between powder and polymer, in improving the disperdibility of oxide powders into polymer matrix, etc.. The dispersion of silica in a rubbery matrix is an indispensable condition to obtain compounds with high physical-mechanical performance. However, the high hydrophilic character of silica makes it very difficult to spread it into an array of hydrophobic rubbery. Therefore, alkoxysilanes, like TESPT (bis(triethoxysilylpropyl)tetrasulfide) and NXT (3-octanoylthio-1-propyltriethoxysilane), are currently used to reduce the hydrophilicity of silica surface and to prevent the formation of particle aggregates. Alkoxy groups of silane condense with free silanols of silica surface, giving rise to Si-O-Si surface. The accessability and then the reactivity of silanols is probably not the same for all of them, and will also depend both on alkoxysilane molecule size and on the number of alkoxy groups present in the same silane molecule.

For several years, our research group has devoted research activity to investigate the influence of the silica modification on the rubber reinforcement (1,2,3).
In this communication, we discuss the surface thermodynamic properties of silica modified with two new alkoxysilanes, prepared by us, with a polybutadiene oligomer tail. The long hydrocarbon chain should facilitate the dispersion of silica into the rubber matrix, due to its high compatibility with the elastomer matrix, as shown in another communication (4). Moreover, polybutadiene tail would have an enhanced reactivity for a new technology of vulcanization of rubber in the tire industry, like irradiation or peroxides.

Materials and Methods

Two new silanes, sb1 and sb3, were prepared by grafting 3- mercaptopropyltrimethoxysilane onto poly-butadiene oligomers of about <Mn> = 900 and 5000 , respectively. Sylilation of precipitated silica Zeosil 1165 MP (Rhône Poulenc) with sb1 and sb3 was performed in accordance with the method described elsewhere (1).
Degree of grafting on the silica was determined by thermal gravimetric analysis (TGA) and elemental analysis (EA), ranging from 4 to 40 wt%. Modified silica was investigated as the stationary phase by inverse gas chromatography (IGC) (1,2). n-alkanes, 1-alkenes, and alkylbenzenes were used as probes for the determination of thermodynamic properties of silica surface. The IGC measurements were performed in the range 80-160°C. Thermodynamic quantities of adsorption, like $\Delta G°$, $\Delta H°$, and $\Delta S°$ were determined, together the dispersive component, γ_s^d , and the interaction parameter, I^{sp}, of surface tension of modified silicas.

Results and Discussion

To determine the real grafting degree onto silica, the loss weight by TGA and the C wt-% of grafted silane obtained by EA were considered. From the real grafting degree the residual OH silanol percentage was calcula-ted. This ranges from about 65 to 98%. The adsorption free energy on the silicas is heavily affected by the sylilation with sb1 and sb3, and then the surface free energy. Both the dispersive component γ_s^d and the interaction parameter are reduced to a half after the graft of about 10 wt% of sb1 or sb3 and do not change more on increasing the degree of grafting. By considering the number of grafted molecules /nm^2 the role of the polybutadiene tail length is clearly put into evidence; in other words, the long hydrocarbon tail acts as a shield, hindering interactions between probe and residual OH silanol groups of silica surface. This phenomenon permits a reduction in the amount of silane to be grafted to decrease the polar character of silica surface.

Conclusions

Silanes sb1 and sb3 are able to change the character of silica surface from hydrophilic to hydrophobic, as a result of very low silane grafts. Moreover, on increasing the length of silane tail decreases the number of silane molecules to be grafted. When sb3 is used , the sylilation of about 5% of OH silanol groups is enough to practically obtain the hydrophobic character of silica.

Introduction

The reinforcement of rubber means the pronounced increase of tear resistance, tensile strength, abrasion resistance and modulus far beyond the values predicted by the theory. It is generally accepted that this phenomenon depends, to a large extent, on physical and chemical characteristics of the elastomer, filler properties (loading, particle size, specific surface area, structure, surface activity, etc..), and processing.

It has been found that precipitated silicas improve performances of the tire tread, increasing wet grip and decreasing rolling resistance, and thus the fuel consumption. These improvements are achieved only if the silica is highly dispersed in the elastomeric matrix. This is obtained by reducing the highly hydrophilic character of silica particles preventing the phenomenon of aggregate formation. To do this some silanes, like bis(triethoxysilylpropyl)tetrasulfide (TESPT), and 3-octanoylthio-1-propyltriethoxysilane (NXT and NXT Z silanes) have been proposed and are currently applied. We have suggested that an interesting new modifier of silica could be an alkoxysilane with an oligomer polybutadiene tail (1). Such a modifier should facilitate the silica dispersion into SBR matrix, due to its compatibility with the elastomer matrix, and would have an enhanced reactivity for a radical process vulcanization to be performed by thermal initiators (for instance, peroxides) or irradiation. To this end, we have prepared two new modifiers by grafting 3-mercaptoprop-yltrimethoxysilane onto polybutadiene oligomers. Surface thermodynamic properties of a precipitated silica modified with such silanes are reported in another communication (2).

In this communication we present results concerning the curing kinetics, tensile, and dynamic-mechanical properties of compounds of e-SBR /silica modified with aforementioned new silanes.

Materials and Methods

The new alkoxysilanes coupling agents, sb1 and sb3, were prepared by grafting 3-mercaptopropyltrime-thoxysilane onto polybutadiene oligomers of about <Mn> = 900 and 5000 , respectively. Precipitated silica Zeosil 1165 MP (Rhône Poulenc) was modified with sb1 and sb3 according to a procedure previously described (3). e-SBR-based compounds were prepared by mixing e-SBR with 30 phr of carbon black , 30 phr of silica modified with several degrees of grafting, and all the ingredients used in tire production. Silica was used unmodified, modified with TESPT during mixing, modified with sb1 or sb3 during the mixing, and pre-modified with sb1 or sb3.

The compounds were characterized by vulcanization kinetics, tensile testing at low (10%) and high (300%) deformation, dynamic-mechanical behaviour (G*, G', G'', tanδ) as a function of temperature and strain , and morphological observation by transmission electron microscopy.

The results are compared with those of the compound loaded with silica modified with TESPT.

Results and Discussion

Silanes with long chains of polybutadiene act as a plasticizer of e-SBR matrix ; they, moreover, negatively affect the scorch time, but speed up the process of curing , leading to the same final crosslink density of compound loaded with TESPT-modified silica.

sb1 and sb3 silanes have hardly any effect on the tensile properties of compounds; however, they reduce the value of G' modulus at low deformation leading it to a practically constant value at 10% of strain . In other words, they facilitate the dispersion of silica into e-SBR matrix, reducing the Payne effect , i.e. the interactions filler-filler. The extent of such an effect depends on length of polybutadiene tail, on the degree of grafting of silica, and on the procedure of silica grafting.

Conclusions

These results indicate that the new silanes are technologically interesting coupling agents, that could be an alternative to currently used silanes. Work is still in progress to evaluate the minimum amount of sb1 or sb3 silane, sufficient to provide a hydrophobic silica to prepare rubber-based compounds, with high silica content for interesting technical developments in the future, for instance, vulcanization by irradiation or thermal initiators.

Introduction

Recently, a great deal of the scientific interest was devoted to the research into different types of polymer-based photoswitching systems because of their potential use as elements of future logic and memory devices [1,2]. Conjugated polymers, like poly(phenylene vinylene) and polythiophene derivatives, possess excellent semiconducting and luminescent properties accompanied by relatively easy processing and low cost. Charge carrier transport in these materials proceeds predominantly along the conjugated polymer backbones with the participation of the inter-chain hopping. If the frequency of the external electric field is not too high, the slow inter-chain motion acts as a bottleneck determining the macroscopic charge carrier mobility. In this paper, a combined quantum mechanical / semi-classical model of the charge carrier transport in polymers doped by a polar additive is put forward.

Model and Methods

The proposed model involves the quantum mechanical description of the charge carrier states on the conjugated polymer chain segments, the charge carrier thermalization, and the semi-classical description of the charge carrier hops between different chain segments.

The conjugated chain segments are modeled as sequences of interacting sites corresponding to the repeat units. The charge carrier states on such a segment can be described by the tight-binding Hamiltonian. Taking the wave function as a superposition of the states located at individual sites, the time-independent Schrödinger equation can be solved and the stationary states can be found.

The model considers full charge carrier thermalization over all states of the given chain segment between two subsequent hops. This thermalization is usually accomplished within several picoseconds. Thus, it is much faster than the inter-chain hopping. Our model can assume alternatively the charge carrier thermalization either to the Fermi-Dirac distribution, or to the more simple Boltzmann distribution, that is appropriate for low charge carrier concentrations. While the former distribution is useful for the modeling of the charge carrier concentration dependence of the dc mobility, the latter one enables to calculate the frequency dependence of the ac mobility.

Description of the inter-chain charge carrier jumps is based on the Marcus theory. The use of the quasi-classical Marcus concept instead of the quantum mechanical one is justified by the fact that the inter-chain transfer integrals are much smaller than the charge carrier reorganization energy. Consequently, due to its interaction with the phonon reservoir the charge carrier residing on a given chain segment looses any quantum coherence before jumping to another segment. Finally, our model solves master equations determining the time evolution of the charge carrier distribution.

Results and Discussion

The hole transport in two conjugated polymers (poly(phenylene vinylene) and polythiophene) doped with a polar photochromic additive (spiropyrane derivative) was calculated. Upon irradiation with light of an appropriate wavelength, the admixed molecule undergoes a ring-opening reaction from the closed form to the open form, which is accompanied by a charge redistribution resulting in a two- or three-fold increase of the molecular dipole moment. It was found, that the photochromic transformation of the additive results in a broadening of the distribution of the local charge carrier site energies and, consequently, in the decrease of the inter-chain hole dc mobility by two or three orders of magnitude at the experimentally achievable concentrations of the additive. While the mobility in the polymer with a low value of the local energy disorder (low additive concentration or low additive dipole moment) is frequency-independent, for higher values of the local energy disorder there is a certain increase of the mobility with the frequency. The calculated temperature dependence of the mobility shows essentially Arrhenius–type behavior with a moderate sub-Arrhenius deviation at the low additive concentration and the low-temperature saturation at the high additive concentration.

Conclusions

The results confirm the possibility to construct an efficient optoelectrical modulator based on a polymer doped with a photochromic polar additive. The proposed model can be used for the selection of suitable molecular systems and finding the optimal conditions in order to improve the device performance.

The use of edible and biodegradable films is a good alternative to replace part of those polymers made from non renewable raw material used in the market. In this work, we developed flexible bioplastic composites based on lipophilic corn starch and gelatin plasticized with glycerol (20% compared to the mass of starch), obtained by thermoplastic extrusion process, followed by blowing for film formation. Different concentrations of gelatin were added (0%, 10% e 20% w/w) to follow the behavior of mechanical properties. The mechanical (tensile strength and elongation) and thermal properties (Thermogravimetric analysis, Differential Scanning Calorimetry and Termodynamic mechanical analysis were characterized for all biofilms studied. Balloons of 12 to 14.5 cm in diameter were formed by blowing and, at nacked aye did not show insoluble particles or fractures (Figure 1).

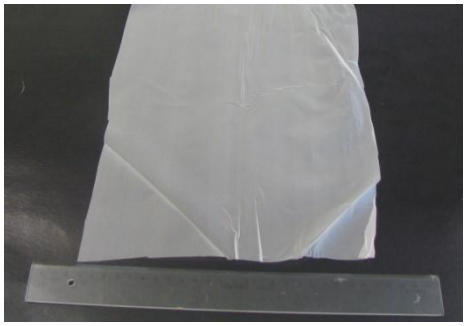

Figure 1. Biofilms

As expected, the addition of gelatin resulted in an increase of mechanical properties of the biofilms in longitudinal and transversal directions (Figure 2).

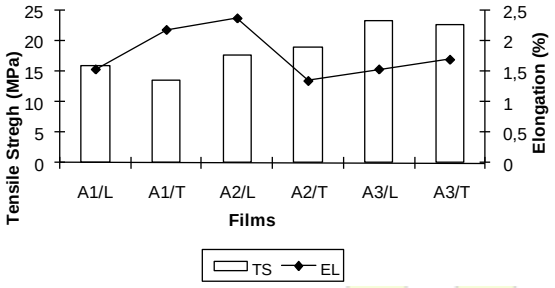

Figure2. Mechanical Properties

The thermal analyses showed that the behavior of the glass transitions of these bioplastics are very similar (Figure 3).

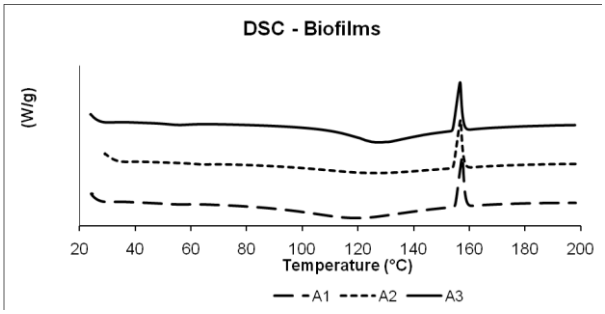

Figure 3. Differential Scanning Calorimetry

Desarrollo de una espuma polimérica atóxica con propiedades de resilencia

Introducción: Las úlceras o escaras de la piel representan un grave problema que afecta a las personas inmovilizadas ya que se forman por la presión y el contacto prolongado de la piel con el material de apoyo. Para evitarlas se intenta que el material de soporte y apoyo actúe como un intercambiador de calor, enfriando y evitando el aumento de temperatura de la piel en contacto.
Con el objetivo de conocer la composición de este tipo de materiales de soporte para desarrollar un material polimérico similar, a base de materias primas nacionales y/o disponibles en el país, se estudió una espuma o masilla blanda que conforma el relleno de un almohadón "antiescaras" utilizado como asiento de automóviles para discapacitados. Según la bibliografía consultada el material investigado debería tener una composición atóxica y resistente al fuego, además de consistir en un material deformable ante la aplicación de presión externa y adaptable al contorno particular del cuerpo humano.

Materiales y métodos: La espuma polimérica original y fracciones de la misma, obtenidas aplicando diversas técnicas de separación, se analizaron por espectroscopía infrarroja (IR), resonancia magnética nuclear de protón (^{1}H RMN), de carbono (^{13}C RMN) y por correlaciones nucleares (COSY, HMQC y HMBC), así como por fluorescencia (XRF) y difracción de rayos X (XRD).

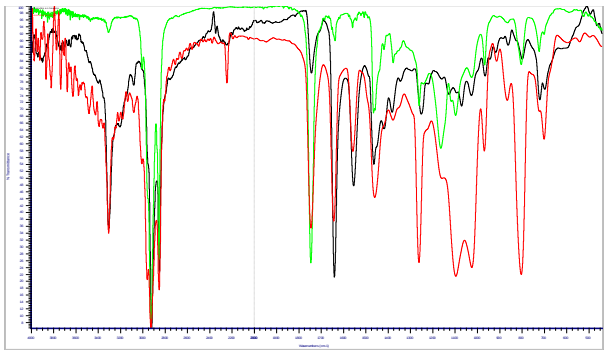

Figura 1. Comparativo por FTIR de la fracción de la muestra soluble en cloroformo (verde) vs. la fracción insoluble en hexano (negro) y vs. la fracción insoluble en etanol (rojo).

La identificación general se realizó por IR, utilizando un equipo FTIR Nicolet Impact 400D. La figura 1 muestra algunos de los espectros logrados.
Del análisis de las diferentes fracciones obtenidas, resulta útil y representativo realizar un examen comparativo entre los respectivos espectros ^{1}H RMN. Para estos registros se utilizó un equipo Bruker Avance DPX 400 con sonda multinuclear de gradiente.
La figura 2 muestra la comparación entre tres de las fracciones antedichas.

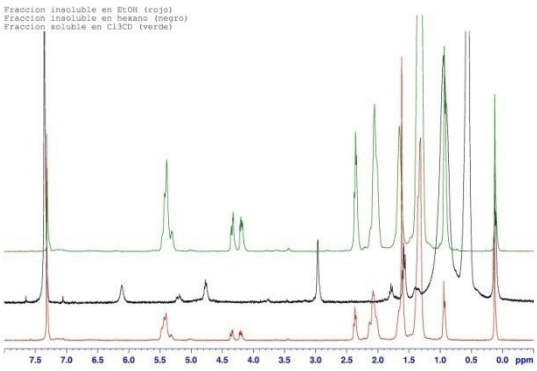

Figura 2. Comparativo ^{1}H RMN de la fracción de la muestra soluble en cloroformo (verde) vs. la fracción insoluble en hexano (negro) y vs. la fracción insoluble en etanol (rojo).

Las propiedades reológicas del producto desarrollado se midieron con un reómetro oscilatorio Anton-Paar MCR 300, obteniéndose curvas comparativas de módulo elástico (G') y módulo viscoso (G'').

Resultados y discusión: El estudio realizado fue un punto de partida para el desarrollo de un material polimérico similar. Se ensayaron varias formulaciones potenciales a escala laboratorio. Se estudió la influencia de las diferentes formas de incorporación de los componentes y posteriormente se evaluaron las propiedades reológicas y el desempeño de los materiales desarrollados.

Conclusiones: Se obtuvo un producto de propiedades similares al de referencia, empleando materias primas económicas y de fácil acceso en el mercado local.

Abstract:

Styrenic thermoplastic elastomers (TPE-S) exhibit rubbery behavior without the need of chemical crosslinking. In these materials, the polystyrene blocks phase-separate from the rubber phase to form glassy domains that act as physical crosslinks. Upon variation of the copolymer topology or of the glass transition temperature of either one of the two phases, the characteristic thermo-mechanical behavior of the thermoplastic elastomers will also change. In this study, thermoplastic elastomers are synthesized that possess a graft copolymer topology. This is achieved by synthesizing chain end-functional polystyrene (PS) or chain end-functional poly(styrene-alt-phenylmaleimide) P(SMI) via reversible addition fragmentation chain transfer polymerization, atom transfer radical polymerization or nitroxide mediated radical polymerization and grafting these chain end-functional polymers onto functional elastomers. According to dynamic mechanical thermal analysis of the samples, elastomeric behaviour is observed for the synthesized graft copolymers. The width of the rubber plateau is increased in the examples of TPE-S synthesized with P(SMI).

This work is part of the research Programme of the Dutch Polymer Institute DPI, Eindhoven, the Netherlands, project nr. #649.

esteban_araya84@yahoo.es

Alginate is a polysaccharide obtained from seaweed, it is a linear copolymer composed of 1,4-linked β-D-mannuronate (M) and α-L-guluronate (G). It has a carboxylate group in each M or G unit, and it is also a polyelectrolyte, highly negatively charged at neutral or basic pH[1]. Alginate is used in food products, cosmetics, drug formulation, and as an antigens coater for oral fish vaccines[2,3,4]. Therefore, evaluating the course of calcium alginate beads through digestive system of fishes, by labeling them, is very important from a pharmacokinetic point of view. Short-range aromatic-aromatic interactions between fluorescent dyes and polyelectrolytes bearing aromatic groups can help to retain the dye inside the calcium alginate microcapsules. It may also enhance the fluorescence of the system due to the dispersion of the dye when an excess of polymer is present[5].

Thus, Rhodamine 6G (R6G) has been included in calcium alginate beads in the absence and in the presence of poly(sodium 4-styrenesulfonate) (PSS). Solutions were injected in a microencapsulator (Biotech Encapsulator) and the shower of drops produced by the encapsulator's vibration was captured in flasks containing 200 ml of calcium chloride to form calcium alginate microcapsules. Microscopic photographs, using fluorescent and natural light, were taken, and the amounts of R6G analyzed by UV-Vis spectroscopy. A larger amount of microencapsulated R6G was obtained when PSS was present (Figure 1), due to a slower diffusion of the dye from the beads to the bulk.

The beads containing PSS and R6G were filtered and put in deionized water. Up to 40 % of the encapsulated R6G, is released. As deduced from spectroscopic measurements, the released R6G is bound to PSS, so that the dye serves to evaluate the diffusion of the polyelectrolyte from the beads (Figure 2). In the presence of NaCl 0.1 M up to 90 % of the encapsulated R6G is released, which is also bound to PSS.

With the aim to control the release of PSS/R6G complexes from the beads, the beads were filtered and incubated in solutions of different concentrations of chitosan. The beads coated with chitosan were put in NaCl 0.1 M aqueous solution. The release of PSS/R6G complexes diminished drastically when the chitosan concentration was higher or equivalent to the alginate concentration (Figure 2).

The short-range aromatic-aromatic interaction between the PSS and R6G favors the retention of the dye inside the calcium alginate beads. The release of PSS/R6G complexes in deionized water may be due to swelling produced by water absorption, and consequent diffusion until reaching equilibrium. In the presence of NaCl 0.1 M, sodium ions compete with the calcium breaking the crosslinking of the M blocks, increasing swelling[1] and pore aperture. Besides, the entrance of Na^+ and Cl^- ions into the beads may also increase the osmotic strength, thus favoring the swelling of the systems. The polycation chitosan may form a coating that produces a positive potential inhibiting the release of PSS/R6G complexes.

Introduction

Renewable sources of polymeric materials offer an alternative to maintain sustainable development of economically and ecologically attractive technology. In the family of renewable sources based biodegradable polymeric materials, starch has been considered as one of the most promising materials because it is readily available and may form cost effective end products.[1,2] Starch-based materials have received great attention for packaging applications as they exhibit low oxygen permeability at dry state. Nevertheless, pure native starch films are brittle. Plasticizers are then often added to improve the polymer flexibility. Despite their enhanced mechanical properties, plasticized starch based films cannot meet all the requirements of packaging applications. In particular, these materials remain water sensitive and, therefore, loose their barrier properties upon hydration. In this context, the nanocomposites concept, with the introduction of lamellar fillers like nanoclays, can be a promising option as it could lead to decrease the initial gas permeability of the plasticized film as well as to keep a low oxygen flux upon hydration[3]. Beyond the degradability and the barrier properties, the development of materials that interact with the food, playing an active role in the preservation is more and more considered for packaging application. Antimicrobial active film can be obtained by incorporating an antimicrobial agent in the films. In the family of antimicrobial agent, metal nanoparticle such as silver is one of the most promising.[4] One method can be used to prepare such nanocomposites materials is to generate in situ silver nanoparticles in the starch polymer thanks to a silver complex.[5] Interactions between starch and the silver precursor are required to obtain a homogeneous dispersion of nanoparticles in the matrix. In this way, the aim of this work is to prepare biodegradable films based on potato starch, montmorillonite and silver nanoparticules as antimicrobial agents.

Materials and methods

Native potato starch (Sigma), glycerol, silver nitrate (Aldrich) and Nanofil® 757 (Süd Chemie) were used to films processing. Films were prepared by a solution/cast process of starch with different amounts of nanoclays and silver nitrate. The silver nanoparticles have been generated in situ by thermal treatment. The structure and the morphology of the films were characterized using different techniques: X-ray diffraction (XRD), transmission electron microscopy (TEM) and UV-spectroscopy. Thermal stability of the different films was studied by thermogravimetric analyses (TGA). Water sorption analysis and oxygen permeability measurements were performed at 25°C as a function of the film composition.

Results and discussion

The favorable interactions established between the nanoclays gallery and the hydroxyl groups of starch, were at the origin of the rather good clay dispersion state: a mixture of exfoliated and intercalated structures was indeed observed whatever the nanocomposites composition. Concerning the in situ generation of silver nanoparticles, a homogeneous dispersion of nanometer size was obtained.

The water sorption mechanism was studied as a function of the composition of the films and modeled by Park equation "Eq.1", considering three sorption modes.

$$C = \frac{A_L \cdot b_L \cdot a_w}{1 + b_L \cdot a_w} + k_H \cdot a_w + K_a \cdot a_w^n \qquad (1)$$

where, A_L the Langmuir capacity constant, b_L the Langmuir affinity constant, k_H the Henry's solubility coefficient, K_a the equilibrium constant for the clustering reaction, n the mean number of water molecules per cluster, C the water concentration in polymer, and a_w the water activity. By this fitting approach, it was shown that the water uptakes were the results of different contributions. The polar groups present in starch, in glycerol and at the clay surface could contribute to the sorption mechanism.

Oxygen permeability was studied for a wide range of relative humidity and the following general trends were observed. For all films, the permeability coefficient slightly increased in the range of relative humidity between 30 to 45% and highly increased at higher activities. Introducing clays led to decrease the gas permeability whatever the matrix.

Conclusions

In this work we showed the feasibility of making films based on starch biodegradable, montmorillonite and silver nanoparticules as antimicrobial agents. To obtain satisfactory mechanical properties, barrier properties and antimicrobial properties, it is important to have optimal concentration of different components in order to obtain a good dispersion of the nanoclays and also the silver nanoparticles in starch matrix.

*antonioluismedina@ugr.es

Introductions: The pH monitoring is crucial on many (bio)chemical process. The ability to create a copolymer whose optical properties change with the microenvironmental pH can be useful for many applications, such as controlling the catalytic activity of immobilized enzymes or the binding affinities of ligands to metal ions. Furthermore, immobilization of these copolymers on multiple sites of an imaging fiber could give rise to the elaboration of a wide range pH optical sensor. In this work, Reverse Atom Transfer Radical Polymerization (ATRP)[1] were used for synthesizing novel fluorescent-tuneable, pH-sensitive, waterinsoluble lineal copolymers which were used for designing new pH-sensitive, nanostructured sensing films based on nanofibres made by electrospinning.

Materials ands Methods: The copolymers are based on the copolymerization of fluorescein o-acrylate (fluorescent pH-sensitive monomer) with methyl methacrylate and hydroxyl ethyl methacrylate (principal framework of the copolymers). 3- methacryloylaminopropyl-trimethylammoniumchloride (positively charged monomer) and 2-acrylamido-2- methylpropane sulfonic acid (negatively charged monomer) were used to introduced and modify the electrostatic properties of the copolymer synthesized.

Result and discussions: In order to obtain a fluorescent-tuneable pH-sensitive lineal copolymer, fluorescein o-acrylate (FOA) was selected as fluorescence pH-sensitive probe, MMA and HEMA were selected as the principal framework of the copolymers by their adequate reactivity ratios to provide statistical copolymers, and by their compatibility with a wide range of pure solvents and solvent mixtures, and MAPTAC and AAMPS were selected for modifying the electrostatic properties of the copolymers and therefore their microenvironmental pH because the quaternary ammonium groups ($R4N^+$) of MAPTAC remains cationic at all pH values and the sulfonate group ($SO3^-$) of AAMPS remains ionized even in highly acidic conditions. The electrostatic properties of these copolymers were investigated and perfectly adjusted to allow changes in the microenvironmental pH and to maintain their insolubility in aqueous media. The copolymers were characterized by Fourier Transform Infrared spectroscopy (FT-IR), nuclear magnetic resonance (^{1}HNMR) spectroscopy. Molecular weight and polydispersity (M_w/M_n) were calculated by triple detection gel permeation chromatography (GPC). The copolymers were used for providing highly fluorescent pH-sensitive nanofibres made by electrospinning. The selected flow rates and voltages within of the electrospinning configuration allowed the collection of dry fibers in non-wovenmats. The nanofibres were characterized by scanning electron microscopy (SEM) and fluorescence microscopy (see Fig.1.) and the fiber mats were successful used for pH-monitoring in two different pH ranges (6.5-8 and 8-10) showing reversibility, high sensitive and low response times (see Fig.2.)

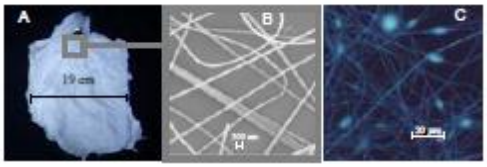

Fig.1. SEM Pictures of nanofibre mats at pH 9.5 and 7.8, respectively.

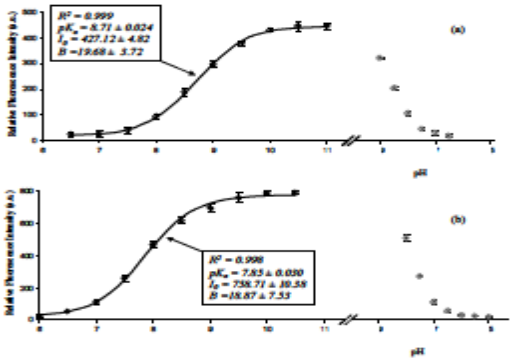

Fig.2. pH calibration of a) N-F-NP1 and b) N-F-NP1(X) fiber mats and reversibility of the optical signals.

Conclusions: Four novel lineal copolymers based on the copolymerization of FOA, as a fluorescence pHsensitive probe, were synthesised by reverse-ATRP. We demonstrate that the microenviromental pH of the water-insoluble lineal copolymers can be modified by a light modification of the electrostatic properties of the copolymers. In addition, the copolymers synthesized in this work are highly soluble in organic solvents (between 25-30 wt %) such as THF, acetone or DMF, but insoluble in water. Due to these facts, they can be considered as potential candidates for an easy preparation of novel, nanostructured optical pHsensitive sensing films with different structures, morphologies and geometries by several techniques (electrospinning, spin coating, layer by layer deposition by deep coating, spray dry, spray coating, etc…).

Introduction

The use of polymeric surfactants, mainly amphiphilic block copolymers, as stabilizer in emulsion polymerization has attracted attention because of the several advantages imparted to the properties of the resulting latex. Besides the low critical micelle concentration, amphiphic block copolymers exhibit low diffusion coefficient and can be anchored or adsorbed to the particles. Therefore the use of block copolymers as surfactants in emulsion polymerization can lead to the preparation of "hairy" particles. Whereas the hydrophilic segments of the block copolymer provide the colloidal stabilization of the polymer particles along with a specific surface functionality, the hydrophobic segments strongly adsorb or anchor to the polymer-water interface and therefore relatively long hydrophobic lengths are expected to be more efficient. In this sense the compatibility or miscibility between the hydrophobic block and the growing polymer particle is a very relevant parameter that determines how the amphiphilic block copolymer is anchored to the particle surface. We report the synthesis of hairy particles by the emulsion polymerization of methyl methacrylate using amphiphilic block copolymers of polystyrene-*b*-poly[poly(ethylene glycol) methyl ether methacrylate] (PS_{40}-*b*-$PPEGMA_{70}$) as stabilizer. In this case the hydrophobic PS segment is different from the polymer in growing latex particles, PMMA, and since PS and PMMA are immiscible, an incompatibility effect may occur and the mechanism of emulsion polymerization reaction could be affected.

Materials and Methods

Amphiphilic block copolymer (PS_{40}-*b*-$PPEGMA_{70}$) was synthesized via atom transfer radical polymerization (ATRP) as previously reported.[1] Methyl methacrylate, MMA, was purified by passing over a basic alumina column. Ammonium persulfate and sodium thiosulfate were used as received.

Preparation of micellar solution. The micellar solution was prepared by dissolving the block copolymer in a few drops of THF and subsequently distilled water was added dropwise with vigorous stirring. The sample was transferred to dialysis tubing and dialyzed against distilled water.

Emulsion polymerization of MMA using PS_{40}-b-$PPEGMA_{70}$ as surfactant. All the emulsion polymerizations of MMA (overall solids contents of 16.6 %) were carried out in batch. The micellar solution was added to the double-walled reactor. The monomer, MMA was added dropwise into the reactor and the mixture was purged with argon. Then, the mixture was heated at 35 °C. The redox initiator solution ammonium persulfate/sodium thiosulfate was injected to start the polymerization. At different reaction times, aliquots were extracted by syringe and the monomer conversion was determined by gravimetry.

Results and Discussion

It was shown that the incompatibility between the growing polymer particles of poly(methyl methacrylate) and the hydrophobic segment of the block copolymer surfactant (polystyrene) affects both the kinetics of the emulsion polymerization and the resulting particle morphology. Because of the incompatibility of the two polymers, phase separation occurs and the morphology of the particles changes from rough spherical core-shell particles to more irregular particles (see Figure 1) as the amount of block copolymer surfactant increases. This, in turn, has an effect on the film formation resulting in turbid films.

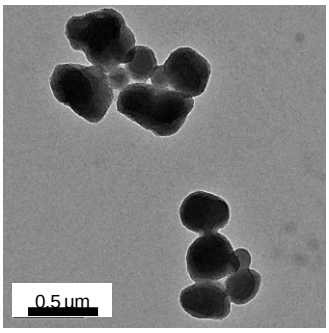

Figure 1. TEM image of PMMA latex stabilized with 5.5 wt% of PS_{40}-*b*-$PPEGMA_{70}$ copolymer surfactant.

The emulsion polymerization of methyl methacrylate, the obtained hairy latex particles and the film formation process were compared with the results obtained in the emulsion polymerization of styrene where both the core of the particles and the hydrophobic segment of the block copolymer are the same polymer. In this case spherical and monodisperse particles are obtained irrespectively of the block copolymer surfactant concentration, and transparent films are formed after annealing above the glass transition temperature.

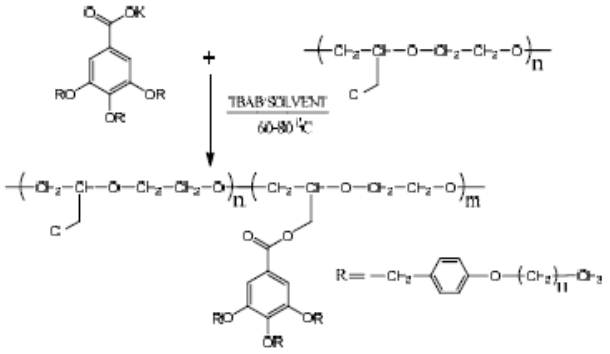
The design, synthesis, and study of supramolecular assemblies capable of transporting ions across membranes by the channel mechanism have been the subject of increasing interest. Some of the authors[1-3] obtained liquid crystalline polyethers which selfassembled into columnar structures by grafting a tapered mesogenic group onto commercial poly(epichlorohydrin) (PECH). In this work, our objective was to prepare side-chain liquid crystalline columnar polyethers by chemical modification of the copolyethers, poly[epichlorohydrin-co-(ethylene oxide)] [P(ECH-co-EO)] 1:1, with tapered 3,4,5-tris[4-(*n*-dodecan-1-yloxy)benzyloxy]benzoate group. This class of polymers could be an alternative approach for the preparation of new proton conducting membranes to be applied, for instance, in Direct Methanol Fuel Cells (DMFCs)

Materials and methods

All organic and inorganic chemicals were supplied by Aldrich and used as such as received. Tetrahydrofuran (THF) was freshly distilled from sodium benzophenone ketyl under argon. Tetrabutylammonium bromide (TBAB) ≥99% (Fluka) was dried at 50 °C *in vacuo* for 1 day. The side-chain liquid-crystalline (LC) copolyethers were obtained by chemical modification of P(ECH-co-EO) with potassium 3,4,5-tris[4-(*n*-dodecan-1-yloxy)benzyloxy]benzoate[2] using different solvents like anhydrous THF, dimethylformamide (DMF), and N-methyl-2-pyrrolidone (NMP). It was heated at 65 °C in THF and in the case of NMP, it was heated at 80 °C. The DMF was used in catalytic amount. In case of TBAB, stoichiometric amounts were used. The structure and composition of the copolymers were characterized by NMR spectroscopy. Thermal characterization was carried out by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). Mesomorphic behavior was characterized on the basis of DSC, polarized optical microscopy (POM) and X-ray diffraction.

Results and discussion

We have obtained co-polyethers bearing tapered 3,4,5-tris[4-(*n*-dodecan-1-yloxy)benzyloxy]benzoate group. The bimolecular substitution of the chlorine atom in P(ECH-co-EO) with these tapered potassium carboxylate gave the desired polymer with no substantial modification in either the backbone size or the polymer microstructure as shown in the given chemical reaction scheme.



The composition of the copolymer was calculated by NMR spectroscopy. The average degrees of modifications ranging from 30-60% were estimated by ^{1}H NMR spectra and chlorine elemental analysis. On the basis of average degree of modification, the percentage yields ranging from 80-90% were calculated. The glass transition temperatures were determined by DSC and ranged from -20 ºC to 18 ºC; TGA showed maximum weight loss at around 550-600 °C. The materials were mesomorphically characterized on the basis of DSC, polarized optical microscopy, and X-ray diffraction experiments. In most copolymers a hexagonal columnar mesophase was recognized.

Conclusions

In this work, we prepared a family of side-chain LC copolymers by modification at different extent of poly[epichlorohydrin-co-(ethylene oxide)] 1:1 with tapered mesogenic potassium 3,4,5-tris[4-(*n*-dodecan-1-yloxy)benzyloxy]benzoate. Most copolymers exhibited a hexagonal columnar mesophase. The columnar organization should allow proton transport by the channel mechanism. Therefore, these copolymers will be used to prepare oriented membranes and tested for proton transport.

Introduction: In this contribution we explore the possibility of preparing electrospun fibres containing the metallo-organic polymer [Fe(II) (4-octadecyl-1,2,4-triazole)$_3$(ClO$_4$)$_2$]$_n$ (PFe(II)), using an atactic polystyrene matrix. We evaluate the structure, morphology, phase transitions and properties of the fibres.

The metallo-organic polymer exhibits a thermally induced transition between two electronic states: a low-spin (LS) and a high-spin (HS) state which are dia- and paramagnetic, respectively. The spin-crossover is accompanied by a strong thermochromism that provides additional applications for the system as new materials with especial optical, magnetic and electronic properties.

The limiting step for the development of applications with these systems is the transfer of the bulk properties of the metallo-organic polymer in the solid state to systems suitable for technologic applications. The ability to isolate and preserve such linear metallo-organic polymers in fibres would provide as with a new way to obtain new functional materials.

Preliminary results showing the suitability of the electrospinning method to obtain hybrid fibres preserving the spin-crossover phenomenon of the metallo-organic polymer are shown here.

Materials and methods: Electrospinning was performed using a glass syringe mounted in a syringe pump fitted with a 22-gauge needle with an internal diameter of 0.41mm. A flow rate of 0.13 ml/min was employed. A Glassman High Voltage power supply was used which allowed defined voltages over the range of 15 kV. In this work we have used a flat aluminium collector placed 15 cm from the needle.

Fibres were electrospun from a DMF based solution containing 30% w/w of atactic polystyrene with variable proportions of PFe(II) of 0.0, 0.5, 1.0, 5.0 and 10 %.

Results and Discussion: During electrospinning, the electric field overcomes the surface tension of the droplet at the needle to produce firstly a Taylor cone and subsequently a jet producing fibres. These fibres were deposited chaotically on a flat electrode with no preferred orientation within the plane of the electrode.

It was not possible to prepare electrospun fibres from pure PFe(II), however, it was possible to prepare fibres using a range of PFe(II) concentrations dispersed in a polystyrene matrix. Generally, at the higher the concentration it was more difficult to prepare the fibres (see Figure 1).

The mean fibre diameter of the fibres varies with the level of the PFe(II). There appears to be a systematic reduction in diameter with increasing PFe(II) content at low concentration. Whereas at higher concentration the fibre diameter is invariant with compositions, and beads formation appears.

The magnetic properties of the fibres appear to be very similar to those exhibited by the pure PFe(II). DSC studies show a transition at ~60 ºC associated with a structural transition of the metallo-organic polymer, but which is not repeated during a second heating, whereas wide angle x-ray scattering studies show that the local structure of the atactic polystyrene matrix has been largely preserved. At the higher concentration of the PFe(II) there are some distinctive peaks at low angles which show that the basic structure of the PFe(II) is also preserved.

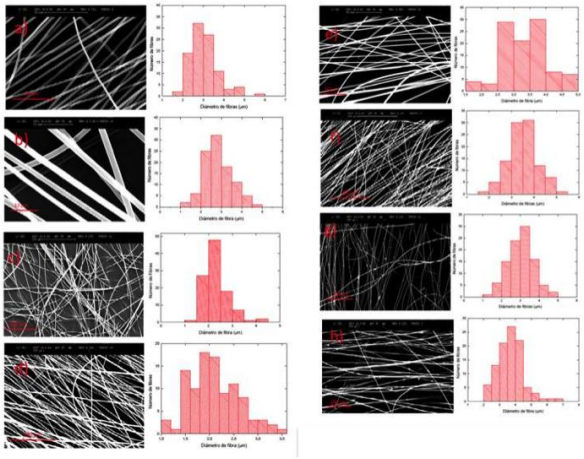

Figure 1 SEM images of aPS-PFe(II) fibres of different compositions and fibre size distribution

Conclusions: This study shows that microscale electrospun fibres of polystyrene containing PFe(II) can be prepared. The properties and structure of the PFe(II) appear to be largely retained, although the disappearance of the structural transition at 60 ºC during a second heating of the electrospun fibres suggests structural rearrangement on heating above the glass transition of the polymer.

Dissolution Modeling of Smart Nano-Scale Coated Polymer Particles in Polymer Flooding Process

M. Ashrafizade[a], *A. Ramazani*[a] *S. A.*, *S. Sadeghnejad*[a]

Introduction

The main purpose of this paper is simulation of in-situ release of nano-size polyacrylamide (PAA) with water-insoluble coatings (i.e. Polystyrene, PS) (Fig. 1a) at the water-oil interface during the polymer flooding of oil reservoirs. Reaching at the water-oil interface, the oil soluble coat of PAA particles solves into the oil phase. Subsequently, the main polymer (i.e. PAA) which is not soluble in the oil phase starts to diffuse and solve into the water phase and increase the in-situ viscosity of water.

Using this method, the amount of polymer, used in flooding, will reduce. Moreover, because of the in-situ release of the polymer and consequently the viscosity reduction of the injected fluid, the driving force for polymer injection will reduce. In addition, using nano-size particles reduces the trapping of the polymer near the wellbore. Finally, smart coatings can decrease PAA degradation caused by salinity, pH, and high temperature of the reservoir. All of these effects together increase the polymer flooding efficiency and reduce the cost of EOR projects.

Physical Description and Modelling of the Process

The physical process of in-situ release can be considered under the term of controlled release in drug delivery systems [1-2]. However, this work is the first one that considers controlled release application in polymer flooding.

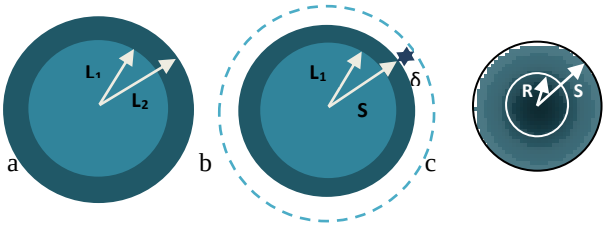

Fig.1. a) PAA core with radius of L_1 and PS coating with radius of L_2. b) Dissolution of PS into the oil phase c) Dissolution of PAA into the water phase

PS dissolution model is considered as a spherical diffusion followed by the polymer chain disentanglement through a diffusion boundary layer of thickness, δ (Fig. 1b):

$$\frac{\partial C_p}{\partial t} = \frac{D_p}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial C_p}{\partial r}\right) \qquad (1)$$

where C_p is volume fraction of polymer, and D_p is polymer diffusion coefficient in the boundary layer. At initial condition as well as the exterior of the boundary layer $C_p = 0$. At the inner side of boundary layer, it is assumed that a polymer chain requires a minimum time to disentangle (i.e. $\frac{\partial C_p}{\partial r} = 0$). After this period, the rate of diffusion is sufficiently high and hence the flux is disentanglement-limited (i.e. $-D_p \frac{\partial C_p}{\partial r} = cte$) until the polymer concentration reaches an equilibrium value in the boundary layer. The interface, S, moves due to polymer chain disentanglement (i.e. $\frac{dS}{dt} = D_p \frac{\partial C_p}{\partial r}$).

A swellable-chain disentanglement model is considered for PAA dissolution into the water phase. Initially, the glassy polymer starts swelling due to water penetration and the simultaneous transition from the glassy to the rubbery state. Thus two distinct fronts are observed (Fig.1c), the swelling interface at position R and the polymer-water interface at position S. Initially, front R moves inwards whereas front S moves outwards as long as swelling prevails. When the water concentration exceeds critical value chain disentanglement begins and both R and S start to decrease.

Water transport can be expressed by Eq.1 but with the water properties (i.e. C_w, D_w). The moving boundary condition at the interface R is given by $C_w \frac{\partial R}{\partial t} = -D_w \frac{\partial C_w}{\partial r}$.

Besides, the PPA dissolution model is the same as PS dissolution model but with different boundary conditions. Finally, the interface S moves due to polymer swelling and subsequent chain disentanglement as: $\frac{dS}{dt} = D_w \frac{\partial C_w}{\partial r} + D_p \frac{\partial C_p}{\partial r}$

By defining proper dimensionless parameters and fixing the moving boundary condition of the governing equations [3], the governing equations are discretized using fully implicit finite difference scheme and solved with Broyden method [4].

The impact of different sensitivity parameters on dissolution time is analysed (e.g. Fig. 2).

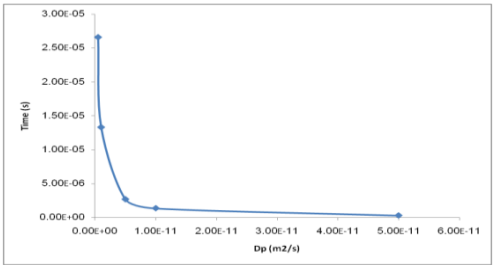

Figure 2: Impact of diffusivity coefficient on dissolution time

Summary

We have introduced a new state of the art methodology for improving polymer flooding efficiency. The polymer dissolution process is numerically modelled by finding the governing equation of the moving boundary problem. Consequently, the sets of governing equations are discretized using fully implicit finite difference scheme and solved with Broyden method.

Nanoclay Composite Barrier Coating for Plastic Substrate of Flexible Display

Sung Soo Kim and Hana Ra

Kyung Hee University, Korea

sungkim@khu.ac.kr

Introduction: Plastic substrates are gaining much interest for its application to flexible display, since it has several advantages over the glass substrate such as light weight, flexibility and transparency.[1] PES films had good clarity and a high thermal resistance to be operated at high temperature,[2] and it could be used as substrates for flexible devices, such as organic thin film transistor(OTFT),[3] liquid crystal display(LCD)[4] and OLED[5-7]. Flexible substrate should have comparable barrier properties to water vapor and oxygen comparable to those of glass. Therefore, additional layer should be formed on plastic substrate to achieve the requirements, and many technologies have been proposed including the thin oxide films, which were prone to mechanical damages and poor adhesion. Functional coating of nanoclay composite layer was proposed can solve the problems, and it can play a role to improve the mechanical properties and barrier properties due to large aspect ratio of nanoclay.[13]In this work, sodium montmorillonite nanoclay was modified with cationic surfactant to enhance the intercalation, and effects of alkyl chain length were examined by various methods such as treatments by cationic surfactant and coupling agent. Nanoclay was functionalized with isophorone diisocyanate- 2-hydroxyethyl acrylate (IPDI-HEA) for subsequent reaction with UV curable polymer. Improvement of mechanical and barrier property of composite layer was examined. Any deterioration in optical performances of substrate after composite layer formation was also examined.

Experimental: Sodium montmorillonite(Na^+-MMT) nanoclay was modified with cationic surfactants was conducted via a cationic-exchange process, and isophorone diisocyanate and 2-hydroxyethyl acrylate (IPDI-HEA) containing a catalyst, dibutyltin dilaurate(DBTDL), at 0.1 wt% and p-hydroxyanisole at 1000 ppm were added and stirred vigorously at 70 ℃ for 48 hrs. Thus obtained functionalized clays were added into the pre-polymer mixture consisted of PU acrylate to make composite solution. The polymer/functionalized nanoclay composite solution was spin coated on PES substrate and was UV-cured.

The X-ray diffraction (XRD) patterns were recorded and the Fourier transformed infrared (FTIR) spectra were obtained. The thermogravimetric analysis (TGA) was performed at a heating rate of 5 ℃/min from room temperature to 900 ℃ under N_2 atmosphere. The mechanical properties were measured using a pencil hardness tester and a falling ball impact testerThe light transmittance of the cured film was measured using a color filter spectral multi channel, and haze was determined. The barrier properties were determined oxygen transmission rate and water vapor transmission rate.

Results: The TGA curves for Na^+-MMT, modified and functionalized clays were compared Fig. 1(a). The weight loss of functionalized clays was increased due to the decomposition of organic groups adsorbed between the interlayer after grafting of IPDI-HEA. The XRD patterns in Fig. 1(b) show that the interlayer spacing of functionalized clays was more increased due to the grafting occurred inside the clay layers. From the XRD and TGA results, it could be found that the IPDI-HEA with reactive acrylate groups was successfully grafted on the nanoclay for the functionalization of clays.

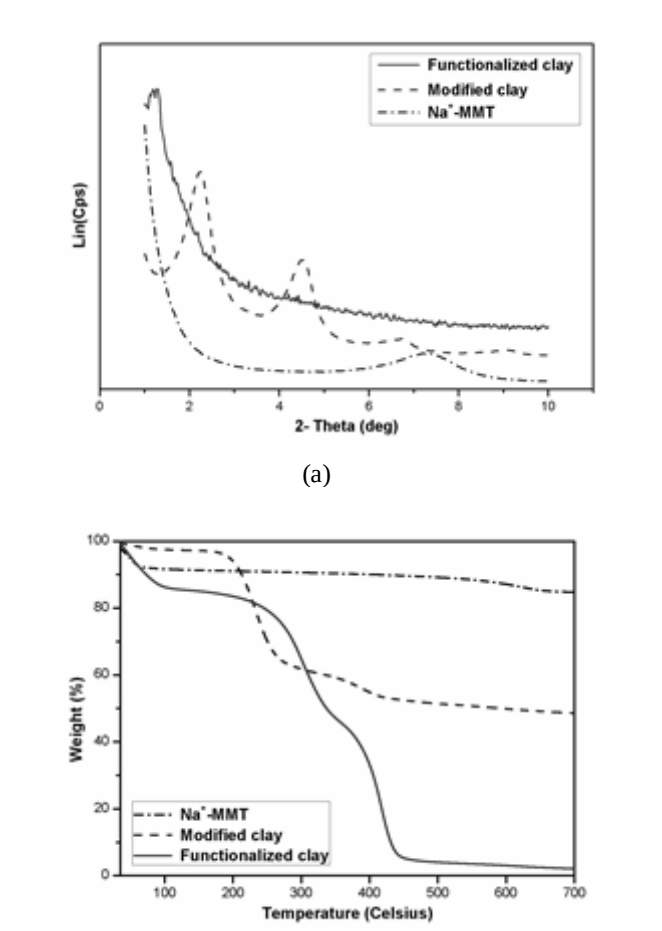

Figure 1. (a) XRD and (b) TGA analyses of nanoclay before and after grafting with IPDI-HEA.

New phenol functionalized polyamides: a new polymer family for multiple applications

Stéphane Jéol[1], *Franck Touraud*[1], *Cécile Corriol*[1], *Jean-Pierre Marchand*[2]

[1] Rhodia Centre de Recherches et Technologies de Lyon, 85 avenue des frères Perret, 69192 Saint-Fons, France
[2] Rhodia Engineering Plastics, Avenue Ramboz – BP64, 69192 Saint-Fons, France

stephane.jeol@eu.rhodia.com

Since the discovery of polyamide more than 70 years ago, several industrial polyamides have been extensively studied and produced industrially to address well-known markets such as textile, industrial yarns, packaging, automotive, electric and electronic, industrial consumer goods, … Efforts to provide the right macromolecular structure to obtain the right properties were reported : the choice of monomers and comonomers, the molecular weight and its distribution or the architecture (linear, stars, branched, hyperbranched, …) are the classical levers. For some new applications of polyamides, it is not always possible to reach the desired properties by using these levers.

One particularity of polyamides is to have their properties (thermal, mechanical, …) more governed by the presence of inter-chains interactions (H-bond) than by the chain length or the nature of the monomers (aliphatic, cycloaliphatic, aromatic).

In this context, we have developed (Ref. A) a novel approach to bring new properties to polyamides, by modulating the inter-chain interactions of polyamides. We present here the development of new polyamides bearing pendant phenol functions, that provide new H-bond having high energy between phenol Ø-OH and amide -NH-(C=O)- groups.

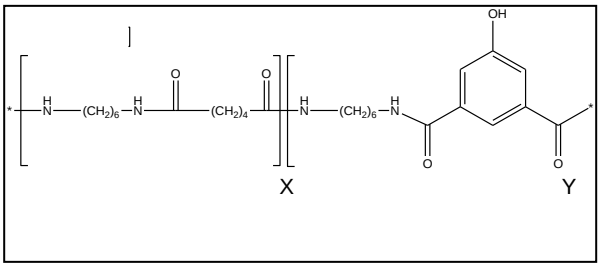

Figure 1. Molecular structure of copolyamides PA 66/6HIA X/Y, bearing pendant phenol groups.

The functional PA 66 named PA 66/6HIA X/Y (Figure 1) are presented. Chemical characterizations (NMR, SEC, end-group titration) of the bulk synthesized PA 66/6HIA indicate the desired structure is obtained.

Molecular modelling (Figure 2) and thermal properties of the functional polyamide are used to highlight the presence of new interactions and how they modify the chain mobility. Well-known copolyamide PA 66/6I (I=Isophthalic acid) having an aromatic structure but without any functionality are used as a comparison. Higher Tg was found by DSC for PA 66/6HIA than for the non functional PA 66/6I.

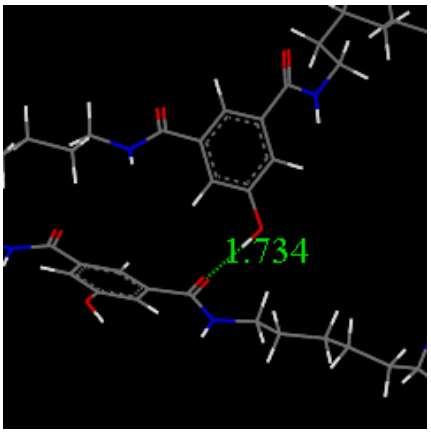

Figure 2. Example of molecular modelling of the H-bond happening in the functional PA.

These functional polyamides can address several new applications where the performances of standard polyamides are limited. Some example of applications are developed.

Optical CO_2-Sensing Film for Clinical Applications based on a Fluorescent pH-Sensitive and Water-Insoluble Lineal Copolymer

P.K. Contreras-Gutierrez, A.L. Medina-Castillo, J.F. Fernandez-Sanchez, A. Fernandez-Gutiérrez

Department of Analytical Chemistry, University of Granada. C/Fuentenueva s/n 18071, Granada, Spain

jffernan@ugr.es

Introduction

The quantitative detection of CO_2 is important in such fields as environmental protection, food packaging and medical monitoring (breath-by-breath analysis).[1]

Many papers have been published on the development of optical CO_2-sensing layers and several patents have been filed. Nevertheless, the response and recovery times of these methods are often too slow for breath-by-breath analysis and also the number of fluorescent compounds that change in intensity in the presence of CO_2 is extremely limited and their useful lifetime tends to be short and unpredictable.

A suitable CO_2 sensor for clinical applications must provide a linear response function within a range of about 2% and 20% CO_2 vol/vol in air; it must not be very sensitive to humidity, should be stable for at least one month and easy to produce. In addition, luminescence properties are ideally required in order to avoid interferences.

In 1997 Mills et al.[1] developed an optical phase which was based on a ethyl cellulose containing the pH-sensitive hydrophilic indicator dye combined with a phase-transfer agent, tretraoctylammonium hydroxide (TONOH), and a plasticizer. In 2007, Fernandez-Sanchez et al.[2] optimized Mills's membrane. They determined that the CO_2-sensitive dye should have a $pK_a \geq 7.5$ and two types of functional groups, one that can to be deprotonated (e.g. a phenol) and one that can stabilize the negative charge (e.g. lactone, sulphite or diazo groups).

Our research group has recently synthesized a novel fluorescent pH-sensitive and water-insoluble lineal copolymer (NP1(x)) which has an apparent pK_a of 7.8, a phenol group and a lactone group thus it should be suitable for developing CO_2-sensing films. In this work, we analyze the potential application of this new polymer for the development of CO_2-sensing films for breath-to-breath analysis.

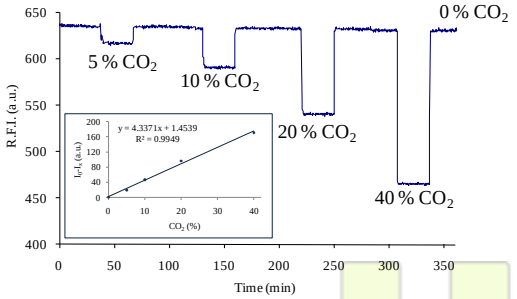

Fig. 1. Response of the proposed sensing layer with different concentrations of CO_2.

Materials and Methods

150 mg of NP1(X) and 375 mg of TONOH were dissolved in 3 mL of MeOH. 500µL of this solution were coated in a glass support with a spin coating at 700 r.p.m.

The sensing films were characterized by measuring the florescence signal (I_0-I_x) at $\lambda_{exc/em}$=480/520 nm, where I_0 is the fluorescence emission of the film in synthetic air (40% RH and flow-rate of 100 mL min^{-1}) and I_x is the fluorescence emission on exposure to different percentages of CO_2 (vol/vol) for 300 s at 40% RH and a flow-rate of 100 mL min^{-1}.

Results and Discussion

In order to test the applicability of NP1(X) in the development of CO_2-sensing films for medical applications, the concentration of NP1(X), the amount of TONOH, the effect of the flow-rate, the effect of the humidity and the study of interferences were developed.

We determined that the best cocktail composition for the determination of % CO_2 (vol/vol) at 40% relative humidity (RH) and a flow-rate of 100 mL min^{-1} is: 50 mg mL^{-1} NP1(X) and 125 mg mL^{-1} of TONOH in methanol.

The study of the effect of the flow-rate reveals that the (I_0-I_x) florescence signal is not influenced by the flow-rate thus it could be used for detecting CO_2 in flow-rates from 50 to 250 mL min^{-1}.

The study of the RH shows that the RH of the media has to be highest than 25% for a good recognition of CO_2. When the RH>25% the sensing film is not affected by the humidity.

Lastly, NO_x, CO and O_2 were tested as potential interferences. Any of them interfere significantly in the determination of CO_2.

Conclusions

The experiments and results described in this work show that the fluorescent pH-sensitive and water-insoluble lineal copolymer described by our research group can be used for developing optical CO_2-sensing films.

The stokes shift (40 nm), sensitivity to CO_2 (detection limit of 0.5 % CO_2 (vol/vol)), absence of relevant interference species, reversibility and short response time allow this sensing-films to be used in breath-by-breath CO_2 analysis (see Fig. 1).

Properties of conductive layers printed by ink-jet printing.

Monika Rom, Jaroslaw Janicki, Stanislawa Przybylo, Ewa Sarna, Ryszard Fryczkowski

University of Bielsko-Biala, Institute of Textile Engineering and Polymer Materials, POLAND

mrom@ath.bielsko.pl

Introduction

There are numerous trials on application of conductive polymers in various areas from so called 'plastic electronics' through implantable biomedical scaffolds to sensors. Most of conductive polymers can be deposited on different surfaces by electrochemical deposition, self-assembly or spin-coating, but those methods have some restrictions such as rather small areas and require special conditions. Processability of conductive polyaniline (PANI) and polypyrrole (PPy) strongly depends on route of synthesis.

Among different methods of polymer deposition inkjet printing seems to be very attractive as it allows to obtain not only patterns of high resolution and high repeatability but also repeatable layer-by-layer deposition. Inkjet printing demands preparation of inks which despite of appropriate particle sizes (in order to avoid clogging of nozzles), must be stable in time. Moreover viscosity of inks has to be low enough to enable jetting and high enough to avoid wicking from the nozzle.

Materials and methods

Both polyaniline and polypyrrole were synthesized by oxidative polymerization in water at presence of ammonium persulfate (APS) and dodecylbenzylsulfonic acid (DBSA) as a micellar and simultaneously doping agent. Synthesis was performed at room temperature [1,2]. As synthesized polymers were subjected to dialysis for 48h [3].

Stability of PANI and PPy dispersions in water was checked at first by visual method. Viscosity measurements were done using rotational viscometer (Myr) equipped with device for low viscosity and small quantity samples. UV-Vis spectrophotometric analysis by was used to confirm conductive state of synthesized polymers.

„Inks" were deposited layer by layer on various substrates including textiles using Dimatix Fujifilm inkjet printer DMP-2831. Printings were observed using Scanning Electron Microscopy and printer's visualisation system.

Results and Discussion

Stable in time PANI and PPy dispersions were obtained by micellar polymerization. UV-Vis spectra indicated the conductive form of both PPy and PANI. Such a dispersions of PANI and PPy after dialysis did not need viscosity optimization, as they meet requirements. After deposition and during drying of inks phase separation occurred, as the result of phase separation polymers agglomerated and DBSA spots could be distinguished on the printed surfaces. That phase separation affected also rubbing fastnesses of printings.

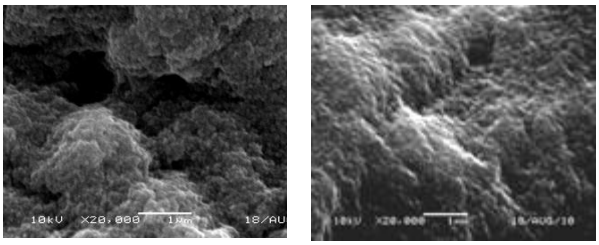

Fig.1. PPy (left) and PANI (right) – form ink, dried and extracted with ethanol.

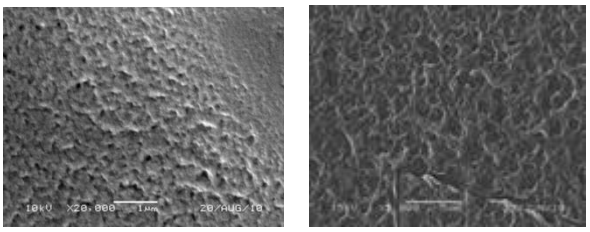

Fig.2. PPy (left) and PANI (right) printed layers, both on PET film.

Conclusions

The concentration of inks was not high enough to allow to obtain continuous printings after one layer deposition, on the other hand increasing of concentration was leading to higher viscosity of compositions which then agglomerated and were problematic for filtration indispensable before filling the cartridge with ink. One of the possible ways of improvement is layer by layer deposition, however phase separation and the excess amount of DBSA remaining in the ink is the challenge.

Polymethacrylamides´s synthesis. Dendronized Polymers

Nancy Alvarado, Deodato Radic´

Pontificia Universidad Católica de Chile

nlalvara@uc.cl

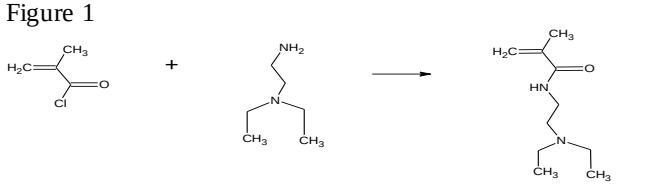
Introduction

A dendronized polymers is a linear polymer with highly branched substituents, where due to be presented tubular type polymers are also called "comb". It is interesting to study this type of structures where, due to the size of dendron interactions can be found on the type dendron / dendron, dendron / dendron main chain or / solvent [1]. Dendronized polymers have a spherical or cylindrical shape, depending on size and generation number of dendritic side chain due to the large size of individual chains [2,3]. These "molecular cylinders" can be adapted to a specific chemical composition, stiffness, surface functionalization, and properties of the chain as well as their counterpart spherical dendrimers [4]. The size of the cylinder depends on the degree of polymerization, which determines the length, and moreover dendron generation determines the diameter. Conventional polymers have a diameter in the range of angstroms, whereas the linear polymers dendronizados have diameters in the range of nanometers.

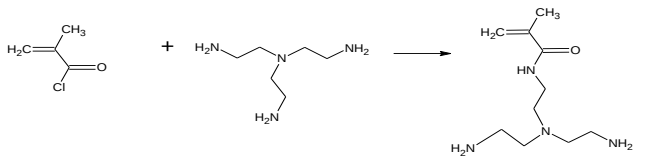
These well-defined architecture could then be used for applications at the nanoscale level, eg in catalysis or as carriers of chemical [5].

Materials and Methods

DEAEMA monomers (diethylaminoethylmethacrylamide) and 2.2 'DAEAEMA (diaminoethylaminoethylmethacrylamide) were obtained through the synthesis of methacrylic acid chloride with diethylethylenediamine in the case of the first monomer and tris (2-aminoetthylamine) for the second monomer both in THF and using triethylamine as acid acceptor. Figure 1



DEAEMA



DAEAEMA

Figure 1. Synthesis of DEAEMA and DAEAEMA.

Meanwhile, polymerization was carried out as follows: the dendronized polymer PG0, shown in Figure 1 was obtained through bulk polymerization method using the following procedure: weighed 1.0 g of the corresponding monomer, was added 0.5% of AIBN under N_2 atmosphere, the balloon was left in a water bath at 65 °C for 48 hours. The solid obtained was dissolved in $CHCl_3$ and then was precipitated with petroleum ether. The dendronized polymer PG1-NH2 (Figure 1b) was obtained by polymerization in vacuum line, then left in a water bath at 65 °C for 16 hours. Viscous solution was obtained which was added acetone and got a yellow precipitate. The polymers were characterized by NMR-^{1}H, which ensures that we are in the presence of polymers. Figure 2.

Figure 2. Dendronized Polymers

Results and Discussion

Structures have been obtained dendronized polymers, which have been characterized by thermal analysis (TGA) and differential scanning calorimetry (DSC) values were obtained according to their structures, ie, the decomposition temperature increases with the dendrimeric structure. Is currently conducting a study of mixtures of dendronizedpolymers and polymers classics, to investigate the interaction between them, and mixes with small molecules among which include ibuprofen and thus study its possible inclusion as a guest on a host of dendronized polymer type.

Conclusions

Dendronized polymers are particular structures, whereby due to its unique shape may undergo various studies aimed at finding properties that are not present in their linear analogues. Another interesting approach is to insert small molecules into the cavities of these polymers. The scope for this type of structure is so varied ranging from material science to medical applications.

Zinc dithiocarbimates as accelerators for natural rubber vulcanization

Cunha, L. M. G.[a,*]; *Rubinger, M. M. M.*[b]; *Oliveira, M. R. L.*[b]; *Visconte, L. L. Y.*[a]

[a]Instituto de Macromoléculas Professora Eloisa Mano – Universidade Federal do Rio de Janeiro
[b]Departamento de Química – Universidade Federal de Viçosa

[*] leandromgc@ima.ufrj.br

Introduction

Metal complexes of dithiocarbamates are used worldwide in rubber vulcanization but are frequently criticized for their potential production of nitrosamines during the vulcanization processes [1].

The interest on metal complexes of dithiocarbimates is related to their similarity with the dithiocarbamate complexes (Figure 1), especially as far as the presence of the $Zn(S_2C{=}NR)_2$ moiety in the former structures is concerned.

Figure 1: Basic structure for: (a) dithiocarbamate; (b) dithiocarbimate

In this work the vulcanization efficiency of new compounds containing the anionic complex bis(alkylsulfonyldithiocarbimate)zincate(II) with the chemical structure $(Ph_4N)_2[Zn(RSO_2N{=}CS_2)_2]$, where Ph_4N = tetraphenylphosphonium cation, R = ethyl (**1**), or octyl (**2**), towards the vulcanization process of natural rubber compounds has been investigated and compared with the commercial accelerators TBBS and ZDEC. The presence of the R-sulphonyl group linked to the nitrogen atom of the dithiocarbimate moiety is important and may prevent the production of nitrosamines.

Experimental

The compounds were synthesized according to the methodology described in a previous work [2].

Natural rubber was compounded following the formulation: natural rubber, NR (100 phr), stearic acid (2.5 phr), zinc oxide (3.5 phr), sulfur (2.5 phr), Irganox® (1.0 phr), accelerator (3.2 mmol).

The mixture was carried out in a roll mill with 1:1.25 friction ratio, at room temperature. Rheometric parameters were determined in an oscillating disk rheometer from Tecnologia Industrial, at 150 °C and 1° arc, according to ASTM D 2084.

Results and Discussion

Figure 2 shows the rheometric curves obtained for compositions with the new accelerators as well as with TBBS and ZDEC. Considering that the increase in torque values is directly related to the amount of crosslinks formed during vulcanization process, it is possible to conclude that the new accelerators promote crosslink formation in the same magnitude as compared with TBBS. These results indicate that compounds 1 and 2 are effective in forming crosslinks during natural rubber vulcanization.

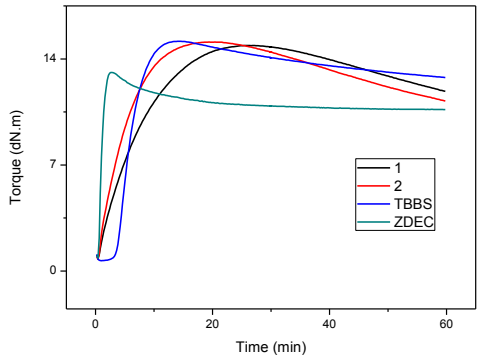

Figure 2: Rheometric curves for compositions with the new and commercial accelerators at 150ºC

Table 1 shows the values of the rheometric parameters for natural rubber compositions with the new and commercial accelerators.

Table 1: Rheometric parameters for natural rubber compositions with new and commercial accelerators

Accelerator	ts_1 (min)	ΔM (dN.m)	t_{90} (min)	R_{30} (%)
1	0.86	14.03	15.45	19
2	0.76	14.36	10.41	10
TBBS	0.68	14.49	9.10	9
ZDEC	0.80	12.32	1.71	18

ts_1 = scorch time; ΔM = maximum torque – minimum torque; t_{90} = optimum vulcanization time; R_{30} = reversion rate

The obtained values for t_{90} showed that accelerator **1** is slower than accelerator **2**. These results can be due to the size of the aliphatic chain. Longer aliphatic chains can improve the solubility of the vulcanization agent in the polymer matrix, making easier the access of the reaction site by the reactive species.

Conclusion

The new accelerators **1** and **2** are active in natural rubber vulcanization. New tests for mechanical properties and crosslink density are being conducted.

Characterization of Gas-Barrier Coated Polyethersulfone Substrate for Flexible Display Application

*Yeonseon Ahn, Mansu Kim, Sang-Hyon Paek, Young Chul Kim**

Department of Chemical Engineering, Kyung Hee University, Yongin-si, Gyeonggi-do 446-107, Korea

kimyc@khu.ac.kr

Introduction: Flexible displays, which can be rolled-up or folded for storage, have been at the focus of many research activities. To realize flexible displays, the development of high gas-barrier plastic substrates and encapsulation layers is recognized as one of key technologies. Researchers reported that the water vapor transmission rate (WVTR) of plastic substrates requires below 10^{-6} g/m^{2}day for flexible OLEDs (FOLEDs) [1]. However, the detection limit of the most widely used measurement system (MOCON Inc.) is 5×10^{-4} g/m^{2}day [2]. As the barrier property of plastic substrates is enhanced, the ultra-low water vapor permeation measuring system becomes required and useful for the study on the permeation mechanism and understanding of device lifetime and degradation phenomena [3].

In this study, we characterized the gas-barrier property of SiN_x- or SiO_x- coated polyethersulfone (PES) substrates by the calcium (Ca) cell test with time dependent quantitative permeation data and Fickian diffusion models, which can estimate the steady-state gas flux as well as the lag time for gas permeation.

Materials and Methods: In order to prepare gas-barrier plastic substrate specimens, 30 nm-thick SiN_x or SiO_x layer was deposited by plasma-enhanced chemical vapor deposition (PECVD) onto 200 μm-thick polyethersulfone (PES) substrates (i-Components Co., Korea).

And the Ca test cells employed for the barrier property characterization were fabricated as follows: On a carefully cleaned glass substrate, a 250 nm-thick Ag electrode was deposited and then the central 3 x 3 cm^2 area was covered with a 250 nm-thick Ca layer to contact with the electrode in a vacuum evaporator. A 4 x 4 cm^2 piece of a barrier substrate specimen, after cleaned with isopropyl alcohol and dried in vacuum for several hours, was attached to the Ca and electrode-coated glass substrate using UV-sealant.

Results and Discussion: We first obtained the time-dependent water vapor permeation data from the neat PES substrates in a 38 ℃ and 90% RH condition. By measuring the time taken until the steady-state water vapor concentration profile builds up across the cross section of the PES substrate, we could estimate the lag time which may be directly related to the shelf-life of the device made using the substrate. Also, The WVTRs of the neat PES substrates with 125 and 200 μm thicknesses were estimated by analyzing the electrical degradation rate of the Ca cells to be 29.3 and 34.1 g/m^{2}day, respectively. The WVTR of the 200 μm-thick neat PES substrate measured by the MOCON test at 38 ℃/100% RH was 54.1 g/m^{2}day. This confirms that the permeation rate measured by Ca cell test is fairly accurate.

We characterized the barrier properties of the two substrates, PES/SiN_x and PES/SiO_x. In the steady-state permeation region, the slop of water vapor fluence is directly related to the permeation rate, which was calculated to be 1.5×10^{-1} and 6.0×10^{-2} g/m^{2}day, respectively. Also, we could estimate the water vapor diffusivity and solubility of the each barrier layer by using a series resistance model and the lag time equation for a two-layer system. The PES/SiO_x substrate showed higher gas-barrier property with lower water vapor diffusivity and solubility than the PES/SiN_x substrate.

The lag times and WVTRs measured for the neat PES (200 μm), PES/SiN_x and PES/SiO_x substrates are shown in the table below.

Atomic force microscopic (AFM) observation on the PES/SiN_x and PES/SiO_x substrates revealed that the SiO_x surface was smoother than the SiN_x surface with the root mean square (RMS) roughness values of 0.70 and 1.43 , respectively. It is considered that the more densely packed layer of SiO_x with the smoother surface gave the better barrier properties.

	Lag time (hour)	Diffusivity (barrier layer) (cm^2/s)	WVTR (g/m^2 day)	
			Ca test	MOCON
PES	0.37		34.05	54.1
PES/SiNx	7.9	6.48×10^{-18}	1.5×10^{-1}	2.8×10^{-1}
PES/SiOx	122	3.45×10^{-18}	6.0×10^{-2}	7×10^{-2}

Environmental condition: 38℃, 90%RH (Ca test)

Conclusions: The course of degradation of Ca test cells via water vapor permeation could be divided into 3 regions; transient, steady-state, and saturated permeation. By determining the transient permeation region, where the concentration gradient across the substrate cross section is building up, we could estimate the lag time before degradation starts. From the time-dependent quantitative permeation data obtained by the Ca cell test, the water vapor diffusivity and solubility of each layer were estimated for the two layer systems. We propose that this approach for characterizing the barrier properties of polymer-based multilayer substrates can be utilized to design ultra-barrier substrates for flexible display application.

Aromatic polyimides containing methyl substituents and study of their physical properties

Stefan Chisca, Ion Sava, Valentina Elena Musteata, Maria Bruma

„Petru Poni" Institute of Macromolecular Chemistry, Aleea Gr. Ghica Voda 41 A, Iasi 700487, Romania

e-mail: stefan.chisca@icmpp.ro

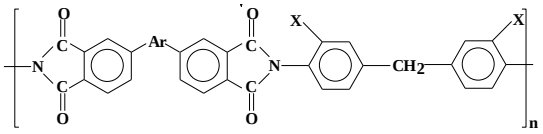
Introduction

Aromatic polyimides are unique due to their high thermal stability, chemical resistance, electrical characteristics, toughness, and dimensional stability. Therefore, they have gained much interest in many applications, such as insulating layers for semiconductor devices, microelectromechanical systems or substrates for flexible printed circuits, particularly owing to their relatively low dielectric constant [1,2].

The focus of this work is to investigate a series of polyimides having various structures by using dielectric spectroscopy to gain insight into the molecular mechanism determinning its dielectric properties and kinetic characteristics [3].

Materials and Methods

Aromatic polyimides were prepared by polycondensation reaction of two aromatic diamines, such as 4,4'-diaminodiphenylmethane (DDM) and 3,3'-dimethyl- 4,4'-diaminodiphenylmethane (MDDM), with aromatic dianhydrides, such as 4,4'-isopropylidene-diphenoxy-bis(phthalic anhydride) (6HDA), benzophenonetetracarboxylic dianhydride (BTDA) and hexafluoroisopropylidene-bis(phthalic anhydride) (6FDA) (scheme 1) [4].



a: Ar = - O-C_6H_4- $C(CH_3)_2$ - C_6H_4- O -; X = H ;
b: Ar = - O-C_6H_4- $C(CH_3)_2$ - C_6H_4- O -; X = CH_3
c: Ar = CO; X = H ;
d: Ar = CO; X = CH_3
e: Ar = $C(CF_3)_2$; X = H ;
f: Ar = $C(CF_3)_2$; X = CH_3

Scheme 1. Structure of the aromatic polyimides

The structures of these polymers were determinated by FT-IR, and the thermal properties were investigated by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). Dielectric parameters and molecular relaxations were characterized by dielectric relaxation spectroscopy (DRS).

Results and Discussion

These polyimides exhibited high thermal stability, with decomposition temperature being above 430 ºC in air, and high glass transition temperature being in the range of 200 – 287 ºC.

Dielectric properties of polyimides were evaluated on the basis of dielectric constant, dielectric loss and electric modulus, and their variation with frequency and temperature. These dependencies constitute very important factors to be considered for dielectric materials in their microelectronic applications. The polyimide films exhibited low dielectric constant values, being in the range of 2.88 - 3.48 at 1 Hz at room temperature.

The sub-glass relaxation processes were investigated and showed that for polymers based on 6HDA and 6FDA three relaxation processes (γ, β_1 and β_2) were observed, and for polymers based on BTDA only two (γ and β) relaxations were detected (figure 1).

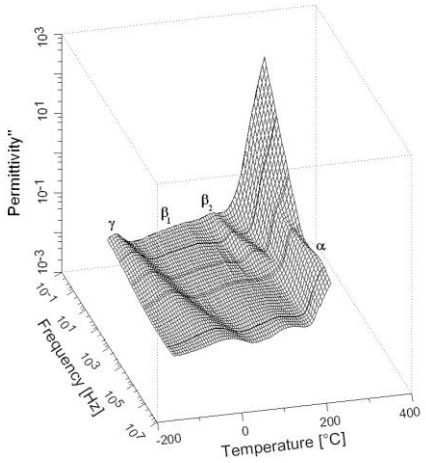


Figure 1. Dielectric loss vs. frequency and temperature, for polyimide **a**

The γ transition was correlated with water absorbed from atmosphere. β_1 relaxation was associated with motions in the diamine part and has a higher activation energy for polymers having methyl substituents on diamine segment. β_2 relaxation was attributed to the rotation of side groups (CF_3 and CH_3) in the dianhydride part and is dependent on local conformation.

Conclusions

All these characteristics make the present polymers potential candidates for applications as high performance dielectrics.

Introduction

The performance of an organic photovoltaic (OPV) cell is mainly determined by the properties of the active layer, which is generally composed of a blend of an electron donor and an acceptor. Since both, donor and acceptor materials tend to phase separate on a macroscopic scale the morphology of this active layer is of utmost importance. Block-copolymers have been known to exhibit the ability to stabilize polymer blends. Their use in OPV devices, however, has apart from a few examples,[1-3] been mainly neglected.

We thus embarked on a project which aims to develop a generic synthetic methodology for obtaining electron donor-acceptor (D-A) functionalized block copolymers with tailored properties, which will be used to fabricate stable and efficient OPV devices.

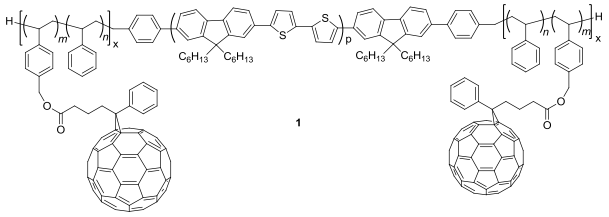
Results and Discussion

The aim of this project is to develop a generic synthetic approach for D-A block copolymers, where the donor and acceptor blocks are made from a conjugated polymer and a coil macromolecule with attached C60-pendant, respectively. So far the most promising polymers for the conjugated block are synthesized by polycondensation reactions such as Stille and Suzuki coupling. For the coil part, reversible addition fragmentation chain transfer (RAFT) technique was employed and a combination of those techniques was chosen for the synthesis of D-A block copolymers. As a proof of concept, it was decided to use poly(9,9-dihexylfluorene-alt-bithiophene) (F6T2) as a model system for the conjugated block because the monomers are commercially available and the polymer has been widely studied.

The coil polymer was obtained by copolymerizing styrene with benzoylbutyric acid functionalized vinylbenzyl chloride under the control of a trithiocarbonate RAFT-agent. The product so obtained contained pendant keto groups which were subsequently directly modified with tosylhydrazone to facilitate the C60 attachment. This direct modification, however, appeared to be problematic as the RAFT groups are easily cleaved by a nucleophilic attack by the tosylhydrazine yielding thiol end groups, which can couple through disulfide formation. A possible way around is the chemical removal of the RAFT end group using *N*-ethylpiperidine hypophosphite and a radical initiator, resulting in a complete disappearance of it.[4]

After removing the RAFT groups the polymer was converted to the corresponding polytosylhydrazone, which reacted further with fullerene to give the final coil block. The attachment of C60 to the polymer was confirmed by gel permeation chromatography analysis equipped with a photo-diode array detector (GPC-PDA) and ^{13}C-NMR.

The conjugated rod block was synthesized as reported in the literature by a Suzuki coupling reaction and in the presence of a small excess of diboronic acid to ensure the presence of terminal boronic ester end-groups, which were subsequently end capped with the coil polymer obtained after the RAFT group removal.[5] The further functionalization of the coil part with fullerene was carried out in a similar way as describe above yielding rod-coil D-A block copolymer **1**. The link between the rod and coil part was verified through GPC-PDA measurements and the presence of the polymer blocks was confirmed by IR and UV spectroscopy.



1

A further confirmation of the successful synthesis of block-copolymer **1** was inferred from fluorescence spectroscopy, where the presence of the C60 acceptor completely quenched the fluorescence of the conjugated polymer donor in a thin film due to an electron transfer process.

Conclusion

In this contribution we successfully developed a generic methodology for the synthesis of D-A block copolymers through a combination of Suzuki-coupling and RAFT polymerization. We found that it is essential to remove the trithiocarbonate end-groups in order to prevent disulfide formation through the nucleophilic attack of tosylhydrazine. The final structure of the D-A block copolymer was analysed and confirmed by spectroscopic analysis. The interaction of the donor and the acceptor block was verified by fluorescence quenching of a thin film of the polymer and as such it might find useful application in OPV devices.

New Highly Thermostable Phthalonitrile-Containing Aromatic Polyamides and Poly(amide imide)s for High Performance Applications

Ionela-Daniela Carja, Corneliu Hamciuc, Elena Hamciuc, Tachita Vlad-Bubulac

"Petru Poni" Institute of Macromolecular Chemistry, Aleea Gr. Ghica Voda 41A, Iasi-700487, Romania

daniela.carja@icmpp.ro

Introduction

Aromatic polyamides and polyimides are well known due to their excellent thermal stability and electric insulation properties [1, 2]. However, their applications are limited because most of these rigid polymers are insoluble and infusible. Aromatic poly(amide imide)s have been developed as alternative materials offering a compromise between excellent thermal stability and processability. It has been shown that the introduction of voluminous pendant groups, such as phthalonitrile bulky group, into rigid polymer chain can impart a significant increase of glass transition temperature by restricting the segmental mobility while providing good solubility because of decreased packing and crystallinity. Also, the solvent resistance and thermal properties of the phthalonitrile-containing polymers were enhanced by thermal treatment around the glass transition temperature for an extended period of time due to the crossslinking site formation through the thermal polymerization of the nitrile groups on pendant phthalonitrile units [3].

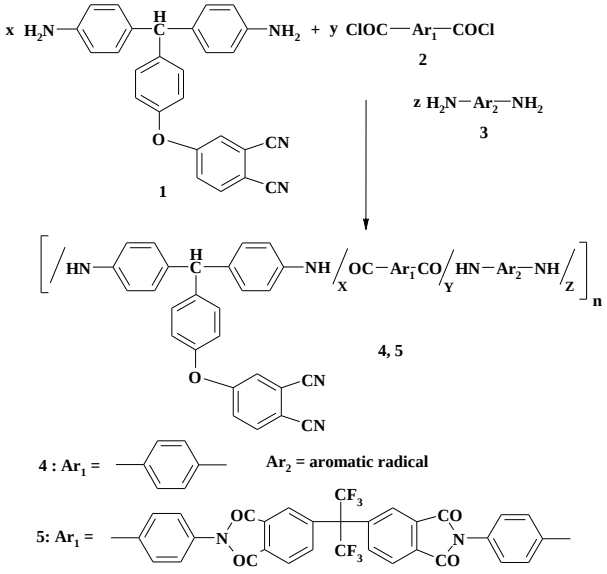
Material and Methods

Monomer **1** was prepared by nucleophilic displacement reaction of 4-nitrophthalonitrile with 4,4′-diamino-4″-hydroxy-triphenylmethane, in the presence of anhydrous potassium carbonate. Aromatic polyamides **4** and poly(amide imide)s **5** were synthesized by low temperature solution polycondensation of terephthaloyl chloride or 2,2-bis[N-(4-chloroformylphenyl)phthalimidyl]hexafluoro-propane, respectively, with a mixture of **1** and other aromatic diamines **3**, in various ratios, using NMP as solvent and pyridine as acid acceptor (Scheme 1). The polymers were characterized by using different techniques: FTIR and ^{1}H NMR spectroscopy, GPC, AFM, ATG, DSC, DMA, BDS, WAXD.

Results and Discussion

A new diamine **1** was prepared and characterized and its self-promoted cure behavior was investigated. It exhibited a low melting point of 78.4°C and could be cured at temperatures of 230-250°C. The resulting resins had exceptional high thermal and thermo-oxidative stability, the 5% weight loss being above 500°C and the char yield at 700°C being over 62%, in air or inert atmosphere.

Based on diamine **1**, new aromatic polyamides **4** and poly(amide imide)s **5** containing phthalonitrile groups were synthesized. The molecular structure was identified by FTIR and ^{1}H NMR spectroscopy. The polymers exhibited good solubility in organic solvents and film forming properties. They showed high thermal stability, the decomposition temperature being above 400°C. Electrical properties of the polymer films were evaluated on the basis of dielectric constant and dielectric loss and their variation with frequency and temperature.



Scheme 1. Synthesis of the polymers.

The electromechanical properties of some poly(amide imide) films were investigated. Nanoactuation has been determined to be in the range of 300-400 nm, at 130-220 V, with plane flexible thin electrodes.

Conclusions

New polyamide and poly(amide imide)s were synthesized based on a new diamine containing phthalonitrile group. The polymers had good solubility in organic solvents and could be processed from solutions into thin flexible films having the thickness in the range of tens of micrometers. The presence of the phthalonitrile groups in the macromolecular chains increased the humidity absorption and dielectric constant of the polymers. By applying a thermal treatment an increase of the solvent resistance was observed. The polymers showed high thermal and thermo-oxidative stability. They exhibited flame retardancy, the chair yield at 700°C having high values both in air and inert atmosphere.

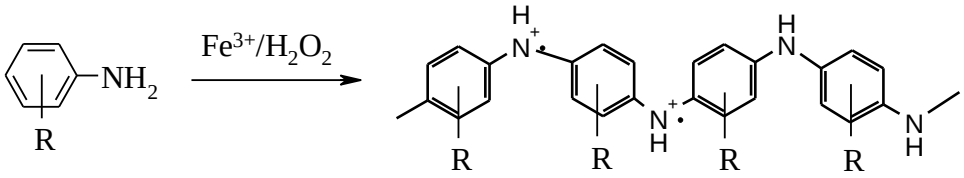
Polyaniline Synthesis Using Fenton Reagent: Effect of Substitution of Aniline

Michal Blaha, Jiri Zednik, Jan Svoboda and Jiri Vohlidal

Charles University in Prague, Faculty of Science, Department of Physical and Macromolecular Chemistry, Hlavova 2030, CZ-128 43 Prague 2

e-mail: Michal.Blaha@csop.cz



Polyaniline (PANI) is conjugated polymer that has already found practical applications in the construction of capacitors, analytical sensors, antistatic films and coatings, materials for electrostatic discharge protection, electrochromic windows, anticorrosion paints, etc. It is usually prepared by chemical oxidative polymerization. Its replacement by catalytic process can lower contamination of forming polymers by oxidant residues and it can reduce production of waste solvents (their recycling represents half of cost of polymer production). This aim can be achieved by using a catalyst system that mediates the oxidation of a monomer by oxidant such as hydrogen peroxide, which is transformed into water during the polymerization. Also other systems have been examined, but Fenton system (Fe^{3+}/H_2O_2 in acidic aqueous environment) is the most promising one.

Although few papers were published in last fifteen years in this field, no one of them was dealing with reaction course of polymerization and dependence of physical and chemical properties of resulting PANI on H_2O_2-to-aniline mole ratio, to which we paid attention in our previous work. We previously focused on dependence of spectral properties of PANI on H_2O_2-to-aniline mole ratio. While PANIs prepared with substoichiometric H_2O_2-to-aniline mole ratio exbibit spectral properties comparable to PANI prepared with ammonium persulfate, PANIs prepared with overstoichiometric H_2O_2-to-aniline mole ratio exbibit some differences in UV/vis, FTIR and Raman spectra, which is an evidence of structure defects. These differences compared to spectra of PANI prepared with ammonium persulfate indicate presence of protonized structures also in base (dedoped) forms of polymers, which is typical for self-doped PANIs. NMR spectra of oligomers resulting from polymerization done with high overstoichiometric H_2O_2-to-aniline mole ratio indicate presence of C–OH or C–O–C bonds in their structure.

To get information about the reaction course we used mainly combination of potential time profiling, capillary zone electrophoresis and also gravimetry of resulting polymer.

As already known, from our previous work, extent of structure defects does not depend only on H_2O_2-to-aniline mole ratio, but also on ring substitution of aniline. We recently studied polymerization of aniline, 2-methoxyaniline and 2-chloroaniline and we have found that extent of structure defects is high in case of electron donating methoxy group and is low in case of electron withdrawing chloro atom.

Nowadays, we present more detailed study of the effect of the substituent on properties of corresponding polyaniline. Potential time profiling measurements were done for all studied monomers (aniline, 2-methoxyaniline, 2-chloroaniline and 2-ethylaniline). Results obtained are discussed concerning to ionization energies (potentials) of these compounds, which were calculated by Gaussian using B3LYP method, and concerning to oxidation potentials of monomers measured on cyclic voltammetry instrumentation in acidic solutions having same concentrations of monomer and hydrochloric acid as in case potential time profiling measurements.

annalisa.chiappone@polito.it

Introduction

Nowadays natural fibers are used as reinforcements for the production of polymer composites since they are low-cost, biodegradable, readily available and characterized by low density and high specific properties.[1] Microfibrillated cellulose (CMF) is obtained through an easy process that does not involve chemical reactions. The cellulose particles obtained have a diameter range of 10–100 nm, length in the microscale and show a web-like structure alternating crystals and amorphous strings[2].

Free radical photo-polymerisation is a successful approach for the production of composite thermo-set polymer membranes, the process takes place at room temperature under UV light, is easy, reliable and rapid[3]. Considering the interesting properties of CMF and the potentiality of photo-polymerisation this work describes a UV cured CMF-polymer composite membrane to be applied as electrolyte in Li batteries[4]. Studies on UV-cured methacrylic-based polymer membranes as gel-electrolytes have already been developed[5-7] and good performances in terms of electrochemical properties are reported, membranes are flexible, self standing and easy to handle. The use of a mechanical reinforcement such as CMF could lead to interesting results.

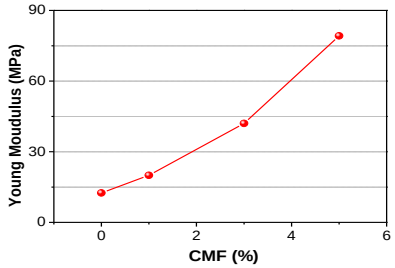
Materials and Methods

CMF nanoparticles were prepared by treating bleached cellulose fibres in a microfluidizer processor. A CMF aqueous suspension (1%wt) has been prepared. The reactive formulation for polymer membranes was based on a dimethacrylic monomer, bisphenol A ethoxylate (15 EO/phenol) dimethacrylate (BEMA, Mn: 1700, Aldrich), and poly(ethylene glycol) methyl ether methacrylate (PEGMA, Mn: 475, Aldrich) in 1:1 ratio. 2hydroxy-2methyl-1phenyl-1propanon (Darocur 1173, Ciba Specialty Chemicals) was the free radical photo-initiator (2%wt). The CMF suspension was added to the reactive formulation in different ratios in order to obtain nanocomposites containing 1, 3, 5% wt of microfibrils. The liquid mixture was left 12 hours in oven at 60°C to obtain the water evaporation and subsequently UV cured for 3 min. under N_2 flux by using a medium vapour pressure Hg lamp (30mWcm^{-2}). Later free, self standing films obtained after photopolymerisation were treated in vacuum at 70°C overnight. Membranes were then swelled with a liquid electrolyte solution containing a 1.0 M $LiPF_6$ in Ethylen-carbonate/Diethyl-carbonate (EC/DEC 1:1 w/w) solution (Ferro Corp., battery grade).

Results and Discussion

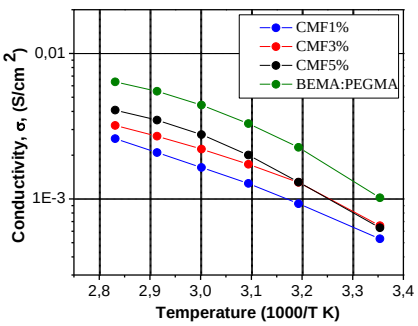
The polymer membrane obtained copolymerising the monomers BEMA and PEGMA with the in situ addition of CMF was a freestanding, extremely flexible and non-sticky membrane.

a



The addition of CMF to the polymer did not affect the Tg, slightly increased the thermal stability and enhanced remarkably the mechanical properties both before and after swelling in the liquid electrolyte. Tensile test performed on the composite membranes (figure a) and bending test performed on the swelled ones showed the enormous difference in the mechanical performances given by the use of CMF. The electrochemical characterisation showed that the membranes swelled in the liquid electrolyte present high values of ionic conductivity also in presence of CMF (Figure b), an appreciably high electrochemical stability window and good cyclability.

b



Conclusion

Microfibrillated cellulose was successfully used to reinforce methacrylic-based composite polymer membranes prepared by UV-curing for the application in the field of lithium batteries. The prepared membranes gave interesting results in terms of mechanical properties and electrochemical performances, therefore, these kinds of polymer electrolytes are particularly promising in the field of Li-based thin flexible batteries.

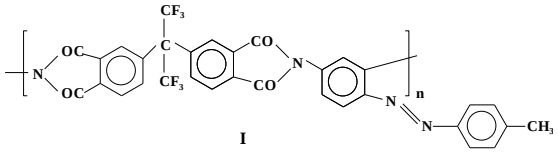
Azobenzene and many of its derivatives have been studied for a long time due to their properties that allow various applications triggered by light. Usually these applications are based on the, photoinduced isomerism of the azobenzene which result in significant conformational and dipole moment changes.[1-3]

This paper presents the UV photochromic response of azo-polyimide compared with azo-polysiloxane thin films for surface relief gratings.

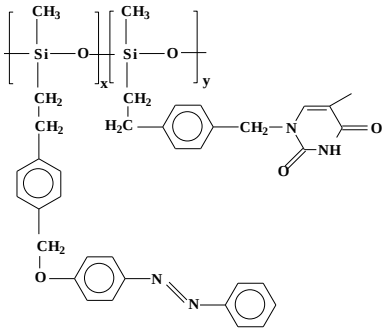
Experimental

The structures of the investigated azo-polymer are shown bellow:



I

Azo-polyimide



II

Tymine modified azo-polysiloxane

The azobenzene *trans-cis* isomerization and *cis-trans* relaxation photocromic process, was investigated both in solution and in solid state by UV spectroscopy with BOECO S1 UV spectrophotometer. The light source, was an Nd:YAG laser working on his third harmonic at 355 nm and with a pulse length at FWHM (full width half maximum) of 6 ns. The obtained structurated surfaces were characterized by optical microscopy and atomic force microscopy (AFM). AFM investigations were done using a Solver PRO-M, NT-MDT apparatus. The film topography was analyzed in *semicontact mode*, in air, using a rectangular cantilever NSG10/Au with a nominal elasticity constant K_N = 11.5 N/m.

Results and discussion

Both polymers present a high thermal stability with the initial decomposition temperature over 300°C, good solubility in different solvents and good film forming ability. An important difference concerning the glass transition temperature was observed. Therefore, the azo-polyimide shows a value of 228°C, higher than the azo-polysiloxane one (34 °C).

The time dependence of the photoisomerisation process shows that the maximum conversion degree of polyimide from *trans* to *cis* isomer in the solid state is lower (only 39%) compared with the modified azo-polysiloxane (55%). Also, it was observed that the time scale for the *cis-trans* relaxation activated by visible light is similar to the reverse UV induced *trans–cis* isomerization; this aspect is favourable to generate the photoinduced fluid state according to the conformational instability concept.[4]

The induced surface relief grating AFM profile evidenced the evolution of the surface structuration from disorder to order, up to a sinusoidal profile corresponding to the surface grating formation. The structuration time depends on the incident laser fluence / intensity and number of irradiation pulses. AFM profiles of the surface relief induced by an interference field with a medium fluency of 8.4 mJ/cm^2 and 100 subsequent laser pulses are similar for both azo-polymers.[5] The depth of the photoinduced structure is about 90 nm for the azo-polysiloxane film and 100-110 nm for the azo-polyimide film. The difference consists in the evolution of the structure with the number of incident laser pulses, respectively irradiation time. After only 10 irradiation pulses the height of the ''hills'' on the surface of azo-polyimide was half of those on the azo-polysiloxane surface. This should be the effect of the azo-polyimide main chain rigidity which slows down the molecular reorganization.

Conclusions

The SRG induced on the films surface of azo-polyimide and azo-polysiloxane modified with thymine have a very good time stability and a good contrast of the surface volume structuration.

Heterocyclic polynaphthaleneimides containing siloxane groups in the main chain

Radu-Dan Rusu, Mariana-Dana Damaceanu, Maria Bruma

"Petru Poni" Institute of Macromolecular Chemistry, Aleea Gr. Ghica Voda 41A, Iasi-700487, Romania

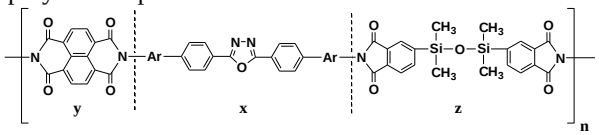
Email: radu.rusu@icmpp.ro

Introduction

High-performance polymers are used in applications that demand service at enhanced temperatures, while structural integrity and an excellent combination of chemical, physical and mechanical properties are maintained. Some of the important polymers in this respect are polyimides and poly(1,3,4-oxadiazole)s [1,2]. However, these polymers have the common problem of being difficult to process owing to their infusibility and poor solubility in organic solvents. Therefore, much effort has been done to develop structurally modified aromatic polymers that have increased solubility without sacrificing their thermal stability. A combination of several structural modifications, that is, the incorporation of 1,3,4-oxadiazole rings, naphthalene units and flexible groups in the polymer backbones, minimizes the trade-off between the solubility and properties of wholly aromatic polyimides. This work describes the synthesis and characterization of a series of polynaphthaleneimides containing flexible siloxane bridges and oxadiazole moieties in the main chain.

Materials and methods

A series of new aromatic poly(1,3,4-oxadiazole-naphthaleneimide)s have been synthesized by two-step solution polycondensation reaction of three different aromatic diamines containing oxadiazole ring with a mixture of naphthalenetetracarboxylic dianhydride and 1,3-bis(4'-phthalic anhydride) tetramethyldisiloxane taken as 1:0.5:0.5 molar ratio. The general structure of these copolymers is presented in the scheme below.



x : y : z = 2 : 1 : 1

Ar = PI 1 : - ; PI 2 :  ; PI 3 : 
The polycondensation reaction was carried out in 1-methyl-2-pyrrolidinone (NMP) in the presence of benzoic acid as catalyst, under anhydrous conditions in nitrogen atmosphere, at high temperatures (200°C). The relative amounts of monomers and NMP were adjusted to maintain a solid content of 8%.

The solubility, inherent viscosity, thermal stability, glass transition temperatures, UV absorption and photoluminescence properties of these polymers have been evaluated with respect to their chemical structure.

Results and discussion

The poly(1,3,4-oxadiazole-naphthylimide)s are soluble in a convenient aprotic amidic solvent such as NMP, and, except for polymer **PI 2**, in N,N-dimethylacetamide and dimethyl sulfoxide, when slightly heated. Copolyimide **PI 3** containing *m*-catenated phenylene rings proved to be also soluble in N,N-dimethylformamide, and even in less polar solvents such as chloroform. The inherent viscosity values of these polymers are in the range of 0.15-0.2 dL/g.

The structures of the polymers were identified by means of elemental analysis, IR and ^{1}H NMR spectroscopy.

The thermal properties of these copolynaphthaleneimides were evaluated by means of DSC and TGA. The copolyimides exhibited Tg values in the range of 201-255°C. The polymers showed excellent thermal stability, as expected in case of aromatic polyimides: the initial decomposition temperatures were about 477-489°C and the temperatures of 10% gravimetric loss were in the range of 497-508°C. The temperature of the maximum decomposition rate of polymer **PI 1** is 515°C, while the decomposition of copolyimides **PI 2** and **PI 3** takes place in two steps as shown by DTG curves: the first step occurs in the range 512-516°C and the second in the range 520-525°C.

Since the 1,3,4-oxadiazole ring is known as a light emissive unit [3], we have also performed a study of the UV absorption and photoluminescence properties of these polymers. It was found that all the oxadiazole-containing copolyimides in NMP solutions show one strong UV absorption maximum around 302 nm, mainly determined by the diphenyl-1,3,4-oxadiazole unit [4], and two peaks at 360 nm and 380 nm, due to the naphthylimide chain segments [5], the spectra being quite identical. All three poly(oxadiazole-imide)s showed blue photoluminescence, in the range 410–445 nm, which makes them promising candidates for future use as high-performance materials in the construction of light-emitting devices.

Conclusion

The incorporation of naphthylimide units, oxadiazole rings and of flexible siloxane bridges in the main chain gave products with good solubility and satisfying properties, which would be useful for various high-performance applications, especially in electroluminescent devices with high stability.

Aliphatic polyesters play a significant role as biodegradable polymers due to their potentially hydrolyzable ester bonds. Polyalkylene dicarboxylates constitute a specific family of polyesters that is receiving great attention since the excellent mechanical and thermal properties of poly(butylene succinate) make feasible its commercialization. Many works have been focused on the structural study and degradation mechanism of different members of this family and particularly those derived from even diols and even dicarboxylic acids. On the contrary, scarce information is available on odd-odd derivatives. This point merits attention since both structure and properties should be sensitive to the so called odd-even effect. Specifically, the polyester constituted by 1,9-nonanediol and azelaic acid is interesting since the high methylene content of its repeat unit gives rise to a semicrystalline polymer with a higher melting point than polycaprolactone, one of the most applied biodegradable polymeric material. Properties can be easily modified by copolymerization with a second dicarboxylic acid. Thus, the effect of the incorporation of pimelic acid units on the crystallization process, crystalline structure and morphology has also been considered in this work.

Polyesters were synthesized from the appropriate mixture of dicarboxylic acids and an excess of 1,9-nonanediol (molar ratio 2.2/1) by thermal polycondensation. The reaction was first performed in a nitrogen atmosphere at 150 ºC for 6 h and then in vacuum at 180 ºC for 18 h. Titanium tetrabutoxyde was used as a catalyst. The polymer was dissolved in chloroform and precipitated with ethanol. The polymerization yield was always close to 70%. Calorimetric studies indicated that all samples were able to crystallize showing a eutectic point at the intermediate composition which also gave rise to a small decrease on the degree of crystallinity (Figure 1a). Crystallization from the melt rendered negative birefringent spherulites with ringed or fibrilar textures depending on the degree of supercooling and even on the composition (Figure 1b).

X-ray fiber diffraction patterns indicate that poly(nonamethylene azelate) crystallizes according to an orthorhombic unit cell with a large *b* parameter (i.e. close to 1.5 nm) and a practically all trans molecular conformation (Figure 2a). Patterns of copolymers showed similar trends although the intensity of some *hkl* reflections was enhanced (Figure 2b).

All copolymers crystallized from dilute 1,6-hexanediol solutions as lozenge crystals (Figure 3) with a degree of truncation that increased with the crystallization temperature as was also reported for other even-even polyesters. Electron diffraction patterns of the different samples were similar and compatible with rectangular unit cells of smaller dimensions than those deduced from fiber patterns. Crystalline structure is consequently defined by an arrangement of only two distinctive chain segments in chain axis projection.

Introduction:

Conventional elastomers are characterized by a long-range elasticity obtained after the vulcanization process because of the creation of covalent cross-links between the polymer chains. These materials present many recycling problems because of the permanent character of the covalent cross-links.

Moreover, ionic elastomers have a thermo-reversible network structure that allows their recycling. Ionic elastomers are characterized by a strong physically crosslinked network resulting from a phase separation of ionic-rich nano-domains. The ionic domains are formed by the association of ionic groups that tend to aggregate forming multiplets and clusters that act as cross-links promoting the elastic behaviour of these polymers[1, 2]. In addition, the trapped glassy rubber around them improves the physical properties of these materials acting as reinforcement of the soft rubbery matrix.

However, the thermal lability of ionic cross-links leads poor mechanical properties at high temperatures, restricting their possible applications.[3, 4, 5] In order overcome these inconveniences, covalent cross-links on the thermo-reversible network structure of ionic elastomers have been formed.

The principal aim of this work is combining both types of cross-links in an elastomeric matrix to obtain thermo-reversible elastomers with enhanced properties at high temperatures.

Materials and Methods:

In order to study the effect of covalent crosslinks on the ionic network structure, we have used a polymer matrix based on carboxylated nitrile rubber (XNBR), with a carboxylic group content of 7 wt % which allows its crosslink via metallic oxides (MgO) resulting in a controlled ionic network. The covalent bonds between the polymeric chains were created by the addition of dicumyl peroxide.

The properties of the compounds have been obtained through uniaxial strain-stress tests and rheological measurements and the structure has been studied through dynamic mechanical measurements and low field NMR based on Multiple Quantum experiments.

Results and Discussion:

Formation of covalent cross-links provokes the increase on the number of ionic nano-domains that present smaller and more homogeneous size distribution. This variation in the network structure is closely related with the enhanced properties showed by these materials. The properties at high temperatures improve with low contents of covalent cross-links in the ionic elastomer but without altering their reversible thermoplastic nature (Figure 1).

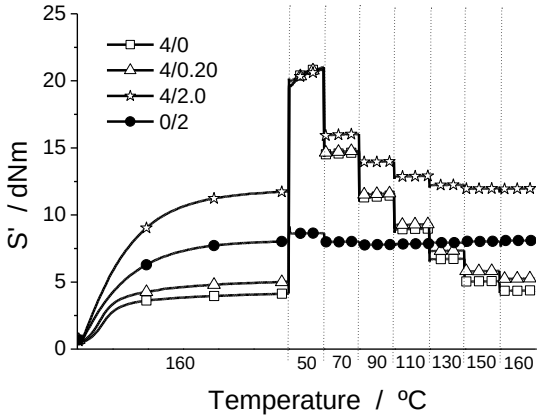

Figure 1. Variation of the elastic torque component with the temperature of different compounds with a MgO/Dicumyl peroxide ratio from the moving rheometer.

Conclusions:

According to the obtained results it is possible to conclude that the proper combination of covalent and ionic cross-links allows us to control the network structure of ionic elastomers in order to tune the properties of these materials.

The enhancement of mechanical properties of polymer/clay nanocomposites over polymers is clearly obtained in most of the polymers [1, 2]. The aims of this study are to control the mechanical properties of nanocomposites and to design materials with better properties.

In this work nanocomposites of high density polyethylene with organoclay modified with polyvinyl (alcohol) by in situ polymerization, were prepared for the melt intercalation technique. It was used two different routes to prepare the modified organoclay. The clay MMT$_{HDTMA/PVA}$ (POH) was dispersed in propylic alcohol and the clay MMT$_{HDTMA/PVA}$ (AV) was dispersed in the monomer, vinyl acetate.

The morphology and structure of these materials were studied by X-ray diffraction (XRD), optic microscopy (OM), scanning and transmission electronic microscopy (SEM, TEM). The mechanical properties of traction were performed in an Instron universal machine (Model 5569). The results showed that the morphology changed with the route of organoclay preparation. In the figure 1 the material with HDPE/MMT$_{HDTMA/PVA}$ (POH) 0.6%, presented an agglomerated and intercalated clay morphology whereas the material with HDPE/MMT$_{HDTMA/PVA}$ (AV) 0.6%, presented the intercalated-exfoliated structure (figure 2)

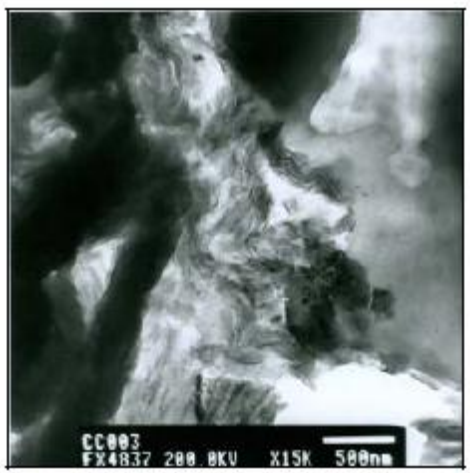

Figure 1. TEM of HDPE/MMT$_{HDTMA/PVA}$ 0.6% (POH)

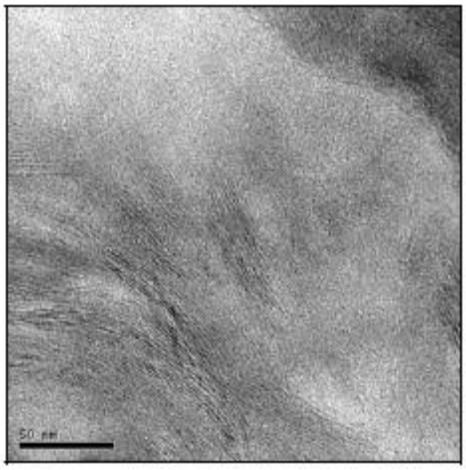

Figure 2. TEM of HDPE/MMT$_{HDTMA/PVA}$ 0.6% (AV)

The table 1 shows that the best Young modulus and break elongation values correspond to HDE/MMT$_{HDTMA/PVA}$ 0.6% (AV).

Table 1. Mechanical properties of: HDPE, HDPE/MMT$_{HDTMA/PVA}$ 0.6% (POH) and HDPE/MMT$_{HDTMA/PVA}$ 0.6% (AV).

Sample	Young Modulus (MPa)	Break strength (MPa)	Break elongation (%)
HDPE	745	20,4	431
HDPE/ MMT$_{HDTMA/PVA}$ 0.6% (POH)	657	18,8	365
HDPE/ MMT$_{HDTMA/PVA}$ 0.6% (AV)	824	19,9	503

A relationship between the mechanical properties and the clay morphology observed by TEM has been detected.

Introduction:

The nitrate ion in groundwater is becoming an environmental problem of major concern due to its high toxicity that causing cancer and nethemoglobinemia [1,2]. The important sources of nitrate can be inorganic fertilizer, industrial and sanitary waste waters, vegetable residues and compost, as well as rainfall and spontaneous nitrification of atmospheric nitrogen by nitrification bacteria. The dissolved nitrates filtrate through the ground by rainfall or irrigation and contaminate phreatic waters that feed wells from which drinking water is taken. Nitrates consumed with drinking water can be converted into nitrites in human body and may cause health problem. The increasing rigorousity of the drinking water quality standard, 50 mg/L in the European Union or 25 mg/L in USA, generates the urgent need to develop a new technology for nitrate removal from aqueous solutions. Recently, the catalytic reduction of nitrate by platinum and palladium metals is attracting considerable interest [3]

Experimental and Methods:

The nanocomposites of polymers/MWCNTs were synthesized via in situ chemical oxidation polymerization method. These nanocomposites synthesized in different mass proportions of monomer to MWCNTs.

Results and Discussion:

In this research, we prepared nanocomposites of multiwalled carbon nanotubes (MWCNTs) with different polymers (such as: polyaniline (PANI), polypyrrole (PPY), poly(1,8-diaminonaphthalene) (poly(1,8-DAN)), poly (3,4-ethylenedioxythiophene) (PEDOT)) and poly (vinyl pyridine) (PVP), as effective and reusable nanocomposites for nitrate removal from drinking water. The nitrate removed from water with toxic concentration using ion-exchange mechanism with synthesized polymers counter ions without any toxic byproducts. We used different dopants as polymers counter ions and results shown that effective exchange of nitrate with Cl^- ions.

The different experimental parameters such as pH of the sample, polymers ion-pairs or dopants, temperature, nanocomposite loading, and ratio of polymer versus MWCNTs in nanocomposites, affect the amount of nitrate removal.

In order to examination of different nanocomposites in nitrate removal, every nanocomposite with different proportion in mass of polymer/MWCNTs was used. Results shown that effective nanocomposite with lower concentration of polyaniline is 3:1 and 4:1 nanocomposite. Since the pH of the aqueous solution is an important analytical factor in nitrate ions removal, the influence of pH on removation was examined in the pH range of 2-12 for each nanocomposite.

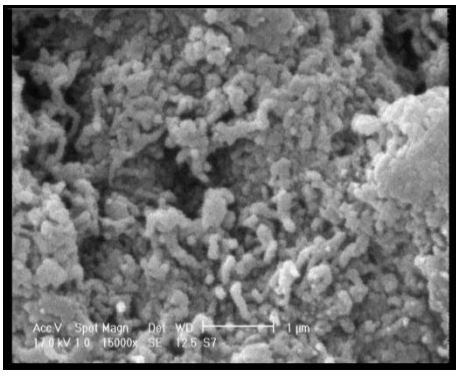

Fig. 1. SEM image of PANI/MWCNTs nanocomposite in 3:1 proportion.

In nanocomposite with higher concentration of PANI more remove percent has never been seen. For optimization of other factors that affecting nitrate removal the 3:1 portion selected because of higher physical stabilization in reusing for several times. In higher polymer concentration in nanocomposite the processability shows decrease.

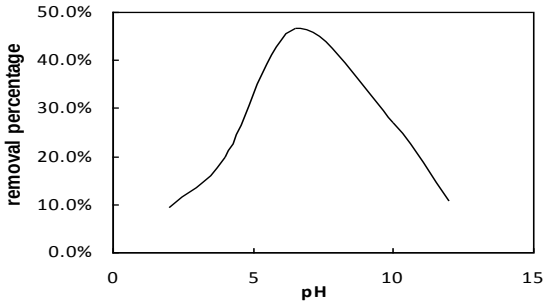

Fig. 2. Effect of water acidity on nitrate removal percent with PANI/MWCNTs.

Since the pH of the aqueous solution is an important analytical factor in the nitrate ions removal, the influence of pH on removing was examined in the pH range of 2-12 for each nanocomposite. The effect of solution acidity was investigated under prior found optimum condition. The results for PANI nanocomposite are shown in figure 2. It is obvious that the best removal of nitrate was done in pH= 6.5.

Conclusions:

The better performances explain by high degree of doping for PANI that allows the more exchange between nitrate and dopant anion of the conducting polymer.

Introduction

Hydrogels for mediated electron transfer electrodes (MTE) are composed of redox units, potentially crosslinking units and monomer units[1]. In Bio Fuel Cells containing MTEs the diffusion of charge carriers is a crucial power factor which has an immense influence on the efficiency [2]. Based on Fick's law of diffusion the electron flow J_e can be described as follows [3]:

$$J_e = D_{ap}\frac{dC_B}{dx} = -D_{ap}\frac{dC_A}{dx} \quad (1)$$

At constant concentrations of the mediators J_e is influenced only by D_{ap} which is available via Blauche-Savéant equation:

$$D_{ap} = \frac{1}{6}k_{ex}(\delta^2 + 3\lambda^2)C_{A,B} \quad (2)$$

k_{ex} identifies the transfer rate of the mediator and δ the electron hopping distance. The variable λ is related to the flexibility of redox units and is of utmost importance, as λ is the only variable which can be influenced by variation of the chemical and physical environment of the mediator molecules.

By variation of the content of crosslinking molecules or by using different polymer backbones the influence of those parameters on λ can be discovered. Furthermore, the stability of MTEs at decreasing crosslinker concentration is of general interest.

Materials and Methods

A series of copolymers containing DMMA, MABP as the crosslinking unit and an active ester was synthesized and the crosslinker content was varied. In the subsequent step the polymer was converted to a redox gel by attaching a ferrocene unit to the active ester (see Figure 1). The chemical composition was verified by using FTIR and NMR. Molecular weights were examined using GPC.

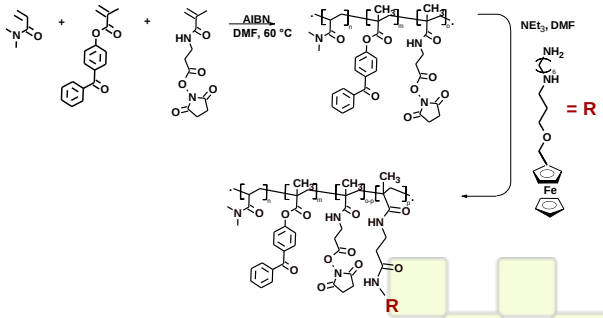

Figure 1: Reaction scheme for the polymerization and the incorporation of ferrocene moieties.

In order to characterize the swelling behavior of these films SPR measurements were employed (see Figure 2a). Substrates were dip coated in a polymer solution and were then crosslinked by UV irradiation (365 nm). The benzophenone unit reacted via CH insertion with other polymer chains to form a polymer network [4]. For CV measurements (see Figure 2b) the electrode tips were spin coated followed by a crosslinking step [5].

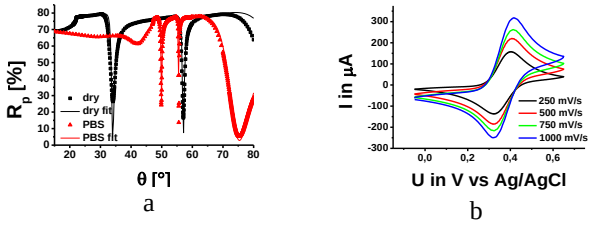

Figure 2: Graphs for SPR measurements in swollen and dry state (a) and cyclic voltammograms at different currents (b).

Results and Discussion

SPR measurements showed that the amount of the crosslinking unit has an influence on the swelling behavior of the hydrogel. A reduction of the benzophenone content from 12 to 1% causes an increase of the swelling of 59%, as shown in Figure 2a. CV measurements showed a better electron transport at smaller amounts of benzophenone. By using the Randles-Sevcik equation the diffusion of the electrons in the hydrogel was obtained.

Conclusion

In this work we show that the transport of electrons is directly related to the swelling behavior of the gel. By reducing the oncentration of the crosslinking unit the swelling of the hydrogel increases and the diffusion of electrons through the hydrogel is increased as well.

Introduction

In today's information rich society the role of lithium ion batteries can not be overestimated, as their applications are ranging from mobile electronic devices to hybrid vehicles. Thus research needs to take into account not only improvements of their performance but also reduction of cost, environmental impact and improved safety [1]. The main areas of research are directed towards the key elements of a Li battery: electrode materials, electrolyte and separator (porous membrane). The latter being the focus of our research.

Using the existing organic electrolytes embedded into a polymer membrane as electrolyte/separator combination raises safety concerns due to the flammability of such electrolyte. In addition current manufacturing processes of separators involve several steps making the process costly. Our approach is to combine the benefits of existing printing technologies with an ink formulation which produces an electrolyte-filled separator in a single processing step. As ink we investigated high internal phase emulsions (HIPE) which can be polymerised in situ as a method of producing a porous thin film network. [2-3].

Experimental Part

Non aqueous high internal phase emulsions were prepared by dropwise addition of the dispersed phase (ionic liquid or mixture of propylene carbonate (PC) with ethylene carbonate (EC) doped with Li salt) into the external phase (thermal or UV radical polymerisation initiators, monomer, crosslinker and a surfactant) at constant stirrer speed. The emulsion was then cast as film and polymerised using thermal (at 70°C) or room temperature UV-activated radical initiation (larger polyHIPE monoliths were prepared in parallel).

Results and discussion

The choice of the internal phase was determined by a number of factors. A PC/EC doped with lithium salt is widely used as electrolyte for batteries and useful as baseline for our research. An ionic liquid was chosen because of their extremely low vapour pressure (simplifying printing), non-flammability and high conductivity.

Conditions to form stable HIPEs were identified and it was observed that content of an internal phase has a strong influence on the stability of HIPEs. Independent of content and polymerisation method, the obtained polymerised HIPEs (polyHIPEs) possess a highly porous interconnected structure. Figure 1 shows the morphology of the polyHIPE after removing the dispersed phase. As the polyHIPEs are already filled with electrolyte, they can be used as deposited and exhibit ionic conductivities in the range of 5-10 mS/cm as prepared. Details on the properties of the synthesised polyHIPEs and printing results of thin polyHIPE films will be presented at the meeting.

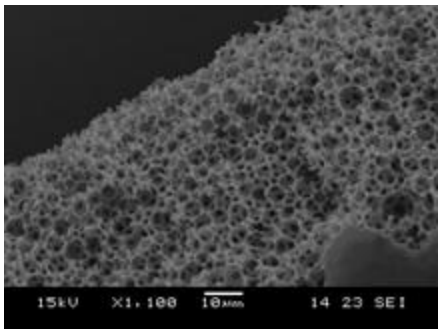

Figure 1. SEM micrographs of polyHIPEs after removing internal phase.

Conclusions

In conclusion, by selecting appropriate conditions and monomer/crosslinker/surfactant formulations we were able to produce a (highly porous) polyHIPE thin film prefilled with ionic liquid or a mixture of propylene and ethylene carbonates electrolyte with high ionic conductivity values. This is a key advance in the ability to realise more environmentally friendly and more cost effective thin film batteries via multi-layer printing with roll-to-roll compatibility.

Natural antioxidants for polymer

Anna Masek, Anna Kosmalska, Marian Zaborski

Technical University of Lodz, Institute of Polymer and Dye Technology, Stefanowskiego 12/16, 90-924 Lodz, Poland

anna.masek@p.lodz.pl

Introduction:

Ozone is a strong oxidant agent and has an influence on the rate of rubber ageing. The degradation by ozone is characterised by the appearance of cracks on the polymer surface [1-2]. The aim of this work was the research on antioxidation activity of flavonoides towards ozone ageing of EPM rubber.

Materials and Methods:

The object of the study was *trans*-chalcone (1phr) and flavone (0,5phr) obtained from Aldrich. The compositions of the prepared mixes were as follows: ethylene-propylene rubber (EPM, Dutral CO-054, Mentedison Ferrara, Italy) 100 phr, dicumyl peroxide (DCP, Fluka) 2 phr - used as a cross-linking agent and hexadecyltrimethylammonium bromide (CTBA, Sigma Aldrich) 2 phr - as dispersing agent. Fumed silica Aerosil 380 (Degussa) was used as a filler (30 phr). Rubber blends were prepared by means of a laboratory mixing mill with rolls of the following dimensions: length L = 330 mm, diameter D = 140 mm. The speed of rotation of the front roll was V_p = 20 rpm, friction 1.1, the average temperature of rolls was about 40°C. The vulcanization of rubber blends was carried out with the use of steel vulcanization molds placed between the shelves of electrically heated hydraulic press. A teflon film was used as spacers preventing the adherence of blends to the press plates. Samples were vulcanized at a temperature of 160°C, under a pressure of 15 MPa for 30 min. The density of crosslinks in the rubber network of vulcanizates was determined by the method of equilibrium swelling. The vulcanizates were subjected to equilibrium swelling in toluene for 48 h at room temperature. The swollen samples were then weighed on a torsion balance and dried in a dryer at a temperature of 60°C to a constant weight and after 48 h they were reweighed. The cross-linking density was determined on the basis of Flory-Rehner's equation:

$$\vartheta_e = -\frac{1}{V_0} * \frac{\ln(1-V_r)+V_r+\mu V_r^2}{(V_r^{\frac{1}{3}}-\frac{V_r}{2})}$$

for the elastomer-solvent interactions amounting to $\mu = 0{,}501 + 0{,}273\ V_r$, where V_r is the volume fraction of the elastomer in the swollen gel. The tensile strength of vulcanizates was tested according to standard PN-ISO 37:1998 by means of a ZWICK tester, model 1435, for dumbbell w-3. Ageing characteristics were determined according to standard PN-82/C-04216. Ozone ageing was performed by means of an Anseros SIM 6300 apparatus from Anseros Klaus Nonnenmacher GmbH. The measurement lasted for 50 and 150 h, the ozone concentration was 300 pphm at 40°C.

Result and Discussion

After ozone ageing no significant changes in the mechanical properties and cross-link density were observed in the sample, when compared to the reference sample. The ageing coefficients, equal to 1,03 and 0,98, indicate considerable protection of vulcanizates against ozone ageing, provided by the applied natural antioxidants.

Table 1. Effect of flavonoids on the cross-linking density of EPM vulcanizates, $\nu_{(t)}$ – crosslinking density calculated on the basis of swelling in toluene.

	$\nu_{(t)}*10^5$, (mol/cm^3) Before ageing	$\nu_{(t)}*10^5$, (mol/cm^3) After ozone ageing (50h)	$\nu_{(t)}*10^5$, (mol/cm^3) After ozone ageing (150h)
EPM	3,46	1,72	0,70
EPM/ chalcone/ flavone	4,49	3,74	3,65

Table 2. Effect of flavonoids on the tensile strength of EPM vulcanizates. SE300% – stress at 300% of elongation, TS – tensile strength, Eb – elongation at break, TS_A - tensile strength after ageing, TS_B - tensile strength before ageing.

	SE_{300}, (MPa)	TS, (MPa)	Eb, (%)	TS_A/TS_{BA}
EPM	3,10	17,67	670	-
EPM/ chalcone/flavone	2,32	19,50	653	-
After ozone ageing (50h)				
EPM	2,92	6,39	557	0,66
EPM/ chalcone/flavone	3,09	20,10	562	1,03
After ozone ageing (150h)				
EPM	1,12	4,33	674	0,36
EPM/ chalcone/flavone	2,97	19,30	575	0,98

Conclusion:

Flavonoide derivatives improve the great resistance of elastomers to ozone ageing. Flavonoides can be pro-ecological alternative antioxidants for polymers.

Introduction

Electroless plating is a process in which a metal salt is reduced to metal onto a surface from solution. This process has been widely utilized in coating many materials with metal films for numerous applications [1.2]. It allows to obtain uniformity thick coatings and gives the possibility to regulate physical-chemical properties of coatings (such as electrical conductivity). Dielectric substrates must be catalytically activated prior to the plating to provide a surface that can interact with silver ions in the solution causing their reduction on the surface and growth of a coating.

Experimental

In present study, we prepared silver films by electroless plating on PET poly (ethylene terephthalate) considering this approach in fabricating templates for DTR process nanostructures. We investigated the effects of the micro-struture surface and electrical properties on the growth of the electroless silver film,

the negative substrates used for silver films were initialy exposure by DLP (Digital light process) as interlayer method was verified by a metallization process following.

Electroless plating on the polymer

The plating bath was coposed as following: 80ml of NaCl, 658 ml water, 10ml of VDL ($AgNO_3$), 266 ml of Natriumthiosulfat ($Na_2S_2O_3$), 66 ml of EDTA (HO_2CCH_2), with incrise VDL concentration and decrise the water amount to comparation (deposited in freshly prepared solution in absence of additives the simplest conditions) other three types formulation solutions were carried out include (1 ml, 1%) of inhibitor VG (ethanol solution). The process of electroless deposition was divided in stages; firstly submersed vertically the samples in solution with carbon solid as cathode, electrical potential applied at 1.0 to 2.0 Volts range at 30 seconds and 1 minute of potetial exposure, secondly samples dried about 30 min in room temperature. After electrical properties analysis through multimeter connect in electrodes to defined area interpretation; scanning microscopy and microstruture steps analysis.

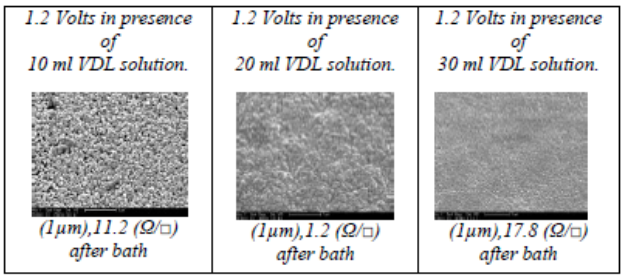
Electrical characterization of electroless Ag plating

The solution with 20 ml of VDL show up better than 10 ml or 30 ml to electrical resistivity as 1.3 or 1.5 (Ω/□) to 1.2V and 1.6V inputting potential when the exposured was 30 seconds. When the samples exposure to 1 minute inputting potential the three type of solution shows up lower electrical resistivity results as 0.7 and 0.4 (Ω/□) since 1.4 , 1.6, 1.8 and 2.0 V. The samples exposure in presence of VG inhibitor reach lower electrical resistivity since 1.2, 1.4, 1.6, 1.8 and 2.0 V inputting potential as 0.9 or 0.7 (Ω/□) not importance the VDL amount were observed.

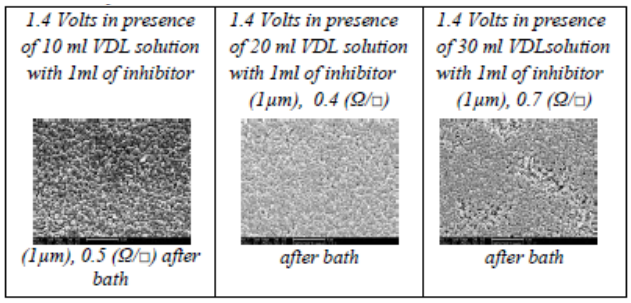
Results and discussion

Most structural investigations were carried out using silver coating types: coatings obtained by fresh electroless plating solution, coating obtained in presence of an accelerator, coatings obtained by electroplating. The thickness of the coatings under inverstigation was approximately 4 μm.

Deposited in a freshly prepared solution in the absence of additives, the simplest conditions; the main part of coating is a uniformly growing layer.



During 30 seconds of exposure to 1.2V in presence of 20 ml VDL type solution reach lower electrical resistivity without inhibitor.



During 1 minute of exposure to 1.4 V in presence of 20 ml VDL type solution reach lower electrical resistivity inhibitor to 30 seconds of bath were the same values to electrical resistivity in presence of 1 ml of inhibitor.

Conclusions

Our investigation sought to obtain the greatest possible number of answer to Ag plating bath which were created patterns of some chemical and physical parameters that have been constant throughout the investigation. The three types of solutions that VDL amount were increase shows up interesting to reducion electrical resistence to range of voltages applied although the values are very close.

The use of inhibitor (1 ml, 1% VG) change the range of voltage applied induce the reduction of electrical resistence, the values are not less after bath plating but were crucial to obtaining homogeneous deposition. In presence of 20 ml of VDL and addition of inhibitor to 30 seconds or 1 minute exposure and 1.2, 1.4 and 1.6.

Synthesis and Characterization of a Ionic Polymers Derived from Disubstituted Acetylenes

Radoslava Sivkova, Dmitrij Bondarev, Jiří Zedník , Jan Sedlaček and Jiří Vohlidal

Department of Physical and Macromolecular Chemistry, Faculty of Science, Charles University in Prague, Hlavova 2030/8, Prague 2, Czech Republic, CZ-12843

r.sivkova@gmail.com

In the last few decades there has been a permanent interest in the investigation of organic conducting and semiconducting polymers for applications in electronics, photonics, nonlinear optics, and related fields. Substituted polyacetylenes, as the fundamental conjugated polymers, belong to the most studied materials of this class.

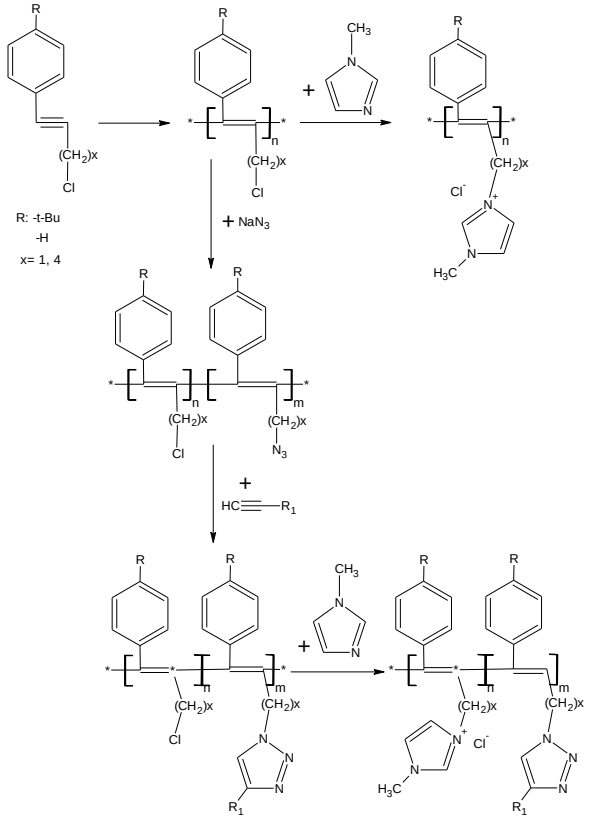
Recently, variety of poly(monosubstituted acetylene)s and poly(disubstituted acetylene)s has been prepared and used in the fields such as liquid crystals, polymeric light-emitting diodes, chemo- and biosensors, gas separation membranes, etc. Poly(disubstituted acetylene)s have become more favorable as they were found to exhibit enhanced resistance to oxidative and thermal degradation.

Polyacetylene-based polyelectrolytes such as poly(propionic)acid, triethylammonium salt of poly(6-bromo-1-hexyne) had been reported. Also a new class of ionic polyacetylenes has been prepared via the activated polymerization of ethynylpyridines with alkyl halides.

In this contribution we report on the synthesis and transformation of several poly(disubstituted acetylene)s containing halogen atom in a pendant group and their modification to ionic polymers.

All monomers were synthesized by the means of Sonogashira coupling. Polymerization was carried out with $TaCl_5$ and $WOCl_4$ catalysts and polymers were purified by repeated precipitation in methanol with the aim to remove the catalytic residua. After careful drying all prepared polymers were characterized by means of SEC and standard spectroscopic methods. The resulting polymers had satisfactory molecular weight characteristics (M_w >50000). These polymers were further modified via two different approaches (i) by quaternization reaction with 1-methylimidazole or (ii) by combination of "click"-modification and quaternization (Fig.1)

The reaction of the parent polymers with 1-methylimidazole was carried out in mixture of methanol and THF for 24 hours at 80°C, then DMSO was added in order to increase the solubility of the polymer in the reaction mixture and the heating was continued for another 24 hours. The resulting product is soluble in polar solvents such as DMSO, acetonitrile and even water.



Scheme 1.: Synthetic route for polyacetylenes

The two step modification was applied as other approach including first transformation of part of the Cl-groups to azido-ones, and following "click" reaction with various terminal triple bond-containing compounds. The resulting modified polymers are still containing free Cl-groups which could be quarternized in the same manner described above.

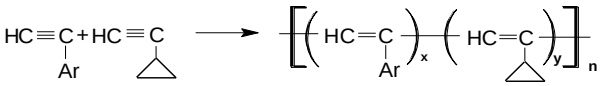
Department of Physical and Macromolecular Chemistry, Faculty of Science, Charles University in Prague, Hlavova 8/2030, CZ-128 40 Prague 2-Albertov, Czech Republic

hankovavladimira@seznam.cz, http:www.natur.cuni.cz/~pm

Cyclopropylacetylene (cPrA) has been homopolymerized and copolymerized with arylacetylenes (phenylacetylene – PhA, 4-biphenylylacetylene – BPhA) into linear polyene-type polymers with cyclopropyl pendant groups (Scheme 1). Coordination polymerization induced with [Rh(NBD)acac] (NBD = norbornadiene) catalyst has been applied (Table 1).



Scheme 1

Table 1: Results of homopolymerization and copolymerization of cPrA with PhA or BPhA on [Rh(NBD)acac]. [cPrA] = 2.4 mol/dm^3, [PhA] = [BPhA] = 0.6 mol/dm^3, [Rh] = 0.024 mol/dm^3. THF, room temperature, 24 h.

Comonomer	Yield (%)	10^{-3} M_w	cPrA units in copolymer (mole%)
-	10	6	100
PhA	24	27	49
BPhA	30	30	55

Table 2: Results of homopolymerization and copolymerization of cPrA with PhA on [Rh(NBD)acac] performed in bulk. [cPrA] = 12 mol/dm^3, [PhA] = 0.6 mol/dm^3, [Rh] = 0.024 mol/dm^3. Room temperature, 24 h.

Comonomer	Yield (%)	10^{-3} M_w	cPrA units in copolymer (mole%)
-	20	11	100
PhA	19	18	87

Various Rh(I) complexes (mainly of the $[Rh(diene)Cl]_2$ type) are well known as active catalysts of polymerization of monoaryacetylenes. In the case of alkyacetylenes either no or only very low polymerization activity of these complexes is being reported. Nevertheless, we succeeded in achievement polymer yields up to 30% (M_w up to 30 000) in homo- and copolymerization of cPrA. Applied catalyst, [Rh(NBD)acac], seems to be appropriate for this kind of polymerization since it does not require any cocatalyst for the activation and can be thus applied also in bulk polymerizations. Particularly, in bulk conditions the enhanced activity of [Rh(NBD)acac] was observed (TON values up to 100, Table 2). The activation of [Rh(NBD)acac] proceeds via acac-ligand liberation in the form of acetylacetone as we reported in [1].

We believe that by a proper optimization of cPrA polymerization systems (example given in Table 3) a broader variability in comonomeric composition can be achieved besides the enhancement of the yield and MW characteristics of products.

Table 3: Results of copolymerization of cPrA with PhA on [Rh(NBD)acac] of various concentration. [cPrA] = 2.4 mol/dm^3, [PhA] = 0.6 mol/dm^3. THF, room temperature, 24 h.

[Rh] in mmol/dm^3	Yield (%)	10^{-3} M_w	cPrA units in copolymer (mole%)
6	13	24	45
24	24	27	49
72	34	20	67

The thermal treatment (250° C, vacuum) of soluble cPr groups containing copolymers resulted in their crosslinking and gave rise to insoluble dark red powder products. The crosslinking proceeded via reaction of cPr pendants as indicated by IR spectroscopy. Research on the preparation, characterization and functional testing of this kind of conjugated polymer networks is now in progress in our laboratory.

The studies of polymer nanocomposites based on thermoplastics and binary conductive nanofillers

V. Levchenko [1,2], Ye. Mamunya [1], G. Boiteux [2], E. Beyou [2], P. Alcouffe [2], E. Lebedev[1]

beyou@univ-lyon1.fr

Nowadays the conductive nanofillers, such as carbon nanotubes (CNT) [1,2] or metal nanoparticles (MNP) [3], are widely used as conductive component for imparting the electrical conductivity and improving thermal conductivity of bulk polymers. Electrical characteristics of composites containing the conductive filler change dramatically when the filler content reaches a critical concentration, commonly known as a percolation threshold. The electrical properties of such conductive polymer composites depend on many reasons, namely the content, shape, size, spatial distribution, interaction with polymer matrix of fillers.

One can assume that combination of two types of the fillers (CNT and MNP), where fillers are interact between each other [4] or MNP decorated on CNT surface [5,6], enables to integrate their properties and even to gain the enhancement of characteristics owing to the mutual influence. To justify such an effect there were chosen the multi-walled carbon nanotubes (MWCNT) with the aspect ratio $l/d \approx 1000$ and nickel (Ni) nanoparticles with average size 60 nm in diameter as the fillers for polypropylene (PP) matrix. Direct current (DC) conductivity σ_{DC} of the PP/MWCNT, PP/Ni and PP/Ni/MWCNT composites as a function of the filler volume content was investigated by two-electrode method.

The PP/MWCNT composites due to high aspect ratio of the nanotubes reveal a low value of the percolation threshold, namely φ_c=0.7 vol.% (curve 2 on Fig.1), whereas the PP/Ni composites are nonconductive within the whole investigated range of filler content (up to 7.5 vol.%) (curve 3). The latter effect can be explained by spherical shape of Ni particles and the presence of polymer-metal interaction. The composites with binary Ni/MWCNT filler revealed a strong effect of enhancement of the DC conductivity. For all PP/Ni/MWCNT composites content of Ni filler was constant and equal to 2.5 vol.%, while content of MWCNT varied. In this case the value of percolation threshold of the PP/2.5%Ni/MWCNT composites decreases sharply and is equal to 0.2 vol.% (curve 1), i.e. it is more than three times lower in comparison with PP/MWCNT composites. Such shift of the percolation threshold to lower content of conductive filler MWCNT can be explained by the presence of bridging effect. Long carbon nanotubes can connect the Ni particles or Ni aggregates and form more conductive pathways in composites. Evidently, in this case considerably lower content of nanotubes is necessary to provide the appearance of conductivity, that results in the shift of the percolation threshold.

DSC results showed that addition of nanotubes into the polymer matrix provides shift of the crystallization peak from 114 °C for pure PP to 127 °C for the composite with 1.5 vol.% of MWCNTs that indicates nucleating action of MWCNTs. Adding of Ni particles into PP/MWCNT composites does not shift the crystallization peak maximum, i.e. the presence of Ni particles does not affect crystallization processes in PP that contains nanotubes. The crystallization behavior was found to be the same for both PP/MWCNT and PP/Ni/MWCNT composites, thus, the percolation threshold reducing caused solely by the bridging effect.

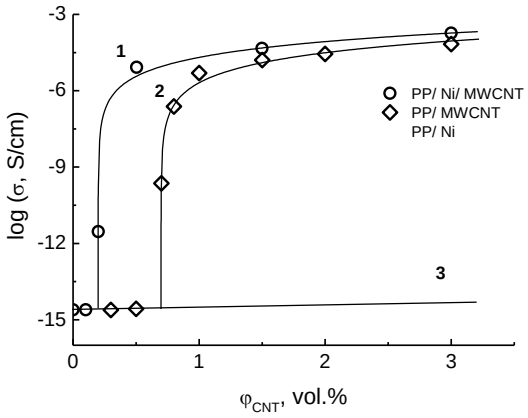

Fig. 1. DC conductivity of the PP/2.5%Ni/MWCNT (1), PP/MWCNT (2) and PP/Ni (3) composites depending on the MWCNT content.

Synthesis and Complexation Properties of Terpyridine Derivatives: Building of Supramolecular Polymers

Tereza Vitvarova, Jiri Zednik, Pavla Stenclova, Jiri Vohlidal and Jan Svoboda

Department of Physical and Macromolecular Chemistry, Charles University in Prague, Faculty of Science, Hlavova 2030, CZ-128 40, Prague 2, Czech Republic

tereza.vitvarova@seznam.cz

Supramolecular polymers are polymers consisted of molecular building blocks, which are connected together by non-covalent intermolecular interactions. The length of their chain depends mainly on stability and character of that interaction. In coordination (or metallo-supramolecular) polymers, the interaction is realized between metal and ligand. Right choice of metal and ligand is the key to obtain polymer with demanding properties. By these we can tune for example magnetic properties, conductivity (thermal or electric). The most important property of complex, which can be used as building block for supramolecular polymers, is stability. One of the most suitable ligands is 2, 2‘: 6’, 2‘‘-terpyridine because of his high affinity to transitive metals and his octahedral geometry (reduced possibility of creating enantiomers). Terpyridine is easy to obtain and it’s not so hard to functionalize it. With different substituents we can expect different stability and also chemical properties (solubility, polarity).

Two terpyridines with thienyl and ethynyl substituent as a model compounds of bis(terpyridines) with all-conjugated bridge were prepared. Reaction with various metals was studied using methods of UV-VIS, photoluminescence and NMR spectroscopy. By these techniques we can observe the complexation and we are also able to calculate the stability constant. Kinetic of complexation was studied using 2D-NMR spectroscopy..

Alkali metal halogenoacetates lead to polyglycolide upon heating at temperatures higher than 100 ºC by a polycondensation reaction that has the formation of a metal halide salt as the driving force of the process. Thus, the reaction conduces to micrometer-sized metal halide crystals dispersed in a matrix of polyglycolide.[1] Despite the advantages derived from the simplicity of this method, its application is hindered due to the limited molecular weight that can be reached as a consequence of secondary reactions and thermal decomposition at the high temperatures required for the progress of the reaction. However, this method was successfully applied to get poly(ester amide)s constituted by an alternating sequence of glycolic acid and ω-amino acid units,[2] whose synthesis was previously proposed in base of high time consuming methods which involved selective protection and deprotection of reactive groups.

New monomers were easily synthesized, in this case, by the reaction of chloroacetyl chloride with the appropriated ω-amino acid and by a subsequent neutralization with the selected metal hydroxide. The proposed synthesis rendered high molecular weight samples when ω-amino acids had high methylene content (i.e. 6-aminohexanoic, 11-aminoundecanoic and 12-aminododecanoic acid derivatives). Polymerizations could take place in the solid phase, the liquefied phase, or both phases, depending on the number of methylene groups and the kind of salt. In fact, these two conditioning factors had an influence on the melting point of the monomer, which can be either higher or lower than the reaction temperature.

Copolymerization of chloroacetate (MGL) with a *N*-chloroacetyl-ω-aminoalkanoate is also an interesting topic since may render random copoly(ester amide)s with tuneable properties as a consequence of the control on the ester/amide ratio. This work is specifically focused into the study of the copolymerization with the 6-aminohexanoic acid derivative (MEA) (Figure 1). In order to favour copolymerization potassium salts were selected due to the low reactivity difference between the two involved monomers. Polymerization kinetics of different MGL/MEA mixtures was evaluated by the FTIR in-situ technique (Figure 2) since it is sensitive to formation and destruction of chemical bonds (e.g. carboxylate groups of the ester and the salt compounds). Calorimetric and spectroscopic observations indicated that polymerization proceeded faster when each monomer was mixed with the corresponding comonomer (Figure 3). The deduced Arrhenius parameters showed a decrease on the activation energy of the monomer mixtures respect to the neat monomers.

Calorimetric, thermogravimetric, chromatographic and NMR spectroscopic techniques were also applied to control polymerization and characterize the final reaction products. In general, promising results can be attained when reaction is performed with MEA content higher than 50%.

Introduction

The industrial production of aqueous polyurethane dispersions (PUDs) is nowadays a well established technology. There are two main synthetic routes to produce PUDs: the acetone process (a former process developed by Bayer AG) and the pre-polymer process (developed as an alternative response to the patented acetone process). Comparatively to the acetone process, the pre-polymer process has one major advantage since it requires none or only small amounts of acetone.

The pre-polymer process, at present, is being forced to readapt due to ongoing developments, partly motivated by process constraints, raw materials restrictions and the need to obtain a true solvent-free product. Allied to this fact it is worth mentioning the European REACH legislation, which is having a considerable influence on the PUD industry.

Most of the industrially produced PUDs use dimethylol propionic acid (DMPA) as the internal emulsifier. DMPA is sparingly soluble in the reactive mixture and needs to be previously dissolved in an organic solvent, usually N-methyl-2-pyrrolidone (NMP). NMP is difficult to remove and will remain in the final product.

There are some alternatives to achieve the NMP-free concept. Among them we can refer the direct NMP replacement by an equivalent solvent, the DMPA replacement by an equivalent hydrophilising diol but with better solubility in the reactive mixture and the pre-neutralization of DMPA prior to reaction with isocyanates [1, 2].

Materials and methods

In this work we present a modified pre-polymer process that includes four main stages: (1) Pre-polymer synthesis, (2) Pre-polymer dispersion, (3) Chain extension and (4) Co-solvent removal, as described in Figure 1. Comparatively to the conventional pre-polymer process the hydrophilising diol was used in its salt form, i.e., after neutralization with a tertiary amine. The chemical system comprises a polyetherdiol (polytetramethylene glycol (PTMG) or polypropylene glycol (PPG)), an isocyanate (isophorone diisocyanate (IPDI)), a hydrophilising diol (DMPA), a neutralizing amine (triethylamine (TEA)), a chain extension agent (ethylenediamina (EDA) diethylenetriamine (DETA) or hydrazine monohydrate (HYD)), a catalyst (stannous octoate – SO) and acetone as the co-solvent for the DMPA salt solubilisation.

The obtained dispersions have been characterized in terms of pH, viscosity, solid content, particle size and stability (thermal and electrolyte presence).

Several samples have been synthesized and compared with a base formulation produced by the conventional pre-polymer process.

Results and conclusions

In this work it has been shown that the use of DMPA in its salt form can provide a way to readapt, with minor modifications, the conventional pre-polymer process to produce dispersions in accordance with the present PUD market requirements (NMP-free). By substituting DMPA through its salt form, NMP can be directly replaced by acetone that provides the possibility to obtain solvent free dispersions since acetone will be easily removed at the end of the synthesis and could be further recycled and reused in the process. Additionally, the developed process was facilitated in what concerns the pre-polymer dispersion stage and chain extension effectiveness. Table 1 shows the comparison between samples produced by the two processes.

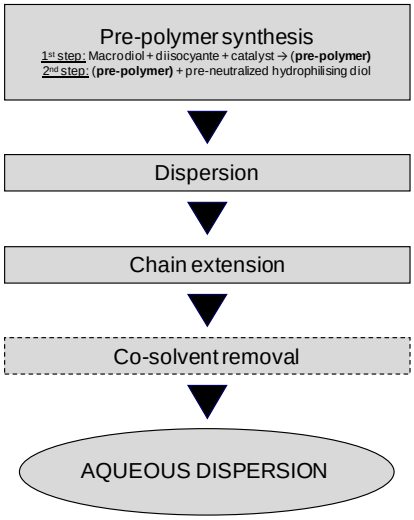

Figure 1. Schematic drawing of the modified pre-polymer process.

Table 1. Dispersion properties obtained by the conventional (A) and the modified (B) processes.

Process	pH	Solid content %(w/w)	Particle size(*) (nm)	Viscosity (mPa.s)

Introduction.

Over the last few decades, hydrogels have attracted considerable attention as biomaterials in the biochemical and biomedical fields. One of the most promising polysaccharides to design such biocompatible matrices promoting cell adhesion and growth is hyaluronan (HA). This linear anionic polymer has important biological properties but also unique viscoelastic properties in aqueous solution.[1] For some time now, we have performed alkylation of hyaluronan, allowing the formation of original physical gels in aqueous solution.[2] The gelation properties were related to the length of the grafted alkyl chains as well as to the density of grafting, but also to polymer and external salt concentration.

Furthermore, reversible hydrogels that can be formed in situ by phase transition (sol-gel transition) in response to a temperature change have become increasingly important because of their potential applications in non-invasive techniques.

Thus, by replacing hydrophobic alkyl chains by a thermosensitive polymer, as it was done on chitosan in previous work [3], it may be possible to control gelation with the temperature. Such a property can facilitate injections. In these systems, the formation of physical junctions required for gelation is generally due to the association of the grafted thermosensitive groups possessing a Lower Critical Solution Temperature (LCST) in aqueous solution. In this context, we grafted thermosensitive polyether groups on HA, consisting of Jeffamine® (or POEP) chains having a LCST close to 32 °C, i.e. near the body temperature.

In this presentation, the gelation properties as a function of environmental conditions and structural parameters of these new hydrogels will be discussed. Then, these properties will be compared to those of alkylated HA derivatives.

Moreover, preliminary studies on cell adhesion and growth within these both physical gels will be developed.

Materials and Methods.

Materials. The hyaluronan used was from A.R.D (Pomacle, France); two batches of a weight-average molecular weight M_w 200 000 g/mol and M_w 700 000 g/mol. POEP was obtained from Texaco Chemical (Austin, Texas, USA) and all other chemicals were purchased from Fluka (Buchs, Switzerland).

^{1}H NMR spectroscopy. Polymers dissolved in D_2O were characterized on a Bruker DRX400 spectrometer operating at 400 MHz.

Rheological experiments. Dynamic experiments were performed with a cone-plate rheometer (AR 2000 from TA Instruments). A cone with a diameter of 4 cm and an angle of 4° was used. Experiments were carried out with a film of silicone to avoid solvent evaporation. All the dynamic rheological data were checked as a function of strain amplitude to ensure that the measurements were performed in the linear viscoelastic region. The solutions of hyaluronan derivatives were prepared by dissolving them in PBS 1X buffer.

Results and Discussion.

According to previous works, alkylation of hyaluronan showed interesting thickening properties in aqueous solution, which were more important using a shorter hyaluronan.[4] By replacing the hydrophobic alkyl chains by chains of a thermoresponsive random copolymer of PEO and PPO (POEP), we obtained new derivatives exhibiting a remarkable thermogelling behaviour.

The resulting Jeffamine®-hyaluronan derivatives obtained have been perfectly characterized by ^{1}H NMR spectroscopy. The dependence of the elastic and viscous moduli as a function of temperature was obtained by dynamic rheology, as well as the study of the reversibility of these systems. Multiwave rheological experiments allowed us to define precisely the phase- transition temperature (or critical temperature).

The phase transition was shown to depend on the length of the hyaluronan chain, having a critical temperature closer to body temperature using a 700 000 g/mol hyaluronan instead of a 200 000 g/mol one. Furthermore, contrary to alkylated HA, better gelation properties were observed for the HA-POEP derivatives using a 700 000 g/mol hyaluronan, of which elastic moduli were significantly higher than those of alkylated HA derivatives.

As the preliminary studies on cell adhesion and growth are underway, the results obtained will be developed during the presentation.

Conclusion and perspectives.

Based on the interesting thermogelling properties of the HA derivatives, we plan to improve their synthesis methodology. This in particular will allow us to investigate deeply the potential of the thermoreversible gels as biomimetic substrates for the growth of various cell types.

Introduction

The supramolecular assemblies based on polymers modified by cyclodextrins (CDs) and/or hydrophobic guest molecules have inspired interesting developments in the biomedical, pharmaceutical and cosmetic fields. Over the last ten years, several works have thus been dedicated to the development of hydrogels, nano/microparticles, nano/microcapsules and thin films. In this context, we have been interested since several years in developing supramolecular assemblies taking advantage of the specific properties of natural polysaccharides. Chitosan (CHI) and hyaluronic acid (HA) were thus selectively modified by β-CD and adamantane (AD), leading to "guest" and "host" polysaccharides.[1,2] Interesting thickening properties or transparent gel formation due to the multivalent complexation between polysaccharide chains were observed in aqueous solution. In the next step, we extended the formation of such assemblies on surfaces. Multilayers based on host-guest complexation were prepared from the alternate deposition of chitosan derivatives bearing either β-CD or hydrophobic guest molecules, on a planar surface functionalized by guest molecules.[3] Such "host-guest" assemblies may be sensitive to various stimuli which can act either on the electrostatic interactions between the polymer chains or on the host-guest complexes stabilizing the multilayers. In this presentation, we will describe our recent studies aimed at better understanding the build-up of such multilayer assemblies and investigate their sensitivity to electrochemical stimuli.

Materials and Methods

Materials. Chitosan Protasan was provided by FMC BioPolymer AS, Novamatrix (Norway). Hyaluronic acid was kindly provided by ARD (France). β-Cyclodextrin (β-CD) was kindly supplied by Roquette Frères (France). All other chemicals were purchased from Sigma-Aldrich-Fluka. β-CD monoalkyne was synthesized from a β-CD monocarboxylic acid derivative as reported previously.[4]

Synthesis of host and guest polysaccharides. The covalent grafting of β-CD and ferrocene (Fc) molecules on the polysaccharides was performed according to procedures described previously.[1,2]

SAM-coated gold electrodes. Self-assembled monolayers (SAMs) of β-CD were prepared by a "click" reaction between the β-CD monoalkyne derivative and azide groups exhibited by SAM as reported previously.[4]

E-QCM-D. Combination of electrochemical and QCM-D measurements was performed using electrochemical QCM-D module (Q-Sense, Sweden), connected with CHI 440 potentiostat (CH-Instruments, Inc., USA).[4]

Results and Discussion

In this work, we investigated several assemblies of host and guest polysaccharides. Taking advantage that complexation between Fc and β-CD is strongly diminished upon electrochemical conversion of Fc to the ferrocenium cation, we functionalized polysaccharides with Fc moieties to make them "electroactive". Moreover, as the number of effective layer-by-layer deposition cycles seems to be strongly dependent on electrostatic repulsions between the layers,[5] we prepared neutral, positively charged and negatively charged polysaccharide derivatives starting from chitosan, hyaluronic acid and dextran.

Having the polymers in hands, we first verified the ability to detach a guest polysaccharide layer on a host surface in response to the electrochemical oxidation of the Fc groups. QCM-D monitoring of detachment process coupled with CV showed that all specifically attached Fc-grafted polymer can be irreversibly released from SAM-β-CD-coated gold surface by applying oxidizing potential. Next, we examined the stepwise construction of multilayer thin films based on host-guest interactions between Fc- and β-CD-functionnalized neutral or charged polysaccharides The multilayer build-up was indeed found to be strongly limited when charged host and guest polysaccharides were assembled.

Conclusion

In summary, the present work establishes the possibility to control the multilayer assembly driving force by switching the redox state of Fc guests grafted on polysaccharides. This appoach offers new opportunities for building at the nanoscale stimuli-responsive films with potential applications in the field of nanobiotechnologies.

Introduction

Control of the morphology, as well as the modulation of the electronic properties, are of utmost importance, in order to provide materials that can meet the prerequisites for application in molecular electronics. Despite the fact that significant improvements on the polymeric electron donors have been made during the last years, the morphology control and the development of proper polymeric electron acceptor remain a challenge. The most efficient electron accepting materials used so far in OPVs are based on modified fullerene species. However, further improvement is needed in order to achieve more efficient separation and transport of the separated charges to the respective electrodes. Attempts to this direction have been made either by influencing the miscibility between the donor and acceptor phases of by the development of more efficient electron donor or acceptor materials. In the case of the acceptors, and since polyquinolines are one of the most promising classes of electron accepting and transporting polymers[1], their combination with other electron active materials is expected to provide new materials with ideal characteristics for use in OPVs.[2,3] Moreover, the modification of the quinoline monomers with electron withdrawing groups can be a simple way to control the electronic properties of the final materials.

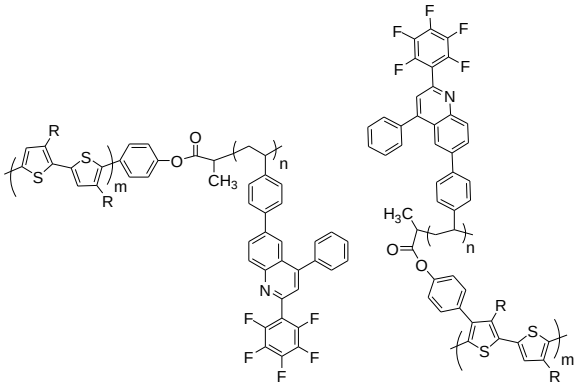
Results & Discussion

In our approach to develop polymeric or hybrid electron acceptors, we have used vinyl quinoline derivatives with different substituents.[1a,3] These materials have been combined with typical polymeric electron donor materials like polythiophene after proper modification in order to develop efficient electron donor-acceptor interphases, *Scheme 1*.

Starting from the modification of quinoline with various electron withdrawing groups, we then synthesized vinyl monomers based on modified quinolines applicable in controlled or free radical polymerizations. Thus we were able to synthesize homopolymers that can be used as electron accepting phases in OPVs since their LUMO level is as low as 3,65 eV.[3]

An additional advantage offered by these quinoline monomers is that they can be easily used in the preparation of more complex polymeric architectures. For example block or brush type rod-coil copolymers can be synthesized employing various properly modified rigid macromolecular entities acting as initiators. As rigid blocks we have selected well established and extensively used as polymeric donors regioregular poly(thiophene)s. Another exceptional case has been their combination with different carbon nanostructures leading to electron accepting hybrid materials.[3] The same approach has also been employed for the preparation of polymer electron donor carbon-based electron accepting hybrid materials.[4]

For the different copolymer architectures like block or brush-type copolymers the influence of the detailed polymeric architecture on the organization behaviour and subsequent phase separation phenomena has been examined.



Scheme 1. Block and Brush-type copolymers of *rr*-poly(thiophene) and poly(vinyl-perfluorophenyl-quinoline).

Introduction:

The presence of high concentrations of chromium in the wastewater is of concern due to the toxicity of this metal ion. Several processes are used to reduce chromium discharge by industry, ultrafiltration combined with water-soluble polymers has been shown to be a useful process for removing metal ions from pollutant wastewaters. In this work, a series of water soluble linear and hyperbranched (HBP) copolymers were synthesized via addition–fragmentation chain transfer polymerization (RAFT), by copolymerization of di(ethyleneglycol) methacrylate (DEGMA), oligo (ethyleneglycol) methacrylate (OEGMA) and ethyleneglycol dimethacrylate (EGDMA) used as crosslinker. The polymers were characterized by analysis of Gel Permeation Chromatography (GPC) and Nuclear Magnetic Resonance (RMN). The lower critical solution temperature (LCST) has been studied by UV-VIS spectroscopy and dynamic light scattering. Due to the properties of these polymers in solution they may be applied in the remediation of contaminated waters, and their capacity of adsorption of chrome has been studied.

Methods:

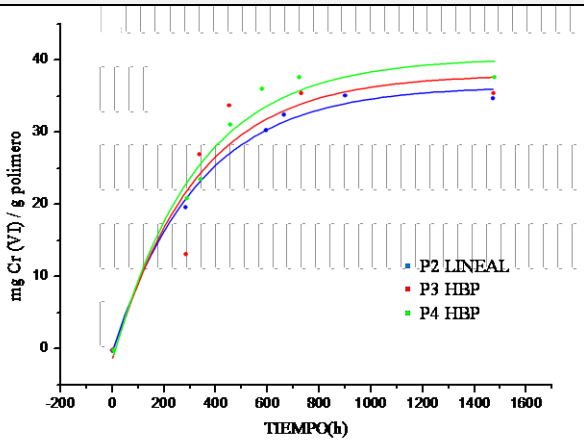
Normalized method for chromium (VI) determination.
The colorimetric method to determine chromium hexavalent[4] was used to know the concentration of chromium in solution. A calibration curve was done before the determination. Dissolved hexavalent chromium may be determined colorimetrically by reaction with diphenylcarbazide in acid solution. The reaction is very sensitive. Addition of an excess of diphenylcarbazide yields the red-violet product, and its absorbance is measured photometrically at 540nm.

Analysis of adsorption of chromium.
To determine the adsorption capacity dialysis experiments were performed.
A dialysis bag (MWCO = 6000-8000 Da) containing 6 mL of the polymer solution was sealed and immersed in ultra pure water solution (70 mL, pH 7) at 45 ºC in a thermostatically controlled oven. The copolymer concentration was 5 g/l for all the polymers, lineal and hyperbranched. Aliquots of 1 mL were withdrawn from the solution periodically. The volume of the solution was held constant by adding 1 mL fresh ultra pure water solution after each sampling to ensure sink conditions. The amount of chromium adsorbed by polymers was determined by a normalized method for chromium (VI) determination.

Results and Discussion:

As it is shown in the figure, the adsorption capacity for chromium (VI) was studied for the different polymers. Hyperbranched polymers adsorb more chromium (VI) than the linear polymer. That is because of the structure of the polymers, hyperbranched polymers form a network with nanocavities where the chromium can adsorb. Hyperbranched polymer with higher ratio of OEGMA/DEGMA is more efficient as adsorbent because there are more ethylene glycol side chains for adsorbing contaminant.

Polymer	%DEGMA[a]	%OEGMA[a]	%EGDMA[a]	LCST[b]
P 2 Lin.	74.4	25.6	-	56.6
P 3 HBP	84.6	12.2	3.2	40.3
P 4 HBP	72.7	23.7	3.6	53.4



Conclusions

In this study, a series of linear and hyperbranched copolymers based in ethylene glycol methacrylate has been synthesized. It was determined its lower critical solution temperature and its capacity for the removal of chromium (VI) from aqueous solution. The values of chromium captured are close to 40 mg per gram of polymer, which means that these polymers could be used as an effective adsorbent[5].

Introduction: The acronym TEXs defines the mixture formed by toluene, ethylbenzene and the three xylene isomers (*o*-, *m*- and *p*- xylene). These compounds are widely used as solvents and raw materials in many industries and are present in many petroleum derivatives. Therefore, for public health reasons, it is necessary the monitoring of these contaminants in situ and in real time through the use of chemical sensors.

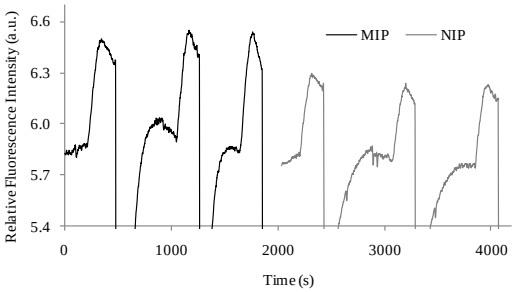
Molecularly imprinted polymers (MIPs) are made by synthesizing highly cross-linked polymers in the presence of "printing" molecules (templates). After removal of the template, the polymer can be used as a selective medium for the template molecule and structurally related compounds. The use of MIPs as optically active surfaces has proved to provide highly selective molecular recognition properties and some excellent physical–chemical and mechanical properties in the design of optosensors. This work describes the use of the semiempirical model[1] proposed by our research group for the synthesis and optimization of a toluene-imprinted polymer and its implementation in a luminescent optosensor for screening TEXs in drinking water.

Materials and Methods: The optimum MIP was prepared in a closed vial by mixing MMA and EDMA (80:20 mol% for a total number of moles of 0.0123) with 13.7 mg AIBN, which was used as radical initiator, 0.783 mL of toluene (molar fraction 0.18) which was used as template molecule, and 2.717 mL of chloroform (molar fraction 0.82). The polymerization was undertaken in an 80 ºC oil bath heated under a nitrogen flow. Non-imprinted polymer (NIP) for use as control was prepared and treated in the same manner.

A flow injection analysis (FIA) system was used for the analytical evaluation of the polymers. The luminescence measurements were developed at $\lambda_{exc/em}$ = 260/284 nm.

Results and Discussion: MIP/NIP ratio was the criterion used to evaluate the imprinting properties of the polymers. The synthesis and the optimization of the MIP were achieved evaluating the following chemical variables: polymer composition (80% MMA, 20% EDMA), solvent (chloroform), molar fraction of toluene (0.18), total reaction volume (3.5 mL) and reaction temperature (80 ºC). Fig. 1 shows the optimum fiagrams when 500 µg L^{-1} of toluene were injected into the flow system using MIP and NIP as sensing materials. The instrumental parameters as detector voltage (700 V) and excitation and emission slit widths (4/4 nm) were also optimized. Lastly, the flow injection variables: flow-rate (1.5 mL/min) and injection volume (2.0 mL) and the presence of organic solvent (absence), pH (7.0) and ionic strength (NaCl 1.0 M) were evaluated. The adjustment of the water samples at pH 11.0 eliminated the possibility of interferences.

Fig. 1. Response of the MIP (black line) and NIP (grey line).



Ethylbenzene was selected as representative compound of TEXs for the establishment of the cut-off level because it provided the lowest signal. The cut-off level selected was established by the maximum contaminant level (MCL) of US-EPA in 700 µg/L. The reliability of the screening test was determined by the percentage of false positives (32%) and false negatives (0%) for a total of 50 samples. To demonstrate its applicability, 15 real water samples were analyzed obtaining 20% false positives and 0% false negatives.

Conclusions: A molecularly imprinted polymer was developed successfully for the TEXs compounds. The MIP/NIP ratio obtained for this type of compounds was acceptable. Response times were short and the reproducibility and repeatability obtained with the MIP was high. The elimination of interferences was performed with the adjustment of the water samples at pH 11.0. The optosensor, which was made up of the synthesized MIP, was used to develop a screening test. The test has been successfully used in the determination of TEXs in drinking water, and it could be an important alternative for using in routine laboratories.

Synthesis and Properties of Aromatic Poly(disubstituted acetylene)s

Jiří Zedník, Zuzana Duchoslavová, Jan Svoboda, Radoslava Sivkova, Vladimíra Hanková, Jan Sedlaček, David Vrbata and Jiří Vohlidal

Dpt. of Physical and Macromolecular Chemistry, Faculty of Science, Charles University in Prague, Hlavova 2030/8, Prague 2, Czech Republic, CZ-12843

jzednik@centrum.cz

Introduction

Conjugated polymers attract great attention of polymer chemists in last few decades due to their unique properties which pave the way to new interesting application of those materials in new fields of modern research, e.g. photovoltaic cells, light-emitting diodes, field effect transistor etc. Poly(disubstituted acetylene)s belong to this interesting family of materials. Compared to their monosubstituted derivatives they exhibit strongly improved oxidative and thermal stability.

Materials and Methods

In this contribution we report synthesis of mostly new disubstituted acetylene based monomers (see Fig.1)

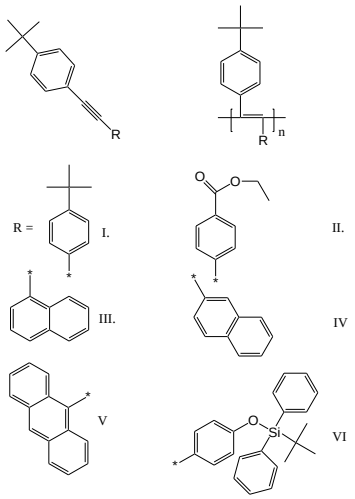

Figure 1. Synthesized monomers and polymers

All monomers were synthesized by the means of standard palladium catalyzed Sonogashira coupling using 4-*t*-butylphenylacetylene as acetylene bearing moiety, appropriate bromo/iodo derivatives and the piperidine as the solvent and base. After the purification by the column chromatography/crystallization all monomers were characterized by the means of standard spectroscopic methods. Also the luminescence properties of the prepared monomers have been studied. For better understanding of experimentally measured UV/vis and luminescence spectra TD-DFT calculation using Gaussian software has been performed.

Prepared monomers were polymerized using the metathesis catalyst based on $TaCl_5/SnPh_4$/toluene using the inert schlenk/glovebox technique. All polymers were purified by repeating dissolving in toluene and precipitation to methanol with a scope to get rid off the catalytic residua. After careful drying all prepared polymers were characterized by means of GPC and standard spectral methods. Also the luminescence study by the means of the time resolved and steady state fluorescence spectroscopy has been done.

Results and discussion

All monomers were prepared in moderate to good yield. Except for the monomer V, monomers do not exhibit absorbance in visible region. Yellowish cast of the monomer V is caused by the extended conjugation through the anthracene condensed aromatic ring. UV/vis spectra of monomers III and IV appear very similar, only the electronic transitions for monomer III are shifted to lower energies. Concerning the luminescence properties: Monomer I and and VI are not fluorescent. Monomer II shows only low quantum fluorescence yield (6 %). Monomers III and monomer IV exhibit very similar luminescence properties (quantum fluorescence yield around 30%). Monomer V exhibits high fluorescence yield (around 60 %) Measured trends in obtained spectra are in good agreement with TD-DFT calculation.

Polymers I and II are insoluble in common solvents. Insolubility of polymer I could be explained probably by the extended symmetry of resulting polymeric chains, which could lead to the enhanced regularity of packing of chains in the solid state. The insolubility of polymer II is caused by the loss of protective ethyl ester group which accompany the polymerization/isolation process. This fact has been proved by the means of NMR spectroscopy. Polymer III is red and non-fluorescent (MW around 10 000 and polymer yield 16 %). Polymer IV is yellow and highly fluorescent (MW around 50 000 and polymer yield 50 %). Consequently the sterical hindrance of 1- or 2- naphtyl pendant group causes dramatic change in the monomers reactivity and resulting polymer properties. Trials to polymerize monomer V ends up only with low molecular weight oligomers (dimers/trimers). Copolymerization of monomer V with monomer IV leads to decrease of the resulting polymer yield and molecular weight. However the yield of polymer VI is only moderate (19 %) the resulting polymer exhibits high MW (200 000) and very interesting luminescence properties. Contrary to the fact, that starting monomer is not fluorescent; prepared polymer exhibits quantum fluorescence yield around 70%. After deprotection, post-polymerization modification could be applied which paves the way for further improvement of polymer properties.

Composite Polymer Materials for Stabilization of Washing Liquid of Oil and Gas Wells

Negmatova K.S., Sobirov B.B., Negmatov S.S. Isakov Sh.S., Kobilov N.S., *Negmatova M.I., Haydarov J.M.*

Tashkent State Technology University, State unitary enterprises "Fan va Taraqqiyot", Tashkent, Uzbekistan

email: polycomft2005@rambler.ru

Introduction. For high-quality drilling oil and gas wells it is required effective drilling fluids, and their quality depends on the used chemicals.

Existing chemicals both domestic and foreign manufacturers, such as the carboxymethylcellulose, K-4, K-9, hydrolyzed polyacrylonitrile, NaOH, CaC03, sulphanol, graphite, and others, which are costly and many of them are imported to Uzbekistan from abroad. Of these the most widely used and imported in large quantities, is the chemical reagent carboxymethylcellulose. However, these reagents do not always meet those requirements that apply to reagents used in complicated geological technical conditions of Uzbekistan.

In this regard, in a number of years scientific and pedagogical staff of State Unitary Enterprise "Fan va Taraqqiyot in conjunction with research staff of the Central Experimental firm "MEF", OOO "Kompozit" and OOO "Mehanokimiyo Tehnologiya" conducted research to develop effective composite polymeric reagents, using local and secondary natural resources of the country.

Materials and methods. In the development of composite polymer materials for the stabilization of drilling fluids used in drilling oil wells, we used mainly waste oil and fat production - gossypol resin, as well as carboxymethylcellulose, polyacrylamide, and the production of nitrogen fertilizers nedopal (waste based fertilizer). Gossypol resin consists of 52 to 64% of free fatty acids and their derivatives, and the rest - a product of condensation and polymerization of gossypol and its transformation, resulting from the extraction of cottonseed oil, mainly in the process of distillation of fatty acids from soapstok. In the gossypol resin found 12% of the nitrogen-containing compounds, 36% of the transformation products of gossypol fatty and oxidefatty acids. It is a homogeneous fluid mass from dark brown to black color [1]. Regarding nedopal it formed in process of cleaning of produced water of nitrogen fertilizers production from such salts, as NaCl, KCl, $CaCl_2$, Mg, Cl_2 and others. Wastes, called nedopal, with humidity 50-60% consist of $CaCO_3$, $MgCO_3$, $Ca(OH)_2$, NaOH and cation compounds KCOO Na, KCOOK [2].

It should be noted that gossypol resin before use has been previously transformed into a powder by physical and chemical processing [3, 4]. Nedopal was previously released and crushed to particle size of not more than 0,02 mm. All of these and other components in the ratio according to the developed formulations were mixed in a mixer with a z-shaped blade until smooth. To determine the physical and chemical properties of drilling fluids on the basis of the developed composite polymer chemicals samples were selected in sufficient amount to conduct a comprehensive analysis and prepare drilling fluids. By adjusting the ratio of the components included in the formula drilling fluids with appropriate technological properties were obtained. Physico-chemical properties of solutions were determined according to existing state standards.

Results and discussions. The table shows the physical and chemical properties of drilling fluids on the basis of the developed composite polymeric reagents.

1. M	2. Technological parameters				
ark of multiphase	3. ensity	4. isco-	5. ater	6. Crust-	7. H
8. C	9.	10. 3	11.	12.	13.
14. C	15.	16. 4	17.	18.	19.
20. C	21.	22. 4	23.	24.	25.
26. C	27.	28. 6	29.	30.	31.
32. C	33.	34. 8	35.	36.	37.
38. C	39.	40. 1	41.	42.	43.

As can be seen from the data muds have different physic-chemical parameters.

In this regard, drilling muds, prepared on the basis of composite chemicals CPM-1-1, CPM-1-2, a density from 0,80 to 0,95 g/cm3 recommended for use in drilling oil and gas wells, where the reservoir pressure below the hydrostatic and drilling fluids on the basis of CPM-2-1, CPM-2-2, having a density from 1.04 to 1.50 g/cm3 with an average hydrostatic formation pressure. Drilling fluids based on CPM-3-1 and CPM-3-2 having a density from 2.05 to 2,25 g/cm3 recommended for use in drilling wells under high reservoir pressures.

Conclusions. Thus, based on obtained results of research, we can say that by selecting appropriate ingredients and adjusting their ratio, we can obtain effective composite materials, like chemical reagents for stabilization of flushing water, used in drilling of oil wells.

Introduction. In the development of composite polymeric materials the most important is the choice of material and fillers. The choice is made by taking into account the purpose of the material: for anti-friction material – it is a low coefficient of friction with raw cotton in various operating conditions, for wear-resistant material - minimal wear and for anti-friction-resistant material - needed a low coefficient of friction and low wear of the material friction with raw cotton [1].

Materials and methods. In the developing of composite polymeric materials as an object of the research following thermoplastic polymers were chosen: high density polyethylene and polypropylene; and as fillers were used: graphite, carbon black, kaolin, talc, glass fibers, wollastonite, and cotton lint. But each of fillers has its shortcomings and good sides. Basic mechanical properties of samples (breaking stress in bending, flexural modulus, resilience, Brinell hardness) determined by standard methods – by state standards. The complex of tribological properties (coefficient of friction, wear-out rate) of composition interacting with raw cotton determined on disc tribometer, the equipment for measuring linear wear.

Results and discussions. Experimental studies have established that glass fibers, wollastonite, cotton lint increase coefficient of friction and decrease wear-out rate. Graphite, carbon black, talc and kaolin decrease coefficient of friction, but increase wear-out rate of composite materials, and also improve thermal conductivity and electrical conductivity, by what decrease the temperature and the charge of the statistical power. Efficiency of these fillers, especially fibrous, significantly appears with little content, that is, with less content of fiber glass the wear-out rate significantly decreases, but with increasing the content of fiber glass, the wear-out rate of composite materials decreases comparatively little, but the coefficient of friction increases highly. When graphite and carbon black are added to composite material, the coefficient of friction effectively decreases [2].

We have developed antifriction and antifriction-wear-resistant composite materials based on polyolefin – high density polyethylene and polypropylene on the established optimal ratios. They provide important physical-mechanical, tribological and operational properties [3].

The table shows strength and tribological properties of developed antifriction polyethylene (APEC) and polypropylene compositions (APPC), also antifriction-wear-resitant polypropylene compositions (AWPPC).

Strength and tribological properties of polyethylene and polypropylene compositions.

As we see from the table, the properties of polyolefin composite polymer materials meet the functional requirements, imposed to the materials for the details of friction parts working bodies of cotton processing machines. The main requirements are manufacturability and cost of used materials, effective damage decrease of cotton wool and cotton seeds, elimination of the accumulation of statistical power and winding fiber on top of the peg, elimination of sparks, appeared due to collision of working parts of machine and foreign bodies in cotton mass (such as pieces of metal, stones).

Index	APEC-1	APEC-2	APPC-1	APPC-2	AWPPC
Breaking stress in bending MPa	33,4	35,4	90,1	85,7	93,3
Toughness kJ/m²	17,5	21,0	97,3	91,3	103,7
Brinell hardness MPa	45,1	48,4	80,3	76,2	73,8
Flexural modulus GPa	0,62	0,65	1,85	0,75	1,7
Coefficient of friction (at P=0,01 MPa V=1,5 m/s W=8,2%)	0,36	0,34	0,27	0,29	0,29
Wear-resistant rate (at P=0,01 MPa V=1,5 m/s W=8,2%)	5,7	5,5	3,12	3,2	2,8

P - unit pressure, V- sliding speed, W- moistness of raw cotton

Conclusions. The produced the parts of friction pairs of working bodies of the cotton machines used for receiving, transportation, development and supply of raw cotton in the subsequent process units.

Using the developed composite polymer materials for the details of friction parts working bodies of cotton processing machines, we achieved the increase of machine productivity to 12-16% and decrease of expendable power to 7-18%, decreasing of cotton seed and cotton wool damage, and elimination of possible cotton fire.

Currently, in modern machines and mechanisms bearings in the friction are widely used. Operation of such sites in the dusty conditions of the atmosphere leads to premature wear of machines and mechanisms; and they fail. Possible regulatory clearance in rolling bearings and their maintenance is not available, but they can be replaced with new bearings, including sliding bearings.

Currently, the original technological principles of formation of composite polymer materials with desired properties are developed and implemented. Herewith, wood (poplar) and modified polymers (polyethylene of high density and polypropylene, filled with graphite and soot) can be used as antifriction material. Developed new composite wood-polymer materials are high wear-resistant, cheep, have production technology with little quantity of waste output, good dumping properties, low coefficient of friction, possible to work with little or no lubrication at all.

Current practice of use of wood-polymer composite materials in antifriction friction units requires exploratory work on the development of optimal construction of model sliding bearings.

Successful development of construction of sliding bearings from made of composite materials based on wood and modified polymers can done only with full analysis of work of friction units of cotton machines and mechanisms, analysis of features of their behavior in different operational conditions, technological abilities of construction.

There are different construction of sliding bearings made of wood-polymer materials based on wood and polymers. Efficient constructive method for improving shape stability of wood-polymer composite materials is to use them in friction units in squeezed condition, what achieved in the combined sliding bearings. The construction of sliding bearings made of wood-polymer materials based on poplar is shown on the picture. Bolster is made of round logs with an allowance for machining and sediment during compaction. Further, it is impregnated with ingredients. After impregnation bolster placed in the cowling and in this position placed in press-form for the further pressing. After the pressing the bearing has the shape as shown on the picture.

Polymer Reagents for Stabilization of Drilling Mud, Used in the Process of Drilling of Oil Wells

email: polycomft2005@rambler.ru

For high-quality oil and gas well drilling require effective drilling fluids, good cleaning of the bottom hole drilled rock forming a thin crust with a smooth surface on the walls of wells, and thereby alert the collapse of rocks.

In turn, the quality of the drilling fluid depends on the used chemicals reagents. In most cases the chemicals for the stabilizer of mud applied carboxymethylcellulose, in Uzbekistan, mainly imported from abroad.

In this connection, in this paper, the physico-chemical properties of polymeric reagents -carboxymethylcellulose, derived from purified linter, poplar and cotton cellulose and their suitability to stabilize the drilling fluids.

It should be noted that in obtaining carboxymethylcellulose from poplar pulp, the degree of substitution of carboxyl groups in carboxymethylcellulose depends on temperature of the etherification process and molar state of cellulose with the sodium salt of monochloroacetic acid or monochloroacetate. So at 40 ^{0}C degree of substitution has a value of 0,60-0,65, and with increasing temperature, the reaction mixture to 80 ^{0}C, an increase of its value to 0,80-0,88.

Such a pattern is observed when obtaining carboxymethylcellulose of cotton cellulose and cellulose from the lint.

The results of preliminary studies of selected physical and chemical properties of the obtained reagents carboxymethylcellulose based on above types of cellulose differ significantly from each other. In this context, we studied the complex physical and chemical properties of the obtained polymeric reagents - carboxymethylcellulose. Studies have shown that physical and chemical properties of carboxymethylcellulose from the poplar and cotton cellulose and purified cotton fibers are within the following limits: the degree of polymerization, -970, 1370 and 1050, the degree of substitution of carboxymethyl group - 82.88 and 85, the content of the basic substance - 50%, 52% and 52%, viscosity 2% aqueous solution - 1200 cps, 1350 cps, 1250 cps, pH environments -10,8, 10,4 and 11,2 respectively.

Herewith high viscosity and high yield of the polymer main chemical reagent carboxymethylcellulose is derived based on cotton cellulose, and all indicators meet the technical requirements 88,2-2-2005. Solubility carboxymethylcellulose based on cotton cellulose is not inferior to foreign analogues.

In the enterprise NTTS "Kompozit" mastered the production of the technology of polymer reagent - carboxymethylcellulose. Currently, the reagent carboxymethylcellulose obtained from the poplar trees, cotton and cotton lint has been used successfully to stabilize the drilling fluids used in drilling oil wells in Uzbekistan.

Atom Transfer Radical Polymerization of Polymerization of MMA and Styrene Initiated by 3,5-bis(perfluorobenzyloxy)benzyl 2-bromopropanoate

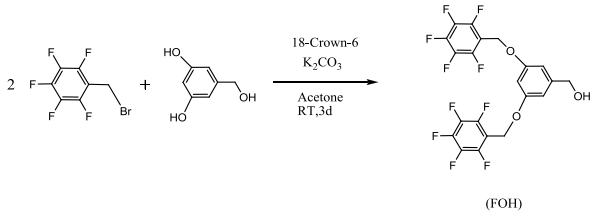
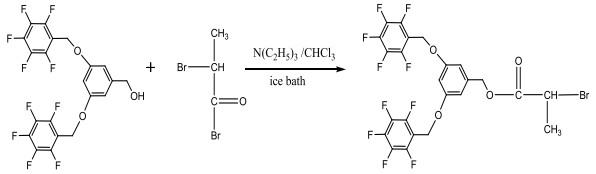
Abstract: The synthesis of polymethylmethacrylate (pMMA) and polystyrene (pSt) were realized with newly synthesized initiator, 3,5-bis(perfluorobenzyloxy)benzyl 2-bromopropanoate (FBr) in the presence of copper bromide (CuBr) and N, N, N', N'', N''-pentamethyl-diethylenetriamine (PMDETA) at several temperatures by using atom transfer radical polymerization (ATRP). The perfluorinated aromatic group containing initiator was prepared by esterification of the (3,5-bis(perfluorobenzyloxy)phenyl)methanol (FOH).



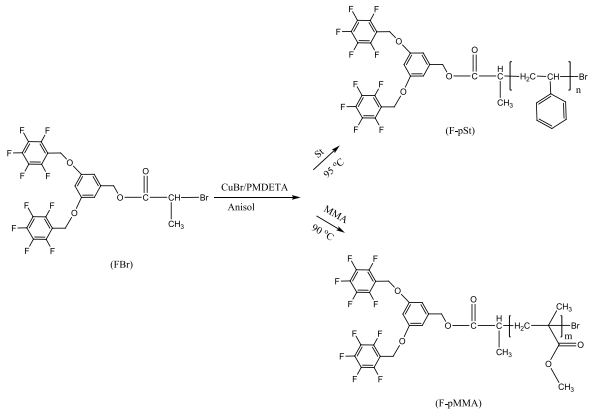
(FOH)

Both initiator and polymers were characterized by ^{1}H-NMR spectroscopy, gel permeation chromatography (GPC), differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA).



(FOH) (FBr)

The ATRP was supported by an increase in the molecular weight of the forming polymers and also by their monomodal molecular weight distribution. Contact angle measurements of water on films of synthesized polymers indicated higher degree of hydrophobicity than that of pure pMMA and pure pSt.



(FBr) (F-pSt) (F-pMMA)

The ATRP was supported by an increase in the molecular weight of the forming polymers and also by their monomodal molecular weight distribution. Contact angle measurements of water on films of synthesized polymers indicated higher degree of hydrophobicity than that of pure pMMA and pure pSt.

ATRP of St and MMA afforded perfluorinated aromatic group-terminated pSt and pMMA with narrow molecular weight distribution. A linear relationships between both $\ln[M]_o/[M]$ vs time and molecular weight vs conversion indicated controlled/living polymerization of St and MMA using FBr as ATRP initiator. The DSC results correlate well with the results of pure pSt and pMMA polymers. Introducing the fluorinated groups into the polymer gave higher residue in the TGA analysis. Contact angle measurements indicated that the surface wettability of the obtained films decreased significantly.

Polymeric micro and nanofibers are highly interesting materials for applications such as tissue engineering and drug delivery because the large surface area to volume ratio affords interesting new properties. Electrospinning is currently one of the most versatile processes for preparing such kind of fibers since it is applicable to a wide range of materials (e.g. synthetic and natural polymers) at a low cost and with high yield. Basically, electrospinning makes use of electrostatic forces (10-100 kV) to stretch a polymer diluted solution as it solidifies. Furthermore, electrospun fibers can be easily loaded with pharmacological active agents by adding the appropriate drug to the polymer solution before performing the electrospinning process.

Aliphatic polyesters constitute the main family of biodegradable polymers despite, in general, they lack of good thermal and mechanical properties. Polylactide (PLA) is one remarkable exception since has high melting point (173-178 ºC) and tensile modulus (2.7-16 GPa). Thus, it seems interesting to use electrospun polylactide micro/nanofibers as reinforcing materials of polyester matrices. In this work, polycaprolactone (PCL), poly(nonamethylene azelate) (P99) and poly(nonamethylene azelate-*co*-pimelate) (COP) were selected as matrices due to their different molecular weight and hydrophobicity. Samples were prepared by pressing the mixture of the powdered polyester (PCL, P99 or COP) and the polylactide fibers at a temperature 10 ºC above the melting point of the polyester matrix. Triclosan, a well demonstrated antimicrobial drug, was loaded in different ways (Figure 1) and the release behaviour studied.

Stress-strain tests demonstrated the improvement on mechanical properties which was more significant for the low molecular weight samples (P99 and COP) and by adding microfibers (M) instead of nanofibers (N). SEM micrographs of fracture surfaces indicated a detachment of fibers as shown in Figure 2 for representative samples.

The triclosan release percentage clearly increased when nanofibers were employed (i.e. PCL-N and PCL-M released 74% and 36% after 4000 min of exposure to a Sörensen/ethanol medium, respectively) and also when more hydrophobic polyester matrices were employed (Figure 3).

The film surface of the more hydrophobic polyesters (P99 and COP) supported the cellular adhesion (human laryngeal epidermoid carcinoma HEp-2 cells) better than polycaprolactone and the culture plate (TCPS). Cellular proliferation was also evaluated after 7 days of culture. It was found that the number of cells that colonized P99 and COP samples was significantly higher ($p < 0.05$) than observed over the control sample. Furthermore, proliferation was not influenced by the morphology of the reinforcing fibers (Figure 4).

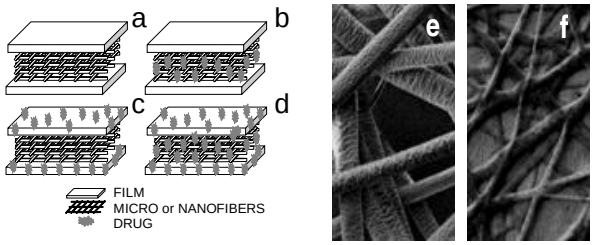

Figure 1. Schematic representation of the different triclosan loaded samples (left) and SEM micrographs showing electrospun micro and nanofibers of PLA (right).

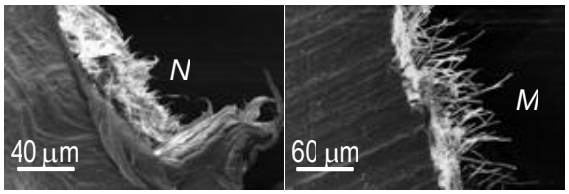

Figure 2. SEM micrographs showing the fracture surface of PCL reinforced with PLA nanofibers (left) and COP reinforced with PLA microfibers (right).

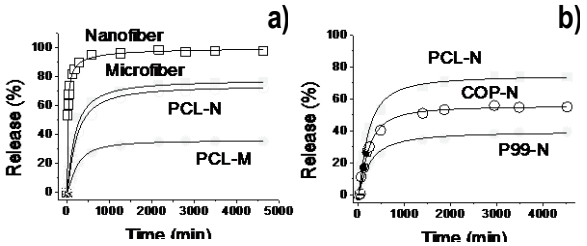

Figure 3. Comparison between cumulative triclosan release in a Sörensen/ethanol medium from samples incorporating micro or nanofibers of PLA (a), and from different polyester matrices incorporating PLA nanofibers (b).

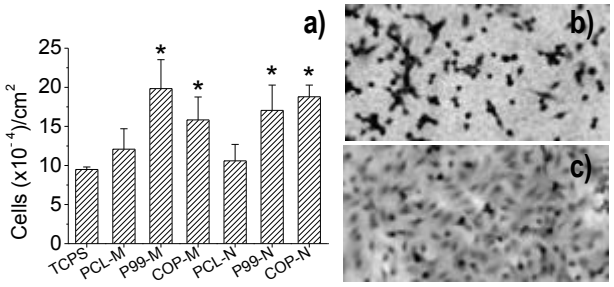

Figure 4. a) HEp-2 cell proliferation on the different studied substrates (asterisk denotes $p < 0.05$ versus control). b) and c) Optical micrographs showing the morphology of HEp-2 cells adhered to PCL and COP substrates, respectively.

Supramolecular polymers are chains of small molecules held together through reversible non-covalent interactions. The dynamic character of such weak interactions is responsible for the appearance of new properties, as compared to those of usual covalently bonded polymers. For example, these materials can display thermoreversible polymer-like properties (such as viscoelasticity)[1], or even form self-healing elastomers.[2]

An interesting application of supramolecular chemistry is the combination of flexible polymers with hard domains containing self-assembled polar groups. A typical example of supramolecular polymer is a flexible polymer or oligomer functionalized with hydrogen bonding end-groups. The structure and the rheological properties of such systems have been reported and they typically show an increase in the long relaxation times and hence of the viscosity[3],[4]. The dissipation of energy upon deformation, corresponding to this increased viscosity, is precisely what is needed to manufacture self-adhesive materials also called pressure-sensitive-adhesives (PSA).

In this context, some low T_g polymers with a bis-urea moiety in the middle of the chain have been synthesized. For example, in solution in a non polar solvent, we have shown that one of them (PIBUT) readily associates in a comb-shaped polymer with a reversibly associating backbone[5]. The supramolecular structure of the bulk polymer[6], the rheological measurements and the promising adhesive properties both on steel surfaces and on typical low adhesion surfaces such as silicone will be reported.

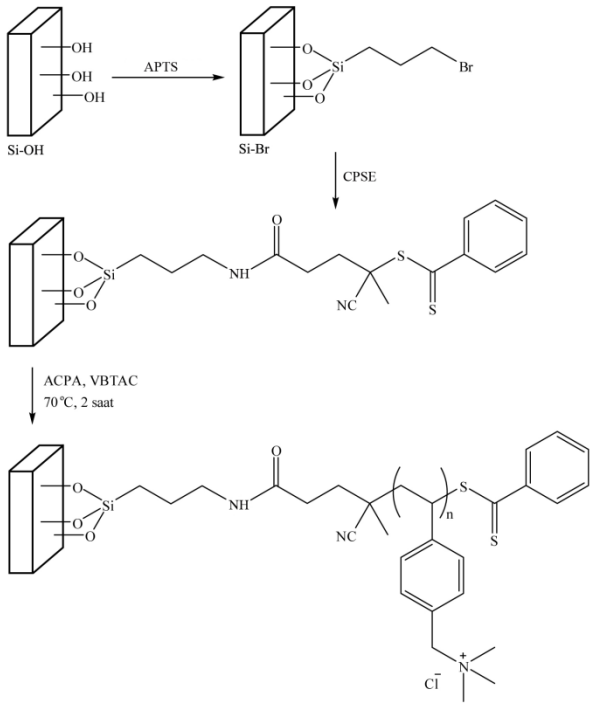
Abstract

Polymer brushes consist of ordered assemblies of polymeric chains that are terminally grafted or adsorbed onto a substrate surface at one or more anchoring points [1].

Generally, polymer brushes are prepared via two basic methods such as "grafting to" and "grafting from" [1]. The most widely used and versatile polymerization technique to prepare polymer brushes by the "grafting from" method are the various surface-initiated controlled living free radical polymerization (CLRP) methods, such as atom transfer radical polymerization [2], nitroxide-mediated polymerization [3], and reversible addition-fragmentation chain transfer (RAFT) polymerization [4].

The main advantages of RAFT polymerization when compared to other CLRP techniques include the ability to polymerize a wide variety of monomers; polymerizations may be conducted over a wide range of temperatures; it allows for the preparation of polymer brushes with functional end-groups [4,5].



Scheme 1. The immobilization of RAFT agent onto silicon surface and the RAFT mediated synthesis of PVBTAC brushes.

In this study, RAFT polymerization technique has been used to synthesize cationic poly((*ar*-vinylbenzyl) trimethylammonium chloride) (PVBTAC) polymer brushes were prepared under RAFT conditions using silicon wafer surfaces that were modified with surface immobilized RAFT agent (4-cyanopentanoic acid dithiobenzoate).

The formation of homogeneous tethered PVBTAC brushes, whose thickness can be tuned by reaction time varying, is evidenced by using the combination of Fourier transform infrared spectroscopy, x-ray photoelectron spectroscopy, atomic force microscopy and water contact-angle measurements. The calculation of grafting parameters from the number-average molecular weight, $\overline{M}_n$ (g/mol) and ellipsometric thickness, h (nm) values indicated the synthesis of densely grafted poly((*ar*-vinylbenzyl)trimethyl ammonium chloride) films and allowed us to predict a polymerization time for forming a "brushlike" conformation for the chains.

The addition of sacrificial RAFT agent results in the formation of free polymer in solution, which was characterized and confirmed the formation of well defined polymers. The possibility to tune the surface properties (e.g., film thickness, grafting density, wettability, and surface morphology) by varying reaction time is also demonstrated.

evasaez@ugr.es

Introduction. Many of the diseases in the musculoskeletal system are characterized by local inflammatory processes which are currently treated with non-steroidal anti-inflammatory drugs (NSAIDs) or corticosteroids. Diclofenac sodium is a NSAID that has been shown to be effective in the treatment of acute pain and a broad variety of inflammatory processes including arthritis. Despite its efficient activity, this drug suffers from several drawbacks, e.g., a short plasma half life, a high percentage of protein binding, and a very high pre-systemic metabolism [1].
In this communication we describe a reproducible technique for the preparation of magnetically responsive polymeric nanoparticles (NPs) loaded with diclofenac sodium for arthritis treatment.

Materials and Methods. Superparamagnetic Fe_3O_4 NPs (mean size ≈ 10 nm) were prepared following the chemical co-precipitation method [2]. Poly(ε-caprolactone) (PCL) NPs were synthesized by an interfacial polymer disposition process (average diameter ≈ 100 nm) [3]. The method followed to formulate Fe_3O_4/PCL (core/shell) NPs (mean size ≈ 90 nm) was similar to that above mentioned for the preparation of PCL NPs, except that the aqueous phase was a Fe_3O_4 suspension. Inspection of the coating efficiency of the magnetic cores was done through analysis of HRTEM pictures. FTIR spectrometry data was used for the characterization of the chemistry of the three different types of NPs. The magnetic properties of Fe_3O_4 and magnetic nanocomposites were determined using a vibrating magnetometer at room temperature.
Diclofenac sodium loading to the NPs was achieved by: *i*) single drug surface adsorption onto preformed NPs; and, *ii*) entrapment procedure or drug absorption into the Fe_3O_4/PCL NPs. Drug release from core/shell NPs was performed *in vitro* following the dialysis bag method, where PBS of pH 7.4 was the release medium.
Spectrophotometry was validated and used successfully, at the maximum absorbance wavelength of diclofenac sodium (276 nm), as the analytical technique in the determination of drug loading and release. A qualitative estimation of the adsorption process was possible by electrophoresis. All the experiments were carried out in triplicate.

Results and Discussion. HRTEM photographs of the magnetic core/shell NPs established that the Fe_3O_4 nuclei were covered by a well-defined polymeric shell. The main feature of the infrared spectra of the three types of NPs was the presence of all the bands corresponding to PCL in the spectrum of the nanocomposites, thus confirming that the shell observed by HRTEM corresponded well to the polymeric coating. We determined the initial susceptibility of Fe_3O_4 (χ_i ≈ 0.15), and Fe_3O_4/PCL (χ_i ≈ 3.15) for the core/shell NPs.
A positive effect of NSAID concentration in the incubation medium on the adsorption efficiency onto Fe_3O_4/PCL NPs was observed. The entrapment efficiency of diclofenac sodium to NPs increased with the amount of drug in solution up to ≈ 11 % for the range of concentrations investigated. However, NSAID loading remained very low when using the surface adsorption procedure (maximum drug loading ≈ 4 %). Electrokinetic measurements qualitatively confirmed the conclusions based on adsorption determinations.
A thermodynamically favoured drug entrapment into nanocomposites led to high NSAID loading values: the hydrophobic drug kept in contact with the hydrophobic PCL when the NPs were formed, rather than as isolated molecules in water. Like the adsorption procedure, a positive effect of drug concentration on the absorption efficiency into the NPs was observed. Compared to surface adsorption, both the entrapment efficiency and the drug loading were significantly enhanced whatever the initial NSAID concentration fixed. For instance, when the initial drug concentration in the adsorption/absorption medium was 10^{-2} M, these parameters rise from ≈ 11 % and ≈ 4 % (after drug adsorption) to ≈ 49 % and ≈ 18 % (when the drug was absorbed into the matrix), respectively. The release of diclofenac sodium adsorbed onto the nanocomposites was a rapid desorption process from the polymeric surface. On the opposite, the release of drug absorbed into Fe_3O_4/PCL NPs was a biphasic process. The rapid first phase likely corresponded to the leakage of the surface-associated and/or poorly entrapped NSAID. Diclofenac release during the slower release phase may result from drug diffusion through the polymeric matrix.

Conclusions. The optimal preparation conditions to obtain diclofenac-loaded Fe_3O_4/PCL NPs suitable for parenteral administration have been determined. We put forward that such formulation hold very important properties (e.g., very suitable response to weak magnetic fields, high drug loading and sustained drug release), suggesting its potential application for efficient delivery of diclofenac sodium to inflammation.

Introduction. One of the problems associated to chemotherapy is the inability to target a specific area of the body. To reach an acceptable therapeutic level at the desired site, high drug doses must be administered even though severe toxicity will occur. As an alternative, magnetically responsive nanoparticles (NPs) can specifically deliver anticancer drugs to targeted tumors under the guidance of magnetic gradients. Then, the magnetic force will focus the magnetic particle into the tumor interstitium (or tumor neovasculature) until the drug is completely released.

In order to increase the therapeutic activity of 5-fluorouracil (5-FU) along with an overcome of their important drawbacks, we investigated their formulation into a magnetic nanoplatform made of biodegradable poly(ε-caprolactone) nanoparticles (NPs) with a superparamagnetic core (magnetite, Fe_3O_4). It is expected that the polymeric shell will play the role of transporting the drug to the tumor tissue (controlling its release). Simultaneously, iron oxide cores will allow the magnetic guidance of the NPs towards the site of action.

Materials and Methods. PCL (mean size: 97 ± 7 nm) and superparamagnetic Fe_3O_4 (9 ± 2 nm) NPs were prepared following the interfacial polymer disposition method [2], and the chemical co-precipitation process [3], respectively. The method followed to synthesize Fe_3O_4/PCL (core/shell) NPs was similar to that followed for the preparation of polymeric NPs, except that the aqueous phase was a Fe_3O_4 suspension.

Particle size was determined by HRTEM photographs and PCS. Characterization of the internal structure of Fe_3O_4 and core/shell NPs was performed by X-ray diffractometry. Surface electrical properties of the NPs were analyzed by electrophoresis measurements as a function of both pH and KNO_3 concentration. Magnetic properties of Fe_3O_4 and Fe_3O_4/PCL NPs were determined with a vibrating magnetometer at room temperature.

Two possible routes can be thought of for 5-FU loading to the core/shell nanoplatform: surface adsorption onto NPs previously formed, after incubation in a drug solution; and, drug incorporation into the polymeric matrix, by its addition to the aqueous medium before the NP formation. Drug release from nanocomposites was performed *in vitro* following the dialysis bag method, using PBS (pH ≈ 7.4) as the release medium. UV-Vis spectrophotometry was validated and used successfully (maximum absorbance wavelength of 5-FU: 266 nm) to quantify drug loading and release. Electrokinetic determinations were used to qualitatively confirm the conclusions based on adsorption determinations. The experiments were done in triplicate.

Results and Discussion. The interfacial polymer disposition method followed for the preparation of Fe_3O_4/PCL NPs allowed the formation of a well-stabilized spherical nanocarrier with an average diameter of 86 ± 12 nm. HRTEM photographs further established that iron oxides were well-covered by the PCL shell. X-ray diffractograms of composite and Fe_3O_4 NPs showed excellent coincidence with the ASTM pattern of Fe_3O_4, an indication of the mineralogical purity and high crystalline nature of the synthesized Fe_3O_4 NPs. Since the ζ–pH and ζ–ionic strength trends of the core/shell NPs were almost identical to those of pure PCL and considering that, oppositely, pure Fe_3O_4 NPs displayed very different electrical profile, it was concluded that the deposition of the PCL coat onto Fe_3O_4 has effectively taken place. The enhancement of saturation magnetization when the magnetic nuclei were merged into a PCL layer was significant: ≈ 12 kA/m for Fe_3O_4, and ≈ 260 kA/m for Fe_3O_4/PCL.

5-FU adsorption efficiency onto Fe_3O_4/PCL NPs was positively influenced by the drug concentration in the incubation medium. Similar effect was also observed when the drug was entrapped into the nanocomposites. However, much higher 5-FU loading values were obtained by following the drug absorption procedure. For instance, when the initial drug concentration in the adsorption/absorption medium was 0.01 M, these parameters rise from ≈ 18 % and ≈ 2.5 % (after drug adsorption) to ≈ 51 % and ≈ 8 % (by 5-FU absorption into the nanocomposite matrix), respectively. Sustained drug release properties were only possible upon drug absorption. The release of drug absorbed into Fe_3O_4/PCL NPs was a biphasic process. The rapid first phase likely corresponded to the leakage of the surface-associated and/or poorly entrapped drug. 5-FU release during the slower release phase may result from drug diffusion through the polymeric matrix.

Conclusions. It was defined the optimal formulation conditions to obtain 5-FU-loaded Fe_3O_4/PCL NPs for parenteral administration. The nanocomposites are characterized by an unusually high drug loading, a significant magnetic susceptibility, and a low burst release. Consequently, the magnetic nanoplatform opens promising possibilities to improve the delivery of 5-FU to cancer.

Abstract

Polymer brushes are generally defined as layers of polymer chains end-grafted to a solid surface and some of them show controlled dynamic behavior in response to external stimuli, such as temperature and pH [1].

Stimuli-responsive surfaces have a great potential in many technologically important areas such as bioanalysis, biomimetics, and nanoelectromechanical systems [2,3].

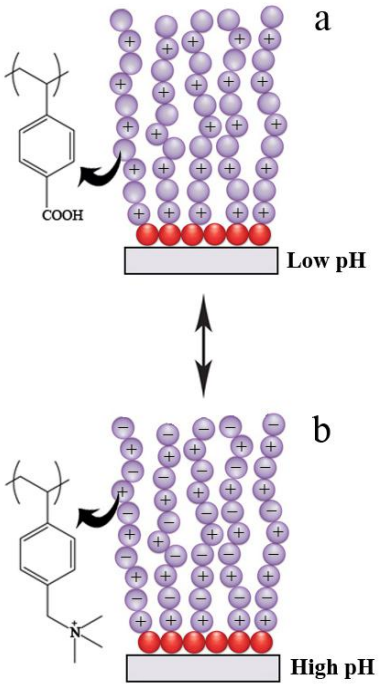

Figure 1. A surface switching from cationic to neutral in response to environmental pH change (a) in low pH solutions, (b) in neutral or higher pH solutions.

In this study, pH responsive copolymer brushes which contain positively-charged (*ar*-vinylbenzyl)trimethyl ammonium chloride (VBTAC) and negatively-charged 4-vinylbenzoic acid (VBA) on silicon wafer surface were synthesized by reversible addition-fragmentation chain transfer (RAFT) polymerization.

The azo initiator immobilized substrate, was prepared by the silanization of hydroxyl groups on silicon wafer with 3-aminopropylthriethoxysilane (APTS) and by the amide reaction of APTS with 4,4'-azobis-4-cyanopentanoil chloride; followed by the RAFT polymerization of VBTAC and VBA using a "free" initiator, that is, 4,4'-azobis-4-cyanopentanoic acid and RAFT agent, that is, 2-(2-carboxy-ethylsulfanylthiocarbonylsulfanyl) propionic acid.

The resulting polymer brushes were characterized by Fourier transform infrared spectroscopy, x-ray photoelectron spectroscopy, atomic force microscopy, water contact-angle measurements, gel permeation chromatography and ellipsometry techniques.

VBTAC and VBA were grafted from silicon wafer surface by combining the self-assembly and the RAFT technique, leading to highly pH responsive surface. The surface has charge neutrality under neutral and basic conditions, and is positively charged under acidic conditions due to the protonation of the carboxylic acid group.

Introduction:

Melamine-formaldehyde (MF) microcapsules with water-immiscible core material are prepared by *in situ* polymerization. Polymerization of MF resin occurs in the continuous water phase and as pre-polymer molecular weight increases, pre-polymer deposits on the surface of the dispersed phase. By further polymerization and crosslinking MF shell is formed.

In this work, microencapsulation of butyl stearate (a phase change material) with melamine-formaldehyde resin using different decreasing rates of pH value was investigated.

Materials and Methods:

Materials: Etherified MF resin (70 wt. %), butyl stearate (technical 40-60 %), sodium dodecyl sulfate (96%), 1 wt. % formic acid solution, deionized water.

Emulsion preparation: 25 g of butyl stearate, 2.5 g of sodium dodecyl sulfate, 15 g of MF resin and 458 g of deionized water were mixed at a rate of 1000 rpm using dispermat for 30 minutes.

Microencapsulation: The emulsion was poured into a 500 ml glass reactor equipped with a reflux condenser, a mechanical stirrer, a digital thermometer and a glass electrode for pH measurements. The pH value of reactor content was adjusted to 6.0 using 1 wt. % formic acid and heated to 70 °C at the stirring speed of 500 rpm. The pH value of reaction mixture was controlled and regulated during the whole microencapsulation process as presented in Fig. 1.

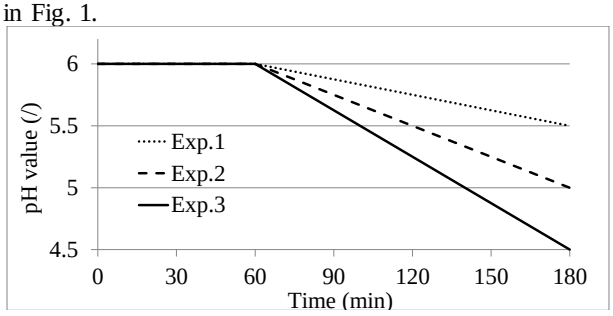

Fig. 1: pH value of reaction mixture during encapsulation process.

During the microencapsulation several samples were taken to investigate core/shell ratio, thermal stability of microcapsules and shell morphology. The core/shell ratio was determined by differential scanning calorimetry (from melting enthalpy of butyl stearate). Thermal stability of microcapsules was determined by thermogravimetric analysis. Shell morphology and its thickness were investigated by scanning electron microscopy.

Results and Discussion:

The wt. % of shell material increased during microencapsulation (Fig.2). Depositing of MF pre-polymer and pure MF particles on the microcapsules surface depended on pH value of reaction mixture. Lower pH value resulted in higher wt. % of shell material in microcapsules. The increase in wt. % of shell material was mainly due to the deposition of pure MF particles on the surface (Fig.3). However, the shell thickness also increased.

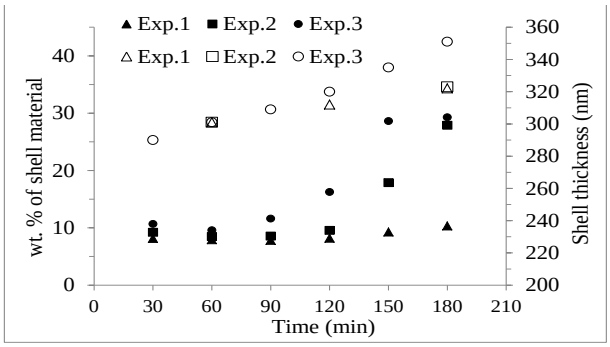

Fig. 2: The wt. % of shell material (plain symbols) and shell thickness (open) during microencapsulation.

As expected, thermal stability of microcapsules increased with the time of microencapsulation. For microcapsules containing over 70 % of core material (final products) only about 20 % mass loss was observed at temperatures where pure core material completely evaporates. The rest of core material (already decomposed) evaporated at temperatures above 340 °C when MF shell decomposed. From TGA and DSC analysis it was concluded that for a better thermal stability slow deposition of MF pre-polymer on the surface of the dispersed phase is necessary.

Polymerization of Octamethylcyclotetrasiloxane in a Microtube Reactor with Liquid-Liquid Slug Flow Pattern

Ervin Šinkovec and Matjaž Krajnc

University of Ljubljana, Faculty of Chemistry and Chemical Technology, Aškerčeva cesta 5, 1000 Ljubljana, Slovenia

matjaz.krajnc@fkkt.uni-lj.si

Introduction, Results and Discussion: A controlled hydrodynamic flow is an important feature of microstructured reactors. When two immiscible liquids in a microchannel are used, different flow patterns such as annular flow, parallel flow, drop flow or slug flow can be obtained. Circulation patterns in liquid-liquid microchannel flow vary with the physical properties of liquids as well as with operating parameters such as flow ratio of two immiscible liquids, mixing elements geometry, channel geometry and capillary dimensions[1]. In a microtube reactor with stable two-phase slug flow pattern a high degree of control over the slug size distribution can be achieved and the liquid-liquid interfacial surface-to-volume ratio may be strictly defined. A known specific interfacial area enables to investigate processes in heterogeneous systems, such as mass transport between two immiscible liquids and/or chemical reaction on the liquid-liquid interface.

Here as a case study anionic polymerization of octamethylcyclotetrasiloxane was chosen. Systematic studies of anionic ring-opening polymerization (AROP) in emulsion[2-4] showed that during AROP in emulsion, different chemical reactions by which polymer is formed (initiation, propagation and termination) take place on the polymer particle surface (organic-aqueous interphase) and inside the particle (organic phase). Chain growth is initiated by hydroxide anion of a water-soluble initiator, which is coupled with a cationic emulsifier on the particle surface. The emulsifier cation remains associated to the active center (hydroxide anion) of growing polymer chain during the propagation step. Termination occurs through protonation by water to give silanol end-groups. The reversibility of termination reaction is a key factor for long chain generation[3]. Backbiting reactions, also occurring at the interface, produce small oligomeric cycles accumulating on the particle surface, where the steric constraints imposed by the ion-pairing limit the size of the obtained rings. In the particle interior condensation and redistribution reactions take place, which do not affect the monomer conversion. In this work, an attempt was done to follow the extent of reactions occurring at the interface by varying surface-to-volume ratio of organic phase. The surface-to-volume ratio was controlled by varying organic and aqueous volumetric flow rate. Desired residence time was achieved by varying total flow rate and/or length of microtube reactor. Effects of emulsifier and initiator concentrations on the slug flow stability and on the kinetics were investigated as well. Monomer conversion was determined by gravimetric analysis, by which the amount of monomer converted to large non-volatilizable polymeric chains was determined. All volatile oligomeric cycles, which are formed during polymerization, were treated as monomer in conversion calculations.

It was observed that the composition of aqueous phase has a significant influence on the slug flow stability. Varying the emulsifier and initiator concentrations had a strong impact on the stability of the flow regime. Since microreactor studies request a stable and reproducible two-phase flow pattern, which allows a high control over the slug size distribution, chemical kinetics and mass transfer between phases were investigated only at stable operating regime. In a microtube reactor, a stable regime is characterized by a reproducible slug flow (Figure 1).

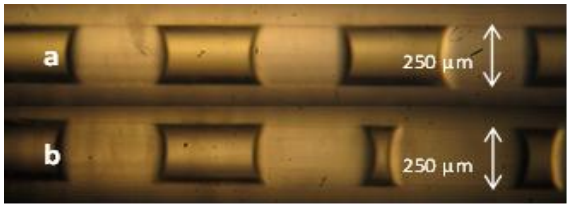

Figure 1. a) Stable two phase slug flow, b) unstable two phase slug flow

Materials and Apparatus: Cationic emulsifier (hexadecyltrimethylammonium bromide, benzalkonium chloride), potassium hydroxide (p.a., Merck), deionized water.

Microreactor experiments were carried out in the microtube reactor connected to high performance syringe pumps (Harvard Apparatus, Holliston, USA) with fluorinated ethylene propylene tubes (Vici AG, Schenkon, Switzerland). Syringe pumps ensured highly controllable flow rates. The reaction in the fluorinated ethylene propylene microtube reactor with an internal diameter of 250 µm was carried out at a slug-flow regime. The organic phase feed consisted of octamethylcyclotetrasiloxane. The aqueous phase consisted of aqueous solution of ionic, nonionic emulsifiers and initiator (potassium hydroxide) in various proportions. The mixing of phases was done in a poly-etheretherketone T-mixer (Vici AG, Schenkon, Switzerland) with an internal diameter of 250 µm.

Introduccion

As well known, most polymers are thermally and electrically insulating. The increase of thermal and electrical conductivities of polymers opens large new markets. The advantages of conductive polymer composites when compared with typically used metals includes improved corrosion resistance, lighter weight, and the ability to adapt the conductivity properties to suit the application needs (1).

There is a critical composition (percolation threshold) at which the conductivity increases by some orders of magnitude from the insulating range to values in the semiconductive or conductive range.

This work is concerned with the preparation, characterization and study of the electrical conductivity of composite materials prepared by compression moulding of mixtures of copper powder and a commercial grade thermosetting resin of urea–formaldehyde filled with alpha-cellulose in powder form.

Materials

The matrix polymer used in our experiments was a commercial grade urea–formaldehyde embedded in alpha-cellulose (30 wt %) supplied in the form of powder.

The electrical conducting filler used was copper, average particle size of 150–200 µm, density of around 8.92 g/cm3, and electrical conductivity of the order of 6.3 x 10^5 S/cm. Both the polymer and the metal powders were dried before use at 60 ºC during 48 h.

Composite Fabrication

Composites of urea–formaldehyde embedded in alpha-cellulose powder filled with copper were fabricated by mixing the polymer matrix and the filler powders for 2 h in an internal mixer, followed by compression moulding in a specially designed mould with three cavities of 30.0-mm diameter and 3.0-mm thickness each one. The moulding parameters were 20 MPa and 150 ºC for 30 min (2).

The homogeneity of composites was controlled by morphological pictures obtained by optical microscopy. Furthermore, to check the void level within the samples, which influences remarkably the electroconductivity, the porosity rate has been calculated from the densities of the composites.

Results and Discussion

By comparison between experimental and theoretical densities of samples, the porosity of composites. was obtained Even though the average fraction voids in volume begins to increase for low values of filler concentration, for values higher than 12 vol % that fraction is almost constant, with a value of 11% ± 2%, thus assuring the good quality of the obtained composites.

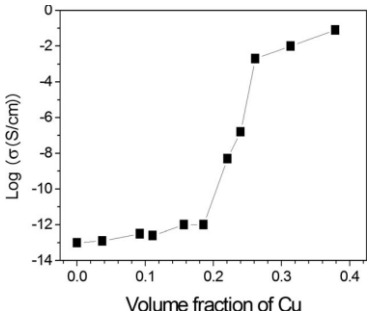

Figure 1. Variation of the electrical conductivity of urea-formaldehyde embedded in cellulose powder/Cu composites with Cu content

The electrical conductivity of the composites as a function of filler content for the samples shows the typical S shaped dependency (Figure 1) with three regions (dielectric, transition, and conductive). As expected, samples with low-filler content are almost nonconductive. However, the electrical conductivity of the composites increases dramatically as the copper content reaches the percolation threshold at 24.0 vol % of filler. The value of the percolation threshold is obtained from the maximum of the derivative of the conductivity as a function of filler volume fraction.

The electrical conductivity of the composites is $<10^{-12}$ S/cm, unless the metal content reaches the percolation threshold of 24.0 vol %, beyond which the conductivity increases markedly by as much as 11 orders of magnitude, indicating an insulator–conductor phase transition.

The obtained results on electrical conductivity have been well interpreted with the statistical percolation theory. The deduced critical parameters, such as the threshold of percolation, V_f*, the critical exponent, t, and the packing density coefficient, F, were in good accord with earlier studies. In addition, the hardness of samples remained almost constant with the increase of metal concentration.

Ruthenium olefin metathesis initiators bearing one or two N,O chelating coligands in the triggered polymerization of DCPD

Julia Wappel,[1] *Christian Slugovc*[1]*

[1] Graz University of Technology, Institute for Chemistry and Technology of Materials, Stremayrgasse 9/V, AT-8010 Graz, Austria.

e-mail: julia.wappel@tugraz.at

Over the last past decade olefin metathesis has emerged as an important tool for the formation of carbon-carbon double bonds. Particularly due to their good group, oxygen and moisture tolerance and the possibility of a controllable reaction progress, metathesis has gained more and more popularity.[1] In polymer chemistry, especially the ring opening metathesis polymerization (ROMP) has been a field of great interest.

The cheap industrial side product DCPD, an auspicious product for many commercial applications, is easily polymerized by the means of ROMP. Driven by the challenge to prepare well defined DCPD polymers under easy manageable processing conditions, latent initiator systems are desirable. These systems allow to store the initiator and the polymer together and to initiate the polymerization whenever requested. Feasible initiation mechanisms are thermal or acid activation.

Many ruthenium based complexes featuring an *O,N*-bidentate ligand exhibit such latency and olefin metathesis activity can be neglected.[2,3,4] Herein we present the influence of various initiators bearing *N,O*-chelating co ligands on the polymerization characteristics of DCPD. The catalysts vary in terms of their carbene and the *N,O* ligand(s), as well as of the steric arrangement of the N,O ligand(s). Different activation techniques are taken into account.
The new initiators are compared to well established commercially available metathesis catalysts.

Biocide Finishing of poly(Isoprene) by Thiol-ene Click Chemistry

Julia Kienberger[1], *Nadja Noormofidi*[1], *Christian Slugovc*[1]*

[1] Graz University of Technology, Institute for Chemistry and Technology of Materials, Stremayrgasse 9/V, 8010 Graz, Austria.

e-mail: julia.kienberger@tugraz.at

In many fields of applications, the maintenance of high hygienic standards is of absolute necessity. Regarding medical devices, water pipe systems or food packaging facilities, biocide surfaces are partly inevitable or, at least, simplify and cheapen industrial processes. Conventional methods implement the use of low-molecular weight disinfectants, however, such particles often suffer from disadvantageous leaching or accumulation effects.[1] In order to circumvent such problems, high molecular weight materials like polymers with integrated biocidic properties are an attractive alternative. Moreover, the combination of hydrophobic backbone and hydrophilic attributes, which repulse destroyed bacteria cells, is an efficient and variable tool to obtain potent and long-term active antimicrobial polymers.

Thiol-ene click chemistry is a powerful and versatile tool, awakening more and more interest not only in the scientific community, but also for industrial applications.[2] The ability to combine a wide range of aliphatic and aromatic mercaptans with an endless possibility of double bonds accessible and nevertheless most simple and easy to handle conditions makes this reaction unique.

In our approach we apply thiol-ene reactions to functionalise poly(isoprene) with a high content of 1,2-linked repeating units with thiolamines. This polymer is perfectly applicable for biocide purposes, as it features hydrophobicity as an intrinsic property and by either alkylation or protonation of the amino functionality quaternary ammonium salts “QUAT”s[3] are introduced into the polymer.

A series of new polymers is synthesized and characterised in terms of thermal stability and antimicrobial activity, yielding very promising new materials suitable for compounding purposes.

e-mail: flo_pp@sbox.tugraz.at

Introduction

Porous polymers have gained a lot of attention in the last years due to their unique morphology that opens a wide field of possible applications. Materials with pore sizes ranging from a few to several hundred micrometers are successfully applied in tissue engineering, catalyst support materials, filtration media and chromatography.[1]

Results and Discussion

Successful preparation of high internal phase emulsions (HIPE) with a variety of monomers has been reported. Ring opening metathesis polymerization (ROMP) of DCPD (dicyclopentadiene) with initiator M2 was employed for the preparation of well defined poly-HIPE structures (Fig. 2, left).[2] A similar approach with cyclooctene (COE) led to a material with a different structure (Fig. 2, right) and distinctly different mechanical properties.

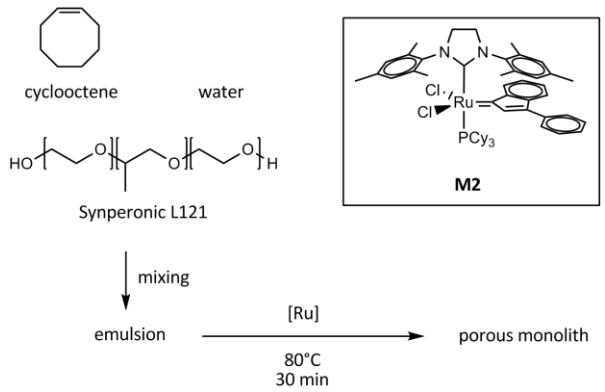

Fig. 1 – Preparation procedure.

Poly(cyclooctene) without any crosslinker is characterized by a low glass transition temperature (T_g) of about -80°C and a melting point of 65°C, depending on the *cis-trans*-ratio of the polymer. In contrast to norbornene-derived polymers, poly(cyclooctene) possesses secondary allylic carbons making it less sensitive to oxidation.[3] This is a valuable advantage that protects the polymer from aging and decomposition.

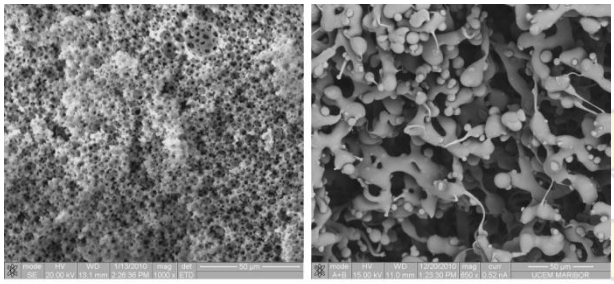

Fig. 2 - Structural differences between DCPD-polyHIPE material (left) and porous poly-COE monolith (right); scale bars 50 µm.

The low melting point of the polymer is a significant drawback for the synthesis of the material. For a proper handling of the emulsion, the initiator loading must be low; otherwise the mixture can not be transferred to the mold. As a consequence, the curing temperature has to be rather high to guarantee a complete conversion of the monomer. This high temperature may affect the inner structure of the monolith and it has turned out to be a difficult hurdle on the way towards a poly-HIPE structure in poly-COE.

Conclusion

The synthesis of highly porous polycyclooctene monoliths via ROMP has been shown. The good oxidation stability of the polymer compared to polynorbornenes makes it a promising candidate for further applications. Mechanical properties and chemical characterization will be disclosed in the contribution. Further modifications concerning morphology will be carried out.

Water-soluble polymers prepared by Ring opening metathesis polymerization

Katharina Gallas,[1] *Tanja Wrodnigg*,[2] *Christian Slugovc*[1*]

[1] Graz University of Technology, Institute for Chemistry and Technology of Materials, Stremayrgasse 9/V, AT-8010 Graz, Austria.

[2] Graz University of Technology, Institute for Organic Chemistry, Stremayrgasse 9/V, AT-8010 Graz, Austria.

e-mail: gallas@tugraz.at

There is a great demand for new and well defined water soluble polymers because of their broad variety of applications in fields like bioseparation, diagnostics, sensor applications or controlled release of bioactive agents.[1] An approach towards the release of substances is to make use of phase separation driven by increasing temperature. This effect is called the lower critical solution temperature (LCST)[2] which is a feature of, among others, polymers bearing oligo(ethylene oxide) groups in the side chain.[3] Recently, work on poly(norbornenes) bearing oligoglycol side chains was published.[4] In this case, the LCST is largely independent from the molecular weight and the macromolecular architecture. Only polymers prepared from *endo*,*exo*-bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic-acid, bis[2-[2-(2-ethoxyethoxy)ethoxy] ethyl] ester (**1**) showed satisfactory water solubility and a LCST of about 25°C.[4] Herein we aim at tuning the LCST by copolymerization with mannose (**2**) or alkyl amino hydrochloride (**3**) bearing monomers.

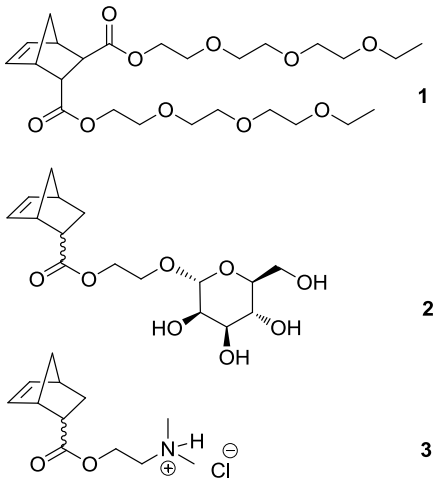

Figure 1: Water-soluble monomers *endo*,*exo*-bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylicacid,bis[2-[2-(2-ethoxyethoxy)ethoxy]ethyl]ester (**1**), mixture of *endo*- and *exo*-bicyclo[2.2.1]hept-5-ene-2- methacrylate-2-(α-D-mannopyranosyloxy)ethyl (**2**), mixture of *endo*- and *exo*-bicyclo[2.2.1]hept-5-ene-2-carboxylicacid(2-dimethylaminoethyl)ester hydrochloride (**3**)

2 was prepared through an *O*-glycosylation reaction of the acetyl protected mannose with excellent α-anomer selectivity following the work of Obata et al. who prepared similar acrylates.[5] Ring opening metathesis polymerization has been chosen because of its high functional group tolerance, the reliability and the capability to synthesize a plenitude of different polymer architectures. Complex **M31** has been chosen as the initiator in this case.[6]

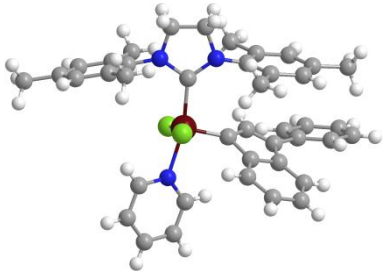

Figure 2: [(H_2IMes)(py)Cl_2Ru(3-phenylindenylid-1-ene)] (H_2IMes = N,N-bis(mesityl)-4,5-dihydroimidazol-2-yl, py = pyridine) (**M31**)

Homopolymers of **1**, **2** and **3** were prepared using initiator : monomer ratios of 1 : 100, 1 : 200 and 1 : 300 and their solubility in water as well as their LCST was determined. Furthermore, random copolymers consisting of different ratios of **1**, **2** and **3** as well as block copolymers were prepared and the properties of those copolymers were compared with those of the homopolymers. The contribution will display these data in detail.

Thermal Studies of Interpenetrating Methacrylate/Epoxy Resins

Nicoleta M. Florea, Adriana Lungu, Raluca Stan, Horia Iovu

Faculty of Applied Chemistry and Materials Science, University Politehnica of Bucharest, Romania

s_nicoleta2005us@yahoo.com

Introduction

Most thermosetting resins are used with reinforcing agents to produce a composite material with better mechanical and thermal properties. Optimisation of the properties of thermosetting polymers for a specific application has been achieved by blending of thermosets to form "Interpenetrating Polymer Networks" (IPNs). IPNs are blends of two or more crosslinking polymers and appropriate blending should allow their properties to be tailored to the application. Two types of IPNs may be formed, depending on the polymer components are crosslinked or not: full-IPNs (presence of crosslinks in both network polymers) and semi-IPNs (one of the components is crosslinked and the other is linear) [1-3].

In this study, full-IPNs composed of bisphenol A diglycidyl dimethacrylate (BisGMA) and diglycidyl ether of bisphenol A (DGEBA) epoxy resin were prepared by *in situ* polymerization. The presence of the bisphenol A diglycidyl structure in both the vinyl esters and epoxy resins respectively enhance miscibility in the formed IPN. Moreover, the OH groups from BisGMA can play a catalytic role in the epoxy cure.

Materials and Methods

An organic peroxide such as azobisisobutyronitrile (AIBN) was used as initiator for BisGMA, and an anionic polymerizing curing agent 1 methyl-imidazole (1-MeI) for DGEBA, respectively. Both, dimethacrylate and epoxy monomers were mixed separately at ambient temperature with their respective initiators before being combined in different ratios (75:25; 50:50; 25:75 wt%).

The polymerization process was done at 120°C for 2h and then post-cured at 160°C for 30 min. As references, BisGMA and DGEBA homopolymers were also prepared in the same conditions as the corresponding IPNs.

The obtained IPNs were characterized by ATR-FTIR, TGA, DSC and DMA techniques in order to investigate the properties of the IPNs which are dependent on the phase separation of the individual thermosseting components.

Results and Discussion

The ATR-FTIR spectra for initial blends confirm the presence of the C=C double bonds from methacrylic groups which appear at 1638 cm^{-1} and the epoxy groups at 915 cm^{-1}. These bands can be used to monitor the reaction and calculate the final conversion after the polymerization process.

DSC analysis was performed in order to obtain the individual heats of polymerization.

The DSC thermograms of the initial blends for IPN exhibit two distinct exothermic peaks, one at ~ 80°C, which corresponds to heat polymerization for methacrylic groups from BisGMA and anotherone at ~ 120°C assigned to the epoxy groups from DGEBA (Fig. 1). During the crosslinking process these peaks completelly dissapear due to the methacrylic and epoxy groups consumption during the polymerization process.

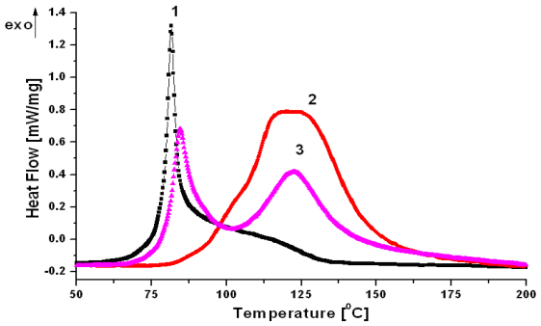

Fig.1. DSC thermograms for: 1)BisGMA, 2) DGEBA, 3) 50:50 wt% BisGMA-DGEBA before polymerization

The bisGMA and DGEBA curing exotherms are shifted to higher temperatures in the IPNs, which is consistent with the effects of dilution [2].

DMA tests was also performed for the final full-IPNs and homopolymers respectively (Fig. 2).

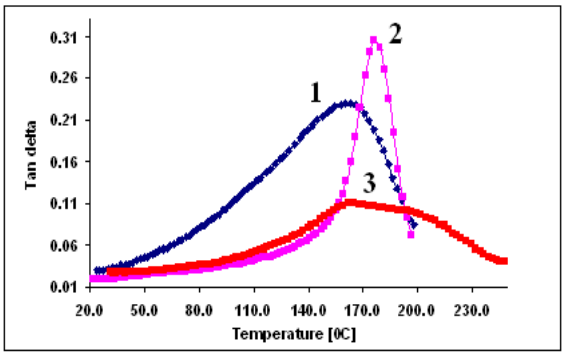

Fig. 2. DMA plots of: 1)BisGMA, 2) DGEBA, 3) 50:50 wt% BisGMA-DGEBA after polymerization

T_g of the neat BisGMA/AIBN is 160°C, while the T_g of the neat DGEBA/1-MeI is 176°C. The T_g of 50:50 full IPN is 169°C, which is an average between the two T_g values of DGEBA and BisGMA, suggesting a single phase morphology.

Conclusions

Mechanical properties will be also investigated to confirm if the bisphenol-A addition in IPNs increases the rigidity of the polymer backbone.

Further, nanocomposites with polyhedral oligomeric silsesquioxane (POSS) will be obtained for the IPN with highest thermal and mechanical properties.

Abstract

Epoxy resins have a wide range of applications in materials science. By incorporating high aspect ratio fillers like carbon nanotubes (CNT) or vapour grown carbon nanofibers (VGCNF), the epoxy mechanical and electrical properties are tailored and the range of applications extended. As both the electrical and mechanical, and therefore, the electromechanical response of the polymer composites depend of the filler content and dispersion, this investigation reports on the piezoresisitive response of epoxy/VGCNF composites prepared by four different dispersion methods. The composite response is investigated as a function of VGNNF loading and dispersion. Strain sensing by variation of the electrical resistance in the composites was tested by a four-point bending and the dependence of the gauge factor as a function of the deformation and velocity of deformation was calculated as well as the reproducibility of the electrical response. The experimental results showed that the composites have an overall appropriate response for being used as piezoresistive sensor. The applications limits will be also addressed.

jcano@leartik.com

The basalt is a basic igneous effusive rock of mineral composition and is the result of cooling of lava at the surface of a planet, in contact with air or water. It is considered an attractive raw material for fiber production because of its relatively homogeneous chemical structure, its wide availability throughout the world, its great purity and its ability to form fibers in the molten state.

The inorganic nature of basalt fibers makes them unsuitable for mixing with carbon based polymers unless a coupling agent is added. These coupling agents or sizings are added by the comercializers of fibers, but the composition of the sizing and in some cases their nature may not be the best option for a specific matrix.

The present work tries to determine the less aggressive sizing removing process for basalt fibers (BASUD280, Basaltex, Belgium) measuring and controlling their morphological and mechanical changes. That must be taken into consideration in order to manufacture a polymeric composite material, since the mechanical properties of an unidirectional composite are mainly dependent on the behavior of the reinforcement.

Calcination is the most used sizing removing technique but this process results in a weakening of the fiber that is not often measured. In the present work different removing processes are used to take out the surface treatment of basalt fibers such as a partial elimination of the coating by sohxlet extractions in several solvents like acetone (PANREAC, 99.5 %,), tetrahydrofuran (PANREAC, 99.9 %,) or chloroform (PANREAC, 99.0 %,). The nonsoluble part is then removed by pyrolysis; and is compared with the results obtained by direct taking out the sizing by pyrolysis and calcination.

The effectiveness of all processes has been analyzed taking into account the loss of weight of the fibers after treatments and to check the partial or total sizing elimination after the different treatments thermogravimetric analysis (TGA) has been used.

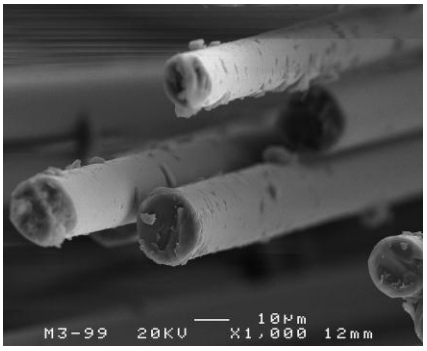
Besides, the surface of treated and untreated (with original sizing) fibers and the extracts resulted from the extractions have been chemically analyzed by Fourier transform infrared spectroscopy (FTIR) and attenuated total reflection spectroscopy (ATR).

The fibers have been mechanically characterized using monofilament stress-strain test in a Rheometrics RSII analyzer. The results have been analyzed statistically using the Weibull two parameter distribution.

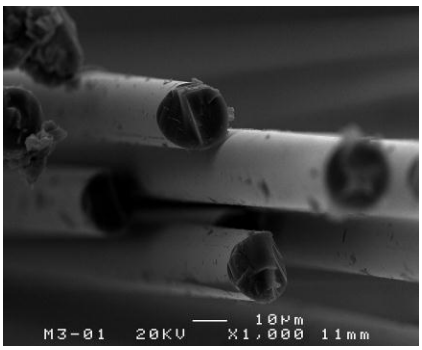
To determine the morphological changes suffered by the fibers in the surface scanning electron microscopy (SEM) tests have been performed for each sizing removing technique used. The chemical composition of the surface of the treated and untreated fibers has been also analyzed by energy dispersive spectroscopy (EDX).

Figure 1: a) basalt fibers with the original sizing; b) basalt fibers after acetone extraction

a)



b)



CONCLUSIONS:

Preliminary results have shown that with all the solvents used in the extractions part of the sizing is removed, being the acetone the most effective as can be observed in figure 1.

email: ibacosca@icmpp.ro

Introduction

Aromatic polyimides are high performance polymers used in applications which demand resistance at high temperature maintaining in the same time their structural integrity and a good balance between their chemical, physical and mechanical properties.[1] Particularly interesting is the potential use of polyimides in microelectromechanical systems (MEMS) devices due to their chemical and thermal stability necessary to withstand conventional MEMS processing. However, wholly aromatic polyimides, though thermally stable, do not always provide the optimum properties for many specialty applications because of deficiencies in processability and solubility. Poly(amide imide)s bring together superior mechanical properties associated with amide units and high thermal stability determined by the existence of imide rings.[2]

Materials and Methods

2,6-Bis(*p*-aminophenoxy)benzonitrile, **1a**, and 2,6-bis(*m*-aminophenoxy)benzonitrile, **1b**, were prepared by nucleophilic displacement of 2,6-dichlorobenzo-nitrile with *p*- or *m*-aminophenole using DMAc as solvent.[3] 1,3-Bis-2-cyano-3-(3-aminophenoxy)phenoxybenzene, **1c**, was prepared as reported earlier.[4] The new diacid chlorides, **2a** and **2b**, were synthesized by reflux with thionyl chloride of the corresponding diimide diacids resulting from the reaction of trimellitic anhydride with diamines **1a** and **1b**, respectively.

Results and Discussion

New poly(amide imide)s were synthesized by one step polycondensation reaction, at low temperature, of equimolecular amounts of diamines **1** and diacid chlorides **2** using NMP as a solvent and propylene oxide as acid acceptor. The structure of the diamine and diacid chloride monomers is presented in scheme 1.

Scheme 1. Structure of the monomers.

1a: 
1b: 
1c: 
2a: 
2b: 
The structure of the poly(amide imide)s was identified by FTIR spectroscopy. Infrared spectra of all polymers showed strong absorptions at 1780, 1718, 1378 and 732 cm^{-1} which were assigned to the imide rings. Strong bands of absorbtion characteristic for the new formed amide linkage appeared at 3385 cm^{-1} assigned to the N–H stretching vibration, at 1688 cm^{-1} atributed to the C=O stretching vibration and at 1576 cm^{-1} due to the N–H bending vibration.

The good solubility of the poly(amide imide)s is due to the relatively high flexibility of macromolecular chains which was obtained by the introduction of ether and amide linkages into the structure of the polymers. All polymers were soluble in polar organic solvents such as NMP, DMAc, DMSO or DMF, at room temperature. Polymers containing more meta-catenation were soluble in less polar solvents such as THF.

Thermogravimetric analyses shows that the present poly(amide imide)s are highly thermostable: the temperature of 5% weight loss is situated in the interval of 315-510^{o}C and 10% weight loss in the domain of 430-520^{o}C.

Molecular relaxations of polymer film based on 4,4'-(1,3-phenylenedioxy)dianiline and diacid chloride **2a** were determined and the results evidenced two second order phase transitions γ and β and one primary transition α. A nano-actuation study of the same polymer film was performed using different dc voltage of 70, 100, 130 and 150 V. The best results were obtained at 150 V and an electric field of 833.33 Vm^{-1} when the nano-displacement had a value of -140 nm and a sensibility of 0.933 nm/V.

Conclusions

A new series of poly(amide imide)s containing various amount of CN groups was synthesized by one step polycondensation reaction of new diacide chlorides with different diamines containing flexible linkages. The polymers had a good solubility, high thermal stability and film forming ability. One polymer film exhibited a nano-displacement of -140 nm at 150 V. All these results make the present polymers potential candidates as advanced materials for high performance applications.

alicia.carrero@urjc.es

Metallocene catalysts together with aluminoxanes can polymerize olefins into polyolefins having narrow molecular weight distribution. This type of polyolefins is suitable for precision injection moulding, general injection moulding and fibre production. However, for numerous applications such as thermoforming, extrusion, blow moulding, production of polyolefin foams and films and in packaging such food packaging, wider or bimodal molecular weight distributions (BMWD) are required.[1] Traditionally the production of bimodal resins is carried out by a cascade process, using conventional Ziegler-Natta catalysts or by mixing together two polypropylenes of different molecular weight (M_w). A more attractive and economical route is to use two or more metallocene precursors simultaneously yielding a polypropylene mixture consisting of the polymer fractions produced by the different metallocenes individually[2]. Therefore, catalytic sites that have different kinetic responses, such as different propagation and termination rate constants, would produce a blend of polymeric chains with different predominant molecular masses.

The main driver for this development is the decrease in investment costs for a single reactor compared to a staged process. Also, as it is generally accepted that the high and low molecular weight fractions should be intimately mixed to obtain good product properties, the combination of two or more catalytic systems in the same reactor could lead to such efficient mixing.

As it is known, to replace the conventional heterogeneous Ziegler–Natta catalysts used in industrial slurry and gas-phase processes, metallocene catalysts have to be immobilized a carrier. In general, the heterogeneization of soluble metallocene catalysts implies an activity decrease although polymers produced with supported catalysts present higher molecular weights.

In this work, three metallocene catalysts with C_2 symmetry rac-Me_2Si $(Ind)_2ZrCl_2$ (CAT1), rac-$Et(Ind)_2ZrCl_2$ (CAT2) and rac-Me_2Si(2-Mebenzoind) $_2ZrCl_2$ (CAT3) have been evaluated in homogeneous propylene polymerization at 30, 50 and 70 °C in a 1.0 L stirred-glass reactor filled with 400 cm^3 of n-heptane as diluent and MAO/metallocene molar ratio = 900. The monomer consumption was followed by a mass-flow indicator in order to keep the reactor pressure at 5 bar during the polymerization. After 15 minutes, polymerization reaction was stopped by depressurization and quenched by addition of acidified (HCl) methanol. Polypropylenes obtained were characterized by gel permeation chromatography (GPC) to determine molecular weight and molecular weight distributions; differential scanning calorimetry (DSC) was used to obtain polymer melting temperature and crystallinity.

Table 1 shows the polymerization activity reached with each catalyst at 30 °C and 70 °C as extreme temperatures to show the maximum difference in molecular weights. Attending to molecular weight values, CAT3 can be combined at both temperatures with CAT1 or CAT2 since is one order of magnitude larger, which will allow to observe the high and low fractions of molecular weight that are appropriate for bimodal molecular weight distribution. It is important to remark that also at 70ºC the mixture of CAT1 and CAT2 could lead to a feasible bimodal product.

All the catalysts gave a polymer with a polydispersity index a little bit higher than 2.0, value expected for a single-site metallocene catalyst. Polypropylene samples presented a single melting peak in DSC analysis, showing the typical melting behaviour for metallocenebased isotactic polypropylene. that is a direct relationship between T_m and M_w, decreasing both factors when the polymerization temperature is increased because of the chain transfer reactions).

CAT3 produces PP with a slightly higher melting point value, which suggests an increment in stereo or regioregularity

Table 1. Polymerization activity and polypropylene characterization

Catalyst	Activity 30 ºC (kg PP/molM·h·bar)	M_w (g/mol)	T_m (ºC)	α (%)
CAT1	291	39593	150	58
CAT2	423	25638	144	57
CAT3	374	403876	155	53

.

Catalyst	Activity 70 ºC (kg PP/molM·h·bar)	M_w (g/mol)	T_m (ºC)	α (%)
CAT1	2360	10446	138	54
CAT2	2512	5567	128	53
CAT3	5500	380670	149	50

Based on the above results, it seems reasonable to prepare supported binary catalysts by the consecutive impregnation of CAT1 or CAT2 and CAT3 onto MAOmodified silica for obtaining reactor blends of isotactic polypropylenes with bimodal MWD. Besides, a comparison will be established with mixtures of individual supported catalysts in different proportions.

Introduction

The polymerization of ethylene and propylene by organometallic catalysts is a subject of increasing interest for scientists and industry. This growth is lead by a new catalyst generation, the metallocene systems, which are able to tailor polymer microstructure and physical and mechanical properties.[1]

These characteristics are due to the control of the resulting average molecular weight and distribution, and of the comonomer content and tacticity by careful selection of the appropriate catalyst structure and polymer manufacturing conditions. These novel copolymers constitute a very interesting approach for stiffness/impact resistance optimization.[2,3]

Materials and Methods

Ethylene-propylene copolymers were synthesized in the whole composition range using a metallocene catalyst, both in homogeneous phase (*H* copolymers), and supported (*S* copolymers). Copolymerization reactions were carried out in a 1 liter Büchi stirred glass reactor. Copolymers were obtained with controlled feeding in the whole range of compositions.

The molecular weights and distributions were determined by gel-permeation chromatography (GPC). The experimental propylene and ethylene contents in the copolymers were calculated by ^{13}C NMR. The films obtained by compression molding were characterized from a morphological and thermal standpoint by WAXS and SAXS (with synchrotron radiation) and differential scanning calorimetry. In addition, mechanical properties have been evaluated.

Results and Discussion

Some differences were found between the two series. On the one hand, the amount of ethylene needed to obtain a certain proportion of γ form is lower in *H* than in *S* series. Moreover, the composition for obtaining the pseudo hexagonal form is also different for the two series. Figure 1 depicts the variation with the ethylene content of the spacings corresponding to the (110) and (200) diffractions of the orthorhombic unit cell of polyethylene, for the two series of copolymers, showing the eventual transformation into a pseudo hexagonal structure.

On the other hand, crystallinity degrees, crystal sizes and microhardness values all display a similar variation with the comonomer content for the two series. Consequently, in spite of the structural differences between the two series, from a macroscopic point of view, materials with similar macroscopic mechanical properties can be produced using both supported and homogeneous metallocene catalysts.

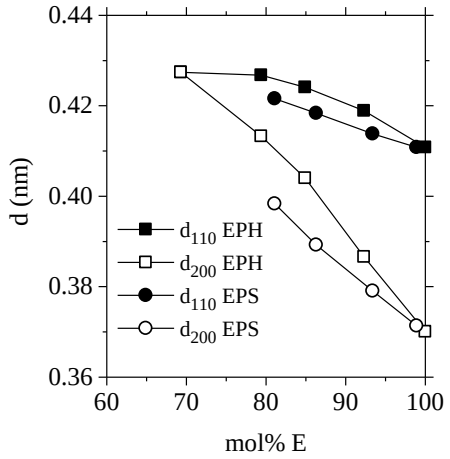

Figure1. Spacings corresponding to the (110) and (200) diffractions versus ethylene content.

Conclusions

Ethylene-propylene copolymers were synthesized in the whole composition range using a metallocene catalyst, both in homogeneous phase (*H* copolymers), and by supporting (*S* copolymers) with the same catalytic system. Although some structural differences have been found between *H* and *S* copolymers, from a macroscopic scale, materials with similar mechanical properties can be produced using both supported and homogeneous metallocene catalysts. And if the macroscopic properties are rather similar, it is evident that the supported catalyst production is the more appropriate choice from the industrial point of view.

Introduction

Isotactic polypropylene, iPP, can be conveniently modified by the introduction of comonomer units, randomly distributed. Polymer crystallinity is disturbed, thus being a powerful tool to modify macroscopic properties. Comonomer insertion interrupts the isotactic sequences, acting as a structural defect, and the formation of γ form is enhanced[1-4]. As a consequence, crystallinity decreases and crystal structure is modified. Comonomer type and concentration determine the extent of these modifications, resulting on important changes on macroscopic properties.

Materials and Methods

Table 1 shows comonomer contents together with molecular weights of the products being studied.

Polymers	Comonomer % mol	Mw (g/mol)	Mn (g/mol)	PI (Mw/Mn)
Homo	0	543,500	82,500	6,6
CPE2.5	2.5	323,000	90,000	3.6
CPE4.8	4.8	385,000	87,500	4.4
CPE8.9	8.9	617,000	124,500	5.0
CPB1.6	1.6	717,000	135,500	5.3
CPB5.0	5.0	523,000	122,000	4.3
CPB8.8	8.8	629,500	147,000	4.3
CPT2.0	1.0 + 1.0	261,500	89,000	2.9
CPT4.5	1.5 + 3.0	249,000	59,000	4.2
CPT9.8	4.2 + 5.6	638,000	173,000	3.7

Table 1. Structure characterization

Results and Discussion

X-ray diffraction is used to study the crystallization of copolymers and terpolymers. Figure 1 shows the diffraction patters obtained.

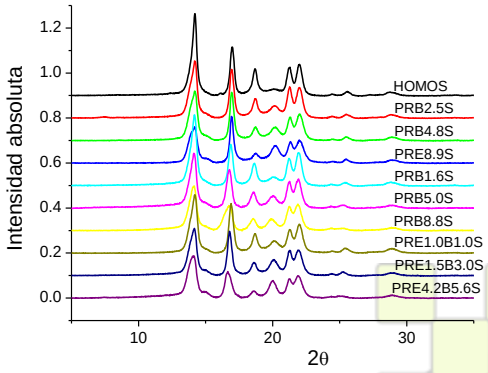

Figure 1. X-ray diffraction patterns.

1-Butene copolymers and terpolymers diffractions show a displacement to lower angles, as a result of a distortion of the crystalline cell, due to cocrystallization and/or by comonomer introduction. This phenomenon is greater in case of 1-butene copolymers than in terpolymers, and it is not observed in ethylene copolymers, showing that 1-butene is included in the crystalline structure in greater proportion than ethylene, and so expanding the crystal cell[5,6,7].

When these polymer samples are rapidly cooled from the melt, they display (Figure 1) the characteristic reflections of monoclinic cell α. This crystalline morphology is not the most favored kinetically, neither the most stable thermodynamically. Nevertheless, it reaches the best commitment between these two criteria, which is why it is the most commonly observed form of crystallization in polypropylene. However, if the cooling is slow, an additional diffraction appears at 20.0º, which is absent in the homopolymer, that corresponds to the orthorhombic form γ. This morphology thus favored by the introduction of defects in the chain and by slow crystallization conditions. Microstructure characterization is performed, using ^{13}C-NMR, to analyze type, content and comonomer distribution, and its influence on the γ-form content.

Conclusions

1-Butene copolymers show higher crystallinity and lower γ-form content than ethylene copolymers and terpolymers. Microstructure analysis shows a random distribution of 1-butene on the polypropylene chain.

Synthesis and Analysis of Properties of Poly (vinyl alcohol) composites

Gulfam Nasar, Mohammad Saleem Khan, Uzma Khalil

National Center of Excellence in Physical Chemistry, University of Peshawar, Pakistan

gulfamnasar@yahoo.com

Introduction:

Material science is the trendiest field of today's research. During the recent years, lot of research is being conducted in search of more handy and cheaper materials. Polymer composites are adding a great deal of material which is more durable and useful as compared to the conventional material. Mechanical and thermal properties of composite materials greatly depend on the nature, proportion and compatibility of the components of the composite materials. In this paper we have tried to find the relationship of these properties i. e. thermal conductivity, tensile strength and Young's Modulus of the composite material. Polyvinyl alcohol has excellent film forming, emulsifying, and adhesive properties. It is also resistant to oil, grease and solvent[1]. It has excellent solubility in water. It also has greater compatibility with inorganic salts when composite materials are synthesized using inorganic salts as fillers[2]. Mechanical, thermal and structural properties of composite materials greatly depend on the nature, proportion and compatibility of the components of the composite materials[3].

Material:

PVA, Na_2SO_4, Li_2SO_4

Method:

For this work, two systems were studied; Poly vinyl alcohol/ Sodium sulphate composite, and Poly vinyl alcohol/ Lithium sulphate composite. Various concentrations of these salts were added to Poly vinyl alcohol, using triply distilled water as solvent. Films were caste, dried at room temperature and were subjected to mechanical, structural and thermal characterization. Thermal conductivity was found out at room temperature using Quick thermal conductivity meter. Polyethylene, silicon and quartz were used as reference. It was found out that the thermal conductivity of both the systems is highly dependent of the nature and the concentration of added salt in the polymeric composite.

Result and discussion:

Thermal conductivity of the Poly vinyl alcohol/ Sodium sulphate composite, and Poly vinyl alcohol/ Lithium sulphate composite, decreased with concentration of the salts in the polymer composite. These composites were also analyzed for their structure and the properties exhibited were explained on the bases of their structure. Similar trends were observed in mechanical properties of these composites, eg tensile strength elongation at break and Young's Modulus. The present study shows that there is a remarkable improvement in the properties in terms of mechanical and thermal properties of the polymeric material. These mechanical properties were studied using UTM (Universal Testing Machine). For morphological study, XRD(X-Ray diffraction\) was used and it was found that crystallinity of the composite decreases with addition of salts in the polymer composite studied.

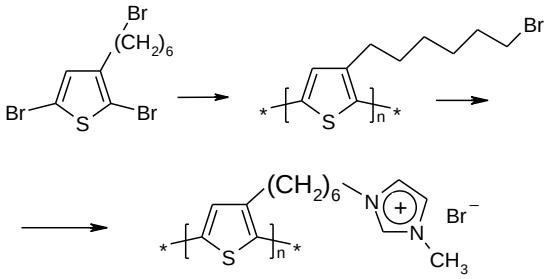
dbondarev@email.cz

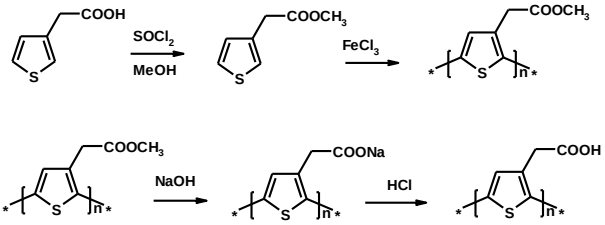
Conjugated polyelectrolytes belong to the class of polymers with potential applications in construction of optoelectronic devices. These polymers possess unique properties which arise from a combination of pi-conjugated main-chain and ionic pendant groups. Main-chain conjugation allows expecting active response to optical or electrical stimuli resulting in potential applications in electroluminescence or photovoltaic devices. Attached ionic groups cause the solubility in water-miscible, environmentally friendly solvents and can mediate specific interactions with ionic polymer carrying oppositely charged moieties, metal nanoparticles or metal oxide surfaces such as titanium dioxide structures which are widely used in construction of photovoltaic devices.



Scheme 1: Preparation of cationic, water soluble polythiophene with HT-regioregular backbone.

Conjugated polymers based on thiophene main-chain units seem to be the promising materials for construction of optoelectronic devices, especially polymer containing photovoltaic solar cells. Polythiopehenes exhibit increased stability contrary to the other conjugated polymers, e.g. polyparaphenylenevinylenes which are also widely used. Also sufficiently high charge (holes) mobility is an advantage. Incorporation of ionic groups on the polymer could produce some benefits such as combination of electronic conductivity provided by the conjugated polymer backbone and the ionic conductivity provided by the side groups. Ionic groups are also utilized for improving the injection of charges from electrodes into the active polymer layers. Polythiophene derivative (Ref. 1) shown in Scheme 1 was selected as a basic material. Described material shows interesting optical properties manifested by formation of micelle-like structures. Further work is aimed at modification of the material by changing the counteranions and incorporation of low band gap units either into the main chain or as a side group to improve optical absorption in the higher wavelength region.

Second class of ionic polythiophenes represents anionic conjugated polymers. Material shown in Scheme 2 is the basic anionic polythiophene. It was shown that interaction with TiO_2 surfaces is sufficient as well as interaction with cationic polythiophenes but the low regioregularity is the serious drawback of this polymer for its utilization as the active layer. Thus the HT-regioregular anionic polythiophene was prepared by catalytic polymerization and experiments described for irregular counterpart are in progress. Nevertheless, the sodium salt irregular anionic polythiophene exhibits interesting optical properties and electrochemical behavior (Ref. 3). All the materials studied are characterized by SEC chromatography and spectroscopic methods such as UV-is, FTIR, NMR a photoluminescence spectroscopy. Interaction of cationic polythiophene with Au nanoparticles also by the Raman spectroscopy.



Scheme 2: Preparation of anionic polythiophene by oxidative polymerization.

Introduction:
Polymer/nanoclay nanocomposite materials are becoming increasingly popular also in the field of pressure sensitive adhesives (PSA). Due to the high surface area of clay particles, novel materials with improved properties can be synthesized at much lower amounts of clay as compared to traditionally used fillers. The nanocomposite material posses improved or novel properties, and often exhibit a balance of previously antagonistic properties. Due to increased environmental concerns a lot of interest is placed in the development of new radiation curable pressure sensitive adhesives (PSA), especially ultraviolet (UV) curable PSA. According to recent papers in this research field covers the synthesis and characterization of UV crosslinkable PSAs synthesized in organic solvents (solution polymerization) [1-3] or as solvent-free acrylic PSAs [4,5].
The improved properties, especially influence on cohesivity, of polymer nanocomposite materials would be also desirable in the field of PSA materials. However, it is highly important that the pressure sensitive character of the adhesive coating is not compromised.
The main research goal of the study was to synthesize 100% solid UV crosslinkable acrylic prepolymers with added modified montmorillonite (MMT) clays. The influence of different types and amounts of modified MMT clays on polymerization kinetics, prepolymer properties, on adhesive properties and on crosslinking process was determined.

Materials and methods: The 100 % solid, UV crosslinkable adhesives were synthesized in 1000 ml glass reactor using Mettler Toledo LabMax system equipped with ReactIR IC10 diamond composite probe which enables in-line monitoring of polymerization process. Different formulations were tested and the polymerizations were carried out at equal process parameters. The basic formulation was equal for all syntheses; the only difference was in type and amount of added MMT clays (amounts from 0.5 to 3 wt. %). MMT clays differ in their hydrophobic nature, which is changed from Cloisite 15A (the most hydrophobic), Cloisite 93A to Cloisite 10A.
Synthesized prepolymer mixtures were coated on siliconized glassine paper on pilot coating machine using a Mayer bar coating system. The pilot coating machine is equipped with UV light - medium pressure Hg vapor lamp, 400 W/in. All adhesive coatings were subjected to UV light for 30 sec, where the total UV exposure equaled 750 mJ/cm^2. Total UV exposure and residence time under UV source was measured with ILT 490 profiling belt radiometer (International Light Inc.). Duration of UV light exposure for successful crosslinking and for determination of the MMT addition influence on crosslinking process was determined by attenuated total reflectance-Fourier transform infrared (ATR-FTIR) spectroscopy with Perkin Elmer Spectrum One FTIR spectrophotometer. Viscosities of synthesized prepolymers were measured using Brookfield viscosimeter. Final conversion of monomers for all syntheses was determined gravimetrically by drying 2 g of PSA in vacuum dryer at 70 °C for 24 h. For the adhesive performance characterization three different test methods were used: the peel adhesion at 180° (FTM 1 – Finat test method 1), the probe test (Polyken test), and the shear resistance (FTM 8).

Results and Discussion:
Results of the study showed, that the addition of MMT clays has a significant influence on all of the measured properties. Viscosity of prepolymers increased with increasing amount of added MMT clay. In-line monitoring of polymerization process showed differences in overall monomer conversion time plots. It seems that polymerization reaction is inhibited in the initial stage when MMT clays 15A and 10A were used, while no differences in overall monomer conversion plots can be determined when MMT clay 93A was used. Monitoring of crosslinking process was based on observation of C=O group conversion upon exposure to UV light, which induces the loss of conjugation between the carbonyl group in the aromatic ring. Therefore, the kinetic profile of UV crosslinkable PSAs may be observed by evaluation of absorption band at 1600 cm^{-1}.
Results showed that the addition of MMT clays at high level (3 wt.%) hindered the crosslinking process. However, 30 sec of UV exposure was enough to achieve complete crosslinking of the prepolymers. The adhesive properties measurements, especially shear strength measurements, showed improved cohesivity of the adhesive coating as a result of nanocomposite structures formation.

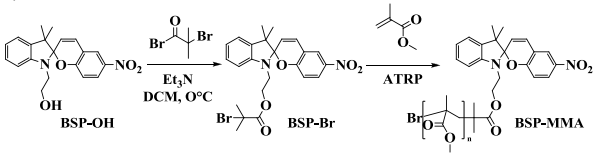
INTRODUCTION

Photo-responsive polymers have been investigated intensively as important elements for the development of smart materials and devices. The ability of these materials to respond with a property transformation triggered by light can be utilized specifically in biomedical applications such as targeted drug delivery and sensing. Photo-responsive polymers have been reported in the literature using various chromophores.[1] Our interest is in polymers functionalized with benzospiropyran (BSP), a well-known photocromic molecule that has the ability to reversibly switch from an uncharged, colorless, spiropyran (SP) form, to a zwitterionic, planar, highly colored merocyanine (MC) form upon exposure to light.[2] Of particular interest is to determine the minimum number of BSP units in a polymer required to trigger a measurable response. In this work we report the synthesis of polymers (PMMA) with a single BSP terminal unit and the investigation of their light responsive.

RESULTS AND DISCUSSION

ATRP was chosen for the synthesis of BSP functional PMMA due to the high end-group fidelity of this technique. A BSP functional ATRP initiator (BSP-Br) was synthesized by the reaction of 2-bromo-2-methylpropionyl bromide with an OH functional BSP (BSP-OH) (Scheme 1).



Scheme 1: Synthesis of benzospiropyrane ATRP initiator (BSP-Br) and benzospiropyrane functionalized poly(methylmethacrylate) (BSP-MMA).

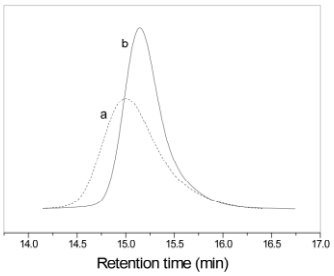


Figure 1: Size exclusion chromatograms of BSP-PMMA1 (a) and BSP-PMMA2 (b).

The polymerizations were carried out using the BSP-Br initiator and methylmethacrylate (MMA) monomer at two different ratios at 60˚C in THF in the presence of the heterogeneous ATRP catalytic system Cu(I)Cl/Cu(II)Cl/HMTETA (Scheme 1). Both polymerizations were stopped after three hours and not further optimized. The resulting number-average molecular weights of BSP-MMA-1 and BSP-MMA-2 were 3600 g/mol and 23800 g/mol, respectively with polydispersities of 1.3 and 1.1 (Figure 1). The polymer structure was confirmed by ^{1}H and ^{13}C NMR, MALDI ToF and UV-Vis spectrophotometry.

Both polymer exhibit conventional SP-MC photochromism in acetonitrile with the strong long-wavelength absorption band located at 568 nm associated with a change from a colorless to a pink solution (Figure 2). The position of the absorption maxima suggests that the SP endgroups experience a non-polar environment with little contact to solvent molecules.

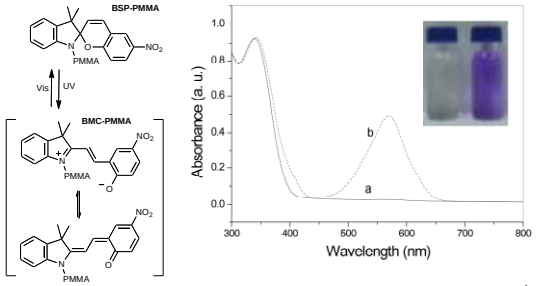

Figure 2:UV-vis spectra of BSP-PMMA1 (1 x 10^{-4} M in acetronitrile) before (a, non colored solution) and after (b, pink solution) 60 s of UV (365nm) irradiation.

Kinetic studies show that the MC to SP transition is increasingly faster with increasing temperature for the longer polymer. The thermodynamic reasons for this unexpected behavior are currently under investigation.

CONCLUSION

In the work presented new light-responsive polymeric methacrylates, bearing a single BSP terminal unit have been synthesized and their photocromic and photoinduced properties have been investigate We were able to show that a single unit is sufficient to obtain effects similar to the multi BSP copolymers and that the switching kintics in acetonitrile depend on the molecular weight.

Synthesis of Hybrid Materials via Photopolymerization of Benzoin Functionalized Silica Nanoparticles

Müfide D. Karahasanoğlu, Ayşen Önen, İ. Ersin Serhatlı

Istanbul Technical University

karahasan5@itu.edu.tr, serhatli@itu.edu.tr, onen@itu.edu.tr

Introduction

Organic–inorganic hybrids that combine the advantages of both kinds of materials, such as mechanical strength and thermal stability with the processability and flexibility of an organic polymer matrix, exhibit multifunctional characteristics.

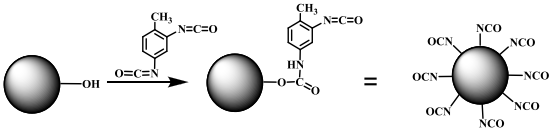
Silica particles have attracted much interest due to their low toxicity, ease of formation in a wide range of sizes and morphologies, high stability, and the surface that can be further functionalized [1-4]

Some chemical agents with more active functional groups are usually employed to substitute the hydroxyl groups to form various functional groups on silica nanoparticle surface. Isocyanate group is considered to be an ideal activator for surface modification of silica nanoparticles. Reactive isocyanate groups of toluene-2,4-diisocyanate enable the reaction of silica nanoparticles with benzoin molecules[5]. Benzoin functionalized silica nanoparticles may be considered as good candidate for photopolymerization systems[6,7].

Materials and Methods

Spherical silica particles, according to Stöber process, were prepared by hydrolysis and condensation reactions of TEOS in an ammonia/absolute ethanol solution.

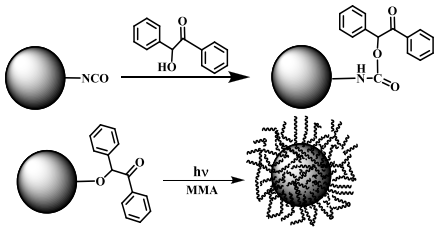
Synthesized silica nanoparticles were dispersed in toluen using ultrasonic sonicator at room temperature. The dispersion was reacted with excess toluene-2,4-diisocyanate (TDI) and catalytic amount of dibutyl tin dilaurate (DBTL) as shown in Scheme 1. The reaction mixture was stirred at 60 °C for 8 hours. In order to remove all the substances physically adsorbed on the surface of the silica nanoparticles, synthesized TDI functionalized silica nanoparticles were sequentially rinsed with toluene and benzene respectively and re-centrifuged.



Scheme 1

TDI reacted silica nanoparticles were dispersed in dimethylformamide using ultrasonic sonicator. Into a three-necked round bottom flask Si-TDI dispersion, excess benzoin, catalytic amount of dibutyl tin dilaurate were charged. The reaction mixture was stirred at 60°C for 10 hours. In order to remove all the substances physically adsorbed on the surface of the nanoparticles, nanoparticles were sequentially rinsed with chloroform and re-centrifuged.

Benzoin functionalized silica nanoparticles were put into dimethylformamide in a tube to disperse in a sonicator under nitrogen atmosphere. Methyl methacrylate was added into the tube containing dispersion of nanoparticles. After UV exposure for photopolymerization, hybrid dispersion was precipitated into methanol. In order to remove homopolymer of polymethyl methacrylate (PMMA), hybrid polymer was dissolved in acetonitrile and centrifuged to obtain PMMA grafted silica nanoparticles as shown in Scheme2.

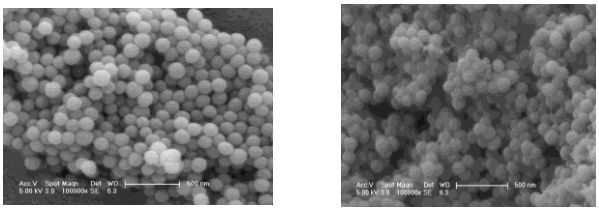


Scheme 2

Results and Discussion

Monodispersed silica nanoparticles were obtained in the size range of 40 nm-100 nm. The size, morphology and dispersity of prepared silica particles were determined by SEM characterization analysis. FTIR spectrums displays characteristic absorptions of synthesized bare, TDI and benzoin grafted silica nanoparticles.

SEM image analysis of Figure 1 shows that the average diameter of silica nanoparticles increases noticeably after the polymerization.



(a) (b)

SEM images of a) bare(60nm) silica nanoparticles and b) PMMA grafted silica nanoparticles (80nm).

Si-TB-PMMA and homopolymer of PMMA were heated up to 900°C by the 20°C/min rate. The residue increased significantly to % 56 for the %10 content of silica. It is obviously seen that silica nanoparticle has an increasing effect on the residue content.

Hybrid Photosensitizers For the Removal of Trace Pollutants from Water

Anna Karewicz, Dorota Bielska, Marta Kumorek, Krzysztof Szczubiałka, Maria Nowakowska

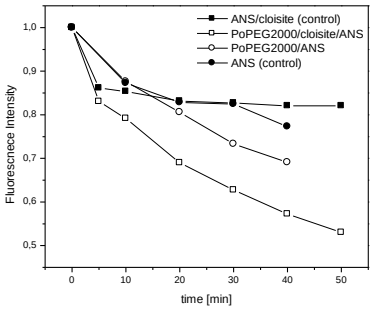
Nanotechnology of Polymers and Biomaterials Research Group, Faculty of Chemistry, Jagiellonian University, 30-060 Cracow, Ingardena 3, Poland

karewicz@chemia.uj.edu.pl

Introduction: Industrial activity is one of the principal causes of water contamination. Large amounts of chemical compounds, which are not capable of degrading by themselves, are dumped into the rivers and lakes. Among them are alkylphenols - one of the most important endocrine disrupting groups of chemicals present in the environment. n-Nonylphenol, a widely used pesticide, belongs to this group. It enters the environment in large amounts, directly through waste waters or indirectly with nonylphenol polyethoxylates. It is stable in water and exhibits aquatic toxicity and estrogenic activity even at very low concentrations. One of the suitable ways to enable biodegradation of toxic water wastes, including n-nonylphenol, is by their photosensitized oxidation using a visible light. In our work we have studied two systems based on the visible light absorbing chromophores, characterized by the high yields of singlet oxygen production. Both chromophores, rose bengal (RB) and porphyrin (Po), are effective photooxidizing agents. However, the removal of sparingly water soluble toxic compounds requires a more complex system allowing efficient interaction between the oxidizing species and the molecules of the contaminant. It is also important to obtain the multiple use photosensitizer. To satisfy these requirements we have designed two hybrid materials where the chromophores are incorporated into the clay nanostructures: 1) water soluble 5,10,15,20-tetrakis(4-hydroxy-phenyl) porphyrin (THPPo) covalently bound to the poly(ethylene glycol) (PEG) chain, 2) molecular rose bengal. The performance of the low molecular weight chromophore and the polymer-modified one before and after their successful intercalation were studied and compared.

Materials and Methods: The porphyrin pegylation product was characterized by ^{1}H NMR and MALDI-TOF analysis. The incorporation of the chromophores into the clay was followed by UV/Vis absorption spectroscopy. Irradiation process was conducted in Rayonet system equipped with 8 lamps emitting at the wavelength of 575 nm. Photooxidation kinetics was followed using UV/Vis absorption and emission spectroscopy and GC-MS analysis.

Results and Discussion: The analysis of the ^{1}H NMR and MALDI-TOF spectra confirmed the attachment of 2000 Da PEG chains to THPPo. Two maxima appear in the spectrum, revealing that the product contains mono- and di-substituted THPPo. The content of the latter was below 9%, as was determined by ^{1}H-NMR analysis. The process of intercalation of THPPo-PEG and rose bengal into the clay was monitored by the UV/Vis absorption measurements. The maximum amount of THPPo-PEG inserted in the Cloisite 30B clay was determined to be 24%, while in the case of rose bengal 69% of the compound was inserted into the halloysite clay. For both chromophore-clay systems their photosensitizing performance was studied in comparison to the chromophore alone. RB or RB-clay sensitizer was added to the aqueous solution of n-nonylphenol (6 mg/l) and irradiated. During irradiation the samples were constantly saturated with oxygen. The oxidation kinetics was followed by UV/Vis absorption measurements. RB alone as well as RB-clay system effectively photosensitize the oxidative decomposition of n-nonylphenol. Within the first 80 minutes over 90% of the pollutant in the case of clay system and almost 80% in the case of the free RB was degraded. The hybrid material proved to be a better photosensitizer compared to the RB alone. The GC-MS allowed characterisation of the oxidation products. For the THPPo-PEG and THPPo-PEG-clay the experiment was performed in an aqueous solution containing anthracene-2-sulfonic acid sodium salt (ANS). ANS was used as a well-known acceptor of singlet oxygen. Using first the model acceptor was found necessary due to the complexity of the hybrid system. During irradiation the samples were constantly saturated with oxygen. Results of the experiment are illustrated below.



Conclusions: The new photoactive dye, THPPo-PEG, was obtained and characterised. The THPPo-PEG-clay system shows a better performance as a photosensitizer of the ANS oxidation in aqueous media compared to the THPPo-PEG alone. RB-clay is more effective in the photooxidation of n-nonylphenol, a widespread water pollutant, than free RB molecule.

Polyanilines (PANI) are environmentally stable conducting polymers with excellent electric, magnetic, and optical properties that have attracted a considerable attention due to high application potential. The unsubstituted polyaniline is insoluble or sparingly soluble in almost all solvents, neither it can be processed thermally. Therefore, there is a permanent interest in development of better processable substituted PANIs though the substituents attached to main chains are known to decrease their conductivity.

PANIs carrying acidic side groups are of particular interest as these groups can also act as internal proton-doping agents; therefore, PANIs of this class are called self-doped PANIs. The emeraldine salt (ES) form of a self-doped PANI is usually doped internally, by the acidic side groups linked to PANI chains, as well as externally, by an added acid (mostly that one used in the preparation of the PANI).

The effect of reaction conditions: feed monomer ratio, oxidant/monomers ratio, reaction temperature, reaction time and concentration of HCl, on the structure and conductivity of copolymers of 2-methoxyaniline (OMA) with anilinic acids (ANIA): 2- and 3-aminobenzoic acids and 2- and 3-aminobenzenesulfonic acids, has been studied using the ICP-AES/elemental analysis, size exclusion chromatography, NMR, FT-IR and UV-vis spectroscopy, and impedance spectroscopy.

To prepare the PANIs the oxidant was dissolved in aqueous HCl and the solution formed was added to a stirred aqueous HCl solution of OMA and particular ANIA monomer of a given composition. The resulting copolymerization mixture was allowed to react under stirring for up to 20 h.

The molar fraction of OMA units in a resulting copolymer, F_1, has been always higher than the OMA fraction in the corresponding feed monomer mixture, f_1, because OMA carrying electron-donating methoxy group is much more reactive than any ANIA tested. Accordingly, the yield and molecular weight (MW) of the copolymers are increasing functions of f_1 and a use of an under-stoichiometric amount of oxidant and/or shortening the copolymerization time favor incorporation of OMA units into copolymer chains. An increase in the polymerization temperature causes a decrease in the content of OMA units (F_1) as well as a decrease in both the yield and MW of the copolymer while an increase in the reaction mixture acidity yields qualitatively opposite effects. The electrical conductivity, σ, of the copolymers prepared lies in the region typical of semiconductors (from 0.05 to 2.5 mS/cm) and, in the first approximation, it is an exponential-growth function of F_1. A good qualitative correlation of σ values with the relative intensity of the Q-band of UV/vis spectra is observed for all copolymers. The data obtained indicate that, in spite of the self-doping effect of ANIA acidic side groups, the incorporation of ANIA units into polymer chains deteriorates the copolymer conductivity and that this effect is caused by a decreased content of emeraldine form in copolymers containing more ANIA units (Fig. 1).

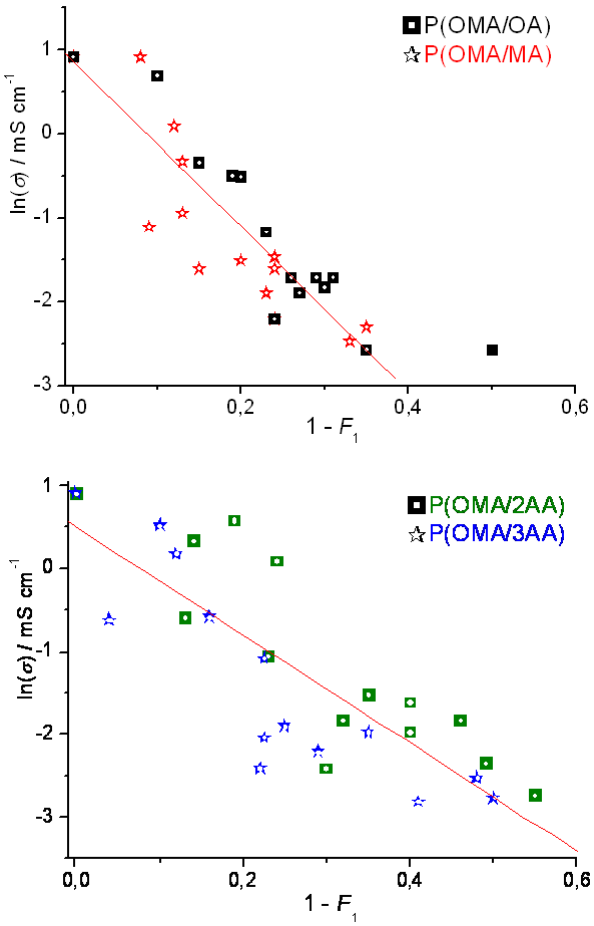

Fig. 1) Semilogarithmic dependences of the σ of P(OMA/ANIA) copolymers on the mole fraction of OMA units in the copolymer, F_1.

The results obtained show that a variation of the reaction conditions such as the feed monomer ratio, oxidant/monomers ratio, reaction time, or acidity and temperature of the copolymerization mixture primarily affects composition of P(OMA/ANIA) copolymers but only little their others structure features.

Morphological Characterization and Mechanical Properties of Poly(Lactic Acid) Blends

Márcia O. Taipina, Márcia M. F. Ferrarezi, Laura C. E. Silva, Maria C. Gonçalves

Institute of Chemistry, University of Campinas (UNICAMP), Campinas, Brazil

maria@iqm.unicamp.br

Introduction

Poly(lactic acid) (PLA) is a high modulus thermoplastic that can be easily processed by conventional techniques. However, PLA is very brittle under tensile and bending loads. PLA properties can be improved by addition of plasticizers, by blending PLA with other polymers or by adding specific fillers. Several research works investigating PLA/thermoplastic starch (TPS) blends have been done. However, the incompatibility between PLA and starch are responsible for formation of blends with poor mechanical properties [1,2]. In this work, the strategy to improve PLA properties and the compatibility between PLA and TPS was the addition of poly(ethylene glycol) (PEG), due to the partial miscibility between PLA and PEG as well as TPS and PEG. Therefore, the main objective was to evaluate the influence of PEG addition on the morphology and mechanical properties of PLA/TPS blends.

Experimental

Materials: PLA (M_W = 300 000 g/mol) was supplied by Nature Works and PEG (M_W = 4 000 g/mol) was obtained from Aldrich. Thermoplastic starch was prepared as described in an earlier work [3].

Processing of the blends: The blends were processed in a twin-screw DSM micro-extruder at 100 rpm for 1 min. Later, the blends were injection molded in a DSM micro-injector in order to prepare tensile and impact specimens (ASTM-D256 and ASTM-D1708). The mold and injection temperatures were 40 and 180°C, respectively. Table 1 shows the blend compositions.

Characterization: The morphologies of the samples were investigated in a field emission scanning electron microscope from JEOL, operating at an accelerating voltage of 3.0 kV. Differential Scanning Calorimetry analyses (DSC) were conducted on a DSC model 2910, TA Instruments.

Table 1: Compositions of the processed blends.

Samples	PLA (%wt)	TPS (%wt)	PEG (%wt)
PLA/TPS (2:1)	67	33	-
PLA/TPS (3:1)	75	25	-
PLA/PEG	75	-	25
PLA/TPS/PEG	56	19	25

Results and Discussion

Figure 1 presents the morphologies of the cryogenic fracture sample surfaces. PLA/TPS blends presented phase separation with cavities generated due to particles detachment during sample fracturing, due to the low adhesion between the phases. PLA/PEG showed continuous morphologies; no phase separation was detected. PLA/TPS/PEG blend showed smooth TPS domains as dispersed phase, rougher PLA phase domains and pores, which were concentrated in PLA phase.

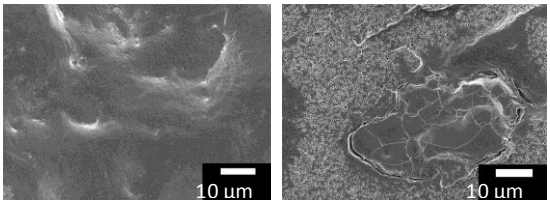

Figure 1: Micrographs (a)PLA/PEG (b) PLA/TPS/PEG.

DSC results are shown in Table 2. The TPS domains of the blends acted as nucleating agents, enhancing the PLA crystallization process. The addition of PEG also facilitated PLA crystallization, as it can act as a plasticizer.

Table 3 shows the mechanical properties of the materials. The presence of the TPS ductile phase resulted in the modulus decrease, but in the increase of the elongation at break and impact strength. Also, a significant increase of the elongation at break was observed for the PLA/PEG blend in relation to PLA. Lastly, the addition of PEG generated an increase of the impact strength, without significantly decreasing the modulus in relation of the values of PLA/TPS blend.

Table 2: DSC results of PLA and PLA blends.

Samples	T_{CC} /°C (PLA)	$\%X_C$ (PLA)
PLA	130	17.7
PLA/TPS (2:1)	109	28.9
PLA/TPS (3:1)	107	30.8
PLA/PEG	80	32.2
PLA/TPS/PEG	81	27.8

Table 3: Mechanical properties of the samples.

Samples	Impact strength (J/m)	Elasticity modulus (MPa)	Elongation at break (%)
PLA	22 ± 3	532 ± 43	13.7 ± 0.7
PLA/TPS (2:1)	52 ± 10	98 ± 25	ND
PLA/TPS (3:1)	55 ± 4	172 ± 34	22 ± 2
PLA/PEG	43 ± 11	9.2 ± 0.8	227 ± 29
PLA/TPS/PEG	119 ± 14	137 ± 17	ND

where: ND = not determined by the equipment.

Conclusions

The results showed that the addition of PEG probably allowed interactions between PLA and TPS phases, as the impact strength increased and the elasticity modulus was similar to the one of PLA/TPS blend.

Introduction:

The carcinogenic dyes are the major constituents of the industrial effluents. Various approaches have been developed to remove organic dyes from the natural environment.

One of the important properties of the inorganic solid TiO_2 nanomaterials is its photocatalytic activity in many applications ranging from antibacterial surfaces to photocatalytic reactions [1,2]. In addition to TiO_2, there are a wide range of metal oxides and sulfides have been successfully tested in photocatalytic reactions [3]. Interaction of these semiconductors with photons having an energy comparable (equal or higher) to the band gap may cause separating the conduction and the valence bands. This event is known as electron–hole pair generation.

Photocatalytic properties of the surface modified TiO_2 catalyst was investigated by degradation of methyl orange (MO) in visible light as a model [4, 5].

Experimental and Methods:

The TiO_2/ZnO/Fe_3O_4/polyaniline (PANI) nanocomposite was prepared according to the following steps: for the preparation of TiO_2 NPs, a solution of 1.5 M ammonium sulfate which consisted of 0.75 M titanium (IV) chloride was used. The precipitated titanium hydroxide was calcined at 400 °C for 4 h. The ZnO nanoparticles prepared via Tang et al. method [6]. The magnetite nanoparticles were prepared by the conventional co-precipitation method with some modifications [7] and PANI synthesized by oxidation polymerization.

Results and Discussion:

The aim of this study is photodegradation of methyl orange in the presence of artificial UV and visible light and nanocatalysts, and then investigates the effectiveness of conducting polymer coated on semiconductor photocatalytic properties.

For degradation of MO, batch experiments were carried out by irradiating the aqueous solution of dye, in the presence of different magnetic nanocomposite such as ZnO/Fe_3O_4/polyaniline and TiO_2/ZnO/Fe_3O_4/PANI in the presence of UV and visible light. The rate of decolorization was estimated from residual concentration spectrophotometerically. For degradation of MO, batch experiments were carried out by irradiating the aqueous solution of dye, in the presence of different magnetic nanocomposite such as ZnO/Fe_3O_4/polyaniline and TiO_2/ZnO/Fe_3O_4/PANI in the presence of UV and visible light. The rate of decolorization was estimated from residual concentration spectrophotometerically. The structure and properties of synthesized photocatalysts were characterized by x-ray diffraction (XRD), UV-vis diffusive reflectance, Differential scanning calorimetry (DSC) and FT-IR spectroscopy.

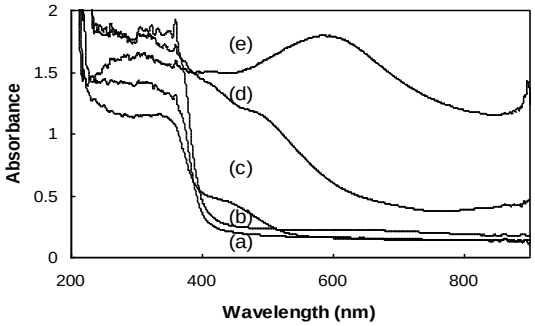

Fig. 1. UV-vis diffusive reflectance of (a) ZnO nanoparticles, (b) TiO_2/ZnO nanocomposite, (c) TiO_2 nanocomposite, (d) TiO_2/ZnO/Fe_3O_4 and TiO_2/ZnO/Fe_3O_4/PANI nanocomposites.

Figure 2 shown degradation of MO under visible light in 60 min. The effect of process parameter viz. pH, initial concentration of MO, and phtocatalyst loading on decolorization of MO solution has also been assessed.

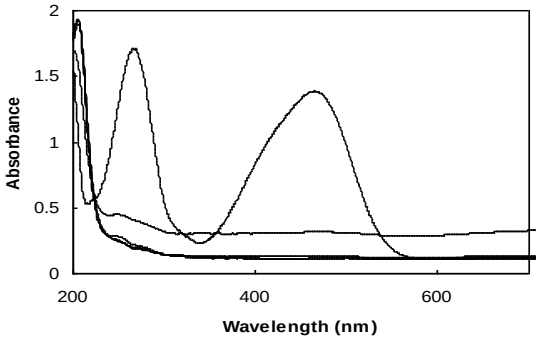

Fig. 2. UV-vis absorption of MO in 15, 30, 45, 60 min under visible light.

Conclusions:

This prepared photocatalyst had a better photocatalytic activity than that of either reported before and the experimental results indicated that 100% degradation of MO in the presence of visible source.

Introduction: Some polymers with amphiphilic character, including acrylamide-based polymers, exhibit in aqueous solution a lower critical solution temperature (LCST). They are fully soluble at low temperatures, but a small increase of temperature above the LCST causes a phase transition. The polymer precipitates from the solution and the solution gets milk-white turbid. On the molecular level, phase separation is a macroscopic manifestation of a coil-globule transition followed by aggregation and formation of so called mesoglobules
[1]. Their thermosensitivity makes these polymers interesting for biomedical and technological applications, e.g. as drug release polymers. In this work, we used NMR spectroscopy and Differential Scanning Calorimetry to investigate changes in the structure and dynamics during temperature-induced phase separation of the poly(acrylamide/*N*-isopropylmethacrylamide) p(AAm/IPMAm) copolymers.

Materials: *N*-isopropylmethacrylamide (IPMAm, Aldrich) and acrylamide (AAm, Fuka) were used to prepare PIPMAm homopolymer and P(AAm/IPMAm) copolymers by radical polymerization. The AAm mole fraction in the copolymers is 0.01, 0.06 and 0.16. The samples were dissolved in D2O, 5 wt.% for NMR and 10 wt.% for DSC.

Methods: The 1H NMR measurements were carried out with Bruker Avance 500 spectrometer operating at 500.1 MHz. The DSC measurements were performed in differential scanning calorimeter Pyris 1 (Perkin-Elmer).
From the temperature dependent integral intensities of NMR signals we calculated the p-factor [2], a fraction of phase separated polymer units. Temperature dependences of p-factor provide quantitative information on the critical temperature, width and extent of the phase separation. Further, using p-factor the van't Hoff's plot was constructed [3] and comparison of obtained thermodynamic parameters with DSC results was made.

Results and Discussion: Temperature dependences of p-factor measured for all samples showed significant increase in the range of the phase separation as the consequence of restricted mobility of polymer units involved in globular structures. From the analysis of these dependences and DSC characteristics (the onset temperatures and enthalpy changes) it follows that increasing fraction of AAm units in the copolymer significantly shifts the transition towards higher temperatures, broadens the transition interval and reduces the maximum value of phase-separated fraction. In contrast to IPMAm units, virtually all hydrophilic AAm units are directly detected in high-resolution NMR spectra of these systems even at temperatures above the phase transition. Because the AAm units are incorporated in polymer chains forming phase-separated globular structures, their rather high mobility suggests that they extensively interact with solvent molecules, i.e., they are hydrated in D2O. This fact results in dynamic heterogeneity of copolymer chains in mesoglobules where AAm sequences and surrounding short IPMAm sequences are hydrated and mobile, while the sufficiently long IPMAm sequences are dehydrated and their mobility is strongly reduced. All these results are consistent with the NMR relaxation experiments [2] showing that P(AAm/IPMAm) copolymer mesoglobules are rather porous and disordered.
The van't Hoff plot calculated from NMR data clearly showed an endothermic two-step process, which have different enthalpic and entropic components. The comparison of these values and the data obtained from the DSC thermograms enables us to estimate number of cooperative units involving in the phase separation as well as to discuss energetic contributions arising from the changes in hydrophilic and hydrophobic interactions.

Conclusion: The information about the critical temperature, degree of the transition and its graduality obtained by NMR and DSC methods corresponds to each other. The increasing fraction of hydrophilic AAm units in the copolymer significantly shifts the transition towards higher temperatures, broadens the transition interval and reduces fraction of phase–separated units.
Relatively high mobility of AAm units incorporated in globular structures results in heterogenity of chains in globules. This conception is consistent with results of relaxation experiments. With both used methods the thermodynamic quanitities of phase transition in the copolymer solutions were determined and compared.

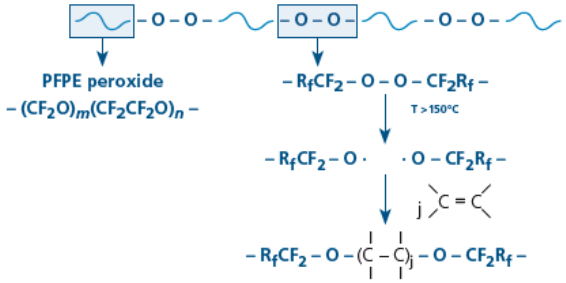
Innovative perfluoropolyether-based copolymers: another breakthrough in fluorine chemistry

M. Avataneo, P.A. Guarda and G. Marchionni

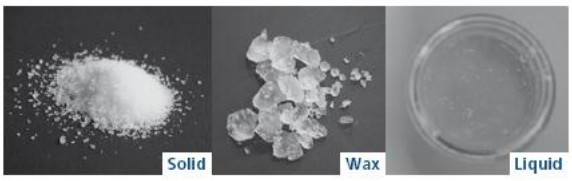
Solvay Solexis S.p.A., R&D Centre, V.le Lombardia, 20 - 20021 Bollate (MI) – Italy

Marco.avataneo@solvay.com

Solvay Solexis has always been engaged in answering to the most challenging needs of high technology markets by developing new and innovative fluorinated products in the field of fluoropolymers [1], fluoroelastomers [2] and fluorinated fluids [3]. Very recently, a new technological platform has been introduced for the synthesis of a pioneering class of perfluoropolyether (PFPE) based copolymers [4, 5] that will fill many of the gaps existing today in markets not currently served by PFPEs. This new chemistry, based on the radical reaction of peroxidic perfluoropolyethers [6] with unsaturated fluorocompounds, can be exploited for the preparation of a huge variety of copolymers not achievable with conventional techniques:



Due to the novelty of these materials, applications are endless, from thin film lubrication to gel based greases [4], to PFPE thermal stabilizer additives [5], polymer processing aids [7,8] and low Tg perfluoroelastomers [5], just to name a few. Many other applications are still under evaluation and development.



PFPE-TFE block copolymers: from solid to liquid

Introduction

Ionomers are polymers containing a certain concentration of ionic groups. The combination of ionic and hydrophobic groups and residues in such materials usually leads to phase separated morphologies, induced by intra and intermolecular aggregation. The resulting aggregation state may be depending on the molecular structure, and can be somehow controlled by the nature and distribution of monomers units [**1**]. A possible strategy to obtain ionomers with controllable structures less depending on spontaneous phase separation is to introduce ionic groups in side chain liquid crystal polymers (**SCLCPs**), obtaining Liquid Crystal Ionomers, **LCIs**. SCLCPs consist of a polymer backbone, a flexible alkyl spacer and a mesogenic group [2]. SCLCPs combine macromolecular characteristics, such as mechanical integrity, with, for example, the electro-optic properties of low molar mass liquid crystals, on a much slower timescale. LCIs can be applied to obtain controllable membranes, since the morphology of the liquid crystal (LC) phases (mesophases) can be regulated by external stimuli. Controlling the resulting structure of the mesophases can also avoid the formation of random ordering morphologies caused by spontaneous phase separation in typical ionomers. We believe that the use of LCIs can be attractive to obtain electrolytes capable to discriminate the diffusion of ions and other molecules by the formation of defined transport pathways. Such is the case of Polymer Electrolyte Membranes used in Direct Methanol Fuel Cells, where high proton conductivities are required with low methanol crossover from the anode to the cathode.

Materials and methods

We have prepared a series of new membranes containing LCIs. The LCIs have been synthesised by radical copolymerization to yield a SCLCP structure, including azo-benzenic units (poly[10-(4-methoxy-4'-oxy-azobenzene) decyl methacrylate, 10-MeOAzB), as the mesogenic units, and sulfonated acrylamide groups (poly[2-acrylamido-2-methyl-1-propanesulfonic acid, AMPS) to provide the copolymers with the ionic sites and potential proton conduction. The structure of the resulting polymers is seen in **Figure 1**. The synthetic route allows for the introduction of other acrylate units as side groups to modify the thermal properties of the resulting LCIs. Thus, we have also investigated the effect of the attachment of methacrylate (MA) and methyl(methacrylate) (MMA) units as a way to obtain tailor made polymers

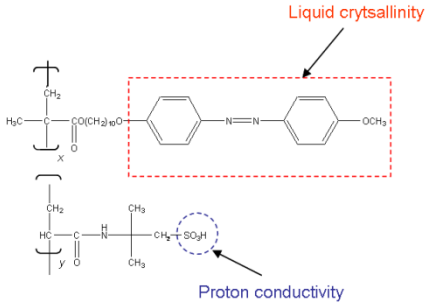

Figure 1. Chemical structure of the LCIs

Results and conclusions

The 10-MeOAzB/AMPS LCIs show mesomorphism in a broad range of compositions ($x_{10\text{-MeOAzB}} \geq 0.5$, molar), by the formation of stable Smectic A phases up to T~135ºC. The introduction of AMPS does not reduce the phase stability to a great extent, possibly by the incorporation of ionic interactions. The disappearance of the liquid crystallinity at higher ionic concentrations ($y_{AMPS} > 0.5$, molar) is possibly due to the formation of ionic aggregates and sudden increase of physical crosslinking. Some experimental results also suggest that the phase stability of the LCI can be easily reduced by the introduction of MA and MMA units in the backbone. Due to the high glass transition of the copolymers, the LCIs have been mixed with several polymers with low glass transitions (T_g) to obtain flexible membranes. Blends of Poly(vinyl acetate), Poly(methyl acrylate), Poly(ethylene oxide) and Poly(vinyl alcohol) are used to form homogeneous films containing the LCIs. The mesogenic behaviour of the membranes is investigated by thermal and spectroscopic analysis to determine the degree of phase separation in the membranes and the possible inhibition of the liquid crystallinity. The absorption properties of the resulting membranes are also studied as a function of their composition and morphology, and the results indicate the potential of the materials to control transport properties.

Crosslinked PVA Membranes for Direct Methanol Fuel Cells

*A. Martínez-Felipe, L. Santonja-Blasco, M. Rosado-Gil, *A. Ribes-Greus*

Institute of Materials Technology, Universidad Politécnica de Valencia

* aribes@ter.upv.es

Introduction

Poly(vinyl alcohol) (PVA) has been proposed an a component in Polymer Electrolyte Membranes (PEM) for Direct Methanol Fuel Cells (DMFC), as a way to reduce methanol crossover through electrolyte, due to its high selectivity for water with respect to alcohols [1, 2]. Prior to be used in the cells, some modifications must be considered in PVA membranes:

- Introduction of ionic groups may be necessary to improve its proton conductivity.
- Physical or chemical crosslinking is required to avoid collapsing in water and to obtain stable films.

Crosslinking with sulfonate diacids combines the formation of stable structures with the introduction of ionic conducting groups [3]. In this work we present some results concerning the preparation and characterisation of PVA-crosslinked membranes, including the effect of the hydrolysis degree in PVA in films formation and the resulting water/methanol absorption properties.

Materials and methods

Samples of PVA with different hydrolysis degrees (HD = 89%, 96% and 99%, MW ~ 85,000 – 124,000 $g \cdot mol^{-1}$, Sigma Aldrich) were mixed with water to form 10%, wt. %, solutions by stirring at 90ºC for 6 hours. Corresponding amounts of a commercial sulfosuccinic acid (SSA) solution (70%, wt. % in H_2O, Sigma Aldrich) were added to the solution, followed with further stirring at room temperature for 24 hours. The resulting homogeneous transparent solutions were cast on a Teflon sheet, and solvent was evaporated at ambient conditions, until no further loss weight was observed. Different PVA-SSA films were obtained in the 0 – 30% SSA weight percentage range (dry weight). Some of the films were submitted to thermal treatment (2 hours, 100ºC) to promote chemical crosslinking by esterification between the OH groups of PVA and the COOH terminations of the di-carboxylic acid (SSA). The proposed mechanism for this esterification is shown in **Figure 1**. Additionally, non-woven Poly(propylene) was used as a substrate in order to enhance the consistency of some of the membranes.

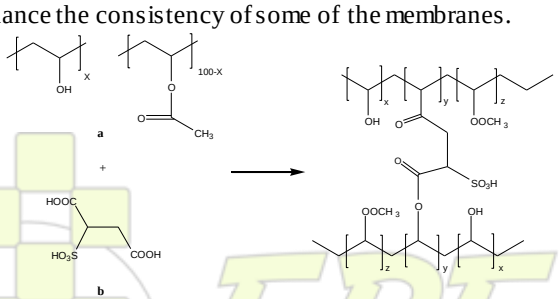

Figure 1. Esterification between PVA (a) and SSA (b)

The structural changes occurring during the formation of the membranes were studied by using Fourier Transform Infrared Spectroscopy (FTIR) and Thermogravimetric Analysis (TGA). Some of the transport properties of the membranes were determined by performing solvent absorption (swelling) and desorption tests. The ionic exchange capacity (IEC) of some of the membranes was also calculated.

Results and conclusions

The formation process of the PVA-SSA membranes was successfully monitored by analysing the IR bands of the OH ($\nu \sim 3000\ cm^{-1}$), C=O ($\nu \sim 1720\ cm^{-1}$) and SO_3 ($\nu \sim 1040\ cm^{-1}$) groups. The results suggest that chemical crosslinking could occur, to some extent, even prior to thermal treatment. On the other hand, HD promotes differences on the efficiency of the crosslinking process. In PVA membranes with low hydrolysis degrees it is possible to observe a threshold concentration at which further increases of SSA contents do not leave to higher crosslinking degrees.

The results also suggest that PVA with HD degrees of 96% are appropriate for the formation of PVA-SSA crosslinked membranes, thus, some of their transport properties were tested. The absorption and desorption tests show considerable differences on the transport mechanisms of water, methanol and their binary mixtures in the PVA-SSA crosslinked membranes. The reduction on the concentration of OH groups caused by crosslinking seems to be the main effect on the reduction of water absorption. On the other hand, methanol is mostly absorbed through non-polar regions, and appears to be unaffected by the crosslinking degree. Increasing the crosslinking degree causes two effects superimposed: increase on the ionic conductivity (as seen from IEC) and reduction of the water/methanol selectivity. Under this view, additional mechanisms to control the polar and non-polar phases of PVA membranes must be carried out to improve the water/methanol selectivity maintaining high ionic contents in the PVA-SSA membranes.

Known, that the bitumen used in road construction as binding materials of asphalt concrete pavements and as joints and cracks sealant, as well as in the production of waterproofing materials for civil and industrial construction.

One of the significant shortcomings of bitumen is their relatively high softening temperature, which does not exceed the 50-55 ^{0}C. For this reason, composite materials based on bitumen cannot be operated in conditions of high temperatures, and pavements are easily damaged and require frequent repairs. This also applies to roofing material, obtained by using bitumen.

Based on the above it follows that the increase of softening point of bitumen in some way would eliminate this disadvantage and increase the time of maintenance-free operation of roads and roofs with bitumen used as binders.

One way to improve the softening temperature of asphalt is the modification of bitumen with macromolecular polymer ingredients softening temperature of which is much higher than the softening point of bitumen. As such modifiers, we used secondary polyethylene, polyvinyl chloride, fine rubber powder.

Obtaining of the effective polymer-bitumen compositions was performed in a reactor heated to a temperature up to 150 ^{0}C.

At the beginning of the reactor was charged with bitumen in an amount of 75 kg, temperature was brought to 100 ^{0}C and was charged with powdered secondary polyethylene in an amount of 25 kg. The temperature was gradually raised to 150 ^{0}C. And a homogeneous mass was formed, i.e. mixture of bitumen with a secondary molten polyethylene (melting temperature of the secondary polyethylene equals 150 ^{0}C). Then the homogeneous bitumen-polymer composition unloaded onto pallets for cooling. After cooling, the softening point was determined by preparing a composition, which was 75 ^{0}C. In the same way bitumen-polymer compositions were obtained using recycled polyvinyl chloride and finely ground rubber powder.

It was revealed that the modification of bitumen with secondary polyvinyl chloride allows obtaining bitumen-polymer composition with a softening point of 75 ^{0}C and more.

Modification of asphalt rubber with finely crushed powder in an amount up to 25 massive particles allowed obtaining bitumen-polymer composition with a softening point at 65 ^{0}C.

Thus, based on the results of studies we can conclude that with the modification of bitumen with macromolecular compounds as the secondary polyethylene, polyvinyl chloride, fine rubber powder it is possible to obtain compositions with softening point in 65-75 ^{0}C, which is 15-20 ^{0}C higher than the softening point of bitumen.

Nanostructures, morphology and properties of Poly[N-(2-cyanoethyl)pyrrole]

Georgina Fabregat[1,2], *Elaine Armelin*[1,2] *and Carlos Alemán*[1,2]

[1]Departament d'Enginyeria Química, ETSEIB, Universitat Politècnica de Catalunya, Av. Diagonal 647, 08028, Barcelona, Spain.

georgina.fabregat@estudiant.upc.edu, elaine.armelin@upc.edu and carlos.aleman@upc.edu

Introduction. In this study we compare the morphology and structure of poly[*N*-(2-cyanoethyl)pyrrole], abbreviated PNCPy, obtained by anodic and oxidative chemical polymerization of *N*-(2-cyanoethyl)pyrrole. In addition, the ability of PNCPy prepared by oxidative polymerization to generate hollow microspheres has been evaluated using the Layer-by-Layer (LbL) self-assembly method.[1] The construction of nanostructures is aimed to use the electrochemical properties of this material for the construction of drug delivery systems. On the other hand, films generated by chronoamperometry (CA) have been used for the detection of dopamine, a neurotransmitter involved in neurological disorders (*i.e.* Parkinson's disease is provoked by a deficiency of dopamine).

Materials and Methods. In all cases chemical polymerization processes were carried out in aqueous ethanol solution using an oxidant/monomer molar ratio of 4:1, the oxidant agent being ferric chloride. The reactants were stirred for 24h at 70 ºC. The fine brown powder obtained was purified washing with ethanol and water solutions. Sulfonated polystyrene microspheres were used as a template in the LbL self-assembly synthesis of PNCPy. Electrochemical polymerizations were carried out by CA using a constant potential of 1.40 V, a polymerization time of 3 s, and an acetonitrile solution with $LiClO_4$ as supporting electrolyte. Electropolymerizations were performed in a three-electrode cell with a working electrode of glassy carbon bare. Structural properties of chemically and electrochemically PNCPy synthesized were studied by Attenuated Total Reflection (ATR) and Specular Reflection (GATR) FTIR spectroscopy. The samples were also examined by ultraviolet-visible reflectance spectroscopy (UV-Vis). Morphological studies were performed using focuses ion beam/scanning electron microscopy (FIB/SEM) and transmission electron microscopy (TEM). The detection of dopamine was investigated by cyclic voltammetry (CV) in the potential range from -0.4 to 0.8 V, in phosphate buffer (pH=7.4), and using glassy carbon bare as working electrode.

Results and Discussion. FTIR studies evidence the loss of the cyano group band (2233 cm^{-1}) in the samples prepared by chemical polymerization. Thus, the cyano group converts into a primary amine, as is schematically represented in Fig. 1A) and 1B), which is expected to be very useful for the detection of biomolecules. In contrast, FTIR spectrum of PNCPy obtained by electrochemical synthesis retains the cyano group.

SEM micrographs of PNCPy showed a globular morphology in all cases, independently of the synthesis procedure. These observations are fully consistent with early studies on polypyrrole and poly(N-methylpyrrole), which described similar morphologies.[2] This globular growth was particularly apparent for powder PNCPy arising from chemical polymerization (*i.e.* in absence of PSS template), in which microspheres of uniform size distribution (2.1µm) and high roughness resulting from subunits aggregation (51nm) were surprisingly identified.

On the other hand, the production of hollow spheres under the experimental conditions described above was not satisfactory. The average layer thickness of some hollow PNCPy microspheres was below 50nm, even though an irregular and not uniform thickness distribution was observed.

The thickness of the PNCPy films generated by CA using a polymerization time of 3 s was around 78 nm. CV assays indicated that these films were useful to detect very small concentrations of dopamine in solution.

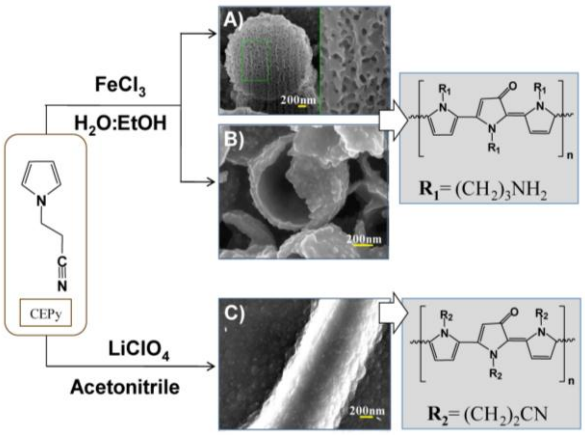

Figure 1. Scheme showing SEM images and chemical structures of: microspheres from oxidative chemical polymerization (A) and (B); and films obtained by electrochemical polymerization (C).

Conclusions. Results suggest that oxidative polymerization provides a simple and fast method to obtain microspheres, the use of PSS templates being not required. The electrochemical properties of the produced materials are currently under study. PNCPy generated by CA is a very useful material for the detection of small concentrations of dopamine.

Durability and safety of the expansion joints of concrete pavement and the maintenance and elimination of cracking of asphalt concrete pavements is an important and urgent task. In solving this problem special emphasis on the use of sealing materials, which enhance effectiveness of joints with maintaining their durability, continuity during the annual cycle, and is not allowed to increase fracture over time.

In practice, this problem is solved by using different types of sealing materials. They can be prepared on the basis of rubber bitumen and gossypol resin which maintain flexibility at both extreme low and high temperatures. They are used to fill the joints of cement concrete pavement of the roads, for repair of chips, and selective termination of shells, as well as for crack repair of asphalt surfaces.

Technological process of obtaining of the bitumen compositions comprises the following steps: preparation of bulk ingredients (clearing of unwanted impurities, fine grinding, mechanical activation), preparation of bitumen, modification of gossypol resin and flow mixing the ingredients and feed for blending, mixing the ingredients for obtaining the bitumen compositions; unloading asphalt compositions on trays, cooled and transferred to a finished product warehouse.

The full technological process includes the following operations: preparation of bulk ingredients carried on the preparatory site. There committed to crushing ingredients such as waste tires, hydrolytic lignin, secondary polyethylene and polyvinyl chloride to a powder, basalt fibers, hydrated lime and wollastonite not only crushed, but mechanically activated as well.

Bitumen grade BN-90/10 comes as a roll, wrapped in a craft paper. First, it is freed from the paper and crushed to small sizes. Then weighed according to the formulary card and loaded into reactor equipped with an adjustable steam or electrically heated to maintain the temperature within 110-120 ºC.

Gossypol resin and modifying additives are loaded into another reactor with heating jacket to a temperature of 170-180 ºC, where gossypol resin is modified.

From the reactor melted to a flow able state modified bitumen BN-90/10 and gossypol resin flow into a third reactor through dispensers for mixing with other ingredients. In turn, the other ingredients are weighed according to the recipe and loaded into the same reactor.

Mixing of the components loaded into the third reactor lasts for 2.5 hours at a temperature of 180±10 ºC.

Then finished bitumen composition is unloaded onto 70 x 50 x 5 cm pallets and cooled to the room temperature on the shelves and sent to finished production storage.

Study of Composition and Technology of Highly Filled Composite Polymeric Materials for Asphalt Roads, Which Can Be Used in Hot Climates and Increasing Their Operation Life

email: polycomft2005@rambler.ru

Our studies over the years have shown that the durability of composite polymer materials designed to cover the roads and sealing of joints and cracks in the first place depends on the heat resistance of the ingredients within the composition.

In these compositions, the least heat resistant ingredient is bitumen and gossypol resin, softening temperature and flow does not exceed 60-70 ^{0}C. In hot climates, as in Central Asia pavements are heated to 100-110 ^{0}C, which leads to a reduction in their longevity as a result of formation of corrugation on the road surface and cracks through which increases the penetration of rain water and intensifies the destruction of the all road bed.

To eliminate these deficiencies and improve the durability of highly filled composite polymeric materials designed to cover the roads we have carried out research into the modification of bitumen grade (bitumen) BN-90/10 BN-70/30 and secondary polyethylene. As a secondary polyethylene we used the used greenhouses' plastic film, domestic packages, bottles and waste polyethylene.

While obtaining a coating the composition temperature is brought up to 150-170 ^{0}C, and the sealing composition is obtained at 170-190 ^{0}C. If we consider that the softening temperature of low density polyethylene is in the range of 100-120 ^{0}C, and the melting temperature and flow at the level of 150-170 ^{0}C, can be expected in terms of production of paving and sealing materials the obtaining of a homogeneous molten mass, which will play the role of the combined polymer binder and determines the heat resistance and durability of the resulting compositions.

Given this assumption, we researched the effect of different amounts of recycled polyethylene on the softening point of bitumen and compositions based on them. In the current study found that the introduction of the bitumen 10-20% recycled polyethylene contributes to their softening temperature at 20-25 ^{0}C.

The composite materials for road paving and sealing of joints with bitumen containing 20% recycled polyethylene were obtained. They have been used in the construction of the road "Fargona Hulka Yuli".

Observations made during the years of the conditions of the roads, showed that on the road surface does not appear corrugation, and joints and cracks remain sealed for 3-3,5 years.

Thus, we conclude that the increase in longevity of highly filled composite polymeric materials designed to cover the roads can be achieved by increasing the softening point of bitumen by introducing to them 20-25% recycled polyethylene, which will lead to longer maintenance-free operation of roads by 2-2,5 times.

COMPATIBILITY STUDIES OF POLY(ETHER IMIDE) WITH LIQUID CRYSTAL MIXTURES

Fatih Çakar, Hale Ocak, Belkis Bilgin-Eran, Özlem Cankurtaran and Ferdane Karaman

ABSTRACT

The liquid crystalline state of matter is a fascinating subject for both basic and technological reasons. Liquid crystalline compounds (LCs) have been developed into a very useful class of materials. They have found a variety of application such as display devices, optical and thermal sensors and stationary phases in chromatographic columns [1]. By introducing a chiral moiety into LC molecules, unusual physical properties can also be obtained [2]. In general, the mesomorphic properties of LCs are strongly affected by the type of molecular core, the structure of the chiral part as well as by the length and character of the non-chiral chain.

Mixing is very important in modern technologies for processing of materials composed of many different chemical components [3]. Polymer and liquid crystal mixtures are an important area of interest in science and engineering because of its many applications in industry. Miscibility can be detected by a number of techniques. Among these techniques, it is well known that determination of the viscometry of a dilute solution is a simple and quick method for determining the miscibility.

This study deals with the determination of the miscibility of poly (ether imide) (Ultem) and their mixtures with liquid crystalline compounds in dilute solutions. Mixtures of variable compositions from 0 to 100 wt% were prepared by solvent casting. Their miscibility was investigated by using viscometry.

Introduction

Organic powder coatings are considered the best alternative for the reduction of volatile organic contents (VOCs) in the anticorrosive-coatings industry because they present VOC emissions lower than 4% [1] and [2], while solvent-based paints present more than 60% of VOCs. Despite this big advantage, organic powder coatings present some limitations like the difficulty to be applied on thermo-sensible substrates as wood, plastic or structural aluminum alloys (e.g. aeronautic industry) due to the high temperatures used on their curing. For this reason there is an interest on creating organic powder coating systems with low curing temperature and time together with good anticorrosive properties.
In many industrial applications such as industrial coatings, thermal and mechanical properties of the thermoset systems determine the quality of the final product. Moreover, in thermosetting coatings, curing at lower temperatures and/or shorter times and the strong adhesion to the metallic substrates are the main objectives to obtain good products to be used in the industry with energy saving. It has been reported that volume shrinkage during curing leads to poor adhesion to the substrate, warping, delamination, and the apparition of microvoids and microcraks, which reduce the durability of the paint [3]; thus, coatings obtained without shrinkage can be expected to have enhanced mechanical properties and longer service lives. Nevertheless, the main difficulty on developing new coatings is to combine fast curing with no shrinkage and maintaining their good mechanical properties.

Materials and Methods

In this study, we produced new polyester coatings using branched polymers and silanes to promote adherence to galvanized steel substrate. In order to have an overall idea of the influence of the silanes on the adhesion of the system, adhesion tests were carried out, in accordance to ISO 4587 (figure 1).

Results and Discussion

These coatings can show big advantages because of their mechanical properties combined with a very fast curing (thus improving the quality of the film and reducing curing costs). In addition, to prove the quality of the new systems, we compare the results to those obtained with a conventional polyester formulation. The study is completed showing the application of a new accelerated electrochemical cyclic test applied to obtain the anticorrosive properties of the coatings formulated, as schematized in fig. 2.

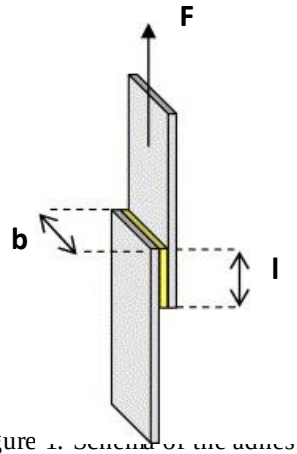

Figure 1. Scheme of the adhesion test

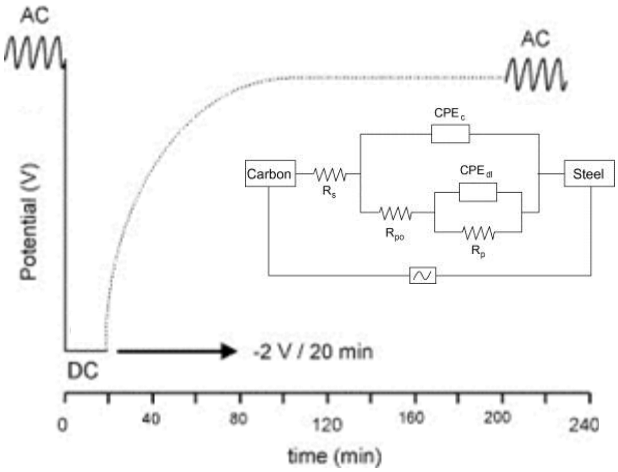

Fig. 2.AC/DC/AC test: schematic figure of Potential (V) vs. time and equivalent circuit used to model the electrochemical cyclic test [3].

Introduction: Poly(urethane-urea) copolymers (PUUs) represent an important subclass of segmented polyurethanes (PUs) in which diamines are used as the chain extenders instead of diols. Due to the stronger hydrogen bonding in the hard domains, the PUUs possess improved mechanical properties compared to conventional thermoplastic PUs. The soft phase (flexible and non-polar) is mainly made up of polyether, polyester or polysiloxane segments, while the hard phase is highly polar urethane and/or urea segments based on different isocyanates and chain-extenders [1]. Siloxane-based segmented PUs and PUUs have attracted much attention because of their properties such as water repellence, heat resistance, anti-adhesion (low surface free energy) as well as biological inertness. Poly(urethane-urea-siloxane)s (PUUSs), which are the subject of this work, have already found commercial applications as elastomers, solvent-based adhesives for automotive industry and biological implants, because of their elasticity, high mechanical stability and biocompatibility [2]. The present work is focused on the synthesis and characterization of PUUS copolymers based on hydroxypropyl terminated polydimethyl-siloxane (PDMS) as the soft segment and 4,4'-methylene diphenyl diisocyanate/ethylene diamine (MDI/ED) as the hard segment. A series of PUUSs with different hard segment content (from 43 to 61 wt.%) was prepared. The effect of the structure and composition of the copolymers on their thermal and morphological properties was investigated.

Materials and Methods: The PUUS copolymers were prepared by two-step polyadition method in the solution. The isocyanate-terminated prepolymer prepared from α,ω-dihidroxypropyl-PDMS (M_n=1000 gmol^{-1}) and MDI in the first reaction step, was further chain-extended by addition of ethylene diamine. The required amount of MDI was also added in the second step and reaction was continued for 3 h. The syntheses were carried out at 40°C with stannous octanoate as a catalyst (0.05 mol% based on PDMS). The concentration of the monomers was 25 wt.% in the mixture of tetrahydrofuran/N-methylpirrolidone (1/9). ^{1}H and ^{13}C NMR spectra were recorded on Varian Gemini-200 spectrometer at 25°C using DMSO-d_6 as solvent. The intrinsic viscosities, [η], were measured at 25°C in NMP. The copolymers were characterized by GPC in NMP as the mobile phase. Thermal analyses (DSC and TGA) were performed under nitrogen atmosphere, with a heating rate of 10 °Cmin^{-1}, over a temperature range of -150 to 200°C (DSC) and 25 to 600°C (TGA). Copolymers were also characterized by AFM measurements.

Results and Discussion: The general structure of the synthesized PUUSs was confirmed by NMR analysis. The ^{1}H spectra of copolymers showed characteristic signals of the NH urea and NH urethane protons. In the ^{13}C NMR spectra, a resonance signals at 153.8 and 155.7 ppm was observed, which indicates the presence of the carbonyl carbons from urethane and urea bonds, respectively. The lengths of the hard segments (L_n) were calculated from quantitative ^{13}C NMR spectroscopy [3] and were in range from 1.94 to 4.73. The samples with higher content of the hard segments generally showed higher [η] values and higher molecular weights (Table 1). The T_g of the soft segments was observed at -108°C, indicating that the PDMS was microphase separated from the hard segment. A broad endothermic peak, observed about 70 °C, can be related to disruption of short-range ordering of the hard segments or to their T_g. High temperature transitions were not detected, because the thermal degradation of the urea and urethane bonds occurs around 200°C, before melting of the copolymers (Table 1). Contact mode AFM images of the surface topology were used to characterize the PUUSs. The distribution of hard and soft phases on the polymer surface was analyzed by 3D- and 2D- mode contact error. The three-dimensional large-scale resolution images clearly showed spherulitic structure. It was also shown that the roughness coefficient varied with the content of the hard segments.

Table 1. Composition, [η], molecular weights (M_n) and thermal stability of the PUUSs

Sample	HS, wt.% (NMR)	L_n (HS)	[η], dL/g	M_n, g/mol	$T_{10\%}$, °C
PUUS1	43	1.94	0.29	19540	211
PUUS2	47	3.11	0.25	15600	262
PUUS3	59	4.35	0.33	23000	239
PUUS4	61	4.73	0.51	37200	249

Conclusions: A series of four samples of segmented PUUSs, with different hard to soft segment ratio, was prepared and characterized. The structure and composition of the PUUSs was confirmed by NMR spectroscopy. DSC analysis and AFM measurements revealed that the copolymers show a high degree of phase separation between hard and soft segments. TG analysis in nitrogen showed that PUUS copolymers were stable up to 200°C.

Physical aging of melt-blown PLA fibres

Jaroslaw Janicki, Monika Rom, Janusz Fabia

University of Bielsko-Biala, Institute of Textile Engineering and Polymer Materials, Poland

jjanicki@ath.bielsko.pl

Introduction

Due to new and more efficient methods of polylactide (PLA) synthesis its bulk production is possible so that the application of PLA to production of conventional materials is more probable and feasible, even though in the past it was restricted to mostly to specialty products such as medical.

PLA is the thermoplastic polyester and can be melt processed at the temperature range comparable with polypropylene's, however it requires careful drying prior to processing in order to avoid degradation during process [1].

Formation of PLA fibres can be carried out either by dry or melt spinning processes. Manufacturing of ultra-fine fibres, which are beneficial for specific applications such as filtration, is possible by electrospinning but also by melt-blown technology, which allows to obtain much better efficiency of the process[2].

Materials and Methods

Commercial grade crystalline NatureWorks®PLA 3051D was processed using lab-scale melt-blown equipment at CENARO Institute (Lodz, Poland). The equipment enables to adjust several parameters including temperatures at different sections, air pressure (velocity) used to attenuate the filaments and the distance between extruder die and collector and others. Polymer before processing was dried to the water content of 250ppm. Crystallinity of melt-blown PLA was analyzed by WAXS using URD-6 Seifert diffractometer. Observations of morphology were done by SEM (Jeol JSM 5500LV), and thermal analysis by DSC (TA Instruments 5100).

Results and Discussion

Classically PLA filament is formed in a two-stage melt spinning process, in which hot drawing enables for fiber orientation, and crystallinity is achieved as the result of stress-induced crystallization. In case of melt-blown technology drawing is realized by high velocity air which is used to attenuate filaments and there is no possibility of subsequent drawing step leading to crystallization and orientation, so that as-spun PLA melt-blown fibres are amorphous (Fig.1), however the cold crystallization process occurs as the effect of fibres' annealing at temperatures above T_g. Changes in supermolecular structure occurs also at temperatures below T_g as observed from DSC and WAXD of samples analyzed after one year of storage at room temperatures, and samples annealed at the temperature below T_g. Such changes are explained by physical ageing [3,4].

The process of fibres skin and core solidification is radial and uneven and the effects of uneven solidification resulting in shrinkage of outer layer are observed on fibres' surfaces (Fig.2.).

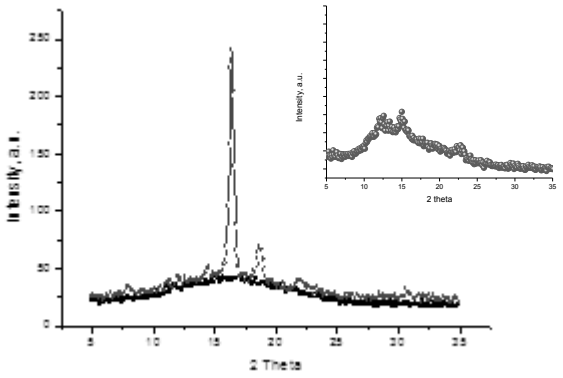

Fig.1. X-Ray scattering patterns of virgin polymer (gray), as-spun fibres (black) and fibres after one year storage (right top corner).

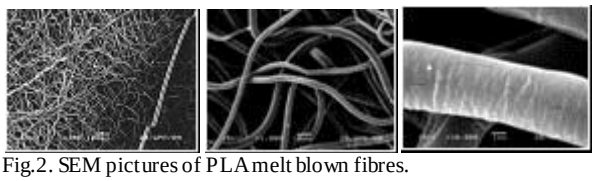

Fig.2. SEM pictures of PLA melt blown fibres.

Conclusions

Melt-blown technology enable to obtain ultra-fine fibrous structures which are of special importance in case of for example filtering materials. When planning production of such materials one need to consider the physical ageing effect, which is resulting with crystallization of materials' structure that may affect properties of final product during storage.

Recovery of Copper with Sulfonated Microcapsules Containing DEHPA

A. Alcázar, A.M. Borreguero, M. Carmona, A. de Lucas and J.F. Rodríguez

Institute of Chemical and Environmental Technology (ITQUIMA), Department of Chemical Engineering, University of Castilla-La Mancha, Avda. Camilo José Cela s/n 13004 Ciudad Real, Spain

Angela.Alcazar@uclm.es

A wide variety of aqueous waste solutions and the natural formation of acidic mine drainage are the most serious difficulties encountered in mining and metallurgy activities and this is a serious environmental problem. Furthermore, these solutions can also constitute a potential source of many valuable and scarce metals.

Solvent extraction and ion exchange technologies have been widely used for the recovery or removal of heavy metals from aqueous phases. However, different problems have been encountered on applying these techniques. Although the extractants are highly selective, this technique requires a high level of mechanical agitation to improve the kinetics of the process, a requirement that promotes leakage of the extractant from the aqueous/organic interface to the aqueous phase during the separation of the two phases (1, 2). On the other hand, ion exchangers can be easily regenerated but gel form resins have low selectivity and those with a high selectivity (chelating resins) have low diffusion coefficients, a characteristic that leads to low mass transfer rates (3, 4). An interesting alternative to overcome these limitations is the microencapsulation of extractants within a functionalizated polymeric shell. This new type of material would be expected to combine the advantages of the aforementioned methods and improve selective removal of heavy metals from an aqueous phase.

The material is formed by a shell of sulfonated poly(styrene-co-divinylbenzene) (P(St-DVB)) and di(2-ethylhexyl)phosphoric acid (DEHPA) as core. The microencapsulation was accomplished by suspension like polymerization technique at 80 ºC. The shell sulfonation was carried out using sulfuric acid at 50 ºC.

According to the TG analysis, a 34.86 % of DEHPA was encapsulated and this microcapsules exhibit a spherical shape with an average particle size in number of 340 µm, close to those reported in literature for commercial resins (5).

Kinetic and equilibrium studies were carried out in order to determine the behaviour of this new material and check the effect of the shell sulfonation in the ion exchange process. Experiments were generated for the H^+/Cu^{+2} system at 25 ºC using different synthesized materials: sulfonated particles without DEHPA (SND), sulfonated microcapsules (SD), non-sulfonated microcapsules (DNS); and Amberlite IR-120 as commercial resin reference material.

Equilibrium data were fitted to the Langmuir isotherm as a first approximation. As can be seen from Fig.1., SD microcapsules show a capacity of 1.702 meq/g, which is almost 13 times higher than that of DNS (0.134 meq/g). This indicates that sulfonation increases the mobility of metal ions up to the extractant agent. In addition, the capacity of the SD is also higher than that of SND (0.938 meq/g), which shows that the presence of DEHPA enhances the metal removal from the aqueous phase. Despite of that fact, SD capacity is still lower than that for the commercial resin (4.444 meq/g). Therefore the content of encapsulated DEHPA should be increased in order to obtain a competitive product for its industrial application.

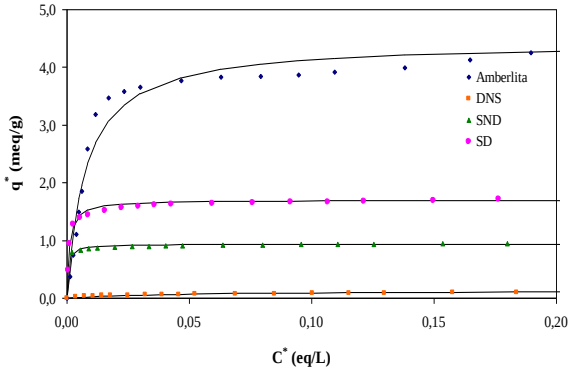

Fig.1. Equilibrium isotherms for the studied materials

Finally, kinetic studies allowed to determine the interdiffusion coefficients of copper for these materials by means of an homogeneous model, which assumes that a quasi-homogeneous phase exists inside the solid particles. Experimental data were perfectly fitted to this model and gave the following intediffusion coefficients: $2.90 \cdot 10^{-8}$, $1.86 \cdot 10^{-7}$, $2.50 \cdot 10^{-7}$ and $8 \cdot 10^{-7}$ cm^2/s for DNS, SD, Amberlite IR-120 and SND, respectively. These values indicate that sulfonated microcapsules have kinectics of the same order of commercial resins and much higher than that of non-sulfonated materials.

These results indicate that this material would be a suitable alternative for the extraction and separation of heavy metal ions from aqueous solutions since kinetic studies show that this kind of microcapsules could be used to remove copper from aqueous solutions, due to their high selectivity and the high rate of the separation process.

Introduction

Stimuli-responsive hydrogels are cross-linked networks built-up at the presence of water that expand or contract by the change of external stimuli. These so called intelligent hydrogels are of increasing interest because of their use in a variety of applications such as drug-delivery and sensors. One of the most studied polymers in this context is poly(N-isopropylacrylamide) (PNIPAM) with a lower critical solution temperature (LCST) around 32 °C in pure water. Below the LCST the PNIPAM chains are hydrophilic and dissolve well in water. Above the LCST the PNIPAM repels the stored water, forms globules and precipitates from water.

Most studies of PNIPAM only take a close look to the behavior in aqueous solutions, but thin film geometries are of special interest especially with regard to sensor application. Thin films of PNIPAM swell significantly by absorption of water molecules when exposed to water vapor [1]. When heated above the LCST a deswelling of the films is observed which is even apparent for model sensors with a metal top-layer [2].

There are only few studies of cyclic PNIPAM, although this topology is of great interest because of the absence of end-groups. End-groups have a significant impact on the LCST, as reported in comparative studies of cyclic and linear PNIPAM [3,4].

Materials, Methods and Results

In this study, we compare the properties of thin films of cyclic and linear PNIPAM with comparable molecular weights and a low polydispersity. Spin coating was used to create thin and homogenous film on silicon substrates that were pre-cleaned using a basic cleaning procedure to achieve a hydrophilic surface. For both polymers we prepared films of different thicknesses from chloroform solution and characterized them with optical microscopy and X-ray reflectivity.

For the investigation of the swelling behavior a small probe cell is used to create saturated water vapor and the film thickness is measured with white light interferometry. The time-dependent swelling when exposed to water vapor is investigated for both systems, the cyclic and the linear PNIPAM thin film, as well as the thickness changes upon heating of the samples above the LCST. The heating was done in steps with a waiting time at each temperature long enough to ensure equilibration of the thin PNIPAM films with the surrounding water vapor.

Interface correlation of the surface of the cyclic PNIPAM thin film with the roughness of the substrate is examined using grazing incidence small angle X-ray scattering (GISAXS). With this non-destructive method we are capable of investigating the correlated roughness not only on a limited spot on the sample surface but averaged statistically over the whole illuminated area [5]. Selected 2d GISAXS images are shown in **figure 1**.

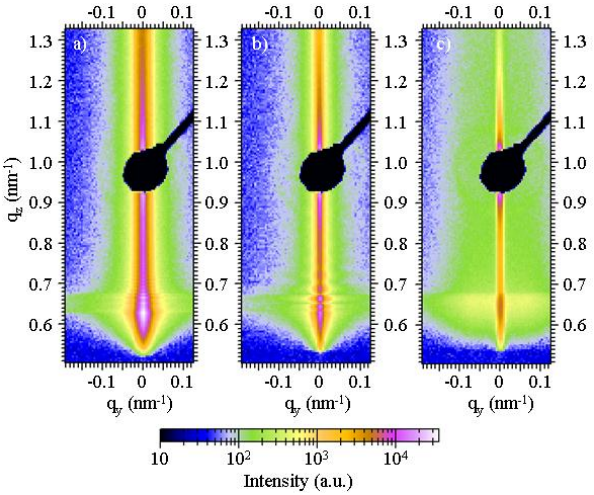

Figure 1. 2D GISAXS images of dry, cyclic PNIPAM films with different film thickness (decreasing from a) to c)). The specular beam is shielded with a beamstop to protect the detector.

Conclusion

By comparison of cyclic and linear PNIPAM thin films we get more detailed information of the influence of end-groups on the LCST as well as the thin film morphology.

Pillip76@empal.com

Introduction

Since the dye-sensitized solar cell (DSSC) was introduced in 1991,[1] it has shown great promise as low-cost, highly efficient power generator for green and renewable energy sources. In recent years, effort has been directed toward conducting polymers as potential counter electrodes (CEs) in DSSCs due to their advantages of high catalytic activity and low material cost.[2,3] Among the conducting polymers, polypyrrole (PPy) is of special interest due to its ease of synthesis, high conductivity, and low cost. Therefore, these advantages of PPy motivated us to explore its feasibility as an alternative material to Pt CEs. Here, we report on PPy nanoparticles coated on FTO glass as a highly efficient CE for DSSC applications.

Materials and Methods

Myristyl trimethyl ammonium bromide and decyl alcohol were dissolved in distilled water. Then, pyrrole monomer was added to the solution. $FeCl_3$ solution was added to the above solution. After polymerization, PPy nanoparticles were re-dispersed in methanol. The resulting PPy dispersions were then dropcast onto an FTO glass. To improve the conductivity of the PPy layers, the PPy/FTO CEs were treated with HCl vapor.

A transparent nanocrystalline layer was prepared on the FTO glass using TiO_2 paste. The TiO_2 electrodes were heated gradually up to 500°C. A paste containing 400-nm anatase TiO_2 particles was deposited using doctor blade printing. The TiO_2 electrodes were heated gradually up to 500°C. Then, the electrodes were immersed in N719 dye solution for 12 hr. The dye-adsorbed TiO_2 electrodes and various PPy CEs were assembled in a sealed sandwich-type cell. Then, the electrolytes were introduced into the cell.

Results and Discussion

The methanol-based PPy dispersions of 5.0 wt% were dropcast onto FTO glass. Fig. 1 shows SEM images of the surface and cross-section of the PPy layer on FTO. The surface of the PPy layer is a nanoporous structure of PPy particles. The porous structure increases the specific surface area, which might facilitate the electrocatalytic activity of the I_3^-/I^- redox reaction in the electrolyte solution. The thickness of the PPy layers coated using 5.0 wt% PPy dispersions was ~10 μm.

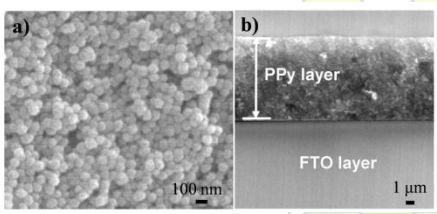

Fig. 1 SEM images of the (a) surface and (b) cross-section CEs coated with 5 wt% PPy on FTO glass.

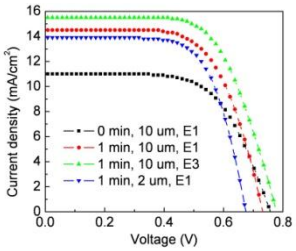

Fig. 2 *J-V* curves of the DSSCs using various PPy/FTO CEs.

The current density-voltage (*J-V*) curves for DSSCs based on various CEs and electrolyte compositions are presented in Fig. 2. When the HCl treatment time for 10-μm PPy-layered CE using electrolyte E1 was increased from 0 to 1 min, J_{sc} increased from 11.0 to 14.5 $mAcm^{-2}$, whereas V_{oc} and *ff* remained essentially constant, so that η = 6.83%. The enhanced photovoltaic performance might be due to the greater catalytic activity and lower surface resistivity of the PPy layer with HCl vapor treatment compared with as-prepared PPy CE. Increasing the HCl treatment time to 10 min reduced η to 5.39%. In addition, when the PPy layer thickness changed from 10 to 2 μm with a fixed HCl treatment time of 1 min and the same electrolyte (E1), V_{oc} and J_{sc} dropped to 675 mV and 13.8 $mAcm^{-2}$, respectively, whereas *ff* remained constant, affording a slightly lower η of 6.35%. When we changed the electrolyte composition from E1 to E4 with a fixed HCl treatment time (1 min) and a PPy layer thickness of 10 μm, the optimized cell gave J_{sc} = 15.5 mA cm^{-2}, V_{oc} = 778 mV, and *ff* = 0.64, corresponding to η = 7.73% using the E3 electrolyte composition.

Conclusions

PPy nanoparticles (~85 nm) were synthesized within micelles. PPy-layered FTO glass as the CE for DSSCs was fabricated by dropcasting a PPy-dispersed colloidal solution. By controlling the thickness and HCl vapor treatment time of the PPy layer on the FTO substrate and adjusting the electrolyte composition, the power conversion efficiency of the DSSC reached a maximum of ~7.73%. Although we obtained a reasonable DSSC performance compared with PEDOT or Pt electrodes, in principle, it is possible to improve the performance of the PPy-based CEs using the same simple approach if the particle size is controlled and the electrical conductivity is increased.

The preparation of nanofiber composites of Poly(butylene succinate)/TS-1 zeolite for drug delivery system

SungYeon Hwang,[1] *EuiSang Yoo*,[2] *SeungSoon Im*[*1]

[1]Department of Fiber and Polymer Engineering, Hanyang University, Seoul 133-791, Republic of Korea. [2]KITECH Textile Ecology Laboratory, 1271-18 Sa 1 Dong, Sangrokgu, Ansan City, Gyungido, Republic of Korea.

Crerw75@hanyang.ac.kr

Introduction

There have been considerable interested in the development of nanofiber composites of biodegradable polymer as effective drug delivery vehicles over the past decade.[1-2] Among various biodegradable polymer, poly(butylene succinate) (PBS) is very promising materials to applied for biomaterials fields. However, nanofiber composites for PBS have not yet energetically studied due to the difficult processing control of PBS nanofiber. In this study, nanofiber composites of PBS/TS-1 zeolite were prepared. TS-1 zeolite is a inorganic ion exchanger with high ion exchange capabilities, resuting in cationic ions that can be easy to process the fine-nanofiber composites. We expected that the unique characteristics of TS-1 zeolite such as adsorption/desorption of polar molecules in pore would be lead to control the released drugs as well as enhanced biodegradability.[3]

Materials and Methods

PBS resins were supported by S-Enpol company. The TS-1 zeolite was kindly provided by the Korea Institue of Ceramic Eng. & Tech (KICET). The amount of Ti(IV) incorporated in the used TS-1 zeolite framework is consistent with a Si:Ti ratio of 62 based on X-ray fluorescence spectrometry. 2,2,2-Trifluoroethanol (TFE) solution (99.8%) was purchase from ACROS. Reagents were used without further purification.

The solutions were stirred at room temperature with magnetic bar for 24 hours to obtain the regular solutions. To investigate the effect of solution concentration on morphological appearance of the as-spun PBS fibers, PBS was dissolved in TFE solutions of varied concentration ranged from 5 to 20 wt% solution. As a result, we confirmed that 15 wt% concentration of PBS solution is suitable for electrospinning. The spinning solutions of PBS/TS-1 zeolite composites were prepared by mixing 15 wt% PBS in TFE solvents with various TS-1 zeolite contents. Table 1 shows the Electrospinning processing condition. The mixed solutions were poured into 10ml plastic syringe equipped with a nozzle (24gauge). An electrode connected with a high voltage supply capable of generating positive DC voltages (15 kV) was fixed to the syringe. An aluminum foil and the cylinder drum were used as collectors. The collected nanofibers were placed in vacuum oven overnight at room temperature to fully eliminate solvent residuals.

Table 1. Electrospinning condition

Processing conditions	Value
Voltage	15 kV
Tip to collector distance	15 cm
Needle gauge	24 gauge
Flow rates	1ml/h
Types of collector	Al foil on cylinder drum

Results and Discussion

Fig 1. Shows the N_2 adsorption-desorption isotherm (Fig 1(a)) and electron microscopic investigation of TS-1 zeolite (Fig 1(b) and (c)). TS-1 zeolite has a Brunauer-Emmett-Teller (BET) surface area of $334 m^2 g^{-1}$ and pore volume of 0.53mL/g. Fig 1 (b) shows SEM images of TS-1 zeolite particles. The particle size is in the range of 80-100 nm with uniformly globular morphologies. .

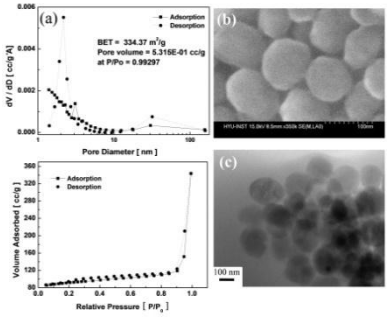

Fig. 1 The pore size distribution curves and N2 adsorption/desorption isotherms of TS-1 zeolite (b) SEM images of TS-1 zeolite at high magnification (c) TEM images.

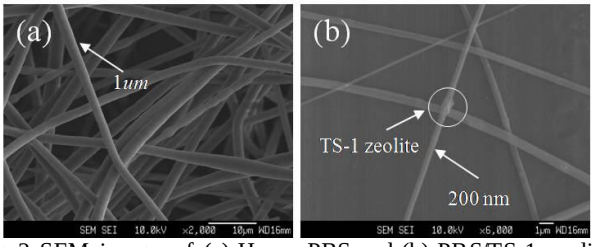

Fig. 2 SEM images of (a) Homo PBS and (b) PBS/TS-1 zeolite composites with 0.2 wt% zeolite contents.

Fig 2 shows SEM morphologies of PBS and PBS/TS-1 zeolite composites. In the case of PBS/TS-1 zeolite composites, the thickness of fiber was drastically decreased compared with Homo PBS. This result attributed that the electrostatic characteric of TS-1 zeolite lead to increase the flow rate of PBS molecular.

Conclusions

The nanofiber of PBS/TS-1 zeolite composites were prepared by electrospinning methods. TS-1 zeolite leads to decrease fiber diameter. The characteristic of molecular uptake for TS-1 zeolite can anticipate the control of released drugs.

Introduction

Poly(*p*-oxybenzoyl) (POB) has received great attention as high performance materials [1] and morphology is of great importance to control the performance. It has been reported that aromatic polyamides could be prepared by the direct polymerization in the presence of 3,4,5-trifluorophenylboronic acid (TFB).[2] This study implies that TFB would work for the direct polymerization of *p*-hydroxybenzoic acid (HBA) to yield POB. This paper described the direct polymerization of HBA in the presence of various anhydrides of boronic acid such as TFB (TFBA), 4-methoxyphenylboronic acid (MPBA) and 4-biphenylboronic acid (BPBA) not only to develop a new procedure for the POB synthesis but also to control the morphology of the POB crystals.

Table Polymerization of HBA in the presence of boronic anhydride

Run no.	Polymerization condition [a]		Yield (%)	Mn (x10^3)	Morphology [b]
	Boronic anhydride	c_B (mol%)			
T-1	TFBA	1	0		
T-2	TFBA	5	21	4.7	needle
T-3	TFBA	10	25	3.8	needle
T-4	TFBA	50	28	4.4	SAS
T-5	TFBA	100	32	5.4	SAS
M-1	MPBA	1	0		
M-2	MPBA	5	13	3.5	slab
M-3	MPBA	10	15	1.9	FS
M-4	MPBA	50	30	5.8	needle
M-5	MPBA	100	19	6.9	SAS
B-1	BPBA	1	0		
B-2	BPBA	5	42	1.8	needle, slab
B-3	BPBA	10	33	2.9	FS
B-4	BPBA	50	44	14.4	FS
B-5	BPBA	100	48	14.7	fibril, SAS

[a] Polymerizations were carried out in DBT at a concentration of 1.0% at 300°C for 24 h. [b] SAS and FS stand for spherical aggregates of slab-like crystals and fibrillated slab-like crystals, respectively.

Experimental

HBA was purchased from TCI. Boronic acids purchased from Sigma-Aldrich were converted into anhydrides during recrystallization from toluene. An isomeric mixture of dibenzyltoluene (DBT) was obtained from Matsumura Oil (Barrel Therm 400) and distilled.

A polymerization of HBA in the presence of TFBA is described as an example. HBA (0.23g, 1.67 mmol) and 20 mL of DBT were placed into a cylindrical flask equipped with a mechanical stirrer and gas inlet and outlet tubes. Polymerization concentration was 1.0 %. The reaction mixture was heated under a slow stream of nitrogen up to 300°C with stirring. HBA was dissolved during heating. TFBA (0.26g, 0.56 mmol) was added into the solution at 300°C and stirring was stopped after TFBA was entirely dissolved. Concentration of boronic acid residue (c_B) was 100 mol%, defined as the molar ratio of boronic acid residue to the HBA, ([TFBA] x 3 / [HBA]) x 100. Temperature was maintained at 300°C for 24 h. The solution became turbid at an initial stage of the polymerization and then precipitates were formed with time. Precipitated POB crystals were collected by filtration at 300°C, and washed with *n*-hexane.

Results and Discussion

Table presents results of the polymerization. HBA was insoluble in DBT at 25°C but it became dissolved during heating. POB crystals were obtained as precipitates at c_Bs from 5 to 100 mol% with the yields from 21 to 32%. Some amounts of oligomers were left in the solution because of the solubility, and therefore the yield of the precipitated crystals was not so high. The POB crystals were formed as precipitates in the solution and the morphology was considerably influenced by not only the structure of the boronic anhydride but also the value of c_B. Needle-like crystals were firmed in the presence of TFBA at c_Bs of 5 and 10 mol% by the spiral growth of lamellae (Fig (a)). Spherical aggregates of slab-like crystals were formed at c_Bs from 50 to 100 mol% (Fig. (b)). The polymerization with MPBA and BPBA also yielded the needle-like crystals at c_Bs of 50 mol% and 5 mol%, respectively. The polymerization with TFBA at lower c_B was favorable to prepare the needle-like crystal. A WAXS intensity profile of the needle-like crystals showed that diffuse halo attributed to amorphous regions was hardly detected and the needle-like crystal possessed high crystallinity. From the morphological change of the crystals during polymerization, it was suggested that they were formed by the spiral growth of lamellae, resembling the POB whiskers prepared from *p*-acetoxybenzoic acid.[3] Molecular weight was also influenced by the structure of the boronic anhydride and c_B. Mn determined by the end-group analysis increased generally with c_B and BPBA gave the highest Mn of 14.7 x 10^3 at c_B of 100 mol%. The loose packing of the molecules in the crystal caused by the bulkiness of the end-groups made the polymerization more efficiently.

Conclusions

POB crystals were formed by the direct polymerization of *p*-hydroxybenzoic acid in the presence of boronic anhydrides. Morphology and molecular weight could be controlled by the chemical structure and the concentration of boronic anhydride.

Selective Synthesis of Aromatic Copolyester Using Reaction-induced Crystallization under Shear Flow Influence of shearing on composition of copolyester

Toshimitsu Ichimori, Shinichi Yamazaki, Kunio Kimura

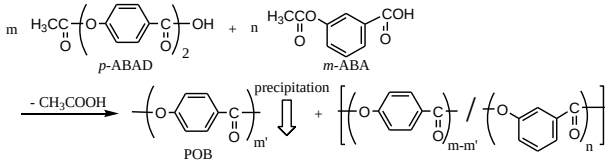
Graduate School of Environmental Science, Okayama University

E-mail: polykim@cc.okayama-u.ac.jp

Introduction

It had been previously reported that copolymers rich in a *p*-oxybenzoyl (*p*-OB) moiety were selectively synthesized from the copolymerization of *p*-acetoxybenzoic acid (*p*-ABA) and *m*-acetoxybenzoic acid (*m*-ABA) by using crystallization of oligomers during polymerization. [1,2] In the copolymerization of 4-(4-acetoxybenzoyloxy)benzoic acid (*p*-ABAD) which is the dimer of *p*-ABA and *m*-ABA, the selectivity became higher because *p*-OB homo-oligomers were more rapidly formed. [3] Furthermore, it was found that the selectivity became much higher by the application of shearing. [4]

In this study, the influence of the timing of shearing on the selectivity was examined in the polymerization of *p*-ABAD and *m*-ABA.



Scheme Copolymerization of *p*-ABAD and *m*-

Materials and Methods

p-ABAD, *m*-ABA and liquid paraffin (LPF) were purified according to the previous procedures[1,2,3]. LPF was placed into a cylindrical vessel equipped with a stir bar, mechanical stirrer and a gas inlet tube, and heated under a slow stream of nitrogen. *p*-ABAD and *m*-ABA were added into LPF at 330°C with varying the content of *p*-OB moiety (χ_f) in feed. The solution was stirred after a certain time with the share rate (γ) of 489s^{-1} and the polymerization was carried out at 330°C. The solution becomes turbid and then the polymers were precipitated. The precipitated polymers were collected by filtration at 330°C, and washed with *n*-hexane. The content of *p*-OB moiety in the precipitated polymers (χ_p) was determined by gas chromatograph after hydrolysis of polymers.

Results and Discussion

Results of the polymerization at χ_f of 40mol% were plotted in Fig. Although the yield of polymers became lower, the value of χ_p increased by shearing. The solution became turbid due to the precipitation of oligomers at 40min in this polymerization. Therefore, shearing was applied after 30 min (before turbid) and 70 min (after turbid). The value of χ_p of the polymers prepared without shearing was 82.5 mol% after 6 h. On the other hand, it prepared under shearing became much higher. The values of χ_p prepared under shearing before and after turbid were 93.4 mol% and 96.1 mol%, respectively. The mechanism of selective polymerization between *p*-ABAD and *m*-ABA is explainable as follows; *p*-OB homo-oligomers are more rapidly formed in the solution than co-oligomers due to the dimer effect and the difference in the reactivity. When the molecular weight of the *p*-OB homo-oligomers exceeds a critical value, they are precipitated *via* crystallization to form the crystals at the early stage in the polymerization. Co-oligomers are gradually formed, and they are also phase-separated. While co-oligomers containing a few *m*-oxybenzoyl (*m*-OB) moieties are precipitated *via* crystallization, they are excluded from the crystal by the segregation effect, and the *m*-OB moiety is not present in the crystals. At the middle stage of the polymerization, co-oligomers containing more *m*-OB moiety are formed in the solution, but they are unable to precipitate due to higher miscibility. Further polymerization proceeds between oligomers in the precipitated crystals, and the poly(*p*-oxybenzoyl) is selectively formed. When the shearing was applied before turbid, *m*-OB moieties were slightly incorporated because the reactivity was enhanced by shearing. Thus, co-oligomers containing a few *m*-OB moiety were gradually precipitated with time. In the case of shearing after turbid, the concentration of *m*-OB moiety in the solution became higher when shearing was applied, because the precipitation of *p*-OB homo-oligomers already started. While the reactivity of *m*-ABA was enhanced by the shearing, leading to the formation of co-oligomers containing more *m*-OB moiety, they could not be precipitated because the shearing increased the miscibility. As a result, shearing suppressed precipitating the oligomer rich in *m*-OB moiety and the selectivity was drastically enhanced.

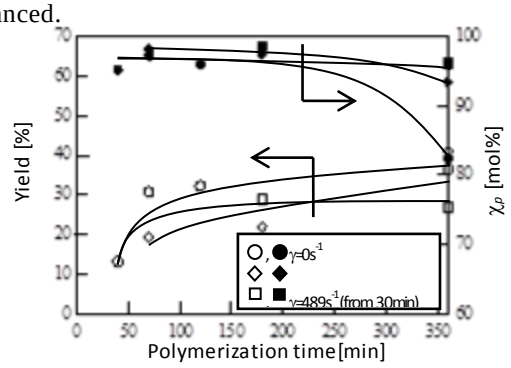


Fig. Time dependencies of yield and χ_p of precipitated polymers in copolymerization at χ_f of 40mol%.

Conclusion

Selectivity was drastically enhanced by the application of shearing after turbid due to the suppression of the precipitation of *m*-OB moiety.

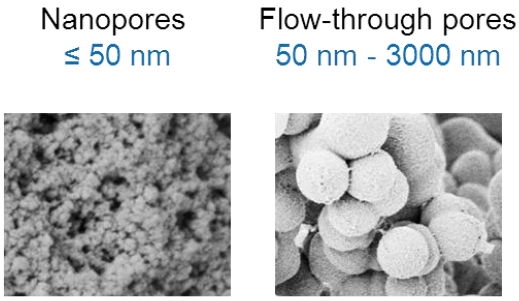
Facile, single-step preparation of versatile, high surface area nanoporous hybrid materials

Ian Teasdale, Ivo Nischang, Oliver Brüggemann*

Institute of Polymer Chemistry (ICP), Johannes Kepler University Linz

ian.teasdale@jku.at

New, facile, porous hybrid polymeric materials based on polyhedral silsesquioxane nanohybrid building blocks are presented. A single-step molding process via a simple vinyl polymerization of the bulky precursors leads to an inherently nanoporous network with good thermal stability and extremely high surface areas for polymeric materials (BET 700-900 m_2g^{-1}). The significant amount of residual vinyl groups from the multi-vinyl precursor can be simply modified by thio-ene click chemistry for ready access to a wide range of surface properties and high loading capability. We also show how through simple solvent variations, hierarchically-structured porous materials with excellent flow-through properties and tailored macroporosity can be readily achieved and describe their preparation as monolithic materials, covalently anchored to a confining container. The versatile and mild chemistry facilitates spacial selectivity and the preparation of a wide range of forms, including microspheres and monolithic materials for micro-fluidic and chip-based applications for which the use of sol-gel processes is limited.



Emulsion Polymerization of Styrene: Simulation the effects of mixed ionic and non-ionic surfactant system in presence of coagulation

Samira Feiz, Amir H. Navarchian

Department of Chemical Engineering, Faculty of Engineering, University of Isfahan

Navarchian@eng.ui.ac.ir

1. Introduction: The end product properties in the emulsion polymerization are strongly correlated with particle size distribution (PSD) of the latex formed. The main factors that in turn affect the PSD are the composition as well as concentration of emulsifier used. These two influence also the average particles diameter, the total number of particles *(N_p)* and conversion. The ionic surfactants stabilize the particles by electrostatic repulsion, while the non-ionic surfactants cause the stabilization by steric hindrance mechanism [1].

Mixed surfactant system is applied to control the average particle size and PSD in industrial processes. The only available work on modeling this system is that published by Unzueta and Forcada (1997) using a monodisperse assumption for particle sizes [2].

In the current work we have modeled the effects of mixed surfactant systems (SDS as ionic and Brij35as nonionic surfactant) on PSD of particles for batch emulsion polymerization of styrene. A new model is developed to compute the rate of coagulation considering the polydispersity of the particle sizes.

2. Modeling:

Using the zero-one model [1] polymer particles are characterized by population density functions ($f(r,t)$). The particles that have a polymeric radical (f^P_1), particles that have no radicals *(f_0)*, and particles that have a monomeric radical (f^M_1) are given as [3]:

$$\frac{\partial f_0(r)}{\partial t} = \rho\left[f_1^P(r) + f_1^M(r) - f_0(r)\right] + k_{dM}.f_1^M(r) - f_0(r)\int_0^\infty \beta(r,r')\left[f_0(r) + f_1^P(r')\right]dr' + \int_0^\infty \beta(r', r-r')\left[f_0(r')\,f_0(r-r') + f_1^P(r')\,f^P_{1(r-r')}\right]dr' \quad (1)$$

$$\frac{\partial f_1^P(r)}{\partial t} = \rho_{init}.f_0(r) - \rho.f_1^P(r) - k_{tr}[M]_p\,f_1^P(r) + k_p[M]_p\,f_1^M(r) - \frac{\partial((dr/dt)\,f_1^P(r))}{\partial r} + R_{nuc}\delta(r-r_{nuc}) - f_1^P(r)\int_0^\infty \beta(r,r')\left[f_0(r') + f_1^P(r')\right]dr' + \int_0^\infty \beta(r', r-r')\left[f_0(r')f_1^P(r-r') + f_1^P(r')f_0(r-r')\right]dr' \quad (2)$$

$$\frac{\partial f_1^M(r)}{\partial t} = k_{tr}[M]_p\,f_1^p(r) - (k_p[M]_p + \rho + k_{dM})\,f_1^M(r) + e^0\,f_0(r)[P_w]^0 \quad (3)$$

Where ρ, k_{dM}, R_{nuc} and β are overall rate of radical entry, coefficient of desorption rate for monomeric radicals, and the nucleation and coagulation rates, respectively. The propagation growth rate is given in terms of monomer concentration in the particles $[M_p]$ [1,3]:

$$\frac{dr}{dt} = \frac{1}{4\pi r^2 \rho_p N_A}\,k_p[M]_p\,M_W \quad (4)$$

The critical micelle concentration of the surfactant mixture *(CMC_{12})* and the composition of micelles (α^m) was calculated according to the thermodynamic theory for non-ideal mixtures, using Rubingh expressions [2].

Micellar nucleation occurs when $[S]_w > CMC_{12}$ [3]:

$$\Re_{Micellar}(t) = \sum_{l=z}^{j_{cr}-1} e^l_{micelle}[P_w]^l\,C_{micelle} \quad (5)$$

In addition, upon reaching the critical chain length, j_{cr}, the oligomers in the aqueous phase precipitate out of the aqueous phase, and form a new particle [3]:

$$\Re_{homogenous}(t) = k_p^w[P_W]^{j_{cr}-1}[M]_w \quad (6)$$

The coagulation rate coefficient β_{ij} between two particles with radius r_{si} and r_{sj} is given by [1,3]:

$$\beta_{ij} = \beta_{ji} = c\,\frac{2k_BTN_A}{3\mu W_{ij}}\left(2 + \frac{r_{si}}{r_{sj}} + \frac{r_{sj}}{r_{si}}\right) \quad (7)$$

The Fuch's stability ratio is found from:

$$W_{ij} = (r_{si} + r_{sj})\int_{(r_{si}+r_{sj})}^\infty \exp\left(\frac{\Phi}{R^2}\right)dR \quad (8)$$

The total potential between the two particles, Φ, is a combination of attractive and repulsive potential of anionic and non-ionic surfactant molecules on the surface of particles.

3. Result and discussion

At the beginning of polymerization, the particle numbers increases, as a result of formation of new particles through nucleation. At high polymer volume fractions, the number of particles tends to decrease upon coagulation, because of collision of any two particles and increase due to secondary micellar nucleation. These two effects occurs with the same rate, so that the N_p remains constant. By increasing Brij35 in composition of the surfactant mixture, the average repulsive potential on the particle surfaces decreases, while the rate of coagulation increases. Hence, the total number of particles and conversion decreases (Fig. 1).

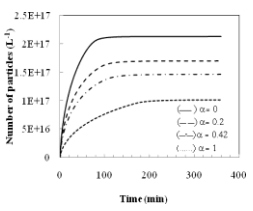


Fig.1. Effect of nonionic surfactant mole fraction in the feed (α) on N_p.

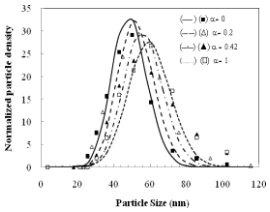

Fig. 2. Effect of nonionic surfactant mole fraction in feed (α) on final PSD

By using Brij35, because of the higher amount of $[S]_w$ in system and the longer time of nucleation [1-3], particles with different size are formed during the polymerization process and a broader PSD curve is obtained finally. Moreover, due to the less stabilization capability of non-ionic surfactant than that of anionic one and therefore increasing the rate of coagulation, the average particle radius increases. The model fits well the experimental data obtained in this work.

4. conclusion

Increasing the non-ionic surfactant in the emulsifier mixture led to a broader PSD with larger particle sizes, and less total particle number and conversion.

Wear Resistance Optimization of PU/TiO_2 Coatings on Aluminium Surfaces

Mehrdad Taheran[1], Amir H. Navarchian[1], Reza Shoja Razavi[2]

[1]Department of Chemical Engineering, Faculty of Engineering, University of Isfahan
[2] Department of Material Engineering, Malek AshtarUniversity of Technology, Shahin Shahr, Isfahan, Iran
navarchian@eng.ui.ac.ir

1. Introduction:

Polyurethane (PU) coatings used in many applications need to have enough wear resistance to satisfy the practical and economical aspects [1]. The aim of this work is to develop a coating on aluminum surface based on PU binder and TiO_2 pigment having maximum wear resistance. The influences of polyol molecular weight (A), diisocyanate type (B), surface pretreatment (C), NCO/OH ratio (D) and pigment volume concentration (E), on wear resistance of PU coatings have been statistically investigated.

Experimental:

To synthesize the prepolymer, 40 g of PTMG (MW = 1000 or 2000) was reacted with diisocyanate (Hexamethylene diisocyanate (HDI), isophorone diisocyanate (IPDI)) according to specified NCO/OH ratio (1.4, 1.6 or 1.8). The reactions were carried out at 80°C for 6 hrs in a three-necked flask. The prepared resin was dissolved in solvent (xylene /n-butyl acetate: 50/50, v/v) and the specified amount of TiO_2 was added to the mixture. TiO_2 pigments (particle size 10µm) were dispersed in resin with a pearl mill apparatus at 800 rpm [2]. Chemical (using alcoholic phosphoric acid cleaner) and anodic (sulfuric acid anodic) methods were used for surface pretreatment. A standard L_{16} Taguchi array was employed for experimental design, using S/N ratio as response.

2. Result and discussion

2.1 Analysis of variance

Table 1 shows the analysis of variance (ANOVA) statistical terms for wear resistance of PU/TiO_2 coatings. The critical F-values for two and three-level factors at confidence level of 95% are 5.33 and 4.46, respectively [3]. According to this table, the important contributors to variability of the results are polyol molecular weight (A), pigment volume concentration (E), diisocyanate type (B), and NCO/OH ratio(D), respectively. Factor C represents the lowest F-ratio in the ANOVA table which implies that surface pretreatment method does not affect the response significantly.

Table 1. ANOVA table for mass loss in wear test (M_L)

Factor	DOF	Sum of squares	Variance	F-ratio	Contribution%
A	1	85.371	85.371	117.884	41.005
B	1	18.534	18.534	25.592	8.627
C	1	2.184	2.184	3.016	0.707
D	2	14.557	7.278	10.05	6.350
E	2	79.987	39.993	55.225	38.046
Other/error	8	5.793	0.724		5.265
Total	**15**	**206.429**			**100**

3.2 Influence of operating variables

As observed in Fig. 1, the use of polyol with higher molecular weight results in higher elongation at break [4] that tolerates higher stresses before breaking and consequently gives higher abrasion wear resistance [5]. Pigment particles serve as reinforcing filler and increase the tensile strength and wear resistance of prepared coating [5]. Formation of allophanate or biuret crosslinks at higher NCO/OH result in also higher wear resistance. The wear resistance of coatings made from IPDI as diisocyanate is higher than those composed of HDI. This behavior can be justified by the structures of these two chemicals.

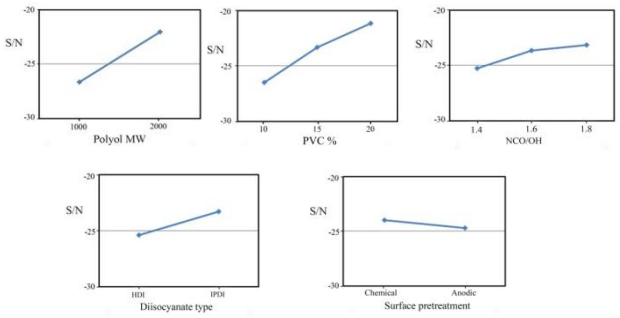

Fig. 1. The effect of factors on wear resistance

3.3 Optimum conditions

The optimum conditions to attain a PU/TiO_2 coating can be determined from maximum points in main effect plots (Fig.1). A new sample was prepared according to proposed factor levels. The predicted value for mass loss in optimum conditions (6.4 mg), was found reasonably in agreement with the experimental data (5.9 mg). The morphology of optimum sample was examined by SEM microscopy (Fig.2 and Fig. 3). The smooth surface of coating was worn and became rough and matt after wear test. These figures suggest that the adhesion mechanism is dominant in wear action [6,7].

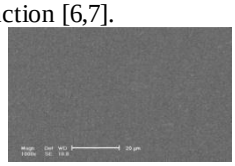

Fig. 2. SEM image of the optimized coating before wear

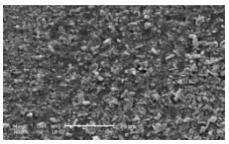

Fig. 3. SEM image of the optimized coating after wear

4. Conclusions

The higher wear resistance is obtained with higher polyol molecular weight, higher pigment volume concentration, with IPDI and at NCO/OH ratio = 1.8. Both the chemical and anodic methods give raise the same wear resistance in this work.

Changes of Supermolecular Structure and Selected Properties of Polymer Matrix of Polyamide Fibres Caused by Addition of LCO Modifier

M. Baczek, J. Janicki

Institute of Textile Engineering and Polymer Materials, University of Bielsko-Biała, Bielsko-Biała, Poland

mbaczek@ath.bielsko.pl

Keywords: Liquid Crystalline Oligoester, PA6/LCO blends, supermolecular structure, WAXS, SAXS, tensile strenght parameters

Polyamides have become essential materials in fibre production for textiles and technical uses.
However, such applications require extremely high strength parameters as well as excellent dimensional stability. In order to improve polymer properties they are reinforced with with very high strength and high modulus liquid crystalline polymers. Blending of thermotropic LCP with semicrystalline thermoplastic polymers to form in-situ polymer composites is very attractive because LCP acts as reinforcing elements in the blends and its addition to a polymer matrix has profound impact on its physical and mechanical properties of the final product [1-3]. Synthesized liquid crystalline oligoester was in this study applied as liquid crystalline polymeric component in fibre forming PA6/LCO blends. Thermotropic Liquid Crystalline Oligoester can be used as a proper compound

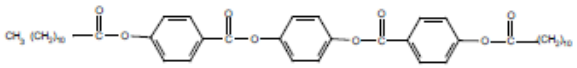

Figure 1. The macromolecular chain of synthesized liquid crystalline oligoester.

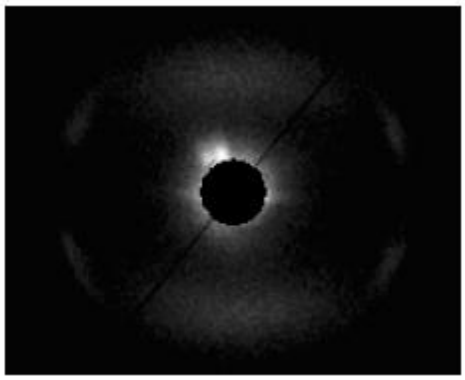
The objective of research presented in this work was to determine the influence of the LCO on the parameters of the supermolecular structure, thermal and mechanical properties of fibres obtained from PA6/LCO blends with 95% of PA6 and 5% of LCO by weight.
The relationship between supermolecular structure and mechanical properties of the obtained fibres was also presented.
The parameters of the supermolecular structure based on the the structural investigations using wide angle X-ray scattering (WAXS) and small angle X-ray scattering (SAXS) methods have been calculated.
The crystalline structure of PA6/LCO fibres was investigated by WAXS methods. The results of measurements were analyzed in the aspect of the structure of PA6 matrix changes caused by addition of LCO modifier. The degree of crystallinity was calculated using a modified Hindeleh & Jonson method [6-7] and a computer program WAXSFIT [8]. Sizes of crystallites were estimated using the Sherrer equation.
The lamelar structure of PA6/LCO fibres was investigated by small angle X-ray scattering methods and the results of measurements were analyzed in the aspect of the lamellar structure of PA6 matrix changes caused by addition of LCO modifier. The parameters of lamellar structure (long period, the lamellar and the amorphous layer thickness) were obtained using the linear correlation function approach
The results of 2D-SAXS measurements have additionally allowed to obtain information concerning the location of for processing with semicrystalline PA6 due to relatively low melting temperature and wide temperature of mesophase [4-5]



oligoester domains in the polyamide matrix of the obtained fibres.

Figure 2. 2D-SAXS pattern for PA6/LCO 95/5 fibres

Based on the results of SAXS investigation, model of the structure of PA6/LCO fibres was proposed. Liquid crystalline oligoester domains which are situated into interfibrillar area of polyamide matrix with lamellar structure is characteristic of these fibres
Specific dispersion of the LCO domains in polymer matrix mentioned before has profound impact on mechanical properties of modyfied fibres. Figure 4 summarized the results of the mechanical tests obtained for both modified and unmodified polyamide fibres.
The comparative analysis shows that presence of liquid crystalline oligoester has positive influence on the tensile strenght parameters.

e-mail:m_arif_kaya@yahoo.com

Introduction

Photopolymerization has been the basis of numerous conventional applications in coatings, adhesives, inks, printing plates, optical waveguides, and microelectronics. Some other less traditional but interesting applications, including production of laser videodiscs, curing of acrylate dental fillings, and fabrication of 3D objects [1].

Photoinitiators for radical photopolymerization are classified as cleavage (type I) and H-abstraction type (type II) initiators [2]. Although alkylamines are very efficient hydrogen donors, high usage of volatile and odorous compounds generate some disadvantages to type II systems [3]. Dendritic photoinitiators may overcome these problems, since dendrimers are unique macromolecules having highly branched, well-defined architectures with a number of interesting characteristics. Their nanoscale structures have a variety of potential applications in the fields of coatings, chemical sensors, catalytic nanoreactors, drug delivery systems and liquid crystalline dendrimers. The introduction of thioxanthone into dendrimers can lead to the novel dendritic macrophotoinitiators, which have obvious advantages; such as intramolecular reactions because of the formation of more reactive species and protecting the active species by macromolecular chain due to the macromolecular effect [4].

Polymerization reaction kinetics are affected with various parameters such as type of photoinitiator [5], light intensity [6], photoinitiator concentration [7], temperature and monomer functionality during the photocuring. In this study, new dendritic macrophotoinitiators (Jeff-(3,6,12)-TX) through introducing thioxanthone moieties were synthesized and the kinetics of polymerization reaction of mono and multifunctional acrylates in the presence of these new dendritic photinitiators with MDEA were studied by means of photo-DSC and RT-FTIR. The effect of light intensity on the photopolymerization of Lauryl acrylate (LA) was also investigated for these new three dendiritic photoinitiators (Jeff-(3,6,12)-TX) by Photo-DSC. The photopolymerization kinetic parameters, the time (t_{max}) to reach the maximum value of the rate of polymerization (Rp_{max}) and final conversion (C_s) were determined by depending on the effects of amounts of thioxanthone group (3,6,12) and the light intensity.

Methods

IR spectra were taken ATI Unicam Mattson 1000 FTIR Spectrophotometer. JOBIN YVON HORIBA FluoroMax-P Fluorescence Spectrophotometer was used to take fluorescence spectra. The photolyzing light was generated by a medium pressure mercury lamp (Flexicure UV system) and was conducted through a flexible fiber optic for the photolysis. DSC spectra were taken on a TA Q Series DSCQ100 with PCA photo unit. The mass of the samples were 2.6 ± 0.1 mg into the aluminum DSC pans and the measurements were carried out in an isothermal mode at 25 °C under a nitrogen atmosphere by UV light with intensities of 30, 40 and 60 mW/cm^2.

Result and Discussion

Increasing light intensity from 30, 40 and 60 mW/cm^2, heat flow of polymerization reaction and the rate of polymerization increased with decreasing order of TX moieties in the dendritic macrophotoinitiator except Jeff-12TX. Jeff-12TX worked well with the 40mW/cm^2 light intensity value. Further increasing of light intensity adversely affected both heat flow and the rate of polymerization for Jeff-6TX and Jeff-12TX. An increase of the light intensity leads to a higher maximum polymerization rate, and the maximum is achieved more rapidly after the start of the reaction.

Conclusion

Dendritic macrophotoinitiators were used in RT-FTIR and Photo-DSC formulations without MDEA and polymerization was not occurred in air atmosphere. Therefore, the initiation mechanism of these three dendritic macrophotoinitiators is similar to thioxanthone itself. The initiating radicals are aminoalkyl radical which obtained from MDEA and ketyl radicals are usually not reactive toward to TMPTA due to steric hindrance and the delocalization of unpaired electron.

Effect of Nanofillers on Curing Kinetics and Thermal Properties of Epoxy Amine Thermosets

Amit Kumar Ghosh, Guy Van Assche, Bruno Van Mele

Vrije Universiteit Brussel, Pleinlaan 2, 1050 Brussels, Belgium

e-mail- aghosh@vub.ac.be

Abstract: The effect of nanoclay (Cloisite 30B) and MWNT (multi-walled carbon nanotube) on the curing kinetics of an epoxy-amine system were studied.

In this work, diglycidyl ether of bisphenol A (DGEBA) epoxy resin was used in combination with 4,4'-methylene dianiline (MDA) and aniline. MDA and aniline were combined to improve the mixing process of resin and hardener, and to improve the dispersion of nanofillers in the nanocomposite samples. The nanofillers were premixed with the epoxy resin by a high speed stirring process. The final samples were prepared by mixing the filled epoxy resin and the mixture of MDA and aniline.

The quality of dispersion of nanofillers (intercalation/exfoliation) was analysed by atomic force microscopy and by X-ray diffraction method. Modulated temperature differential scanning calorimetry (MTDSC) was used to study the cure kinetics of both pure resin and resins with fillers. The reaction enthalpy, the initial and final glass transition temperature (T_g) of the materials and the reaction kinetics were determined for all samples by isothermal and non-isothermal cure measurements. Rheological studies were carried out to determine the point of gelation and vitrification of different samples.

It was found that there is an accelerating influence of nanofillers on the curing kinetics of the system. This effect is more pronounced with nanoclay. Both nanocaly and MWNT showed that the accelerating effect is more pronounced if the nanofillers are dispersed properly in the matrix. The final T_g of the cured samples were significantly higher for nanocomposite than the pure resin.

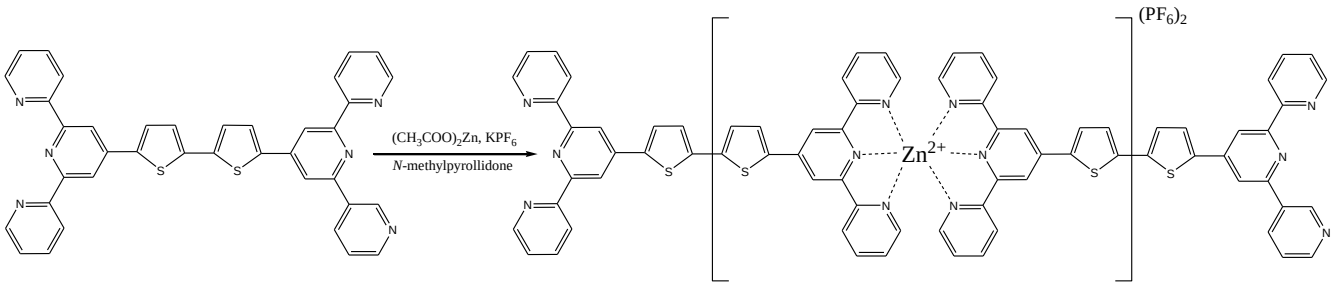

Fig.1: Synthesis of supramolecular polymer

Terpyridines have recently evoked great interest as ligands for preparation of supramolecular systems with diverse chemical properties. Positions of nitrogen atoms of terpyridine ligands allow easy tridentate facial and meridian coordination to various metal atoms (for example Ru, Os, Ir, Fe, Zn, Co) and a formation of metallo-supramolecular assemblies with well-defined stereochemistry (in contrast to many other modules) which is important for reproducible preparation of functional materials.

Among the unique properties of terpyridine compounds, their luminescent behavior upon complexation with metal ions is attractive due to high application potential as light-emitting devices and probes. It has been demonstrated that the ligand choice affects the luminescence properties of a resulting supramolecular assembly. That is the reason why the synthesis of tailored terpyridine ligands has become a fundamental step for preparation of high performance metal-coordination functional materials. The main interest was focused to monotopic terpyridines, but bis-terpyridines with all-conjugated chain between terpyridine units were investigated, too.

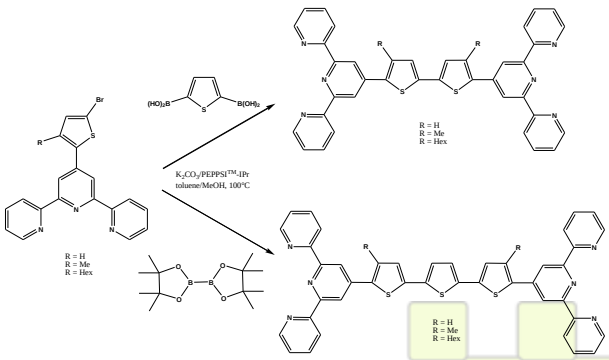

Fig.2: Preparation of ligands using Suzuki-Miyaura reaction.

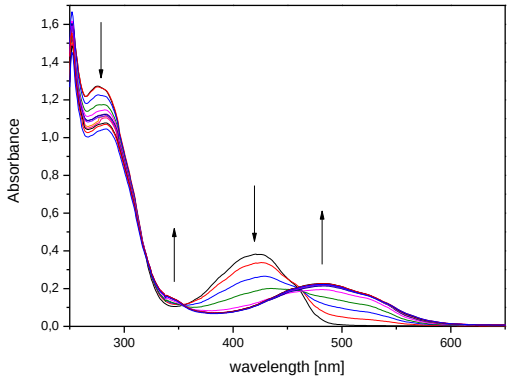

Fig.3: Absorption spectra of titration bis(terpyridyl)terthiophene with zinc (II)

Six novel bis-terpyridines were prepared using palladium-catalyzed Suzuki-Miyaura type cross-coupling reactions and their photophysical properties were investigated.

Complexation of ligands with different metals was studied using UV/vis and emission luminescence spectroscopy.

Supramolecular polymers were prepared from soluble ligands with zinc (II) and iron (II) and their properties were also studied.

Synthesis of Porous Polymeric Organic Frameworks (POFs) with C_{3v} symmetry and controlled pore size

Ester Verde , Eva M. Maya , José G. de la Campa , Javier de Abajo , Ángel E. Lozano

Departamento de Química Macromolecular, Instituto de Ciencia y Tecnología de Polímeros (CSIC)

ester@ictp.csic.es

Introduction and objectives

There is a growing interest in porous organic polymers having anchored metal catalysts, due to their simplicity of synthesis, low density and high selectivity relative to inorganic systems[1]. Recently, Pandey et al. reported a facile, one-pot, quantitative synthesis of imine-linked microporous polymer organic frameworks (POFs) having surface areas up to 1500 m^2/g^{-1} and high H_2 and CO_2 sorption, converting these polymers into good candidates for gas storage and gas separation. These novel polymers can be considered wholly organic analogues of porous materials like metal-organic frameworks[2] (MOFs) and zeolites in terms of pore properties. The highly cross-linked nature of POFs confers them high thermal stability and they also have the ability, depending on the monomer used, to incorporate diverse groups on the pores, which, if they are conveniently modified, permits to tune the surface to interact with different types of guest molecules.

The aim of this work is focused on the preparation and characterization of new POFs with C_{3V} symmetry based on aromatic polyamides with controlled porosity by varying the length and geometry of employed monomers.

Results and Discussion:

In order to optimize the reaction conditions, a model compound was synthesized in a one step reaction using trimesic acid and 4-*tert*-butylaniline by means of the Yamazaki polycondensation reaction[3] (Figure 1). The model compound was obtained with high yield and purity as was checked by DSC, and by elemental analysis. The structure was also confirmed by ^{1}H-NMR, ^{13}C-NMR and FTIR-ATR.

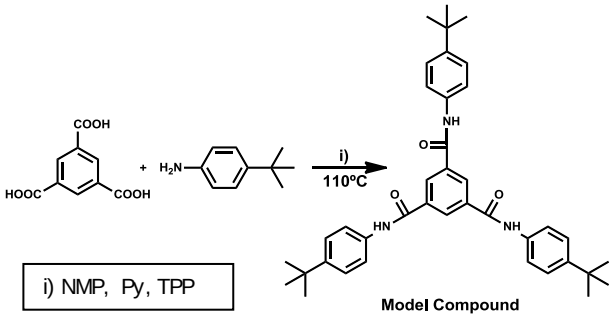

Figure 1: Synthesis of model compound

The synthesis of POFs was carried out by combination of trimesic acid and diamines of different length and geometry (*p*-diamines or *m*-diamines) (Figure 2) using the reaction conditions depicted in Figure 1.

Thermogravimetrical analysis of these POFs revealed high thermal stability, with decomposition temperatures above 450ºC and only one step degradation pattern. DSC curves showed no Tg below 400ºC.

Pore size and pore distribution of these new materials using the BET technique (N_2 gas adsorption/desorption) and also CO_2 and CH_4 sorption at diverse temperatures have been carried out.

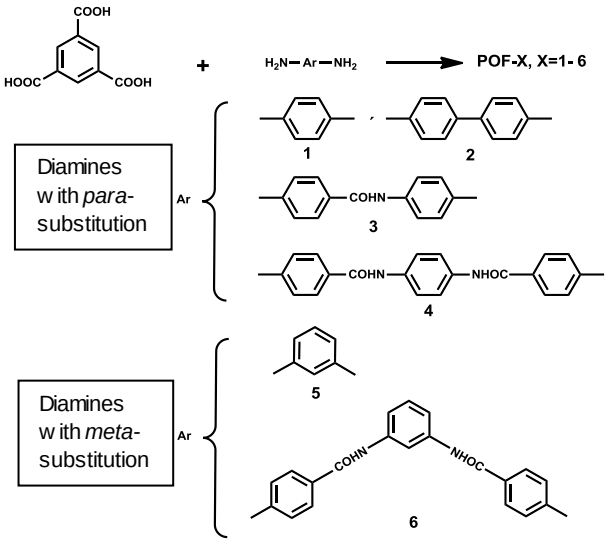

Figure 2: POFs obtained in this work

Finally, diamines having nitro groups have been used to make new POFs. Those nitro moieties will be reduced to amino ones and functionalized with organic moieties able to anchor metals with ability to catalyze organic reactions. In Figure 3, a schematic representation of these new materials is depicted. Reduction reactions and functionalization with designed groups are on the way.

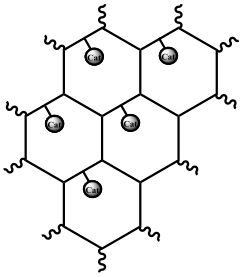

Figure 3: Schematic representation of new POFs with functional groups.

Introduction

The piezoelectricity in amorphous polymers is mainly due to the orientation polarization of the molecular dipoles. Aromatic polyimides are high-performance polymeric materials possessing an exceptional array of properties. The thermal stability, chemical resistance and excellent mechanical and electrical properties makes them able to be used as sensors and actuators(1).
An improvement of piezoelectric response of these polymers can be obtained by adding dipoles in the chain. Previously, piezoelectric polyimides have been synthesized containing –CN dipolar groups in the polymer chain(2). Although the obtained polyimides present interesting mechanical and piezoelectric properties, it has not been possible to combine both properties in the same material.
In order to obtain a material with the best mechanical and piezoelectric response, copolyimides have been synthesized using a mixture of the diamines.

Materials and Methods

The commercial products used for the copolymer synthesis were 1,3-Bis(3-aminophenoxy)benzene, supplied by Acros Organics Ltd, 2,4 dichlorobenzonitrile supplied by Merck., 4,4'-oxydiphthalic anhydride (ODPA), 2,6-dichloro-benzonitrile, and dimethylacetamide (DMAc), supplied by Aldrich. The diamines were recrystallized from EtOH/H_2O(1:1). The dianhydride was dried at 453K in a vacuum chamber, and the solvent was used as received.
Copolyimides were obtained by reaction between the dianhydride ODPA and two aromatic diamines(2), in two-step reaction.
The copolymer films were prepared by thermal treatment of a solution of poly(amic acid) in N, N-dimethylacetamide. For polarization and dielectric measurements, the samples were prepared and poled by standard poling method, using a supply source HITEK Power Series 4000, and the temperature was raised up to 505K during 15 minutes. Then the temperature was decreased to room temperature maintaining the applied electric field to freeze the polarized state. The frozen-in polarization, P_r, of the poled samples was measured by the Thermally Stimulated Depolarization Current (TSDC) method(3) by a Keithley 6517 electrometer.

Results and Discussion

Several copolyimides were synthesized by the conventional two-step method starting with diamines and aromatic dianhydride through ring-opening polyaddition and subsequent thermal cyclodehydration imidization. All of them have been characterized.
Copolymers exhibited only one Tg, indicating that the repetitive units are randomly distributed along the polymer chain. In addition, no endothermic peaks above their glass transition temperatures were observed in DSC measurements which may be attributed to the amorphous molecular structure for all polymers.
The results of the TSDC method show that the temperature dependence of the depolarization current for copolymers is slightly lower than the pure polyimide with higher Pr. The value of this parameter is associated with the composition of the copolymer and increase if the amount of polyimide with higher Pr in the copolymer increases. It is not clear from these initial results if there a direct dependence with copolymer composition exists, or whether it should be considered in terms of sequence distributions.
The obtained copolymers have improved the mechanical properties of the polymers with higher Pr, but have decreased slightly mechanical properties for polymers with low Pr.

Conclusions

Different series of aromatic piezoelectric copolyimides have been obtained and characterized.
The mechanical properties of the piezoelectric polyimides have been improved by means of copolymerization, the value of the polarization being maintained.
A new way to study and control the influence of sequences distribution over mechanical and electrical properties is open.

Plastics with reduced flammability, containing graphite halogen-free additives

Piotr Jankowski, Michał Kędzierski

Industrial Chemistry Research Institute, 8 Rydygiera str., 01-793 Warsaw, Poland.

piotr.jankowski@ichp.pl

Introduction: One of the most important problems related to the production of polymeric materials is their flammability. European regulations for the use of flame retardants demand the development of halogen-free additives for different kind of plastics. Investigations involve reduced flammability of plastics concentrate to replace halogen antipyrene by halogen-free additives. A significant disadvantage of halogen additives is the emission of very toxic and corrosive fumes from the field of the fire to the environment during combustion. On the other side the halogen-free additives characterize usually minor effectiveness than halogen compounds. Graphite is neutral to the environment. Various kind of graphite additives are attractive substitutes for halogen antipyrene. Moreover graphite flame retardants produce less toxic gases and smokes compared to halogen-containing flame retardants. However application of graphite alone, in many cases (for example polystyrene - easy flammable polymer), does not warrant sufficient reduction of fire. In this case halogen additives are commonly utilized [1-3]. Numerous publications emphasize increasing electrical properties of polystyrene modified by graphite, but skeptically assess its resistance to flame [4,5]. In the other side some articles positively refer application of graphite as an antipyrene for the polystyrene [6,7].

The main purpose of our investigations was preparation of effective flame retardant containing modified graphite or its compositions with additional supportive flame retardants – phosphorus compounds.

Materials and Methods: Expanded graphite (**EG**) (Sinograf SA). For graphite modification: melamine (Aldrich), cyanuric acid (Aldrich). Unsaturated polyester resin Polimal-109 („Organika-Sarzyna" Inc.). Dian epoxy resin Epidian 5 („Organika-Sarzyna" Inc.). Phosphorus compounds: triphenyl phosphate (**TP**) (Aldrich), tritolyl phosphate (**TTP**) (Aldrich), triphenylphosphine (**TPP**) (Aldrich). Styrene (POCh).

The flammability of polyester, epoxy and polystyrene compositions has been determined by the oxygen index test (OI) according to ASTM D 2863-97 standard and horizontal and vertical flammability according to PN-EN-60695-11-10:2002 standard. Thermogravimetric analysis were made on Mettler Toledo equipment TGA/SDTA851 in the air environment. Microscopic analysis were made on Scanning Electron Microscope with EDS analysis – JEOL JSM – 6490LV.

Results and Discussion: The method of obtaining additives containing expanded graphite modified by melamine cyanurate was worked out. Synthesis of melamine cyanurate was lead in the presence of expanded graphite [8]. This compound was used as a additive for suspension polymerization of styrene [9]. Epoxy and polyester compositions with this modified expanded graphite were made. Moreover the composition of expanded graphite with phosphorus compound or different type of modified graphite were utilized as a flame retardant for polystyrene, polyester and epoxy resins. It has been observed that the presence of expanded graphite modified by melamine cyanurate in the polystyrene increases the OI from 17 % to 24,5 %. The highest parameters of horizontal and vertical flammability FH-1, V-0 has been received (*tab. 1 p. 1*). The presence of the same type of modified expanded graphite in the epoxy resins increases the OI from 22 % to 26,9 % (*tab. 1 p. 2*). The composition of expanded graphite with phosphorus compound turned out to be effective additive for polystyrene and epoxy resins. In the polystyrene the OI increases from 17 % to 25,5 %. The highest parameters of horizontal and vertical flammability FH-1, V-0 has been received (**EG** with **TP, TPP, TTP**) (*tab. 1 p. 3-5*). The presence of phosphorus expanded graphite composition in the epoxy resins increases the OI from 22 % to 29,8 % (**EG** with **TP, TPP, TTP**) (*tab. 1 p. 6-8*). Different types of modified graphite (graphite oxide modified by melamine formaldehyde resins) turned out to be effective additive for polystyrene and polyester resins. In the polystyrene the highest parameters of horizontal and vertical flammability FH-1, V-0 has been received (*tab. 1, p. 9*). The presence of the same modified graphite in the polyester resins increases the OI from 21 % to 27,3 % (*Tab. 1, Pos. 10*).

	amounts of additives (portion weights)	OI (%)	horizontal flammability	vertical flammability
1	15	24,5	FH-1	V-0
2	10	26,9	FH-1	V-0
3	15	25,5	FH-1	V-0
4	15	-	FH-1	V-0
5	15	-	FH-1	V-0
6	10	27,7	-	-
7	10	28,8	-	-
8	10	29,8	FH-1	V-0
9	15	-	FH-1	V-0
10	10	27,3	-	-

Tab. 1 Flammability analysis

Conclusions:

Modified graphite or its compositions with phosphorus compounds can be effective flame retardants for polystyrene as well as for polyester and epoxy resins. Decreasing flammability of polystyrene by graphite modified by melamine cyanurate is particularly important because of pro-ecological character this type of flame retardants.

Polyhydroxyalkanoates (PHA – Polyester synthetized by bacteria) have been attracting more and more attention in industrial and academic fields due to the global growing conscience relating to the preservation of ecological systems. The specific properties of PHA such as biodegradability, biocompatibility, high renewable carbon content and thermoplasticity with high crystallinity make them interesting for short-lived industrial applications, in replacement of non-degradable petroleum based plastics.

Today, tailoring new eco-friendly plastics represents a wide field of investigation. In this context, polyhydroxybutyrate (PHB), which is the first isolated PHA, and its copolymers such as polyhydroxy(butyrate-co-valerate) (PHBV) are the most produced and investigated biopolymers of this family. Their properties come from their monomer composition depending on carbon source and on the microorganisms used for their production. In addition, the molecular structure differences between PHB and PHBV involved more ductile and processable copolymers compared to PHB properties. The random bio-copolyesters present a lower melting point and a relative lower crystallinity compared to PHB. Consequently, the better processing characteristics of PHBV improved their mechanical properties. Beyond that, depending on the packaging applications requirement, the water vapor permeability comparable to that of LDPE represents an interesting property of PHA.

The purpose of this study dedicated to the water transport properties [1-2] is to evaluate the potential of these bio-copolyesters for film packaging applications. To our knowledge, investigation on barrier properties of PHA are few considered in the literature [3] despite some devoted to physical and thermal properties of PHA. When compared to common polymers such as polyethylene or polypropylene, PHBV copolymers showed a very good balance of barrier properties [4]. In addition, theses bio-copolymers have another advantage which is their low moisture sensitivity with a hydrophobic behavior against water molecules. The results on PHBV films are presented: a dependence of barrier properties against to the film preparation (thermocompression, solvent casting) and to the addition of additives is observed. The low-formulated films present increased gas barrier properties related to the crystallinity index of films. The water vapor sorption measurements proved the reduced ability to sorb water vapor of these biodegradable films, correlated to the gas permeabilities measurements. The tortuosity concept explains that barrier properties are related to the increase in the migration pathways which leads to limited permeability. Despite interesting barrier properties, few extensive applications to replace conventional plastic materials have been found although various production sources not compete with human or animal alimentation can be even envisaged.

Introduction

Post-production annealing is an important step in the preparation of bulk heterojunction solar cells, improving the efficiency [1-2]. It is important to define appropriate annealing temperatures and times, therefore the isothermal crystallisation of a poly(3-hexyl thiophene) (P3HT) and [6,6]–phenyl C_{61} – butyric acid methyl ester (PCBM) blend is investigated in this study in order to better understand the annealing process. In order to achieve this, fast scanning calorimetry techniques are required that allow for high cooling rates, avoiding crystallisation during cooling and achieving a glassy blend. It is then possible to study isothermal crystallisation closer to the glass transition temperature (T_g) than by conventional DSC techniques.

Materials and methods

This study was performed on a 50/50 wt% or 1:1 blend of P3HT (Merck, M_w=35 000 g mol^{-1}, M_w/M_n = 1.8; regioregularity greater than 98.5%) and PCBM (Solenne). A first technique used is "Rapid Heat-Cool" Calorimetry (RHC), that contains a millimeter-sized furnace for operation at scan rates of up to 2000 $K.min^{-1}$ [3]. In addition, ultra fast scanning chip calorimetry (UFSC) was used, based on a chip with a 100 µm x 100 µm heating area, which allows to study 100 nm layers at scan rates of 10^3-10^6 $K.s^{-1}$ [4].

Results and discussion

As annealing and the deterioration of the long-term stability of P3HT:PCBM active layers both involve crystallisation, the crystallisation rate of the 1:1 blend was investigated at temperatures in between the glass transition and melting. The evolution of the crystallisation rate with temperature was compared for annealing from the glassy state and from the melt state. The melting enthalpy after isothermal crystallisation was taken as a measure for isothermal crystallisation and plotted as a function of annealing time. The resulting crystallinity curves were then analysed using Avrami kinetics [5], yielding rates of crystallisation. When plotting the isothermal crystallisation rate versus crystallisation temperature (T_c) ,both from the melt and from the glassy state, bimodal bell-shaped curves are obtained with two maxima, one at lower temperature (70 or 80°C) and the second at higher temperature (110 or 125°C) , as can be seen in figure 1.

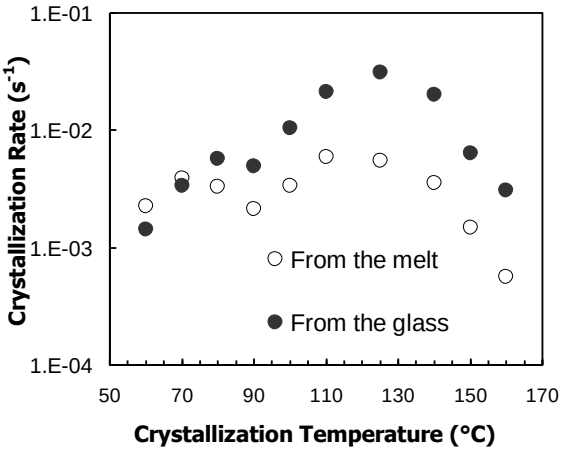

Figure 1: Isothermal crystallisation rates of a 1:1 P3HT/PCBM blend as calculated from Avrami kinetics as a function of temperature. A bimodal behaviour is seen when crystallizing both from the glass and from the melt.

Conclusion

The isothermal crystallisation rate of a 1:1 P3HT:PCBM blend was evaluated at several temperatures. The crystallisation rate curve as a function of temperature shows bimodal behaviour, attaining two maxima. The results found in this study could lead to a more optimised annealing procedure for the P3HT/PCBM devices.

Solvent And Substrate Contributions To The Formation Of Breath Figure Patterns In Polystyrene Films

Elisa Ferrari, Paola Fabbri, Francesco Pilati

Department of Materials and Environmental Engineering, University of Modena and Reggio Emilia, Strada Vignolese 905/a, 41125 Modena, Italy

elisa.ferrari@unimore.it

When moist air is blown over a polymer solution, evaporative cooling can lead to the formation of water droplets on the liquid surface. These droplets can be arranged into a highly ordered hexagonal array because of different thermofluidodynamic mechanisms such as, for instance, Marangoni convection. Complete evaporation of both solvent and water results in formation of 2D or even 3D arrays of holes, often ordered hexagonally, the so-called BREATH FIGURES (BF).

The generation of BF has long been described as a complex phenomenon, in which several parameters combine in a fairly unknown way.

This work reports a detailed investigation over the role played by the solvent in the process of BF generation from polystyrene (PS, MW 192000g/mol) solutions spread over different substrates, and discuss the geometrical aspects of the pores by a quantitative point of view by using a purposely developed software for image analysis.

PS solutions (1% wt/vol) were prepared at room temperature using the following as solvents: acetone, carbon disulfide, chloroform, ethyl acetate, methyl ethyl ketone, dichloromethane, tetrahydrofuran, toluene. PS solutions were spread onto substrates having different surface energy, under humid conditions (RH 75± 2%): glass (43.1 mN/m), glass treated with piranha solution (62.8 mN/m), silicon wafer trated with RCA1 solution (48.1 mN/m), silicon wafer trated with piranha solution and then silanized with 3-glycidoxypropyltrimethoxysilane (49.0 mN/m), silicon wafer trated with piranha solution and then silanized with octyltriethoxysilane (61.5 mN/m), fluorinated glass treated with piranha solution (13.8 mN/m), polyethylene (34.5 mN/m), polyvinylchloride (38.0 mN/m) and polyethylene terephthalate (41.0 mN/m).

Effect of the solvent:

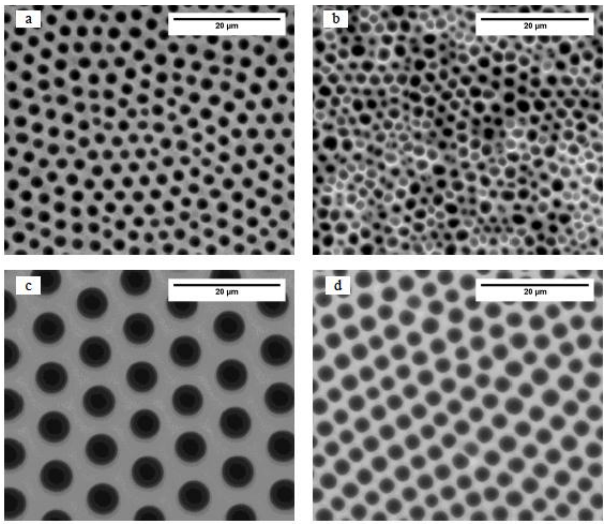
Chloroform and dichloromethane allowed the formation of regular BF, differently from carbon disulfide, that did not allow the formation of an extended hexagonal array of pores on hydrophilic glass GW; it seems that a too fast solidification of the polymer film occurred, favoured by the relatively low boiling point and high vapour pressure of carbon disulfide. The other solvents used were unable to generate porous structures, independently from the substrate. Interestingly, after solvent evaporation, the surface of samples prepared from acetone, methyl ethyl ketone and THF was characterized by the presence of polymer microspheres rather than porous polymer films. This last behaviour, which leads to morphologies quite similar to those recently described and named Reverse Breath Figures, will be discussed in more detail in an upcoming work.

Effect of the substrate:

According to our findings, there is no a quantitative correlation between the substrate surface energy or wettability and pore size and order. From a qualitatively point of view, however, the effect of the substrate (nature, hydrophilicity, wettability) is clear.

All the above reported results suggest that the role of the substrate in the overall mechanism of BFs formation is strictly related to the type of solvent used. In particular the combined effect of solvent and substrate could affect the nucleation of water droplets. Water adsorbed on the substrate before the deposition of the polymer can be removed after the application of the polymer solution and transported to the surface by the Marangoni convective movements. More hydrophilic substrates are able to bind higher amounts of water and this can make the formation of water nuclei faster when the solution is able to remove efficiently this water from the substrate surface.

Figure 1 (a-d) shows SEM micrographs of porous films generated from 1% wt/vol PS/dichloromethane on: (a) PET; (b) PVC; (c) Silanized glass - GWO; (d) pirañha treated glass - GW.



Results show that thermodynamic affinity between polymer and solvent is the key parameter for BFs formation, along with other solvent characteristics such as water miscibility, boiling point and enthalpy. According to our findings, the role played by the substrate is strictly related to the type of solvent used in the generation of BFs.

Collapse of polyelectrolyte star. Theory and modeling

Oleg V. Rud[1], Anna A. Mercurieva[2], Tatiana M. Birshtein[1]

[1]Institute of Macromolecular Compounds RAS, [2]Saint-Petersburg State University

helvrud@gmail.com

Collapse of a hydrophobic polyelectrolyte star is considered using Self-Consistend Field theory and numerical Scheutjens-Fleer method [1, 2]. Star consists of several polyelectrolyte chains, each of these in turn is composed of identical monomers. Monomers can be ionized, and are hydrophobic by itself. For example it can be a polyacid, implying that its chain monomers can be either neutral or negatively charged and all of these have the lateral hydrophobic group.

The aim was to study the interplay between two forces that determine the conformation of polyelectrolyte stars in the solution. These are the hydrophobicity of the polymer and the electrostatic interaction between polyelectrolyte and the dissolved ions. The first one makes the chain monomers stick each other and avoid contact with the solvent molecules, which leads to compression (collapsing) of the polymer. The second one is contrary to swelling of the polymer by increasing the osmotic pressure in the interior region of the polymer coil. Osmotic pressure in turn is caused by the attraction of charged chain groups and oppositely charged low molecular weight counter- and salt ions.

The situation is much more complicated in heterogeneous systems, such as PE brushes or polyelectrolyte stars. Parameters: pH of the solvent, ionic strength turn out local and related to the local concentration of the star PE.

We have shown that the locality of parameters determine the nature of the star collapse process. The transition from swollen to collapsed star goes through an intermediate state. There is a local area in the star, where that is profitable for star chains to be collapsed, and the area where that is profitable to be swollen. As a result we have a microphase segregated star. The inner part of the star is a dense and relatively uncharged core and the outer is swollen strongly charged shell (corona). Large enough corona can support the collapsed core dissolved (or correctly speaking weighted) in a solution.

This state we call quasi-micelle.

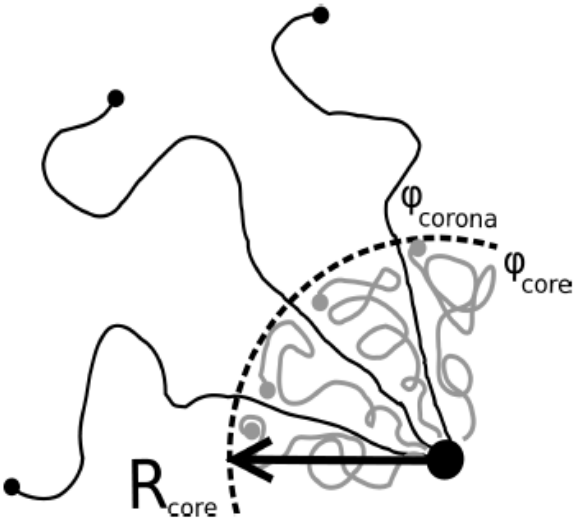

Figure: quasi-micelle state.

A quasi-micell is organised as follows. Each arm of the star can fall either into a collapsed phase or into a swolen one and thus participate in forming either a dense core or a low-density soluble star corona. A number of arms fallen into collapsed phase depends on the solution features, that is by varying solvent parameters one can control relative sizes of a core and a corona.

The possibility to be weighted opens up the prospect to use such systems in well known drug delivery problem.

Substances, soluble in the matter of star core, might be delivered inside the core in the place that we want,where would be released either through star destruction or its transition into the swollen state.

* e-mail: ltammaro@unisa.it

Introduction

A wide variety of biocompatible and biodegradable polymers have been developed for medical applications including synthetic polymers, such as poly(lactide), poly(glycolide), poly(ε-caprolactone), and natural polymers including proteins such as collagen, and fibrogen, and polysaccharides like chitosan. Among them, poly(L-lactide-co-D,L-lactide) (PLDLA) has been widely studied for biomedical applications including substrates for tissue engineering. Although polymeric materials alone have shown some positive results for bone regeneration, efforts have been made to enhance and stimulate their bone response by introduction of fillers similar to the mineral bone phase such as hydroxyapatite, tricalcium phosphate, calcium carbonate. Recently several investigations for producing nanofiber matrices have been performed using electrospinning technique. Nowadays nanofibers are gaining a lot of attention and are being explored as scaffold in bone tissue engineering applications, due to their properties that can modulate cellular behavior.

Materials and Methods

PLDLA was chosen in this study for production of electrospun microfiber non-woven membranes with and without a bone-like β-tricalcium phosphate (β-TCP).

The structure, the morphology and the thermal properties of the obtained membranes have been investigated by X-ray diffraction (XRD), scanning electron microscopy (SEM), thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The feasibility of combining β-TCP with PLDLA nanofibers mats for in vitro tissue engineering was examined using the MC-3T3-E1 osteogenic cell line. The in vitro degradation of the fibers has been tested in a simulated body fluid medium.

Results and Discussion

Microfibers of PLDLA and PLDLA/β-TCP have been successfully produced using the electrospinning method in acetone solvent. The X-ray data indicated that the electrospinning process led to a mixture of PLDLA and β-TCP. The SEM analysis showed very similar diameter values of the fibers with a distribution centered at value less than 1.0 µm and generally uniform thickness along the fibers. The TGA analysis confirmed the amount of β-tricalcium-phosphate in the composite fibers and showed good and similar thermal properties of all membranes (by TGA and DSC). Using the MC-3T3-E1 an excellent cytocompatibility was found for both PLDLA and PLDLA/β-TCP non-wovens.

Conclusions

Taking into account all the results together, it is clearly demonstrated that the obtained PLDLA/β-TCP electrospun fibers form a favorable physical and biological environment suitable in advanced applications as scaffold for bone tissue engineering.

berges@unizar.es

The interest on polymers containing azobenzene moieties in the side chain has increased in the last years due to the optical anisotropy induced by *trans-cis-trans* photoisomerisation and reorientation of azobenzene molecules using polarized light. This phenomenon makes this kind of materials suitable for optical applications[1-3]. However, due to the optical absorption of azo units at the wavelengths of the exciting light (488nm), thick films, needed for some applications (such as volume holographic storage[4]) cannot be illuminated through the complete film thickness.

Lower optical absorption, while keeping the interactions among azo, units can be achieved by using di-block copolymers in which a block contains the azo units while the other block is made of a polymer that does not absorb at the recording wavelength. To further reduce the azo content, blends can be made by mixing these diblock copolymers with the same homopolymer of the transparent block. In this way thick films, in which the exciting light is able to go through them with low attenuation, can be made. Good photoinduced response in di-block copolymers with azo-contents down to 20% in weight, as well as in some blends of these polymers with PMMA has been presviously reported[5,6].

In this communication we present the results of a study comparing the photoinduced response of two methacrylic diblock copolymers with different azo content (Block 24-14 with a 24% wt, and Block 12-30 with a 12% wt) and their blends. The reduction of azo content has been achieved both by increasing the molecular weight of the methacrylic block of Block12-30 and by blending with PMMA of different molecular weights.

Both block copolymers developed a well defined microstructure which has been characterized by Transmission Electron Microscopy (TEM). Block 24-14 shows a lamellar like structure, while for Block 12-30, the observed microstructure is spherical, with an average diameter of the azobenzene microdomain of 25-30nm, as it can be seen in Fig. 1 (the size of the black bar is 200nm).

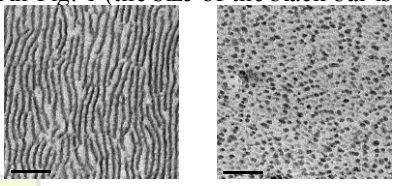

Fig. 1

Blends of Block 24-14 with PMMA of molecular weight 11500, changed the lamellar microdomains into spheres, as the azo content decreased from 24%wt to 12%wt (Blend 1) and to 3%wt (Blend 2). However, blends of Block 12-30, with a decrease in the azo content down to 3%wt (Blend 3), showed the same spherical microstructure as Block 12-30.

Photoinduced anisotropy has been studied in these materials in terms of birefringence (Δn) and dichroism. Since Δn is mainly associated with azobenzene units, the saturation value of /Δn/ decreases when the azo content goes from 24%wt to 12%wt and 3%wt in the case of Block 24-14, and from 12 %wt (Block 12-30) to 3 %wt (Blends 5) in the case of Block 12-30, as it can be seen in Fig. 2. However, values of birefringence normalized to the azo content ($/\Delta n/_{norm}$), are similar in the two block copolymers and in blends of Block 12-30 while lower values are got in blends of Block 24-14.

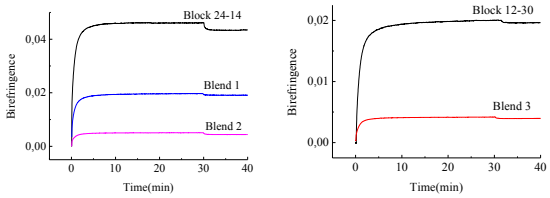

Fig. 2

This can be associated with the lower order achieved in these blends, which was checked by dichroism measurements. The photoinduced orientation was defined by an in plane order parameter η. The values obtained for Blends 1 and 2 are $\eta = 0.47$ and $\eta = 0.40$ respectively, which are smaller than the order parameter measured for Block 24-14 ($\eta = 0.51$). This decrease in the order parameter can be due to the change from lamellar to spherical microstructure. However, Block 12-30 and Blend 3, show η values of approximately 0.51.

We can conclude that Block 12-30 and Blend 3 allow us to maintain values of $/\Delta n/_{norm}$ and η similar to that of Block 24-14, although the azo content is lower; while Blends 1 and 2 have a worse optical response than Block 24-14. Holographic recording has also been studied in blends of Block 12-30 with an azo content reduced down to 0.1%. Stable holographic gratings have been stored in this material.

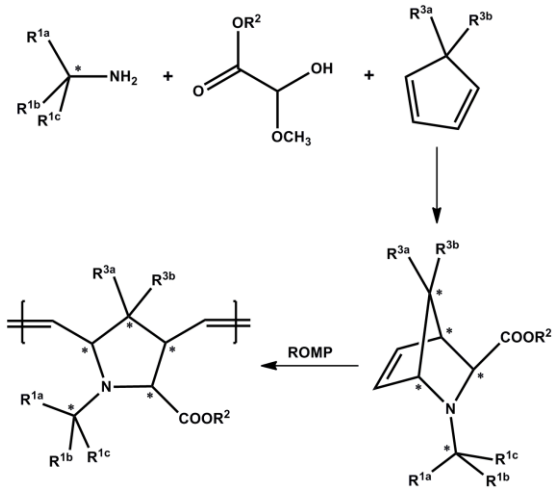
Stremayrgasse 9/V, AT-8010 Graz, Austria.

e-mail: f.wiesbrock@tugraz.at

Introduction

Azanorbornenes are optically active nitrogen-containing compounds that are ideal synthetic precursors for a large variety of natural products like amino acids.[1,2] Consequently, azanorbornenes are of topical interest for the synthesis of various active agents.

Furthermore, there is an increasing demand for the fine-tuning of properties of highly functionalized polymers in virtually all application fields. However, catalytic polymerization methods using transition metal based initiators are limited by the functional-group tolerance. Concomitant with the introduction of 3rd generation Grubbs initiator, state of the art ROMP (ring opening metathesis polymerization) offers the advantage of paramount functional group tolerance these days. Hence, the incorporation of highly diverse chemical groups into the targeted materials is greatly facilitated.



Scheme 1: Synthesis of azanorbornenes by ROMP.

The objective of this research work was to develop synthetic strategies towards well-defined polymers that meet a plethora of requirements; high glass-transition temperatures (T_g) were additionally favored: high T_g materials are attractive for various applications in industry. Until now, only isolated examples of ROM polymers with high T_g are known. A further step in the direction of material design concerns the control of the stereochemistry of the polymers obtained by a hetero-Diels-Alder reaction.

Materials and Methods

Asymmetric Diels-Alder reactions of cyclopentadiene and the phenyl-methyl imine of methyl glyoxylate yielded azanorbornenes (Scheme 1). The following ROM polymerization was initiated by a ruthenium complex. Four structures of poly(azanorbornene)s are possible (Figure 1).

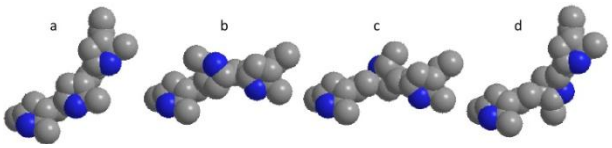


Figure 1: Four possible regular structures of poly(2-azanorbornene) derivatives.[3] (a) cis, HT, isotactic; (b) cis, TT, syndiotactic; (c) trans, HT, isotactic; (d) trans, TT, syndiotactic.

Results and Discussion

Diastereoselective poly(azanorbornene)s were synthesized via ROMP[3] from monomers prepared by aza-Diels-Alder reactions. In general, 16 stereoisomers of the monomers are possible. The ruthenium complexes as initiators for ROM polymerization exhibited sufficient functional group tolerance for polymerizing azanorbornenes.

Conclusions

A general design principle for monomers leading to high T_g ROM polymers is under current investigation. In this poster presentation, the structure characterization of azanorbornenes as well as the subsequent ROM polymerizations will be reported. Furthermore, the characterization of the poly(azanorbornene)s will be presented.

2. Scientific Center of Radiation Medicine and Burns, SCRMB, Davidashen, m/b 25 Yerevan 0108, Armenia

zoefa2000@yahoo.com

Introduction. Risk of internal and external radiation injury exists everywhere where radioactive substances are used or produced. Now these risks are increased because of terrorism attacks and possibilities of using "dirty" bombs [1,2].

In case of penetration of radionuclides in human organism the primary task is their fast removing. At present for this purpose various low-molecular chelating compounds (pentacinum, ferrocinum, trimephacinum) are used in practice. However, almost all of them possess a number of negative properties and can cause headache, nausea, decrease of calcium level in serum, etc [2,3].

We are developing new grades of copolymers that showed high effectiveness in binding and removing of radio nuclides (^{137}Cs, ^{60}Co and ^{90}Sr) from different surfaces [4].

In this connection a possibility of using some of these copolymers (water-soluble) as potential polymeric antidotes with high effectiveness and low toxicity has been examined.

Materials and Methods.Three series of copolymers modified polyvinyl alcohol (MPVAL), derivatives of vinylacetate (VA) - acrylic acid (AC) and N-vinylpyrrolidone – maleic acid (VPMA) have been investigated. The functional compositions of copolymers were examined by methods of chemical, conductometric titration, IR-, NMR spectroscopy. Surface tension of solutions and critical concentration of micelle formation were determined with CAM-101 apparatus

For each series in model conditions (water solutions of non -radioactive salts) functional composition of copolymers providing the maximum binding of Cs, Co and Sr was verifiied [5].

Cytogenetic activities (proliferative activity, chromosomal aberration) of the selected samples of copolymers have been studied *in vivo* (bone marrow cells of white rats).

Results and Discussion.

First the principle possibility of using some of the developed copolymers for binding of radionuclides (^{90}Sr) in blood was verified *in vitro*.

Since in the reactions of strontium binding both blood protein and co-polymers, injected into the blood, may participate, the experiments to find out their role and the share were carried out in the reactions with non-radioactive ions.

To reveal competitiveness between developed copolymers and blood proteins in binding of metals ions the comparative researches by using of albumen were conducted. It is revealed, that efficiency of metals binding in the presence of albumen depends both on polymer type and on its functional composition. It was shown, for example, that mixture of albumen and copolymer VA-AC-16 (1: 0,5) binds 90% of Co^{2+} in water solution, while VA-AC-16 copolymer alone binds 85% of Co^{2+}. MPVAL is more effective in binding of Co^{2+} than albumin. However these copolymers exhibit different citogenetic activity (Table1, substance dose 60 mg/kg).

Table1. Cytogenetic changes of bone marrow cells

Samples	PA (amount)	ChA (%)
MVAL26/05	591.6±48.7	2.08±0.44
VPMA	718.0±90.8	2.0±0.28
VA-AC-16	778±19.8	2.0±0.09
VA-AC-19	1317.0±30.6	1.0±0.1
Control	654.75±55.11	3.31±0.57

Despite the difference in performance, these polymers are considered to be cytogenetically inactive and can be used in *vivo* studies.

Conclusion. The results, received up to now, show that developed copolymers have potentiality to be used in further testing as antidotes in *vivo* with using ^{137}Cs, ^{60}Co and ^{90}Sr radionuclides.

Introduction

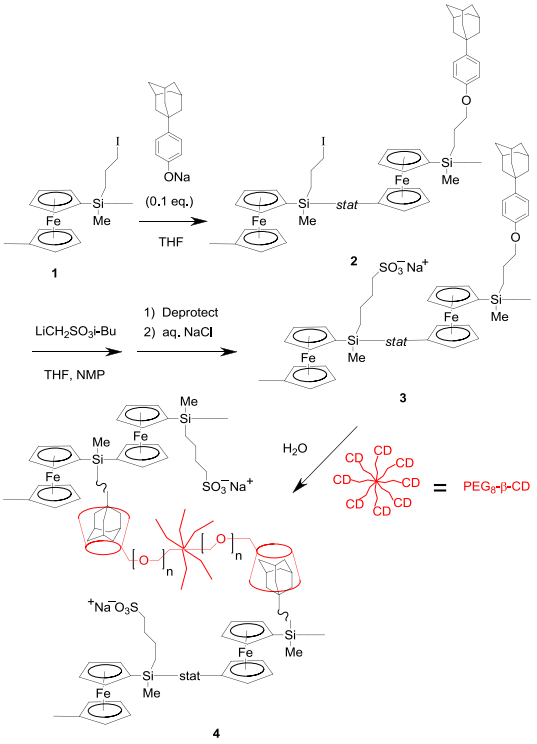
Stimulus-responsive hydrogels are attracting much attention due to their potential use in controlled release systems[1] where drugs or cosmetics can be released upon receiving a specific stimulus, or as actuators, artificial muscles or valves.[2,3] Typical stimuli used to date include temperature, pH, ionic strength, light and to a much lesser extent redox stimuli.[4] Redox stimuli may offer fast and reversible switching between states and can be applied externally. We recently reported redox-responsive poly(ferrocenylsilane) (PFS)[5] polyion hydrogels[6] based on water-soluble PFS polyelectrolyte chains.[7] PFS hydrogels may undergo redox-induced[8] volume changes or changes in viscoelastic properties due to alterations in chain conformation, charge density and polarity of the constituent polymer chains. Networks based on PFS chains soluble in regular organic solvents have been reported.[9] Making use of the PFS redox activity, full-color displays based on the electrical actuation of photonic crystals have been fabricated.[10] However, there are, to our knowledge, no accounts of PFS hydrogels in the literature. Here we report on the synthesis of two distinct types of poly(ferrocenylsilane) hydrogel, featuring PFS chains with negatively charged side groups and a hydrogel based on organic solvent-soluble PFS chains.[11]

Results and Discussion

Poly(ferrocenyl(3-iodopropyl)methylsilane) **1** (Scheme 1) was synthesized as described earlier.[7b] A desired amount of 4(1-adamantyl)phenol was attached to PFS **1** by nucleophilic substitution, followed by reaction of the resulting **2** with α-lithio isobutyl methanesulfonate anion.[7b] Deprotection of the isobutylsulfonate side groups and subsequent ion exchange led to PFS polyanion **3** which possessed a tunable amount of adamantyl side groups. PFS polyanion **3** will then be combined with a *β*-CD-derivatized 8-arm star-shaped poly(ethylene glycol) (Scheme 1), employed earlier by W.E. Hennink *et al.* to form a hydrogel by self-assembly.[12] Side group modification of PFS **1** with sodium acrylate anions yielded a PFS that could be crosslinked using α,ω-poly(ethylene glycol)dithiol via thiol-Michael addition click reaction. A water-swellable network was obtained. The equilibrium swelling ratio, morphology, rheology, and redox responsive properties of this PFS-PEG-based hydrogel were investigated.

Conclusions

PFS hydrogels, composed of water-soluble PFS polyions or of organophilic PFS chains, were produced. The hydrogels could be oxidized and reduced reversibly by chemical and electrochemical means. Their redox-responsive behavior is currently under study.



Scheme 1. PFS polyanion hydrogel formation by self-assembly, using *β*-CD/adamantane host-guest complexation for creating crosslinks.[12]

mpinol@unizar.es

Stimuli-responsive block copolymers have received an increased attention in recent years. One of the most well-known thermal-responsive polymers is PNIPAM. However, alternative polymers such as copolymers containing short oligo(ethylen glycol) methacrylates have being investigated. Their lower solution critical temperature (LSCT) can be tuned by adjusting the monomers ratio.[1] On the other hand, functionalization of amphiphilic copolymers with azobenzene derivates allows obtaining interesting photoresponsive materials.[2]

In this work, block copolymers consisting of a thermoresponsive block linked to an aliphatic polyester fourth-generation dendron functionalized with azobenzene moieties have been synthesized (*Figure 1)*.
The linear block is composed by a copolymer of 2-(2-methoxyethoxy)ethyl methacrylate (MEO_2MA) and oligo(ethylene glycol) methacrylate (OEGMA).

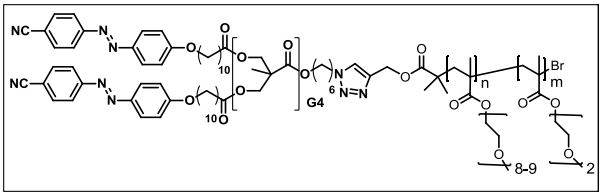

Figure 1. Chemical structure of the block copolymers.

Controlled radical polymerization, in particular ATRP, has been employed to obtain well-defined thermosresposive blocks. An efficient coupling of the preformed blocks has been achieved using copper(I)-catalyzed azide-alkyne cycloaddition (CuAAC).

Chemical structures of the linear-dendritic block copolymers were confirmed by IR, ^{1}H NMR, and ^{13}C NMR espectroscopies. Purity and molecular weight determination were performed by gel permeation chromatography (GPC).

Cloud points of the thermoresponsive linear bock were measured on a photometer. Transmitance of polymer solution in water at 670 nm was monitored as a function of temperature.

Thermal transitions were studied by differential scanning calorimetry (DSC) and polarized optical microscopy (POM).

Morphological study is going to be performed by using electronic microscopy.

This work was supported by the MICINN (Spain) under the project MAT2008-0625-C02-01 and DGA founding.

Development of Active Flexible Packages by the Incorporation in Bulk of Antimicrobial Natural Additives

R. González-Leyba, B. Galindo-Galiana, C. Gadea-Tomás, F. Martí-Ferrer

AIMPLAS, Gustave Eiffel, 4. Parque Tecnológico, 46980 Paterna (Valencia), Spain. Tel. +34 96 136 60 40, Fax +34 96 136 60 41

rgonzalez@aimplas.es

Introduction

Active packaging is referred to packaging systems where the package has active functions beyond containing and protecting the product inside. The interaction produced between the package and the product helps to extend its shelf-life. Different systems of active packaging are well-known, consisting usually in the incorporation of an active agent inside the package in a separated bag or as a coating, interacting with the package head-space or directly with the food. The active package has to be designed specifically to the product to be packed.

In this study, different natural additives were used as antimicrobials by their incorporation into the polymer matrix of flexible packages in order to study their effectiveness on different types of food.

Extracts from grape seeds and garlic were selected among several natural additives due to their good thermal stability, allowing their incorporation in bulk during the extrusion process.

Protection of food against microbial degradation should take place by additive migration from the polymer matrix to the food inside the package.

The two keys of the active packages development are both the correct incorporation of the natural additives into the polymer matrix, withstanding temperature and shear conditions given at a conventional extrusion process, and migration of the additives from the polymer matrix that should take place.

This type of active packages would differ from the current ones on the market as the active additive is incorporated directly into the polymer matrix.

Materials and methods

The natural antimicrobials studied were garlic extract from DOMCA, grape seeds and onion extracts both from NATUREX. The polymeric matrix was polypropylene (PP), grades from REPSOL (standard grade) and BASELL (low melt temperature grade).

The thermal stability of the natural antimicrobials was studied by Thermal Gravimetric Analysis (TGA).

Compounds of PP with natural antimicrobials were prepared by compounding using a co-rotating extruder. Monolayer films of PP containing different amounts of the active additive were obtained by flat film extrusion.

Results and discussion

Results from TGA showed that garlic and grape seed extracts had the best thermal properties, being thermal degradation initiated above 200 ºC. The most stable was the garlic extract. Onion extract showed thermal degradation initiation at 100 ºC, taking place the most part at 160 ºC.

Garlic and grape seeds extracts were selected for the PP compounds preparation. Due to their different thermal stability, a low melt temperature PP grade was used in the preparation of grape seed extract compounds, whereas a standard PP grade was used for garlic extract compounds. Extract compounds containing 10% (w/w) of the antimicrobial additives were prepared in a co-rotating extruder. A specific screw configuration was designed to avoid degradation of the natural additives by shear during the compounding process. The compounds were used in flat film extrusion to obtain PP films with different amounts of each extract. Figure 1 shows a film of PP containing grape seed extract. Temperatures were optimised in order to avoid degradation of the natural extracts. The antimicrobial character of the extruded films is being studied with different types of food like salmon, cheese, jam, avocado and apple.

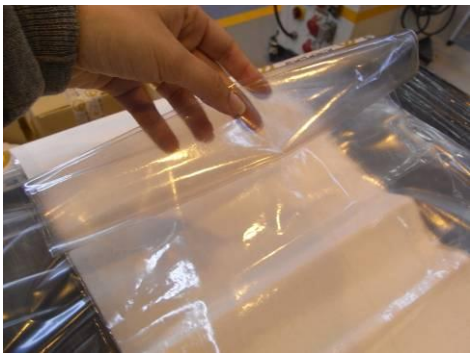

Figure 1: Extruded PP film with grape seed extract incorporated

Conclusions

Natural additives can be incorporated in PP by the conventional processing techniques for polymeric materials. The selection of the most suitable polymer grade in combination with the extrusion equipment and conditions is crucial to maintain the antimicrobial character of the natural additive in the PP matrix.

jlarias@ugr.es

Introduction. Drug delivery to severe diseases can be based on nanomaterials sensitive to external stimuli. Such advanced nanoplatforms (stimuli-sensitive nanocarriers) are capable to experience alterations in their structure and physical properties under small changes in the environment. The consequence will be a controlled delivery of the nanomedicine and/or triggered drug release into the disease site. In this way, one of the major approaches is the use of magnetic nanoparticles (NPs). Such advanced nanomaterials can specifically deliver drugs to targeted sites under the guidance of magnetic gradients. Iron oxide NPs are primarily used in their formulation. However, due to the poor drug loading capacity and uncontrollable drug release frequently exhibited by iron oxides, it is also needed to embed them into a biodegradable shell (mainly a polymer or a lipid vesicle). The shell will play the role of transporting the drug to the non-healthy tissue (controlling its release). At the same time, the iron oxide core will allow the magnetic guidance of the nanomedicine towards the site of action [1, 2].
In this work, we describe the synthesis and characterization of magnetic NPs composed of a core of superparamagnetic magnetite (Fe_3O_4) and a shell of poly(butylcyanoacrylate) (PBCA).

Materials and Methods. Superparamagnetic Fe_3O_4 (size ≈ 10 nm) and PBCA (size ≈ 250 nm) were synthesized following the chemical co-precipitation process [3] and the emulsion/polymerization method [4], respectively. The formulation of the Fe_3O_4/PBCA nanocomposites was possible by anionic polymerization of the BCA monomer (1 %, w/v) in a Fe_3O_4 aqueous suspension (0.4 %, w/v) with a concentration of 10^{-4} N of HCl, during 3 hr under mechanical stirring. Particle size was determined by PCS. The presence of the shell onto the magnetic nuclei was checked by HRTEM.
The characterization of the chemistry and internal structure of the NPs was achieved by FTIR spectrometry and X-ray diffractometry, respectively. Surface electrical properties were analyzed by zeta potential (ζ) determinations as a function of pH and ionic strength. Surface thermodynamics of the nanocomposites were investigated by contact angle measurements of standard liquids (water, formamide, and diiodomethane) on pellets of the NPs.
Finally, the determination of the hysteresis cycle and the way of variation of the first magnetization of the samples with the external applied field were useful tools to completely characterize (at the macroscopic level) the magnetic behavior of these nanosystems.

Results and Discussion. The synthesis procedure followed for the preparation of Fe_3O_4/PBCA NPs allowed the formation of a well-stabilized nanocarrier with an average diameter of ≈ 200 nm. HRTEM photographs proved that Fe_3O_4 cores were well-covered by the biodegradable shell. X-ray diffractograms of composite and Fe_3O_4 NPs showed excellent coincidence with the ASTM pattern of Fe_3O_4. This was an indication of the high crystalline nature of the synthesized magnetic nuclei. All the bands of the polymer were present in the FTIR spectrum of the composite NPs, a clear prove that the shell observed by HRTEM was indeed PBCA coating.
The efficiency of the polymer coating was further demonstrated by comparing ζ values of core/shell NPs with those of the nucleus and of pure PBCA particles. ζ of the nanocomposites were similar to the ones for the PBCA, and clearly different to the ones of the Fe_3O_4 core, this suggesting the efficiency of the coating. The fact that the surface properties of the magnetic core/shell NPs mimic those of the pure polymer was additionally confirmed by thermodynamic analysis. It was determined that the originally hydrophilic Fe_3O_4 changes to hydrophobic when coated by the polymer.
The magnetic responsiveness was completely defined by the determination of the hysteresis cycle. It was observed that both Fe_3O_4 and Fe_3O_4/PBCA NPs were soft magnetic materials, with a very narrow hysteresis cycle. This behavior is useful for our purpose of controlling their magnetization and, eventually, the rate of drug release by application of not very intense magnetic fields.

Conclusions. In this work we have shown that it is possible to reproducibly coat magnetite NPs with a shell of PBCA. Although the existence of the polymer shell was observable under the electron microscope, the efficiency of the coating was demonstrated by the chemical characterization and the surface analysis of the nanocomposites compared to that of their components. The very important magnetic responsiveness of these core/shell NPs opens promising possibilities to improve drug delivery to severe diseases.

Introduction

Considerable efforts have been devoted to the development of nanocomposite foams with good mechanical properties and reduced density[1]. The use of nanoparticles as nucleant agents, especially organoclays, in nanocomposites based on PLA have been reported previously by several research groups[2-4].

Since its discovery in 2004[5], graphene has become of intense interest as fillers in polymeric nanocomposites with novel functional and structural properties.

In this work, the performance potential of the PLA/graphene nanocomposites in foam application was studied. In particular, the main objective was to understand the effect of graphene sheets on both cell morphology (e.g., cell density and cell size) and volume expansion ratio of PLA/graphene nanocomposite foams obtained.

Materials and Methods

A commercial poly(L-lactide) (2002D, NatureWorks®, USA) with approximately 4% of D-lactic acid monomer was used in this work. Graphite fillers with an average particle size of 3 µm were supplied from Avanzare Co. Graphene nanosheets were obtained by chemical reduction of graphite oxide. A co-rotating twin-screw microcompounder (15-cm^3, DSM Xplore, Netherlands) with two conical screws and a bypass was used for the preparation of the PLA/graphene hybrids. The processing temperature was set at 180ºC. The rotor speed and mixing time were fixed at 150 rpm and 8 min, respectively. The foam processing was conducted on PLA/graphene nanocomposites in an autoclave by using supercritical CO_2.The pressure in the chamber was monitored by a connected pressure gauge and adjusted by an ISCO syringe pump (ISCO 260D Syringe Pump). The polymer nanocomposite samples were then foamed by rapid depressurization. Various foaming temperatures (100ºC~140ºC) were investigated. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were utilized to investigate the cellular foam structure of neat PLA as a referent material and PLA/graphene having different nanographene loadings.

The cellular structure analysis of foams was examined by SEM. The effect of the dispersion capability of grapheme layer on the final properties was investigated. Experimental results demonstrated that low additions of graphene induced homogeneous nucleation of extra-cells during foaming at temperatures above 125ºC, while the neat PLA foam shows non-uniform cell structure (Figure 1).

Synthesis and Photopolymerization of Hydrolytically Stable Crosslinkers for Dental Composites

Ayse Altin, *Duygu Avci*

Department of Chemistry, Bogazici University 34342 Bebek Istanbul Turkey

Introduction:

Commonly used dental composites are composed of dimethacrylate monomers such as 2,2-bis[4-(2-hydroxy-3-methacryloyloxy propyloxy)phenyl]propane (Bis-GMA), an inorganic filler coated with methacrylate-functional silane coupling agents and a polymerization initiator system (1,2). A comonomer such as triethylene glycol dimethacrylate (TEGDMA) is added to adjust the viscosity of the dental resin. Dental monomers should have rigid structures and be able to form a crosslinked polymer matrix for good mechanical properties. Biostability, low polymerization shrinkage, low viscosity, adhesion to tooth material and high polymerization reactivity are other characteristics that an ideal monomer should have. Many approaches have been developed to improve these properties. In this study, we develop new dental crosslinkers based on alkyl α-hydroxymethacrylates with improved adhesion, volume shrinkage and stability and investigate their photopolymerization behavior.

Materials and Methods:

Monomer and polymer characterization involved FTIR, ^{1}H-, ^{13}C-NMR. The photo-polymerizations were performed on a TA Instruments Q100 differential photocalorimeter (DPC).

Synthesis of Monomer 1

To a solution of diethyl 1-aminomethylphosphonate (0.0990 g, 0.59 mmol) and anhydrous pyridine (0.0470 g, 0.59 mmol) in 1.13 mL of dry dichloromethane, 2,2'-(4,4'-(propane-2,2-diyl)bis(4,1 phenylene))bis(oxy)bis(methylene)diacryloyl chloride (0.1161 g, 0.268 mmol) was added dropwise in an ice bath under N_2. After stirring overnight at room temperature, 5 mL of chloroform was added and the solution was extracted with water (2x2 mL), 2M HCl (2x3 mL), 2M NaOH (2x 3 mL) and brine (3 mL). After drying the organic phase with anhydrous Na_2SO_4, the solvent was evaporated. The dark yellow viscous product was obtained. ^{1}H-NMR (400 MHz, $CDCl_3$, δ, ppm): 1.29 (t, 12H, CH_3-CH_2), 1.59 (s, 6H, CH_3-C), 2.0 (m, 4H, CH_2-P), 3.6 (m, 4H, CH_2-CH_2), 4.0 (m, 4H, CH_2-CH_3), 4.7 (s, 4H, CH_2-O), 5.65 (s, 2H, CH=C), 5.97 (s, 2H, CH=C), 6.8 (d, 4H, Ar-CH), 7.1 (d, 4H, Ar-CH).

FTIR (cm^{-1}): 3308 (NH), 2966-2868 (C-H), 1660 (C=O), 1616 (C=C), 1180 (C-O), 1243 (P=O), 1014 (P-O-Et) cm^{-1}.

Synthesis of Monomer 2

Thrimethylsilyl bromide (TMSBr) (0.43 g, 2.78 mmol) was added dropwise to a solution of monomer **1** (0.3346 g, 0.463 mmol) in 2 mL dry dichloromethane in an ice bath and under N_2. Then the solution was refluxed for 4 hours at 40 ^{0}C. After evaporation of the solvent, methanol was added and the mixture was stirred at room temperature overnight. The methanol was evaporated.

Results and Discussion:

The monomer synthesis involved the following steps: i) synthesis of t-butyl-α-hydroxymethyl acrylate (TBHMA) from the reaction of t-butyl acrylate and paraformaldehyde in the presence of 1,4-diazobicyclooctane, ii) synthesis of t-butyl-α-bromomethyl acrylate (TBBr) from the reaction of TBHMA and PBr_3, iii) synthesis of TBBr-Bisphenol A Diester from the reaction of TBBr and Bisphenol A, iv) conversion to diacid by cleavage of t-butyl groups using trifluoroacetic acid, v) conversion to dicid chloride using oxalyl chloride vi) reaction of the diacid chloride and diethyl 2-aminoethylphosphonate to give monomer **1**, vii) hydrolysis of phosphonate groups using trimethylsilyl bromide to give monomer **2** (Figure 1).

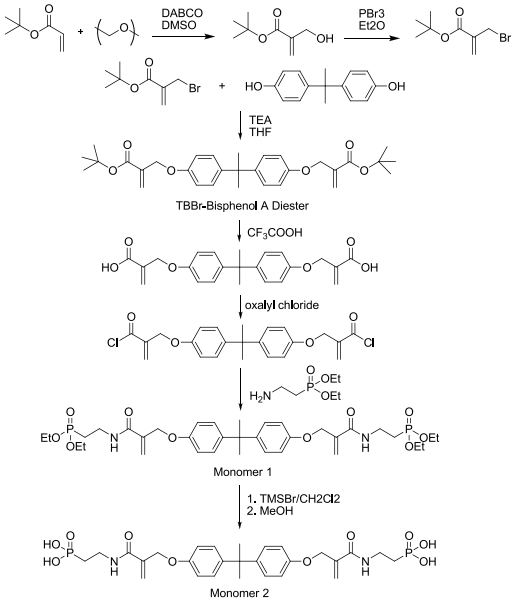

Figure 1. Synthesis of monomers.

^{1}H-NMR and FTIR spectra of the monomers confirmed their structures. The homopolymerization and copolymerization behaviors of these monomers were also examined with Bisphenol A glycolate dimethacrylate (BISGMA) using photo differential scanning calorimeter at 40 ^{0}C with 2,2'-dimethoxy-2-phenylacetophenone (Irgacure 651) as initiator.

Conclusions:

Two novel monomers containing phosphonate or phosphonic acid groups have been prepared. The hydrolytic stability, binding efficiency and copolymerization studies of these monomers are continuing.

Plasma Modification of MWCNTs and Their Use in the Preparation of PA6/MWCNT Nanocomposites

R. Scaffaro, A. Maio

Dipartimento di Ingegneria Industriale, Università di Palermo, Viale delle Scienze, Ed. 6, 90128 Palermo, Italy

e-mail: roberto.scaffaro@unipa.it

Introduction

Carbon nanotubes (CNTs) are suitable as reinforcing fillers for nanocomposites because of their excellent mechanical and electrical properties.[1] Since their bad dispersion in almost all solvents and polymer matrices, CNTs are usually functionalized. Among the several functionalizations, plasma treatment provides a rapid, easy and solvent-free modification of CNT surface.

Plasma treatment was adopted to generate oxygenated moieties on the sidewalls of multi-walled CNTs (MWCNTs). The reaction mechanism of plasma treatment on CNTs can be essentially divided into two steps: (1) ablation of less stable carbonaceous compounds of the CNTs that volatilize as CO_2 and (2) formation of oxygenated functional groups (tipically –COOH and –OH). [2]

Aim of this work is the realization of high performance nanohybrids materials based on polyamide 6 (PA6) and MWCNTs functionalized via plasma. In particular, the possibility to obtain nanocomposites in a rapid, cheap and practicable on industrial scale way was investigated. The process was optimized through the investigation of the role that three parameters, namely plasma power, type of gas and reaction time, played in the surface modification of CNTs.

Materials and methods

A commercial grade of MWCNTs was supplied by Sigma Aldrich (L= 5-9 μm, D=100-170 nm, purity ≥ 90%). The PA6 (Radilon S35 100 NAT, supplied by Radicinova, Italy) has an inherent viscosity (sulfuric acid) equal to 3.4 dl/g. PA6 was dried in a vacuum oven overnight to prevent hydrolytic scission of polymer chains. MWCNTs were used as received.

The functionalization level was measured via Raman and XPS spectroscopy, dispersion tests in water and iso-propyl alcohol.

Nanocomposites were obtained by melt processing. Neat and modified MWCNTs (0, 0.5, 1 and 2% wt/wt) were added to PA6 and mixed in a batch mixer. The specimens were obtained by compression-moulding in order to perform tensile and Izod tests, according to ASTM D882 and ASTM D256, respectively.

Results and Discussion

The XPS and Raman results indicated that the highest content in polar moieties was exhibited by the CNTs modified under the following conditions: 120 W, 10 minutes, oxygen plasma.

The dispersion tests in water and iso-propyl alcohol revealed that neat CNTs precipitated after a few minutes, while air-treated (A-MWCNTs) and oxygen-treated CNTs (O-MWCNTs) remained in suspension, thus confirming the achievement of a more hydrophilic surface. SEM and TEM observations confirmed that functionalized CNTs have less tendency to aggregate in bundles and that plasma treatment did not destruct excessively the CNTs structure. Moreover, TEM observations confirmed that oxygen-plasma treatment removes amorphous carbon by the MWCNTs surface.

A-MWCNTs and O-MWCNTs obtained were selected as fillers for the manufacturing of PA6-based nanocomposites.

Tensile tests demonstrated the higher performance of functionalized MWCNTs-based materials, likely due to a better dispersion and/or a stronger interfacial adhesion. The SEM micrographs of the nanocomposites put into evidence that the wettability of A-MWCNTs and O-MWCNTs in PA6 is better than that observed for neat MWCNTs.

The impact strength (IS) measurements indicate that adding neat MWCNTs to the PA6 induces fragility, so the IS for specimens containing 1% in MWCNT is lower than neat PA6. Otherwise, the use of A-MWCNTs or O-MWCNTs as fillers leads to values of IS up to 2 times higher than PA6+1%CNTs.

Conclusions

The pathway consisting of plasma activation of CNTs and melt blending permits an easy, cheap and rapid fabrication of nanocomposites having improved mechanical properties, achieved at relatively low loading of nanofillers. As process gas, oxygen (more than air) induced the best degree of functionalization in the range investigated. In general, by changing the process parameters it is possible to tune the performances of the materials obtained and XPS and Raman analysis are power tools in order to verify the characteristics of the nanoparticles and to predict their role into the polymer matrix.

Introduction

Several strategies have been adopted to overcome the limitations associated to the bad processability of the inherently conductive form of PANI. Unfortunately, these approaches resulted not particularly effective in obtaining PANI-based composite materials with acceptable mechanical and electrical properties. In this study, we present a general methodology to covalently attach PANI onto a modified polyolefin flexible substrate. Aim of this work is the development of a new polymeric conductive-insulating hybrid material prepared by a simple process, conceptually based on "grafting from" approach, by which the substrate is first activated, then “primed” with suitable reactive groups under mild reaction conditions. A sample of modified ethylene-acrylic acid copolymer (EAA) was selected as a substrate, both in the form of films and fibres. Carboxyl groups of EAA have been first converted into acyl chloride (EAA-Cl) via facile wet chemistry method [1-3]. Later, the acyl groups of EAA-Cl substrates have been first converted by reaction with aniline or para-phenyldiamine (priming) and then coated with "in situ" grown PANI.

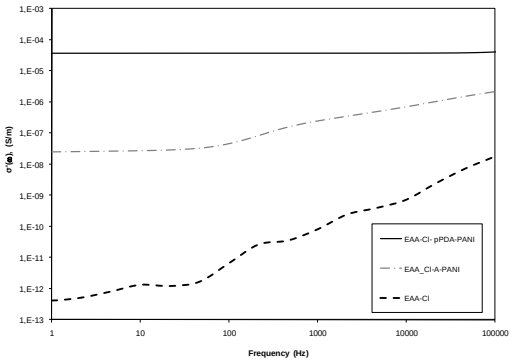
Materials and Methods

EAA (Escor 5001, Exxon Chemical) films with 6.2 % by weight of acrylic acid were prepared using a single screw extruder (Brabender PLE 651, L/D=25, D=19) equipped with a film blowing unit. The thermal profile adopted for the operation was 120–140–160–190 °C, the screw speed 70 rpm and the drawing speed 3 m/min. Wires were obtained by capillary extrusion (Rheologic, CEAST, Italy) at T=190° C and v=10 rpm.

The surface modification consists of three-steps: 1. Activation of the substrate as acyl chloride intermediate (EAA-Cl); 2. Priming of the activated substrate with aniline or para-phenyldiamine (EAA-Cl-A and EAA-Cl-pPDA, respectively); 3. Synthesis of PANI onto primed substrates. The final hybrid materials and corresponding intermediates were fully characterized via FT-IR (Perkin Elmer) Spectroscopy, X-ray Photoelectron Spectroscopy (XPS), SEM-EDAX (FEI QUANTA 200F). Conductivity measurements were carried out via Impedance Spectroscopy (IS) by means of a Frequency Response Analyser and Tensile test, according to ASTM D882, by using a Zwik/Roell Z005.

Results and Discussion

The tensile test on hybrid PANI films, carried out to evaluate their mechanical properties showed that substitution of carboxylic acid groups in acyl groups via wet chemistry promoted a slight increase of the elongation at break value with a slight reduction of Young's modulus and tensile stress values. The second modification, i.e. the conversion of acylic groups into aril substituted amides, caused the decrease of tensile stress and elongation at break, even if the Young's modulus remains pratically constant. Nevertheless, after PANI polymerization, the mechanical properties of the hybrid systems seem to be slightly improved and the elongation at break shows a slight increase, with concomitant increases of tensile stress. EAA is an insulant material with a σ'(1Hz) of ~4 x 10^{-13}, the same film primed with aniline and further coated with PANI shows an increase of bulk conductivity (at 1 Hz) of four orders of magnitude, while when priming is operated with pPDA the increase of conductivity is of eight orders of magnitude. Considering that, by the morphological evaluation, the thickness of the coating is smaller in the case of priming with pPDA, this result is either correlated to a superior electrical conductivity of the PANI grown out from the pPDA-primed films and/or to a deeper penetration of PANI inside the EAA core when reacted with pPDA.



Conclusion

We demonstrated that PANI was successfully polymerized and covalently grafted onto flexible EAA substrates, previously activated. There are no significant differences after each treatment in the mechanical properties, except a faint decrease of the elongation at break. The electrical conductivity shows values of 10^{-4} S/m for the PANI-based hybrid systems drastically enhanced if compared with 10^{-13} S/m value of the neat EAA. The PANI particles obtained have a typical average size of a few tens of nanometers and are thus often regarded as nanogranular typical morphology of PANI polymerized in a strongly acidic solution. All the characterization data strongly suggest that PANI was successfully polymerised and covalently grafted onto the flexible EAA substrates.

Introduction

Polymer-polymer complexes are the result of favourable specific interactions between two dissimilar polymers. The main factors governing their formation are the specific interaction between the component polymers and the solvent in which complex formation takes place. When polymer-polymer interaction outweighs polymer-solvent interaction, the two polymers coprecipitate as highly associated materials, the polymer-polymer complexes. Additional factors such as functional group accessibility, self association of component polymers[1] and differences in the polymer-solvent interactions[2] can prevent interpolymer complexation, and a miscible or inmiscible polymer blend or even a segregative phase separation[3] can be observed.

The influence of solvent on complexation of poly(N-diethylacrylamide) (PNDEAm) and poly(4-vinylphenol) (PVPh) has been studied using methanol, acetone and tetrahydrofuran (THF) as solvents.

Materials and Methods

PVPh used was a commercial sample and PNDEAm sample was obtained by radical polymerization. Complexes were prepared by mixing separate polymer solutions in the selected solvent, at concentration 0.2 mol monomeric unit.L^{-1}.

Differential scanning calorimetry (DSC), Fourier transform infrared spectrometry (FTIR) and Elemental Analysis are the techniques used.

Results and Discussion

Several mixtures for the system PDEAm/PVPh have been prepared for different compositions in methanol. (Table 1)

Table 1.Data of complexes in methanol

Solvent Methanol	35/65	50/50	65/35
Complex yield (% w)	63.8	84.5	69.2
Complex composition (mol% PVPh)	48	46	41
Tg (ºC)	177	170	164

Elemental analysis measurements of the precipitates obtained, once isolated, indicate the formation of interpolymer complexes of composition close to 50% mol PVPh. A single glass transition temperature is observed for the complexes and though not much higher than those of the polymer components (96ºC and 167ºC for PNDEAm and PVPh respectively), as usually occurs in hydrogen bonded complexes, they present positive deviations from additivity.

When using THF and acetone as solvent, the precipitates obtained for 50/50 mixtures present compositions of aprox. 10% mol PVPh, indicating that PNDEAm segregates from the mixture. Tg values obtained for both phases, the precipitate and the solution once evaporated, are 96ºC and 149ºC respectively, making evident the PNDEAm segregation. FTIR measurements confirm these results.

The behaviour of this system contrast to the one observed for the system Poly(N-t-butylacrylamide) /PVPh for which, when using THF as solvent, interpolymer complexes of high stability and very high Tg values, around 190ºC are observed.

Conclusion

Poly(N-diethylacrylamide) and poly(4-vinylphenol) form interpolymer complexes in methanol whereas PNDEAm is segregated from the mixture, as a precipitate, when using acetone and tetrahydrofuran as solvents, as shown by Fourier transform infrared spectrometry and elemental analysis studies.

The fact that a change of solvent causes the disruption of the complex could be interesting for technical applications as, for example, in surfaces modification.

Introduction

The use of synthetic polymers for packaging has evolved to the preparation of films by combining natural and synthetic polymers. Some properties such as hydrophilicity and biocompatibility improve, while maintaining good mechanical properties. Since chitosan (CS) is a biocompatible polysaccharide and its backbone presents electrolyte moieties, CS is ranked among the most widely used natural polymers. However, this polymer has weak mechanical properties that limit its use. Therefore, the enhancement of CS properties is an issue that has gained a great interest lately [1-3]. In this work, the synthesis of biocomposite films from CS and poly(acrylic acid) (PAAc) was studied in order to obtain a material with the best properties.

Materials and Methods

CS, M_w 120 kDa, and an acetylation degree of 85 % (Sigma, USA); PAAc, p.a., Mw 450 KDa (Sigma, USA), acrylic acid (AAc), p.a., (Sigma, USA). Films of CS and PAAc were obtained through different casting methods. Thus, a CS-PAAc blend was obtained from the mixture of 1 wt% aqueous solutions of each polymer, at pH 5, the ratio of moles of CS to PAAc being 4. Interpenetrating films of CS-PAAc were attained by radical polymerization of AAc in a 1% aqueous solution of CS, at pH 5. As initiators sodium persulfate (NaPS) or azo-bis-isobutyronitrile (AIBN) were used. Moreover, films containing 10 % molar of sorbitol as plasticizer were also prepared. Finally, the films were characterized by studying the mechanical properties and gas permeation.

Results and Discussion

Values of permeability (*P*, **eq. 1**), diffusion (*D*, **eq. 2**) and solubility (*S*, **eq. 3**) coefficients for hydrogen, helium, oxygen and carbon dioxide in CS modified films are shown in **Table 1**.

$$P = \frac{273}{76}\frac{Vl}{ATp_0}\lim_{t\to\infty}\frac{dp(t)}{dt} \qquad (1)$$

$$D = \frac{l^2}{6\theta} \qquad (2)$$

$$S = \frac{P}{D} \qquad (3)$$

In eq 1, V is the volume of the downstream chamber, A the area of the film of thickness l through which the flux of gas take place, $p(t)$ is the evolution of the pressure of the permeating gas with time in the downstream chamber, T the absolute temperature at which the measurements were performed and p_0 the pressure of the gas at the upstream chamber. The results for the permeation coefficient, collected in **Table 1,** show that the films exhibit good barrier properties for oxygen and carbon dioxide. However, its behavior towards the hydrogen permeation depends on the nature of the film. The greater diffusion of hydrogen in the interpenetrated films obtained with NaPS as initiator is responsible for the increase in the permeability coefficient of this gas in the films. The permeability decrease in interpenetrated films polymerized with AIBN due to an increase in the membrane tortuosity, presumably arising from crosslinking. Both films exhibit the same behavior towards the helium diffusivity, regardless of the initiator used in acrylic acid polymerization.

Table 1. Gas transport properties of CS-modified films at 30 ºC and 1 bar

Gas	Sample	P x 10^2 (barrer)	D x 10^9 (cm^2/s)	S x 10^5 (cm^3/(cm^3 cm Hg))
H_2	CS	1.92	2.29	83.9
	Blend	0.46	3.79	12.0
	Interp. (NaPS)	6.57	261	2.52
	Interp. (AIBN)	1.92	11.6	17.1
O_2	CS	NP	NP	NP
	Blend	NP	NP	NP
	Interp. (NaPS)	1.08	5.38	20.3
	Interp. (AIBN)	NP	NP	NP
CO_2	CS	NP	NP	NP
	Blend	NP	NP	NP
	Interp. (NaPS)	NP	NP	NP
	Interp. (AIBN)	NP	NP	NP
He	Interp. (NaPS)	10.4	180	5.77
	Interp. (AIBN)	10.9	184	5.9

NP: no evidence of gas permeation. 1 barrer=10^{-10} $cm^3cmcm^{-2}s^{-1}(cm\,Hg)^{-1}$

Table 2 displays the films mechanical properties, where it can be seen that the Young´s modulus (E´) of the CS-PAAc is higher than that of CS. The inclusion of PAAc in the film leads to an increase in the elastic modulus due to electrostatic interactions. Moreover, the presence of sorbitol in the samples decreases the modulus caused by the reduction of polymer backbones interactions.

Table 2. Young´s modulus of the obtained films.

Sample	E´(MPa)
CS	588
CS + sorbitol	9
Blend	2309
Blend + sorbitol	86
NaPS film	6242
NaPS film + sorbitol	836
AIBN film	4808
AIBN film + sorbitol	247

Conclusion

CS-based films were synthesized and characterized by gas permeation and mechanical properties. These materials provide good barrier properties and different behavior to hydrogen transport. The incorporation of PAAc into the films improves their mechanical properties. This behavior was mostly attributed to the formation of electrostatic interactions between polymer chains. Sorbitol also decreases the film crystallinity due the fact that it solvates the polymer chains.

Self-curable PDMS-containing PU Oligomers for Water Repellent Textile Treatment

*Rei-Xin Wu, Jing-Zhong Hwang, Kan-Nan Chen**

Department of Chemistry, Tamkang University, Tamsui, New Taipei, Taiwan 251

E-mail: knchen@mail.tku.edu.tw

ABSTRACT: A moisture-curable NCO-terminated polyurethane (PU) prepolymers and fluoro- or polydimethylsiloxane (PDMS) containing PU oligomers are synthesized, respectively. The coating materials are obtained by blending of these PU oligomers and PU prepolymers, in different ratios. These coating materials are spray coated onto cotton and polyethylene terephthalate (PET) textiles, aiming for hydrophobic surface of textiles. The spray coating on textile surface by blending of these PU prepolymer, fluorinated PU prepolymer or/and PDMS PU oligoemers, an inter-penetrating polymeric network (IPN) system will be resulted and anchored into on textile fibers upon drying and moisture-curing raction at ambient temperature. The resulted IPN coating system with highly cross-linked polymer anchored into fabric fibers that enhance water washing durability of treated textiles. The treated textile surface with fluoro- or/and PDMS containing PU system that demonstrates the long lasting water repellency characters.

Keywords: PU, water repellency, Self-curing, PDMS

Introduction: Polyurethanes (PUs) are proved widely accepted materials for various applications in our life. PU means a polymer material including urethane group, produced by various kinds of polyisocyanates and polyols via polyaddition process and form different performance characters [1]. The soft segments have various characters can be easily modified by introducing distinct function [2]. The chemical modification of a surface can alone lead to water contact angles of up to 120° by using fluoropolymer or silane containing layer[3-5].

Experimental: NCO-terminated PU prepolymer was prepared by polytetramethylene-ether-glycol-2000 (PTMEG-2000) and isophorone diisocyanate (IPDI). This PDMS-containing oligomer was prepared by a reaction of polydimethylsiloxane diol (PDMS) with excess amount of IPDI, the fluorinated oligomer was prepared by PU prepolymer and fluorinated compound. The reaction was carried out and kept for 12 hours (according to ASTM D1638 NCO determination method). The contact angle of de-ionized water droplet on PU treated cotton and PET textile was measured at room temperature after 30 second after dropping water droplet. Five measurements of each sample were performed, and the closest results were chosen and averaged for the mean value.

Results and Discussion

NCO-terminated PU prepolymer was prepared as the conventional process and FT-IR was used to confirm the product by the absorption of NCO group. When the FT-IR figure of PTMEG prepolymer shows the –NCO group still appeared at 2260 cm^{-1}, –C=O group of urethane produced at 1720 cm^{-1} was used to confirm the reaction was completed. And the FT-IR figure of PDMS oligomer shows the –NCO group still appeared at 2264 cm^{-1}, –C=O group of urethane produced at 1708 cm^{-1} was used to confirm the reaction was completed. Effect the blending of PU prepolymer, PDMS-containing and fluorinated oligomer on the contact angle for water and diiodomethane on the cotton or PET textiles (Table 1-2).

Table 1. Contact Angle of Water (°)

Sample	PU-1		PU-2		PU-3	
Fibers	Cotton	PET	Cotton	PET	Cotton	PET
Contact Angle^{1st}	140	137	140	134	138	130
Contact Angle^{2nd}	141	138	141	134	138	132
Contact Angle^{3rd}	141	138	142	135	139	132
Contact Angle^{4th}	142	139	142	135	140	132
Contact Angle^{5th}	143	140	143	136	140	133
Average(°)	143	140	142	140	142	140

Table 2. Contact Angle of Diiodomethane (°)on treated textiles

Sample	PU-1		PU-2		PU-3	
Fibers	Cotton	PET	Cotton	PET	Cotton	PET
Contact Angle^{1st}	110	108	108	100	111	109
Contact Angle^{2nd}	111	108	108	102	112	111
Contact Angle^{3rd}	111	109	110	102	112	111
Contact Angle^{4th}	112	109	111	103	113	112
Contact Angle^{5th}	113	109	112	104	114	113
Average(°)	111	109	110	102	112	111

Conclusions: The self-curable fluorinated PU oligomer with PDMS coated on hydrophilic cotton and PET textile, then successfully turned them into superhydrophobic. The static water contact angle is 143° of PU-1 on the PU treated cotton textile, and the diiodomethane contact angle is 118° of PU-3 on the modified cotton textile. When the blending of PU prepolymer, PDMS prepolymer and fluorinated oligomer modified the surface of cotton or PET textile, it becomes highly hydrophobic and that demonstrated as water-repellency characters.

Novel Reactive Polymeric Supports for Synthesis of Polymer Drug Conjugates

Gamze Tanriver, Rana Sanyal

Bogazici University, Department of Chemistry, Bebek, 34342, Istanbul, Turkey.

email: rana.sanyal@boun.edu.tr

Polymer drug conjugates i.e. covalent combination of macromolecules with small drug molecules are attractive tools for drug delivery since such conjugates offer increased drug efficiency via the enhanced permeation and retention (EPR) effect.[1] Conjugation of the drug molecule to a polymer also provides increased water solubility, reduced toxicity and prolonged half life owing to the slower clearance. Water soluble, non-toxic and biodegradable polymers that can be appended with drug molecules are in demand to design such delivery systems. Novel biocompatible and biodegredable polymers based on poly(ethyleneglycol) (PEG) reactive towards amine and alkyne containing small molecules have been synthesized.[2] These reactive polymeric supports must be biodegradable in order to allow elimination of the polymeric substances from the body after delivery of the drug molecule to the desired site. Synthesis and in vitro biodegradation behaviors of these PEG based copolymers in acidic and neutral medias and release studies of small molecules from these polymeric conjugates will be presented.

Thiol Reactive Hydrogels for Biomolecular Immobilization via Photopolymerization

Tugce Nihal Gevrek, Eun-Ju Park, Amitav Sanyal

Bogazici University, Department of Chemistry, Bebek, 34342, Istanbul, Turkey.

email: amitav.sanyal@boun.edu.tr

Poly(ethylene glycol)-based 3D hydrogel patterns containing thiol reactive maleimide functional groups have been prepared using a novel Diels-Alder/retro Diels-Alder strategy.[1] Bulk-hydrogels and hydrogel micro patterns containing varying amounts of the thiol reactive maleimide functional group were synthesized by photo polymerization. A novel methacrylate based monomer containing a furan protected maleimide group was utilized during the gelation process.[2] The maleimide functional groups were unmasked to their reactive form via the retro-Diels-Alder reaction. These novel reactive hydrogels could be efficiently derivatized with thiolated biotin derivatives under mild condition. Immobilization of FITC-streptavidin onto the biotinylated hydrogel patterns was performed to demonstrate successful efficient biomolecular immobilization.

Dynamic Covalent Reorganization of Polymer/Polymer Systems: Alcoholysis Catalyst Effect on Kinetic and Secondary Reactions

Touhtouh S, Becquart F, Taha M

Université de Lyon, F-42023, Saint Etienne ;
CNRS, UMR 5223, Ingénierie des Matériaux Polymères, 42023, Saint-Etienne, France;
Université de Saint-Etienne, Jean Monnet, F-420023, Saint-Etienne, France;
Samira.Touhtouh@univ-st-etienne.fr, Frederic.Becquart@univ-st-etienne.fr, Mohamed.Taha@univ-st-etienne.fr

Abstract - Dynamic covalent chemistry concept is fully applied to polymer-polymer systems where reversible exchange reactions occurs with a sufficient fast equilibration process under thermodynamic control. This concept takes place here when alcoholysis reaction is involved to prepare graft copolymers and/or to compatibilize polymer/polymer systems bearing alcohol and ester functions. No systematic comparative studies concerning different catalyst effects onto polymer covalent organization by alcoholysis conducted in melt was found in literature. This study first presents kinetic studies on model reactants with different common organometallic catalysts classically used to polymer/polymer systems at 110°C without solvents. A reversible second order kinetic model was applied. The effect of reaction conditions on secondary reactions was analyzed. No secondary reaction were observed, with the most efficient 1,5,7-Triazabicyclo[4.4.0]dec-5-ene (TBD), until 180°C. The obtained results were used for a correct choice of reaction conditions of EVOH/PCL and PMMA/PCL dynamic covalent reorganization. Reactions leaded to graft copolymers synthesis. Compatibilization of the used immiscible polymers was obtained. Important structural changes involve a total disappearance of the EVOH cristallinity and leaded, in all cases, to an elastomer. The effect of shear rate on reaction kinetics of reactions conducted on polymer was also studied.
In the molten state, the reaction was applied to the EVOH/PCL polymer/polymer system. Both these polymers being immiscible and working in a viscous state, the quality of the mixing, directly in relation with the shear of mixing, is an important parameter which affects the reactivity between the involved functions.
For the chosen conditions or mixing, in a reactor with an anchor, it was found a significant and better efficiency of the 1.5.7-triazabicyclo[4.4.0]dec-5-ene controlled by the rate of substitution of the methane protons of EVOH by ^{1}H-NMR spectroscopy.
In all cases, the reactive system aspect really changes during the process. First, the polyester is seriously degraded and its molecular weights fast decrease. This catalyzed degradation systematically happens whatever the chosen catalyst. Slower, the alcoholysis reaction takes places. This typical evolution is observed when the torque to agitate the system at a constant rate, is recorded. The interest of this reaction applied to polymer/polymer system is observed when about 5 - 6% of substitution is reached onto EVOH whatever the chosen catalyst. Indeed, the viscosity of the system seriously increases for around two minutes. At this moment, the properties of the materiel totally changes. The immiscible blend controlled by the poor properties of the PCL at room temperature becomes an interesting elastomer with good mechanical properties.
At this moment, the EVOH cristallinity has totally disappeared.

Introduction

Dynamic covalent reorganization is a class of reaction who was proposed and very described by Stuart J. Rowan and al. [1] in 2002. Takeshi Maeda [2] also contributed by a review in 2009. Dynamic covalent chemistry has a central role in the development of conformational analysis ability to re-adjust the product distribution of a reaction. In the presented study, the dynamic covalent chemistry is applied to polymer/polymer systems with one polyol and one polyester by the alcoholysis reaction, commonly called transesterification. New copolymers with comb structures are synthesized in molten state without solvent. The kind of system is in a continuous evolution with the randomness of the grafting onto the polymer backbone and the free homopolymer remaining in the reactive system. Consequently, important changes in physical and chemical properties of the system are expected. First, a preliminary model study was investigated to define the catalytic system. Well-known organometallic catalysts and more original guanidines, applied to polymers, were tested.

Experimental

Alcoholysis on model reactants and EVOH-g-PCL synthesis in melt processing:

Reactions were made in a 250mL, 90mm diameter glass reactor with a three necked steel cover with a steel anchor stirrer under a dried nitrogen flow.

Results and Discussion

Before applying alcoholysis reaction in dynamic covalent reorganization of polycaprolactone and poly(ethylene-co-vinyl alcohol), model reactions were used to determine reaction parameters effects, particularly on kinetics and side reactions (Figure 1). tin(II) bis(2-ethylhexanoate) and TBD were found as the most efficient and a reversible second order mechanism is confirmed with TBD.

Mechanical Properties of Crosslinked Hybrid PVA Membranes for DEFCs Applications

Aílton de Souza Gomes and José Carlos Dutra Filho

Instituto de Macromoléculas Professora Eloisa Mano, Universidade Federal do Rio de Janeiro. Cidade Universitária, Av. Horácio Macedo, 2.030, Centro de Tecnologia, Prédio do Bloco J, CEP 21941-598, Rio de Janeiro, RJ, Brazil. Tel.: +55 021 2562 7210; fax: +55 021 2270 1317.

asgomes@ima.ufrj.br

Introduction: In the last years, many studies involving the synthesis and characterization of polymer electrolytes presenting proton conductivity at room temperature, allowing their potential use in direct alcohol fuel cells (DAFCs), have been performed. Direct ethanol fuel cells (DEFCs) have recently gained a great deal of attention for their highly potential applications in terms of electric vehicles, stationary applications, and portable power sources, such as cellular phones and notebook computers, etc [1]. Thus, many new materials have been studied for the manufacture of proton conducting membranes for DEFCs. A particularly interesting polymer is poly(vinyl alcohol) (PVA) due to its good chemical and mechanical resistance, reduced ethanol permeability and low cost. The mechanical properties of the polymer membranes used in fuel cells are extremely important to the performance and lifetime of the cell [2]. PVA is a versatile polymer and has been proved to be commercially viable in many fi elds spanning from surface coatings to biomedical applications. But, pristine PVA alone does not meet the required properties and needs to be tailored according to the application. Phosphotungstic acid (HPW) has been described in the literature as a good proton conductor, but the main drawback of its use in membranes is its high solubility in water, leading to HPW loss together with water at medium temperature [3]. The extent and velocity of membrane water uptake depend on the membrane viscoelastic mechanical properties, which are they dependent on membrane hydration, and increased hydration improves proton conductivity and fuel cell performance. Membrane mechanical properties also affect durability and cell longevity, preventing membrane failure from stresses induced by changing temperature and water content during operational cycle. Among the modifications that are viable for PVA, introduction of acid groups such as HPW into PVA matrix and crosslink with diethylenetriamine pentaacetic acid (DTPA) will be discussed in this work, for direct ethanol fuel cells (DEFCs) applications.

Materials and Methods: Poly(vinyl alcohol) (PVA-p) 86,5 – 88,5 % hydrolyzed as supplied by Vetec Química Fina. Poly(vinyl alcohol) (PVA-f) 99% hydrolyzed and phosphotungstic acid hydrate H3PW12O40.xH2O (HPW) 99 % of purity were purchased from Sigma-Aldrich Co. Diethylenetriaminepentaacetic acid (DTPA) 99 % of purity as supplied by Dow Chemical Co. All chemicals were used as received without further puri cation.

Proton conducting hybrid membranes have been prepared by solution casting and all components were dissolved in deionized water under magnetic stirring and heating in a closed system. The hybrid membrane uptake was tested in deionized water and ethanol solution 20 wt.% in deionized water, separately, by measuring the change in the weight before and after the hydration. The ATR-FTIR spectra were recorded i n transmittance mode using a Perkin Elmer FTIR spectrometer model 1720X. Electrochemical impedance spectra (EIS) of the membranes were recorded using an Autolab PGSTAT-30 instrument. PVA partially hydrolyzed and fully hydrolyzed were used as polymer matrix and mechanical properties of this new material will be evaluated by dynamic mechanical analysis (DMA) using a Q800 DMA-Thermal analyzer (T A Instruments).

Results: Results using PVA-p as polymer matrix show that water and ethanol uptake decreases with doping of HPW and addition of DTPA. From the FTIR spectra can be observed a progressive shift corner-shared octahedral band (W -Oc -W) with increasing of PVA-p content. The best conductivity (8.6 x 10-3 Scm-1) at room temperature was obtained for membranes containing 50 wt.% of HPW and crosslinked with 2 wt.% of DTPA by electrochemical impedance spectroscopy (EIS).

Conclusions: The results of dynamic mechanical analysis are being fi nalized and is expected to increase in Young's modulus with increasing content of HPW and DTPA. Moreover, it is expected that the use o f PVA-f promotes better mechanical, barrier and proton conductive properties. The conductivity of the samples also depends of nanostructure and is promoted by the increase on connectivity between the hydrophilic nanodomains.

Study of Natural Aging of PVC Flat-plate Absorber Used for Low Cost Solar Collectors

Julio Roberto Bartoli, Bruna Rosa Prado, Renato Cesar Pereira

Dept. of Polymer Technology, School of Chemical Engineering, State University of Campinas-UNICAMP

bartoli@feq.unicamp.br

Introduction:

Regardless the excellent amount of solar irradiation in Brazil, the development and production of solar water heating systems did not reach the low-income families yet. The relatively high cost of conventional solar water heaters is still the main reason to prevent it. The electrical shower is the main system for bath water heating; it consumes 8.5% of the electric energy produced in the country[1].

The development of a low cost solar water heater (around US$ 200), easy technology, was the scope of previous work[2]. All-plastic solar collector prototypes were developed using unplasticized Polyvinyl chloride (PVC) ceiling panels and tubes, commodities from building engineering. PVC is one of the most important plastics used in various industries like building and construction (around 50%). Despite of common solar collectors, these whole plastic do not use the "greenhouse effect" (transparent cover). This innovative concept allows this solar collector to meet requirements of simplicity, easy manufacturing, low cost and thermal performance. It was measured a thermal efficiency of 67% (hot water reaches 55°C on a sunny day), compared to the 75% of conventional solar collectors made of copper tubes and glass cover[3]. Nevertheless, the main thermal and photo degradation mechanisms for PVC are well known[4]; the unusual application of PVC as solar collector materials should need a specific investigation on environmental aging. Therefore, this work presents a natural aging study of PVC flat-plate absorber of solar collectors after 5 years on use at the State University of Campinas.

Materials and Methods:

Figure 1: Low cost solar collector system for 100 L

Each PVC flat-plate (0.75 m^2) has two pipes connected at the ends. The water enters the cross section of the flat-plate (black painted) from the inlet pipe, then flows up along the internal cavities of the plate and exits at the outlet pipe to the reservoir (Figure 1). The solar collector prototypes were removed after 27, 36, 48 and 60 months of use and test specimens were cut from the PVC panel for mechanical (ASTM D 638, Standard Test Method for Tensile Properties of Plastics) and physico-chemical characterization (FTIR-ATR and SEM analyses).

Results:

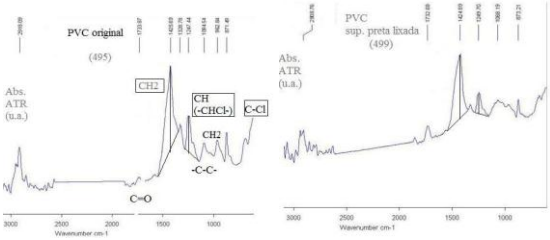

Figure 2: FTIR-ATR spectra of PVC original (left) and after 27 months exposed to sun.

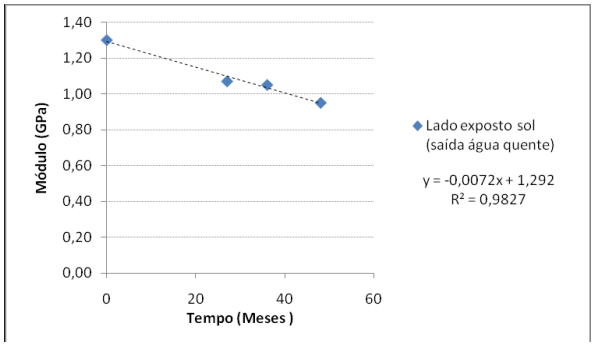

Figure 3: Young Modulus vs Time (month)

Conclusions:

The mechanical properties of PVC flat-plate were significantly modified after 5 years, Young modulus was reduced around 20% and PVC photodegradation was observed as dehydrochlorination. Even that, these low cost solar collectors performed very well, heating water to 50°C and no leakage were found, until being removed for PVC characterization. The linear regression of the PVC Young modulus estimates that a reduction of 50% (0.65 GPa) would take 7.5 years.

Cross-linked organic/inorganic composite gels are widely used in different areas of modern industry. Polymeric hydrogels present very interesting and versatile materials, being sensitive to various environmental stimuli, such as temperature, pH, pressure, ionic strength and electric fields. Hydrogels with incorporated clay particles are a very specific class of such composite materials.

Presented research deals with the preparation of polymeric hydrogels with organically-modified clay particles, distributed in the gel matrix. Hydrogels were obtained by UV polymerization of N-isopropylacrylamide (NIPPAM) crosslinked with N,N`-methylenebisacrylamide (BIS); organically-modified montmorillonite particles (as an active component) were included into the hydrogel formulation. Process parameters (particle concentration, dispersing medium, monomer, cross-linker concentrations and drying procedure) were varied with the aim to thoroughly study the formation of particle-embedded hydrogels. In addition to functional properties of nanocomposites conditioned by the preparation process were analysed.

Scanning electron microscopy was used to evaluate the morphology of synthesized composite hydrogels and to determine the particles distribution in the matrix. Hydrogels with different morphological structure were observed dependent on surfactant addition and drying procedure (vacuum drying and freeze drying, respectively). Swelling behaviour of hydrogels depends on the ratio of cross-linker/monomer concentrations as well as the amount of embedded clay particles and was determined by monitoring the water uptake. Functional properties of nano-hydrogels were determined by organic dyes adsorption on composites. The efficiency of dye-adsorption was studied as a function of time and particle concentration and was correlated to the degree of particles' agglomeration in the polymerized gels.

SEC-MALS and Molecular Dynamics Characterization of an Amphiphilic Poly(Acrylic Acid-*b*-Styrene-*b*-Styrene-*b*-Acrylic Acid) Symmetric Block-Copolymer Synthesized by RAFT

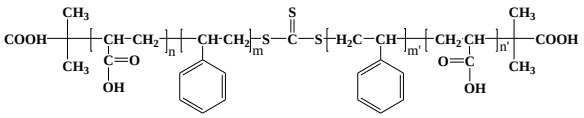
Introduction: Controlled radical polymerization techniques have become increasingly popular for the production of polymers and block-copolymers with predetermined molecular weight, narrow molecular weight distributions and well-defined architecture, from a much larger variety of monomers and under simpler polymerization conditions compared to anionic polymerization. These polymers have attracted much attention because of their versatile self-assembly behavior and potential applications in many areas. The assembly can be controlled by different factors, among them the composition of the solvent. In order to obtain structures by controlled self-assembly, one has to characterize different aspects of the copolymers, namely in terms of composition, structure, molecular weight and molecular weight distribution.

The use of size exclusion chromatography (SEC) with a mass sensitive detector, a multiangle laser light scattering (MALS), has become a polymer characterization standard method and is advantageous since it offers the possibility of obtaining both absolute molecular weights and chain dimensions along the chromatogram.

In this work, a sequential reversible addition-fragmentation chain transfer (RAFT) polymerization strategy was used to prepare a symmetric amphiphilic block-copolymer composed by a poly(acrylic acid-*b*-styrene-*b*-styrene-*b*-acrylic acid) unit with a bridge of trithiocarbonate between the two blocks of styrene (**Scheme 1**).



Scheme1. Block copolymer structure.

Poly(styrene-*b*-acrylic acid) copolymers with different block compositions have been previously prepared and several supermolecular structures were observed in solution. The molecular weight and polydispersity of these polymers has been determined by SEC-MALS in THF, DMF, and 1,4-dioxane solvents.

Materials and methods: SEC measurements were carried out using a Waters Associates equipment with a 510 pump, a 7725 Rheodyne injector and a differential refractive index detector (model 410).

The Amber molecular modelling package, including the Amber force field, was employed for all the Molecular Dynamics (MD) simulations.

Results and discussion: By performing a similar analysis to the bibliography study, SEC-MALS was used to study the aggregation behavior of the copolymer in different solvents: 1,4-Dioxane; THF; THF with different salts, DMF; and DMF with LiBr. To evaluate the influence of acrylic acid, the polymer was methylated and further analyzed in THF. Molecular weights and polydispersity values (**Table 1**) larger than those estimated from the synthetic procedure were obtained in THF, THF with salts, DMF and DMF with salts. However, in 1, 4-dioxane the values are similar to those expected and agree with those obtained to the methylated polymer in THF.

Solvent	M_w / 10^5 (g/mol)	$\langle s^2 \rangle^{1/2}$ (nm)	M_w / M_n
THF	7.58	21.9	1.50
THF/NaCl 0.04 M	1.68	11.4	1.12
THF/LiBr 0.1 M	6.12	21.9	1.56
THF/LiCl 0.2 M	1.85	11.8	1.26
DMF	2.68	74.8	1.69
DMF/LiBr 0.15M	0.343	13.0	1.24
Dioxane	0.161	---	1.13
Methylated copolymer in THF	0.234	---	1.04

Table1. Average molecular weight (M_w), polydispersity (M_w / M_n) and root mean square radii of gyration $\langle s^2 \rangle^{1/2}$ of the copolymer in SEC-MALS solvents.

Molecular Dynamics simulations have been performed on systems formed by one oligomer having a central trithio carbonate unit, -S-(CS)-S- flanked on each side by a block of styrene units followed by a block of either acrylic acid or methyl acrylate ester in the same solvents as used in the SEC measurements. The calculations allowed us to evaluate the correlations among rotational angles over the chain backbone and among distances between different groups that were used to rationalize the experimental results.

Conclusions:

The RAFT polymerization technique allowed us to copolymerize acrylic acid and styrene with very good control of molecular weight and architecture. The copolymer is both water- and organo-soluble and can self-assemble to form different structures and materials.

We also found out that the copolymer in 1,4-dioxane or the methylated copolymer exhibit isolated chains in solution because similar molecular weight distributions are obtained in both systems, and in good agreement with the predicted value for the synthesis. The experimental results obtained for the methylated polymer show that the acrylic acid units are the main cause of inter-chain interactions leading to aggregation.

The results obtained by SEC-MALS were rationalized by performing MD simulations in similar oligomers. The agreement between the experimental results for the polymers and MD simulations for the oligomers in the different solvents is very good.

Development of conducting nanofillers based on polypyrrole and nanoclays

lcabedo@esid.uji.es

Nanocomposites based on the addition of modified nanofillers with conducting polymers have attracted the attention of researches lately due to its potential in a broad variety of applications such as antistatic coatings, electromagnetic shielding, semiconductors, batteries, etc. The intercalation of conducting polymers in the interlaminar region of the nanoclays can lead to a nanocomposite having properties which differ from both original materials, such as an increase in the electric conductivity and mechanical performance.

In this work, two kinds of clays have been utilized: montmorillonite (MMT) and vermiculite (WMT). Nanocomposites of these two clays have been obtained by oxidative polymerization of the polypyrrole (PPy) in an aqueous solution of the clays following several methods and conditions[1,2,3,4]. The resulting materials have been evaluated by different techniques hence studying the influence of the clay type and processing route on the final performance of the nanofillers.

The so-obtained nanofillers have been characterized morphologically by means of wide angle X-ray scattering (WAXS) and electron microscopy. High degree of intercalation of the polymer chains within the interlaminar gallery has been found, being this intercalation higher for the vermiculite. Thermogravimetric analysis of the nanocomposites showed an increase in the thermal stability of the PPy nanocomposites with respect to the pristine polymer.

Finally, the conductive properties of the PPy/clay were evaluated and compared with the ones of the pure PPy using for so the 4-point Van der Pauw technique for measuring the surface conductivity. These experiments proved that the conductivity of the resulting nanocomposites is extremely dependent on the polymerization conditions as well as on the measuring method. Among others, the final conductivity varies with the catalyst, reaction time, clay modifier, temperature and clay concentration. Figure 1 shows the surface electrical dependence with the PPy content in the vermiculite/PPy nanocomposites.

Introduction. Polyvinyl alcohol (PVAL) is known to be one of the most applicable polymers in water compositions for strippable deactivating coatings. However in these compositions the polymer serves only a film- forming functions and in order to provide the demanded operational properties, some plasticizers, chelating agents, etc. are added into compositions [1]. Through the modification of PVAL with chelating functional groups (FG) it is possible to vary many of its characteristics and correspondingly properties and by this to simplify content of compositions and make them more stable, available and cheaper [2]. With this purpose PVAL modified with different content of derivatives of maleic anhydride (MA) have been elaborated and studied (MPVAL).

Materials and Methods. MPVAL-s have been synthesized through two various methods of vinylacetate(VA)-MA loading which provides different distribution of FG: alternating (samples 27/05,1-09/2, 2/06-2MEF) or random (block) (26/05, 2/09-2, 12/08 MAMEF). The ratio of the comonomers was VA:MA=95:5, 90:10 and 93:7(mass.%).

Content and types of FG were determined by methods of chemical analysis, IR and NMR spectroscopy. MM was defined by SEC (Waters). Viscosities of 10-11% solutions were studied by Brookfield viscosimeter.

DF (decontamination factor) and β_F (% of removed contaminations) were examined at SCRMB and Armenian NPP on separate radioactive isotopes (^{60}Co and ^{137}Cs) and in real conditions of radiation contamination (^{137}Cs, ^{110m}Ag, ^{58}Co, ^{60}Co, ^{54}Mn) at one of facilities of Armenian NPP. Testing copolymers solutions were coated over a contaminated plate or floor and were left to be dried. Then the radioactivity of the surface with a polymeric film and after its removing was measured.

Dispersion ALARA-1146 was used as analogues [3].

Testing by fungi resistance was conducted by the use of a set of mycromycites: *Aspergillus flavus, A.niger, A.ochraceus, Penicillium duclauxii, P.cyclopium, Alternaria alternata, Cladosporium herbarum, Trichoderma viride.*

Results and Discussion.

The main parameters allowing to use MPVAL as deactivating strippable films are an ability to bind different RN and to form films with predetermined properties. These properties mainly are stipulated by type, content, distribution of FG and MM of co-polymers.

Data in Table 1 show variation in content of FG depending on MPVAL synthesis methods. Moreover these data considerably deviate from their theoretical values. The reason of this is reactions of cyclization and lactonization, the extent of which is stipulated by FG distribution in a macromolecule.

Film-forming properties of copolymers depend on MM, MMD and type of super-molecular formation.

Table 1. Functionslity of MPVAL sample

Samples (% of comonomer)	$OCOCH_3$ % mass.	COONa % mass.	[η], dl/g
26/05(5%)	9,7	5,5	1.34
2/09-2 (7%)	8.8	9.7	Electrolyte effect
12/08 (10%)	13.1	11.4	2.63
27/05(5%)	8,6	8,2	2.52
1/09-2(7%)	10.5	10.3	1.43
2/06-2(10%)	10,5	17,6	2.12

Comparative studies of M_w, M_n, [η] and Huggins constant K_x, have shown that super-molecular order is realized at least by 3 factors - polyelectrolyte effect, polymer-solvent interaction, hydrophilic-hydrophobic balance of macromolecule. Hence, set of FG, their distribution and type of super-molecular formation are responsible for decontamination efficiency (Fig.1).

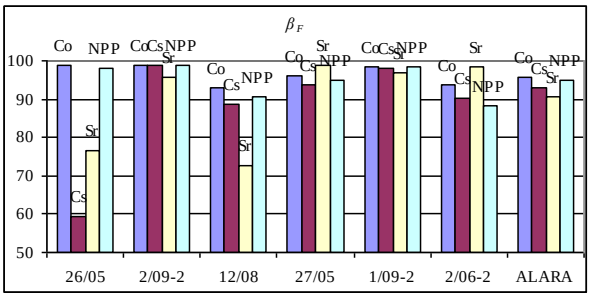

Fig.1 β_F for MPVAL samples

From presented data follows, that independently of synthesis methods, 7% of MA is preferable for creation of copolymers providing high level of deactivation.

Other very important criteria to select grade of MPVAL is storage of radioactive films (there is not a publication about this issue). Evaluation of fungi resistance carried out till now reveals that samples with MEF are the most resistant to fungi damage.

Conclusions. Characteristics of MPVAL allowing to use their solutions for deactivation of contaminated surfaces without addition special chelating agents are revealed.

The technology of MPVAL synthesis at laboratory scale is developed.

Production and Characterization of Starch and Starch Based Composite Biodegradable Films Crosslinked By Glutaraldehyde

Ilknur Gonenc, Ferhunde Us**

* Hacettepe University, Department of Food Engineering, 06800, Beytepe, Ankara, Turkey.

ilknur@hacettepe.edu.tr
ferosh@hacettepe.edu.tr

Plastics made from petroleum that are not degradable in the soil has become a serious environmental pollution problem. Therefore development of starch and starch based composite novel plastics can be interesting solution.

In this study, films composed of corn starch, corn starch-methyl cellulose (MC), corn starch-poly(vinyl)alcohol (PVA) and corn starch-carboxymethyl cellulose (CMC) were prepared. Glutaraldehyde (GLU) was used as crosslinking reagent. The films were plasticized by glycerol and polyehyleneglycol 400 (PEG400). Films prepared without GLU were used as the control group. It was found that starch was not compatible with PEG400 therefore 14 film samples were studied in this study. Tensile strength (TS), %elongation (%E) and water vapor permeability (WVP) of the films were investigated. Water adsorption capacity and opacity of the films were also determined.

The WVP of the films was determined to be $0.25x10^{-10}$ – $1.28x10^{-10}$ g/m.s.Pa, depending on the plasticizer type and GLU. Films prepared with PEG and without GLU had the higest WVP values than the other film samples. The cross linking effect of GLU caused a decrease in film water vapor permeability and %E and caused an increase in film TS. Composite films showed beter flexibility than starch based films.

The whole results, including adsorption capacity and opacity will be presented and discussed.

Validation of an elasto -viscoplastic model for polyvinilidene fluoride (Pvdf)

Introduction

Polyvinylidene fl uoride (PVDF) copolymer is a thermoplastic of great potential to structural applications, such as internal pressure barriers of flexible risers used in offshore petroleum industry and also for lining of corroded onshore oil pipes [1,2]. The time-dependent properties of PVDF are still a subject of concern when higher temperatures are considered. Mechanical properties of polymers are strongly influenced by strain, temperature and time or frequency [3], thus it is important to study the viscoplastic behavior to assess the response of a polymeric structure in structural engineering applications. The aim of this study is to test a constitutive model to be employed in the numerical simulation of PVDF under time dependent thermo-mechanical loading.

Materials and Methods

In this case, the two layer visco-plastic model of Abaqus Software will be tested. For model implementation, several mechanical parameters must be obtained through tensile and relaxation tests in different conditions. The model parameters, such as elastic, viscous and plastic modulus were determined through tensile tests at 25, 40 and 60 °C and strain r ates from
1.2 10-5 s-1 to 1.2 10-1 s-1.

Results and Discussion

Tensile results showed a decrease of elastic modulus and maximum stress with increasing temperature or decreasing strain rate. The relaxation tests were made at 25, 40 and 60°C and initial strains from 3 to 20%. Through these results it was possible to establish a theoretical stress -strain curve for almost zero strain rate to be used in the constitutive model. Also, the time dependent stresses under different temperatures were proposed through the Norton-Hoff equation. The relaxation tests were correlated with the numerical results using a nonlinear finite element modeling under the proposed constitutive model.

Conclusions

The employed methodology generated good correlation within the beginning of the relaxation tests but showed an increasing discrepancy with time for the predicted stresses. These discrepancies were reduced with the manipulation of the convergence parameters and time increments.

E-mail address: jramirez@ciqa.mx

Abstract: Ring-opening polymerization of lactide/glycolide (LA/GA) using different molar ratio at 130°C was studied. Stannous octoate ($Sn(Oct)_2$) was used as catalyst and 1-dodecanol (ROH) as cocatalyst. LA/GA, (LA/GA)/$Sn(Oct)_2$ and ROH/$Sn(Oct)_2$ molar ratios used during the bulk polymerizations were from 100/0 to 75/25, 2000 and 1, respectively. All the polymers synthesized were purified prior to characterizations. The results obtained by ^{1}H-NMR indicated that is possible to obtain copolymers with an experimental composition of LA/GA from 100/0 to 80/20 molar ratio, where the weight-average molecular weight (M_w) decreased (from ≈100,000 to 35,000 Da) conform the GA unit in the backbone structure of copolymer was higher. In addition, the thermograms obtained by differential scanning calorimetry (DSC) also shows that the tg value decreased from ≈50 to 42°C conform the GA unit in the copolymer chain was increased. Finally, the copolymers also were analyzed by infrared spectroscopy (FTIR) in order to obtain more information about these polymerizations.

Internal and external gelling method for alginate hydrogels preparation with planar geometry

eva.papajova@savba.sk@savba.sk; igor.lacik@savba.sk

Introduction: Sodium alginate (SA) is a polysaccharide extracted from natural sources brown algae and bacteria. SA is composed of guluronic (G) and mannuronic (M) acid units arranged in homopolymeric blocks or blocks of alternating units. SA forms three- dimensional hydrogel structures by electrostatic interactions with divalent metal ions (e.g. Ca^{2+} or Ba^{2+}) [1]. In spite of the broad knowledge about SA hydrogel, the research is still needed to provide information on SA hydrogel properties and new applications.

This contribution deals with preparation of externally gelled SA hydrogel slabs with planar geometry. Planar geometry is commonly obtained by internal gelling method [2] based on dispersing the source of gelling cation (commonly $CaCO_3$) within SA alginate solution. A decrease of pH results in slow dissolving of $CaCO_3$ particles, which initiates the gelling process. In the case of external gelling method [1], the preparation of hydrogel starts with diffusion of Ca^{2+} cations into SA solution. Preparation of SA hydrogels with planar geometry by external gelling method needs controlled and slow exposure of SA solution for avoiding the shape distortion. In our approach, the SA planar hydrogel slabs were prepared by slow exposure of SA solution to aerodispersion of $CaCl_2$ following the methodology described for preparation of SA films [3].

Materials and methods: SA with high content of G units (Protanal LF10/60) was purchased from FMC BioPolymer (Norway). All inorganic salts for gelling process and for preparation of solutions were of analytical grade. *External gelling:* A mold with dimensions of 19×19×1 mm filled with SA solution (SA concentration range 1-3 wt.%) was put 40 cm under the airbrush (Rich, AB 200). Airbrush was spraying $CaCl_2$ solution of concentration from 0.5 to 4 wt.% $CaCl_2$ on the surface of SA solution in the mold with flow rate around 7.0 mg/min·cm^2 in the time range from 2.5 to 20 min. *Internal gelling:* $CaCO_3$ particles were homogenously dispersed in SA solution. D-glucono-δ-lactone (GDL) was added into the dispersion. The mixture containing 2 wt.% SA, 20 mM $CaCO_3$, 60 mM GDL was poured between glass plates seprated by 1 mm distance. Hydrogel was formed for 24 hours at 6°C. Saline solution was used as a solvent for preparation of all solutions in both gelling methods. For both types of SA hydrogels, gelling process was followed by treating hydrogel in solution containing 1 mM $BaCl_2$, 50 mM $CaCl_2$, 0.2 M NaCl for 20 min. Then hydrogels were stabilized in storage solution (0.9 wt.%, 5 mM $CaCl_2$, 100 ppm NaN_3) for at least 24 hours at 6°C before characterization.

Mechanical properties of SA hydrogels were determined in a compression mode (Young's modulus). Dimensional stability during hydrogel formation and after stabilization in storage solution was characterized by gravimetry. Permeability was determined by an inverse size exclusion chromatography (iSEC). Internal structure of hydrogels was analyzed by cryo–scanning electron microscopy (cryoSEM) and confocal laser scanning microscopy (CLSM) with SA chains covalently labeled by fluorescein.

Results and discussion: Results are discussed in terms of (1) effect of experimental conditions used for preparation of externally gelled SA, and (2) comparison between internally and externally gelled SA hydrogels.

(1) For the concentration range of SA from 1 to 3 wt.% and 20 min exposure to 2.5 wt.% $CaCl_2$ solution, the syneresis decreased with increased SA concentration from 15% for 1 wt.% SA to 0% for 3 wt.% SA. The Young's modulus increased in this SA concentration range from 40 to 200 kPa. For 2 wt.% SA, these characteristics were neither significantly influenced by changing the $CaCl_2$ concentration nor by changing the exposure time.

(2)The conditions for internal and external gelling processes (2 wt.% SA in both cases) were adjusted to the same stochiometry ratio Ca^{2+}:COO^- = 0.5:1 related to the COO^- groups on GG and MG diads. The Young's modulus of around 80 kPa was determined for both hydrogels. A difference was seen in the dimensional stability after gelling. The internal gelling method resulted in 15% of syneresis while the external one only in 5% syneresis. CSLM revealed a homogeneous distribution of SA chains for both hydrogels in spite of different directions of Ca^{2+} diffusion during internal and external gelling process. Also cryo-SEM analysis showed regular porous structure. The pore size and pore size distribution quantified by iSEC showed for that both hydrogels exhibit rather broad pore size distribution with the molecular weight cut-off of around 450 kDa (viscosity radius ~ 20 nm) determined by pullulan standards.

Conclusion: The methodology for preparation of planar alginate hydrogel slabs by external gelling was developed. It is advantageous in terms of shorter preparation time and physiological conditions maintained throughout the gelling process compared to the internal gelling. The properties of both gels are similar.

Porous methacrylate copolymers as stationary phases for HPLC

Marta Grochowicz, Małgorzata Maciejewska

Department of Polymer Chemistry, Maria Curie Sklodowska University,
Gliniana Street 33, 20-614 Lublin, Poland

mgrochowicz@umcs.pl

Introduction

Porous polymeric particles are important materials used as column packings in different chromatographic methods. The most popular are macroporous copolymers of styrene crosslinked with divinylbenzene (ST-DVB) but growing interest of new copolymers obtained by polymerization of methacrylate monomers is observed. Highly crosslinked polymeric microspheres for chromatographic purposes can be prepared by the polymerization of multifunctional monomers in the presence of thermoinitiator. Among crosslinking monomers multifunctional (meth)acrylate compounds are often used [1,2]. Methacrylate copolymers synthesized from monomers possessing polar functional groups are less hydrophobic than the traditional ST-DVB stationary phases [3]. The electron-donating ability of these functional groups additionally contributes to the adsorption analytes with electron-withdrawing groups. In this work we present new group of methacrylate monomers: 2-hydroxy-3-methacryloyloxypropoxybenzene (1,3-, and 1,4-di(2-hydroxy-3-methacryloyloxypropoxy)benzene) applicable for synthesis of polymeric microspheres. They were synthesized with the intention to use them as polymeric stationary phases in high performance liquid chromatography.

Materials and Methods

The copolymers in a form of porous microspheres were produced by suspension-emulsion polymerization of aromatic methacrylate monomers and TRIM. Copolymerization was made in the aqueous medium, as a surfactant bis (2-ethylhexyl) sulfosuccinate sodium salt was used. In each case, to the water solution of surfactant, the solution containing mixture of pore forming diluents (toluene and decan-1-ol), 15 g of aromatic methacrylate ester and TRIM (molar ratio 1:1), and 0.1 g of α,α'-azoisobisbutyronitrile (initiator) were added while stirring. Copolymerization was performed for 10 h at 80°C. Porous beads of MPH-TRIM, 1,3DMH-TRIM, 1,4DMH-TRIM formed in these processes were sucked off, washed with distilled water, dried and extracted in a Soxhlet apparatus with boiling acetone. The obtained particles (5-15µm) used in further studies were isolated by sedimentation and decantation from acetone.

To determine the textural properties of the studied microspheres nitrogen adsorption–desorption and inverse sized exclusion chromatography measurements were used. To compare the chromatographic properties of porous copolymers the method proposed by Smith et al [4, 5] was applied. The retention indices of five sets of homologous compounds and the selectivity test compounds (toluene, nitrobenzene, p-cresol, 2-phenylethanol, N-methylaniline) were measured. Retention index scale was based on alkyl aryl ketones. Methanol-phosphate buffer pH 7 (70:30; v/v) and acetonitrile-phosphate buffer pH 7 (50:50; v/v) were used as mobile phases.

Results and Discussion

MPH-TRIM, 1,3DMH-TRIM, 1,4DMH-TRIM polymeric microspheres (Fig. 1) are characterized by developed porous structure. Comparison of surface parameters obtained by nitrogen adsorption-desorption and inverse size exclusion chromatography methods shows some differences. Pore volumes for the swollen copolymers are significantly larger than that for the dry copolymers. In the swollen state micropores are revealed in their internal structure, whereas for dry copolymers they are absent.

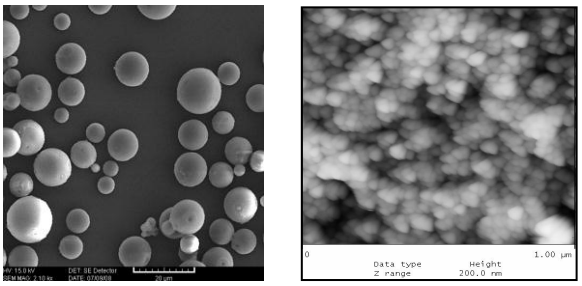

Figure 1. SEM and AFM images of porous MPH-TRIM microspheres.

The lowest value of the retention indices of the test compounds obtained on the studied porous copolymers is observed for 2-phenylethanol whereas the highest – for nitrobenzene. Better separations of homologous compounds are obtained in mobile phase containing acetonitirle.

Conclusions

Polymerization reaction of aromatic methacrylate monomers with TRIM in the presence of pore forming dilutents allows obtaining permanently porous microspheres. In their chemical structures ester and hydroxyl groups are present. They allow using obtained microspheres as polymeric stationary phases in high performance liquid chromatography.

Crosslinked Membranes of PVA/MMT for Direct Ethanol Fuel Cells

Aílton de Souza Gomes, José Carlos Dutra Filho and Gabriel Medeiros Gomes

Instituto de Macromoléculas Professora Eloisa Mano, Universidade Federal do Rio de Janeiro. Cidade Universitária, Av. Horácio Macedo, 2.030, Centro de Tecnologia, Prédio do Bloco J, CEP 21941-598, Rio de Janeiro, RJ, Brazil. Tel.: +55 021 2562 7210; fax: +55 021 2270 1317.

asgomes@ima.ufrj.br

Introduction: The direct ethanol fuel cells (DEFCs) have recently received a lot of attention due to their high-energy density and low emission of pollutants. Many studies involving the use of poly(vinyl alcohol) (PVA) in the preparation of membranes polymer electrolyte have been performed in order to optimize the DEFC's efficiency and circumvent the limitations of Nafion® membranes use [1]. Some studies show the addition of inorganic fillers to improve the barrier properties of PVA polymer. Montmorillonate (MMT) is a well known layered silicate, which was used as the nano-fillers added into the Nafion polymer membrane. The layer structure and high aspect ratio of MMT clays are expected to be able to decrease the ethanol permeability owing to a winding diffusion path. The addition of MMT-H+ in PVA polymer matrix will also increase its ionic conductivity [2-3]. This work aims to develop nanocomposite membranes of PVA/MMT- H+ crosslinked with a melanine/formaldehyde resin and evaluate the changes in different concentrations of inorganic filler and crosslinking agent (CA), in properties such as proton conductivity and mechanical properties

Materials and Methods: Poly(vinyl alcohol) (PVA) 86,5 – 88,5 % hydrolyzed as supplied by Vetec Química Fina. Montmorillonate (MMT-H+) was purchased by Bentonita do Nordeste S.A. Melanine/formaldehyde resin was supplied by Cytec Industries Inc. All chemicals were used as received without further purification. The PVA/MMT nanocomposite polymer membranes were prepared using a solution casting method. PVA was dissolved in deionized water with magnetic stirring, heating and ultrasonic stirring for a better homogenization of inorganic filler.

Membrane uptake was tested in ethanol solution 20 wt.% in deionized water by measuring the change in the weight before and after the hydration. X-ray diffraction measurements were recorded using a Rigaku X-ray diffractometer model Miniflex (30kV, 15mA). Electrochemical impedance spectra (EIS) of the membranes were recorded using an Autolab PGSTAT- 30 instrument and the measurements were made in ethanol solution 20 wt.% in deionized water.

Results: The uptake measurements in ethanol solutrion show that the crosslinked material exhibits chemical resistance to ethanol at temperatures of 30, 50 and 80 °C. X-ray diffraction showed the possible formation of nanocomposite due to the absence of the characteristic peak of MMT (Fig.1). The conductivity measurements show that the addition of inorganic filler confers conductivities of the order of 10-1 mS.cm-1 to the polymer matrix.

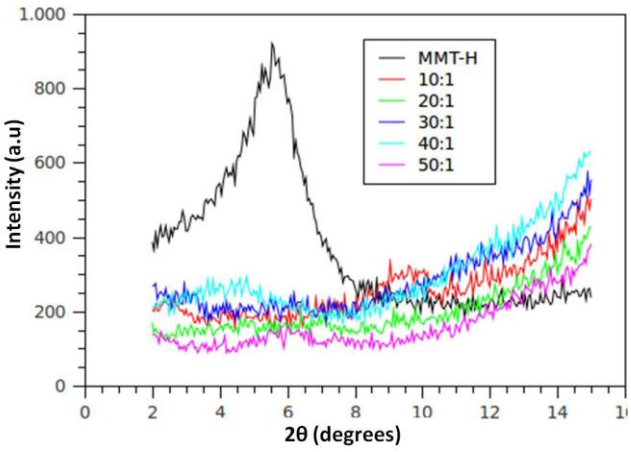

Figure 1. X-ray diffractograms of PVA/MMT-H+ composite membranes.

Conclusions: The absence of the characteristic peak of MMT in the polymer matrix observed by X-ray diffraction measurements is an indication of the formation of nanocomposite by good dispersion of inorganic filler in PVA. The membranes uptake behavior was significantly reduced with decreasing content of MMT and with increasing of CA content. The proton conductivity of membranes increased with decreasing content of MMT mainly in the samples at 80 °C. The conductivity of the samples depends on the nanostructure and are promoted by increased connectivity nanodomains between hydrophilic. The results favor the use of these membranes in direct ethanol fuel cells.

Introduction

The synthesis of novel materials with improved properties and performance is a continually expanding frontier at the interface of chemistry and materials science. While materials possessing structural complexity are common in nature, the development of versatile methods to prepare synthetic nanocomposites remains an exciting challenge that is currently being tackled by research groups around the world. [1,2,3]. Advances in the development of nanotechnology, especially in the use of colloidal silver, have been attracted the attention of researchers worldwide. In this work we described preliminary results about the influence of the nanosilver in the preparation of the polymeric microspheres.

Materials and Methods

Polymeric microspheres were prepared in the system composed by two phases: an aqueous phase (AP) and organic phase (OP). The AP was prepared by addition of gelatin, 2-Hydroxyethycelullose (HEC) and NaCl, in relation to water, while the OP was composed by styrene and divinylbenzene copolymerizations, toluene and benzoyl peroxide as initiator. The reaction was maintained in reflux condenser with mechanical stirrer, at 70 °C for 24 hours. After that, the resin bead was thoroughly washed with hot water and with propanone and dried at 60 °C. The AgNPs were synthesized in an aqueous media by chemical reduction of $AgNO_3$ using $NaBH_4$ as reducing agent and sodium citrate as stabilizer. The nanometric dimension of the Ag particles was monitored by UV–vis and confirmed through Transmission Electron Microscopy (TEM).

Results and Discussion

FEG image of the colloidal silver nanoparticles revealed the presence of nearly spherical particles with diameters ranging 50 nm (Figure 1). The image obtained by an optical microscope (OM) of microspheres sty/DVB is shown in Figure 2. It is observed in this picture the formation of a material with spherical appearance of various sizes. The literature shows that the stirring speed during emulsion polymer synthesis constitutes an important parameter in controlling the size of the microspheres. [4]

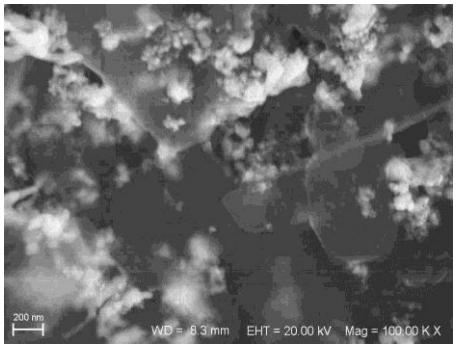

Figure 1. Image obtained by FEG of the nanosilver in aqueous medium.

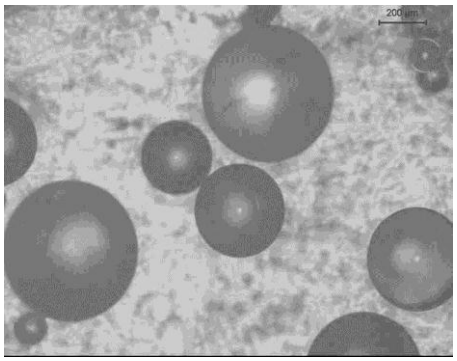

Figure 2. Image obtained by optical microscopy of polymeric type sty/DVB.

Conclusions

The synthesis of the polymeric microspheres in the presence of the silver nanoparticles was done successfully. Antimicrobial aspects from this material were studied. Studies assessing on the release of Ag+ in the culture medium and other issues relating to the understanding of this material is under way in our laboratories

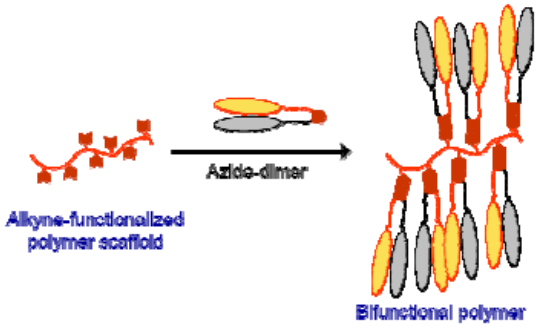
rtejedor@unizar.es

Materials with a controlled molecular architecture have been deeply investigated because it is possible to establish better relations structure-properties, leading to a new generation of materials rationally designed in function of the desired properties. Moreover, photoactive materials have been an area of interest due their capability of respond to a light stimulus and generate a determinate response, such changes on the material alignment, catalysis of a reaction or macroscopic moves[1]. Specifically, azobenzene side chain polymers has also been hardly studied because their optical and electro-optical applications[2].

Here, we present the properties of a series of bifunctional polymers that have been obtained by combining controlled radical polymerization and 'click chemistry' tools. Therefore, by this tandem approach a polymer skeleton with alkyne groups has been modified with dual functional azides giving rise to a family of functional materials were the final properties can be modulated by the nature of the functional units and the regularity on their position, frequency and distribution along the polymeric main chain. Side-chain polymers with pendant units containing photo-addressable azobenzene moieties, cinnamate units and classical liquid crystal moieties have been prepared.



In particular, our interest is focussed on the photoinduction of chirality in polymeric achiral materials when they are put under a chiral stimulus, a phenomena that was recently described. This photoinduction of chirality can be achieved irradiating a photoactive material with circularly polarized light (CPL)[3]. In this family of materials, a switchable phototransference of chirality from the CPL to the material has been achieved. The effect of a precise alternation of the functional units as well as the possible cooperative motion of the liquid crystalline units in the supramolecular chirality is also evaluated.

Abstract

Bio sourced and/or biodegradable polymers attract growing interest in the polymer community since a few decades. Replacing durable petroleum based polymers by biodegradable ones would drastically reduce land and water pollution. Polyhydroxyalkanoate (PHA) is one of the promising materials to reach such an objective as it is a polyester synthesized and accumulated by specific bacteria. This living synthesis results in a biodegradable polymer with specific chemical structure depending on the strain of bacteria and the substrate used.

The aim of this study is to characterize some commercially available PHAs in term of functional properties such as mechanical, thermal and gas and water vapour transmission capacity. The mechanical study first positions PHAs compared to conventional polymers in order to evaluate the applications field for such biopolymer. Glass transition temperature and crystallization behaviour investigations then bring some information about the heat resistance and the process limitation induced by the crystallization completion during a process cycle such as injection moulding. The evaluation of oxygen and water vapor transmition capacity complete this investigation in term of functional properties dedicated to specific application such as food or medical packaging.

Keywords Polyhydroxyalkanoates, PHA, Mechanical properties, Crystallization, Oxygen transmission rate, Water vapor transmission rate.

Preparation and characterization of polystyrene-*graft*-polyethylene glycol copolymers as solid–solid phase change heat storage material

Alper Biçer, Cemil Alkan, Ahmet Sarı, Ali Karaipekli*

Department of Chemistry, Gaziosmanpaşa University, 60240, Tokat, Turkey

In this study, graft copolymers of polystyrene with different PEG6000 content as novel polymeric solid-solid phase change materials (PCMs) were synthesized.

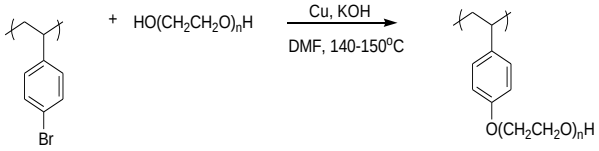

Fig. 1 Synthesis scheme for the preparation of graft copolymers of polystyrene

In these new materials, polystyrene is the skeleton and PEG is a functional side chain that stores and releases heat during its melting and freezing process. The heat storage mechanism of copolymers is the transfer between crystalline and amorphous states of the soft segment PEG in copolymer, and the hard segment polystyrene restricted the free movement of molecular chains of the soft segments at high temperature.

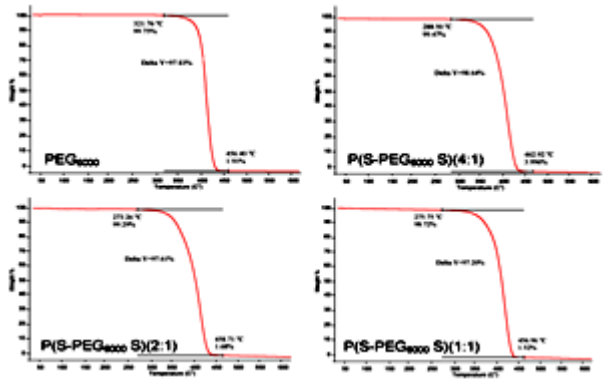

Fig. 2 TG curves of graft copolymers of polystyrene

Thus, these copolymers can keep them solid state in the phase transition processing and were described as form-stable PCM.

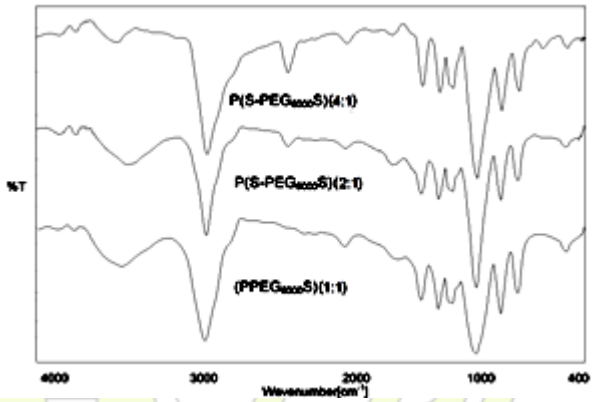

Fig. 3 FT-IR spectra of graft copolymers of polystyrene

To investigate ingredients, thermal properties, thermal reliability and crystalline morphology of the synthesized copolymers, fourier transform infrared spectroscopy (FT-IR), differential scanning calorimetry (DSC), thermogravimetric analyses (TGA), and polarization optical microscopy (POM) analyses were performed.

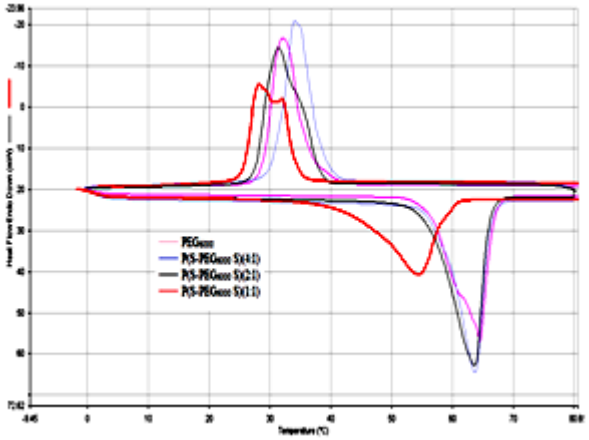

Fig. 4 DSC thermograms of graft copolymers of polystyrene

The results indicated that the PEG chains were successfully grafted onto the polystyrene backbone and the copolymers have typical solid-solid phase transition properties. The synthesized P(S-PEG_{6000}S)(4:1), P(S-PEG_{6000}S)(2:1) and P(S-PEG_{6000}S) (1:1) have solid-solid phase transition temperature of 44.9, 56.5 and 58.0 °C, respectively, and latent heat values of 111.48, 130.98, and 179.47, J/g, respectively.

Moreover, thermal cycling test showed that the copolymers have good thermal reliability and chemical stability although they were subjected to 5000 melting/freezing cycling. Based on all results, it was concluded that the polystyrene-*graft*- PEG copolymers as novel solid-solid PCMs have potential applications for thermal energy storage and temperature control.

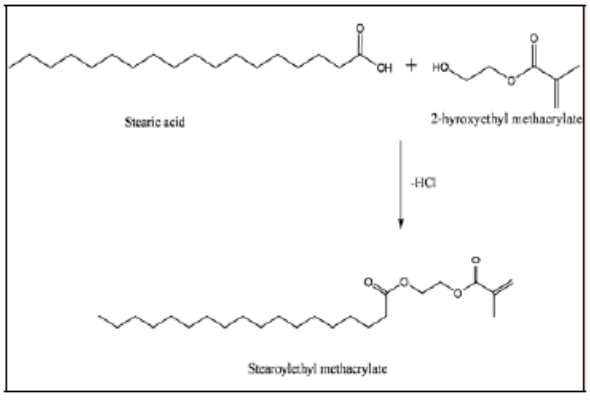
Phase change material is a substance with a high heat of fusion which, melting and solidifying at a certain temperature, is capable of storing and releasing large amounts of energy. Heat is absorbed or released when the material changes from solid to liquid and vice versa; thus, PCMs are classified as latent heat storage (LHS) units. Total amount of energy absorbed or released by a phase change material can be calculated by equation 1.

$$Q = m\Delta H_M + \int_i^M mC_p dT + \int_M^f mC_p dT \quad (1)$$

PCMs should be encapsulated for usage and they are mostly encapsulated in polymers for the ease of application. Polymeric solid solid phase change materials are promising for their easy applicability and expected long lasting property. In this work, 2- hydroxyethyl methacrylate esterified with acyl chlorides of three different fatty acids to obtain monomers with phase changing property at convenient temperatures with high storage density so that copolymerization of these monomers with methylacrylate will result in polymers with solid solid phase changing property at variable phase change temperatures. 9 different polymers have been synthesized as a result of the reaction between produced monomers and methylacrylate at 3 different weight ratios. Produced copolymers were characterized by structural and thermal aspects. For the synthesis of the novel PCMs, myristic acid, palmitic acid, and stearic acid were chosen and they were transformed to acyl chlorides by thionyl chloride in the presence of dimethylformamide catalyst. Fatty acid acyl chlorides were bound to 2-hydroxyethylacrylate monomer from hydroxyl group as shown in the following Figure.



FT-IR and NMR spectroscopy techniques were used to characterize the produced PCMs structurally as molecular weight measurements were done using Gel Permeation Chromatography (GPC) technique. Molecular weight of the polymers produced decreased by the fatty alkyloylethylmethacrylate monomer content

and with increasing paraffinic side length. Phase change temperatures and enthalpies and degradation temperatures of the synthesized PCMs were investigated using Differential Scanning Calorimetry (DSC) and Thermal Gravimetric Analysis instruments respectively and it was found that produced polymers have potential to be used as thermal energy storage materials and stable up to considerably high temperatures. On the other hand structural and thermal consistency of the polymers was confirmed by FT-IR and DSC measurements after accelerated thermalcyclings.

Thermal conductivity of the polymers was found to be in the range of the thermal conductivities of fatty acids.

Besides polarize optical microscopy was used for morphology investigation of polymers below and above phase transition temperatures.

Key words: 2-hydroxyethyl methacrylate, methylacrylate, phase change material, fatty acid

Polyethers As Phase Change Materials for Passive Thermal Energy Storage

Derya Kahraman, Cemil Alkan, Mukaddes Ülkü Önder

Gaziosmanpaşa University, Department of Chemistry, 60240, Tokat / TURKEY

dkahraman@gop.edu.tr

Polyethylene glycols (PEGs) are the most promising polymers for thermal energy storage applications due to their high storage densities and variable phase change temperatures. They are also considered in preparation of solid solid polymeric phase change materials for their functional OH groups at chain ends. In this work it was aimed to determine the physicochemical properties of some of the other aliphatic polyethers for their feasibility to be used as phase change materials for thermal energy storage. For this purpose, polytetrahydrofurane at two different molecular weights were obtained commercially as poly(1,3-dioxolane) and poly(1,3,5-trioxane) polymers at 3 different molecular weights were synthesized and characterized as shown in the Figure 1. 1,3-dioxolane and 1,3,5-trioxane were polymerized with ethylene glycol initiator and $BF_3.Et_2O$ catalyst.

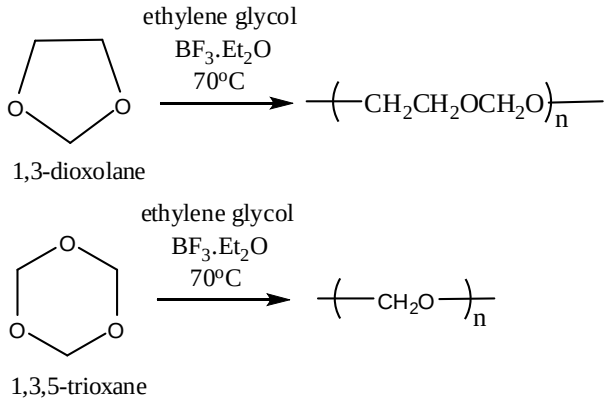

Figure 1: Synthetic route for the synthesis of poly(1,3-dioxolane) and poly(1,3,5-trioxone)

The chemical characterization of poly(1,3-dioxolane) and poly(1,3,5-trioxane) polymers were made by fourier transform infrared radiation (FT-IR) spectroscopy (Figure 2) as their molecular weight analysis were done using gel permeation chromatography (GPC).

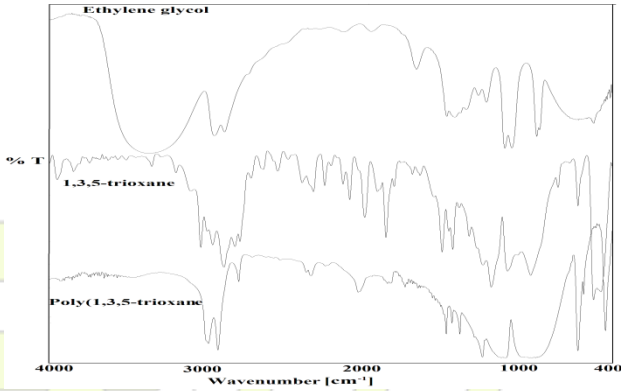

Figure 2: Ethylene glycol, 1,3,5-tioxane, and poly(1,3,5-tioxane) FT-IR spectrum

The melting and freezing temperatures and latent heats of the polyethers as phase change materials were measured using DSC instrument and it was found that polyethers

having different phase change temperatures can be considered as novel phase change materials for some other applications due to their variable phase change temperatures and high thermal energy storage densities. They are also found thermally stable and they have potential for both to be used as solid-liquid phase change material and to be used in the preparations of polymeric solid-solid phase change materials for thermal energy storage. Thermal gravimetric analysis (TGA) indicated that both commercially obtained and synthesized polyethers had good thermal stability up to high temperatures (Figure 3).

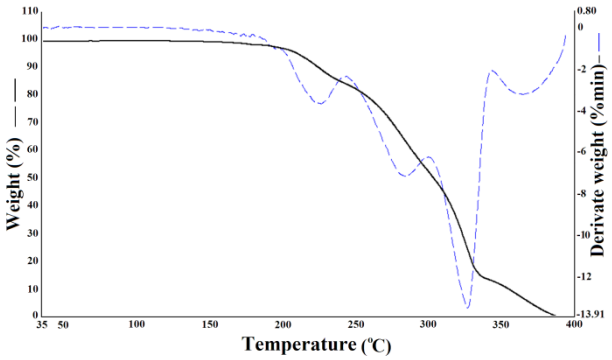

Figure 3: TGA thermogram for one of the poly(1,3,5-trioxane) produced in this research

Polytetrahydrofurane, poly(1,3-dioxolane)s and poly(1,3,5-trioxane)s have also been considered as counterparts of eutectic mixtures of poly(ethylene glycol)s so that polyether mixtures with different phase change temperatures could be obtained. Eutectic temperatures were calculated using following Schröder equation theoretically.

$$lnx_B = -\frac{\Delta H_B}{R}\left(\frac{1}{T^*}+\frac{1}{T_B}\right)$$

Herein, the synthesis of polymeric ionic liquids (PILs) with paramagnetic anions based on tetrachloroferrate(III) ($FeCl_4^-$) and tetrabromoferrate(III) ($FeBr_4^-$) is presented. The formation of the novel polymers encompassing the paramagnetic anions is proven by UV-VIS and Raman spectroscopy. Paramagnetic properties are analyzed using a SQUID measuring system. Some of the obtained PILs show higher magnetic susceptibility values than previously measured for paramagnetic ionic liquids. It is further found that the magnetic susceptibility can be tailored by controlling the iron content in the anion. Interestingly, casted films of the PILs show a strong response to a neodymium magnet. As a potential application, a microgel based on a paramagnetic PIL is used as reusable catalyst in aromatic Friedel–Crafts alkylation. The PIL microgel can be easily removed and reused after the reaction making these new materials interesting for green chemistry processes.

The pictures in **Figure 1** show the response of a polymeric film of poly(1-vinyl-3-ethyl-imidazolium $FeBr_4^-$) (obtained by casting from acetone solution) to a neodymium magnet. The film showed a good response to the magnet field and eventually sticked to the magnet when close enough. Similar behaviour was observed for films of the other paramagnetic PILs.

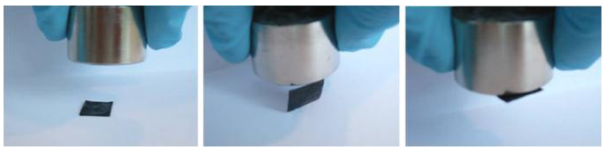

Figure 1. Response of a film of $pViEtIm^+$ $FeBr_4^-$ to a neodymium magnet.

The paramagnetic/Lewis acid character of the presented PILs make them interesting candidates to be applied as "reusable catalyst" in Friedel-Crafts reactions. For this purpose, a microgel of paramagnetic PIL was synthesized. The magnetic response can be beneficial to overcome difficulties in separation/recovery of the catalyst as it can be simply removed by a magnet or by centrifugation, washed and reused. Hence, a microgel of poly(1-vinyl-3-butyl-imidazolium $FeCl_4^-$) was used as reusable catalyst in Friedel-Crafts alkylation. **Figure 2** shows the reaction scheme of the aromatic Friedel-Crafts alkylation and a SEM micrograph of the reusable polymeric microgel. The isomers of benzyl-4-methylbenzene were obtained from toluene and benzyl chloride. The procedure was repeated 10 times without any loss in catalytic performance of the paramagnetic microgel. The product yield ranged constantly above 99%.

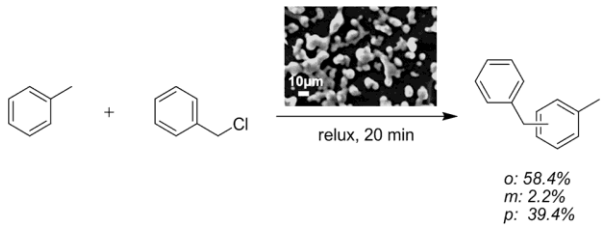

Figure 2. Synthesis scheme of the aromatic Friedel-Crafts alkylation. The SEM micrograph shows the paramagnetic microgel.

Environmentally Friendly Polyurethane Foams

Yu. Savelyev, L.Markovskaya, I.Yanovych, E.Akhranovych

Institute of macromolecular chemistry, NAS of Ukraine, Kharkovskoe shosse, 48, o2160, Kiev, Ukraine

The most of the synthetic polymer materials posses the low degradability in environment due to stability of their chemical structure to external influences, therefore they are a considerable source of environmental pollution. The decision of this problem is not so much removal of such challenges to environment as their prevention that is the aim of the "Green chemistry", the principle of which in increasing frequency have been considered. The best solution of the problem of "polymer wastes" is the creation of polymers retaining their exploitation characteristics only during period of usage, whereupon such polymers undergo physic-chemical and biochemical transformation (hydrolytic, oxidative, photo-, thermo-, mechanic- and biodestruction) under the influence of different factors of environment and are easily enter into metabolism processes of natural biosystems.

The main biological systems damaging polymers are microorganisms (especially mould fungi and bacteria). That is why the commonly used method of giving the polymers an ability to degradation is their combination / blending with biodegradable components (di-, polysaccharides) which are the sours of food for different microorganisms. However, such composite materials are just conditionally degradable, since only carbohydrates, but synthetic polymers in the most cases are not being decomposed.

Polyurethane foams (PUF) are the widespread class of macromolecular compounds used as the base for creation of variety modern polymer materials due to their polyblock structure, which determine unrestricted abilities of their structure and physical properties. The distinctive feature of PUF is their hypothetic biocompatibility as the result of their heterogeneous structure.

Taking into account preceding, the aim of this work is the creation of novel degradable under environment conditions PUF on the basis of saccharid-containing precursors and polysaccharides

Synthesis of PUF was carried out using ethers and esters, activators of the process and water. As diisocyanate component we used saccharid-containing precursors with reactive NCO groups, received by reaction of lactose (mannose, sucrose) with 2,4(2,6)-toluenediisocyanate (TDI). The following polysaccharides were used: starch, cellulose derivatives (hydroxymethyl-, carboxymethyl-), Na-alginate. Spuming was made owing to carbon dioxide, which exude at decomposition of unstable aminoformic acid, formed as the result of interaction between diisocyanate and water.

The character of degradation of PUF has been studied under the influence of different destructive factors: a) long action of heightened humidity (up to 87%) and temperature (37°C); b) mould fungi (*Aspergillus* and *Penicilium*); c) 0,1N solution of KOH and HCl; d) incubation of polymers into the soil for 3, 6, and 9 months. Definition of the soil microflora has shown the presence of *Rhizopus, Aspergillus, Penicillium.*

The degree of destruction is 40-50%, that essentially exceeds the actual content of natural compounds in polymer composition. The mass lost by reference template of PUF (without carbohydrates) even after 270 days' incubation is insignificant (2,4 %). I. e. the introduction of these compounds contributes to degradation of polymer materials.

Thus, the FPU creation using the introduction of nature compounds into the polymer structure serve as the way of the obtaining materials with given properties, biodegradable under the action of different environmental factors.

Effect Of Salt Concentration On Strength And Morphology Of Natural Degradable Additive PP Film Upon Immersion in water.

Due to preservation of our valuable environment, use of natural degradable additive is an important solution to discarded plastics material. Use of degradant additive for non biodegradable plastics such as polyethylene (PE) and polypropylene(PP), are preferred due to their low cost. In this work, natural additive, RM is used as the degradant to impart oxidative degradation and enhanced chain scission to PP before fragmentation. Film are immersed to different pH and two salt concentration. From this study, the greatest degradation for degraded film from PP filled RM additive was at pH value of 7 with 3.5% salt concentration. Tensile strength of PP filled additive at pH 7 (neutral environment) showed lowest strength compared to PP blank.Carbonyl index and surface roughness of film were determined. Presence of chloride ion in salt had enhanced oxidation and degrade PP film. Surface roughness visualized through Atomic Force Microscopy (AFM) of PP filled RM additive with dione was highest and tensile strength was found to be lowered.

Keyword: Degradation, Non degradable PE and PP, Natural Additive, Tensile Strength, Carbonyl index, Atomic force microscopy(AFM)

INTRODUCTION

Current state of global warming and threats to the environment had caused plastics to be blamed and banned in some countries. Plastics for packaging are being scrutinized due to its resistance to degrade. Polymer degradation may occur through thermal, light oxygen and uv degradation or weathering (Singh and Sharma, 2007). Additives had being used as degradant such as metal stearates and cobalt which may affect the environment.(Chiellini 2006) This study differ from others studies whereby natural additive formulations of oil and dione (named RM) are chosen as a pro-oxidant and photosensitizer respectively for Polypropylene (PP). In this study, PP filled with RM additives are studied and investigated.

MATERIALS AND METHODS

Polymer compounding using twin screw, PRISM with L/D ratio of 16:1 were perfomed using Propylene, I102 from *MTBE, Petronas* with MI of 10 and different ratios of RM additives, namely *RM1 and dione*. Films cut according to ASTM D882 were placed in water of three pH, 3,5 and 0 with sodium chloride salt of 3.5% and 5%. Films were immersed for one and three weeks. All film samples were being tested for tensile strength, carbonyl index using Fourier Transform Infrared (FTIR) and morphology using Atomic Force Microscopy (AFM).

RESULTS AND DISCUSSION.

The tensile strength(TS) of PP filled RM at pH 7 were significantly reduced compared to PP Blank. Presence of RM oil had actually accelerated degradation process as this formulation had the lowest tensile strength..

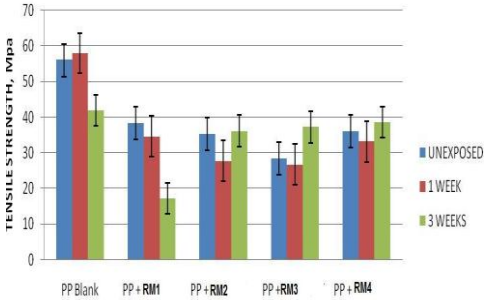

Figure 4.1 Tensile strength versus formulation at pH 7 and 3.5% salt concentration.

The degradation of the PP samples was followed by FTIR. A sharp increase in absorption in the carbonyl region was recorded with time in all the samples exposed. Among films studied, PP filled palm oil at pH 7 with 3.5% salt concentration resulted in higher CO_i.(carbonyl index). Roughness $_{RMS}$ of PP filled palm oil after exposure for three weeks was significantly increased. Obvious changes of PP filled additives was due to more chain scission occurred and the oil could be oxidized by chloride ion resulting in lower TS and CO_i.

Introduction

The identification of people and the monitoring of their history is still issue of great interest today in our society. Radio Frequency Identification (RFID) has a diverse and wide application potential to use in this field. RFID tags require substrates that meet strict requirements in terms of their properties (electromagnetic, mechanical and chemical), this is they should be flexible, biocompatible and with high dielectric constant. Nowadays, the major barrier in the implementation of RFID is the high cost of the system due to the existing conformal antennas is still printed on rigid laminate substrates with curved shapes. Polymers are rapidly getting important among materials for this kind of applications whether used in pure form or combined with ceramic powders. In the present work, polymer-ceramic flexible tags containing ethylene vinyl acetate (EVA) and $SrTiO_3$ were synthesized. Using the optimized substrate and Perfect Magnetic Conductors (PMC) design, a high performance RFID tag were obtained.

Materials and Methods

Polymer-ceramic flexible tags containing ethylene vinyl acetate (EVA) and different percentages of $SrTiO_3$ (4-60% v/v) were synthesized by extrusion and subsequent forming. The chemical characteristics of the different compositions were characterized by Termogravimetric analysis (TGA). Structural characteristics of the composites were investigated using a FTIR spectrometer in the range of 400–4000 cm^{-1} by the KBr pellet method. The microstructure was analyzed by Field Emission Scanning Electron Microscopy (FESEM). The electrical parameters (permittivity and loss tangent) of polymer-ceramic composites were measured with a broadband probe 0.2-20 GHz after depositing a layer of copper on the surface of the samples by Chemical Vapour Deposition (CVD).

Results and Discussion

Flexible tags based on polymer and ceramic composites were obtained. Ethylene Vinyl Acetate was chosen as polymer since it approaches an elastomeric material in softness and flexibility and it is biocompatible with the body. To achieve higher dielectric constant, ceramic powders were introduced into the polymer matrix during the extrusion process. Figure 1 shows the FT-IR absorption spectra for the pure polymer and the composite prepared with 25% v/v $SrTiO_3$. A Sr-O stretching band is seen in the composite spectra at 596 cm^{-1} which is not visible in the pure spectra, indicating the presence of $SrTiO_3$ particles into the polymer matrix. FE-SEM characterization image demonstrate that composites show a homogeneous morphology with the $SrTiO_3$ particles being embedded within the EVA matrix (Figure 2). Polymer-ceramic composites show a high dielectric constant value and great flexible to be used as substrates for RFID tags as is shown in Figure 3.

Introduction

Biodegradable polymers have been investigated during the last few decades as alternatives to non-degradable polymers.[1] PLA is becoming popular as a biodegradable engineering plastic owing to its high mechanical strength, easy processability compared to other biopolymers. The preparation of micro- and nano-composites represents a promising method to improve the physical properties of biopolymers. The incorporation of antimicrobial substances in food-packaging materials to control undesirable growth of microorganisms on the surface of foods, represents a great challenge.[2] Microcrystalline cellulose (MCC) has been used as additive to improve the properties of polymer in several applications, while nanocrystalline cellulose (CNC), produced from the acid hydrolysis of MCC and properly modified, presents increased crystalline phase. CNC shows high mechanical properties, great biodegradability and biocompatibility, high stiffness, and low density.[3-5]

Materials and Methods

Poly-Lactide Acid (PLA) 3051D, supplied by Nature Works®, was used as polymer matrix and commercial silver (Ag) nanopowder were added in order to provide antibacterial properties to the system. Microcrystalline cellulose (MCC, dimensions of 10-15 µm) was supplied by Sigma Aldrich and cellulose nanocrystal (CNC) suspension was prepared from MCC by sulphuric acid hydrolysis.[6] Cellulose nanocrystals were modified with an acid phosphate ester of ethoxylated nonylphenol (s-CNC). Binary and ternary films with 5%wt of MCC, 5%wt of pristine CNC or surfactant modified s-CNC and with 1%wt of Ag were prepared by a melt extrusion followed by a filmature process. New multifunctional materials were characterized in terms of morphology, mechanical, thermal and antibacterial properties and the effect of cellulose crystal micro- and nano-dimension, the presence of surfactant, and the combination with silver nanoparticles were investigated.

Results and Discussion

Cellulose nanocrystals produced by acid hydrolysis appear individualized, with the typical dimensions ranging from 100 to 200 nm in length and 15 nm in width, highlighting the success of the process.

Morphology studies of PLA composite films prepared combining MCC and Ag nanoparticles revealed a well dispersion of silver and the presence of microcrystalline cellulose aggregates, while the mechanical properties demonstrated the MCC reinforcing effect. The presence of surfactant on the CNC surface, favors their dispersion in the polymer and the nucleation effect was remarkably enhanced compared to both MCC and pristine CNC based systems, supporting the positive effect of nanoscale and of surface modifications on the thermal and mechanical properties of resulting PLA composite films.

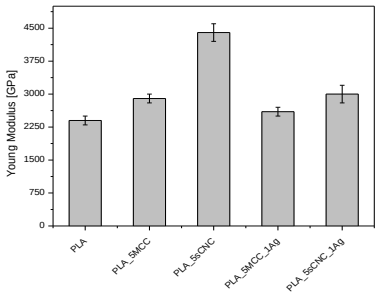

Fig. 1: Mechanical properties of PLA composite films.

Moreover, a bactericidal effect of all the analyzed PLA composites on *S.aureus* and *E.coli* was detected suggesting possible applications which requires an antibacterial effect constant over time.

Conclusions

PLA composites reinforced with micro- and nano-crystalline cellulose combined with silver nanoparticles offer a good perspective for food packaging applications which requires high mechanical performances, good transparency, thermal stability, and an antibacterial effect.

Solid-State Polymerized Conducting Polymers for Highly Efficient, Iodine-Free Dye-Sensitized Solar Cells

*Jeonghun Kim, Jong Kwan Koh, Byeonggwan Kim, Jong Hak Kim,*and Eunkyoung Kim**

e-mail: eunkim@yonsei.kr

Introduction

In solid-state dye sensitized solar cells (ssDSSCs), hole transporting materials (HTMs) and the control of interfacial properties between the nanoporous TiO_2 layer and HTM are critical to the photo conversion efficiency of the cells. Recently, HTMs have been extensively investigated as potential replacements for conventional I_3^- /I^- redox electrolyte systems using iodine (I_2) in DSSCs due to the leakage of electrolyte and corrosion of electrode by I_2. Recently, we have developed the iodine (I_2)-free ssDSSC with high efficiency of 5.4 % using solid-state polymerized conductive polymer conductive polymer as HTM to enhance the penetration of HTM to thick TiO_2 layer.[1] Herein, we present about the application of highly conductive polymers to the I_2 free ssDSSCs with a facile fabrication method.

Materials and Methods

The ssDSSCs were constructed by drop-casting of electrolyte solution onto the photoelectrode and covering with Pt coated counter electrode, using the previously reported procedure.[2-5] The commercial TiO_2 paste (solaronix D20) was casted onto the glass using a doctor-blade technique, followed by successive sintering at 450 °C for 30 min. Nanocrystalline TiO_2 films were immersed into N719 solution (0.5 mM in ethanol) for 24 hr at R.T. The DBEDOT (2,5-dibromo-3,4- ethylene dioxythiophene) was dissolved in anhydrous ethanol (1 wt and 3 wt %) and a few drops of the solution were directly casted onto the TiO_2 photoelectrode and counter electrode. After drying the solvent, the DBEDOT onto the photoelectrode was thermally polymerized at 60 °C for 24 hr in an oven (fig. 1). Then, a drop of the acetonitrile solution consisting of MPII (1.0 M), TBP (0.2 M) and Li salt (0.2 M) was casted onto the photoelectrode. After evaporation of the solvent in a vacuum oven, sandwich-type DSSCs were fabricated by clipping two electrodes. The active area was 0.16 cm^2.

Results and Discussion

SSP, yielding highly conductive polymers, has been reported using halogenated crystalline heterocyclic monomers.[6] The synthesized crystalline monomer (DBEDOT) showed good solubility in many common solvents and was polymerizable in the solid-state upon heating. The crystal DBEDOT is small enough to penetrate into the nanopores of nanocrystalline TiO_2 layers where SSP occurs upon heating without additives.

Successful penetration of DBEDOT and SSP were also confirmed using FT-IR, XRD, SEM, and TEM study. The cell fabricated using the PEDOT/MPII/LiTFSI/TBP system exhibited effective electron lifetime of 30.2 ms, V_{oc} of 0.64 V, J_{sc} of 14.2 mA/cm^2 with excellent energy conversion efficiency of 5.4 %, which is the highest value in iodine-free ssDSSCs with N719 dye.

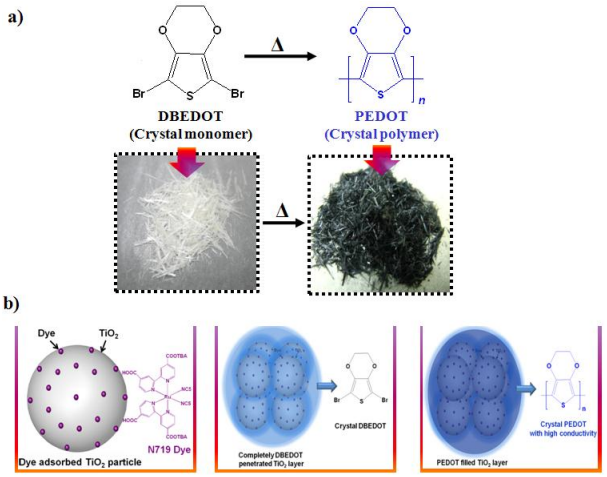

Figure 1. Schematic representation for a) the solid-state polymerization of DBEDOT and b) facile fabrication process of highly efficient iodine-free ssDSSC using N719 dye and conductive polymer as HTM.

Conclusions

We developed a facile method for the preparation of iodine-free ssDSSC with excellent performance and improved electrode/HTM interfacial properties based on the SSP of a conductive polymer. The solid-state polymerizable monomer was small enough to effectively penetrate into the nanopores of TiO_2 film, improving interfacial contact between the electrode and HTM. Importantly, this approach allowed deep penetration of HTM into 11 μm thick TiO_2 film, allowing for enhanced dye adsorption and resulting in high performance. We believe that this SSP approach introduces a new and simple route toward the synthesis of conducting polymer as the HTM in iodine-free ssDSSCs serve as an alternative to the conventional photoelectrochemical polymerization method.

Towards innovating polymer materials for a new generation of organic laser sources

F. Lincker[a], V. Barret-Vivin[a], D. Kreher[a], F. Mathevet[a], A. Barsella[b], A. Boeglin[b], A. Fort[b] and A.-J. Attias[a]

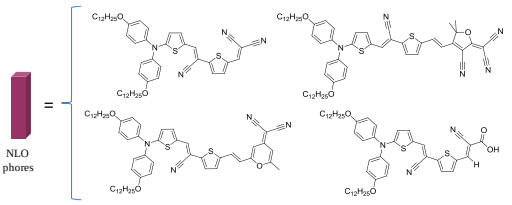
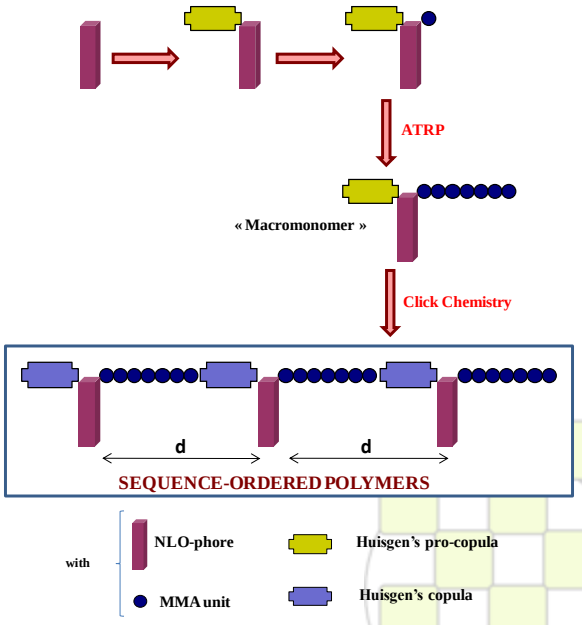
[b] DON, Institut de Physique et Chimie des Matériaux de Strasbourg, 23 rue du Loess, BP 43, 67034 Strasbourg Cedex 2, France.

David.kreher@upmc.fr

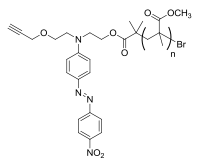
The goal of this multidisciplinary project is the design and synthesis of novel (macro)molecular materials for a new generation of organic laser sources emitting light in the blue/near UV part of the spectrum. Our approach relies on the use of unique Non Linear Optical (NLO) fluorophores, *i.e.* a new class of push-pull molecules associating fluorescence with strong quadratic hyperpolarizabilities. Such "bifunctional" NLO-phores will be able to generate both laser emission in the visible range as well as frequency-doubling of their own laser emission (self-doubling), thus providing a single-element near-UV laser source. (1)



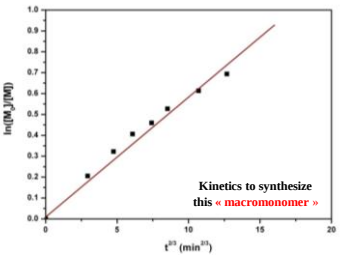
Unfortunately, despite the high-value of the hyperpolarizability, it seems problematical to translate microscopic nonlinearity to macroscopic electro-optic activity. (2) In order to minimize the intermolecular electrostatic interactions between NLO-phores and control the distance between them along the polymer backbone, we propose a new approach combining ATRP controlled radical polymerisation and Click Chemistry to obtain first "macromonomers" and second sequence-ordered polymers (figure below). (3)



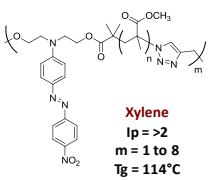
More precisely, we report here the preliminary results concerning the synthesis and characterization of a series of model sequence-ordered polymers based on methyl methacrylate (MMA) backbone and bearing Disperse Red derivatives (DR19) as pendant model chromophores. As an example, by controlling the kinetics of the ATRP stage, we can obtain the following macromonomer :



DR19:PMMA = 7.8 w% (n = 57)
As an example, at t = 55 min :
Ip = 1.1, Mn = 6220 g.mol^{-1}
Tg = 94°C



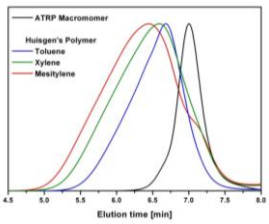
Then, we made a systematic study of the experimental conditions to realize the ultimate Click Chemistry step, modifying for example the solvent and/or of the type of Huisgen's copula, …, in order to see the impact of such parameters on optical properties already (see an illustration below) before to make films with these materials to measure their NLO response.



Toluene
Ip = 1.1
m = 2 to 4
Tg = 116°C

Xylene
Ip = >2
m = 1 to 8
Tg = 114°C

Mesitylene
Ip = >2
m = 1 to 8
Tg = 111°C



To conclude, our approach based on the combination of ATRP and Click Chemistry allowed us to obtain model sequence-ordered polymers, these latter being chemically and structurally fully characterized. Now we try to take advantage of this strategy to attach our innovating NLO-phores to the PMMA matrix in order to reach, we hope, innovating and efficient (macro)molecular self-doubling materials.

Abstract: Leather is natural polymer of amino acid monomer. For tanning of raw leather a lot of chemical process are involved. As result a huge amount of solid waste are coming from the leather industry. In this study an attempt was taken to use solid leather waste as reinforcing agent with polymeric substance such as polyester resin. Leather fiber reinforced polyester resin based composites were prepared by Wet layup method. Resin content in the composite was varied from 100 ml to 40 ml. After mixing the matrix with the reinforcement, benzoyl peroxide was used as a radical initiator to induce polymerizations. Tensile strength(TS) ,Young modulus and elongation at break (E_b) was measured were measured and found to increase TS and Young modulus up to certain ratio and also found to decrease after certain level. Elongation at break was found to decrease with increasing leather materials upto certain level and again found to increase with increasing leather materials. Leather waste reinforced matrix was found to better result compare to polyester matrix. As a result it will reduce the environmental pollution and also reduce of polymeric pollution . So it can be concluded that natural amino acid fiber, leather can be used as a reinforcing material and found to have better result than matrix and reinforced material.

Key: leather waste, polyester resin, tensile strength, environmental pollution.

Studying PMMA/PVC polymer blend for its use as lithium polymer electrolyte

Leire Zubizarreta[a], *Abel García-Bernabé*[a], *Mayte Gil-Agustí*[a], *Pedro Llovera*[b]

1. Introduction

The ever increasing effort for the development of storage systems for sustainable energy supplies make the lithium (Li) ion battery technology one of the most promising future energy resources. This technology has tremendous scope to be used in many applications from modern hi-tech devices to electric vehicle. Polymer electrolyte has been attractive for developing Li batteries due to its advantages respect to liquid electrolytes. It not only promises better safety as the polymer electrolyte do not ignite easily but also the possibility of making battery cells very thin [1].
Currently, poly (methyl methacrylate) (PMMA) and polyvinyl chloride (PVC) are polymers extensively studied for this application due to its ability to solvate inorganic salts to form a polymer salt complex, and its good mechanical properties, respectively [2]. Preparation of PMMA/PVC blends could allow taking the advantages that these polymers have separately in a new polymer blend electrolyte. However, in spite of these good properties, the ionic conductivity of lithium salt solution in these polymers is still low to use in Polymer-Li Batteries applications. The addition of some plasticizers such as ethylene carbonate (EC), propylene carbonate (PC) or γ-butyrolactone (BL), in PMMA/PVC composites could increase the ionic conductivity of polymer electrolytes.
The objective of this work is to study the effect of the amount of different Li salts and organic plasticizers on ionic conductivity of PMMA/PVC polymer blend electrolyte.

2. Materials and methods

All reagents were used without any further purification, and they were obtained from Sigma-Aldrich. Dry and gel polymer electrolytes were prepared. $LiCF_3SO_3$ lithium salt and a mixture of PC:EC (1:1) plasticizer were used for this study. PMMA, PVC, Li salt and plasticizers were dissolved in 15 ml of tetrahydrofuran (THF). The polymer solution was cast as film and THF was allowed to evaporate slowly at room temperature. Obtained films were regular and with a thickness of 100µm. Ionic conductivity was determined by sandwiching of the sample between two gold electrodes. The measurements were realized using a Potentiostat from AUTOLAB in the frequency range of 10^{-3} to 10^{6} Hz at room temperature.

3. Results and discussions

Different series of membranes were synthesised varying the amounts of Li salt and plasticizers. Figure 1 shows how the ionic conductivity of PMMA/PVC synthesized with a 5wt. % of Li salt varies with the amount of plasticizer. It can be seen that the conductivity increases with the amount of plasticizer used, especially when a 35 and 45 wt. % of plasticizer is used. It should be noted that the consistency of the membranes with this amount of plasticizer is good.

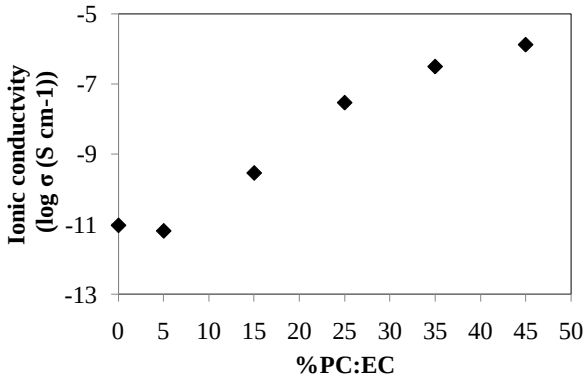

Figure 1. *Variation of ionic conductivity with amount of plasticizer in PMMA/PVC membranes with 5% of* $LiCF_3SO_3$

In addition, the effect of the Li salt amount was studied. In dry polymer electrolytes (without plasticizer) it was observed that conductivity increased considerably with the amount of Li salt. However, in case of gel polymer electrolytes (with plasticizer) the influence of this parameter is lower.

4. Conclusions

In this work, the effect of the amount of plasticizer and lithium salt on the ionic conductivity of PMMA/PVC based membranes have been study. The effect of the amount of plasticizer on ionic conductivity is strong and it seems a very good strategy to increase considerably the ionic conductivity of this type of membranes without alter the good mechanical properties of the blend. The increase of the Li salt amount also increases the conductivity of the PMMA/PVC blend, especially, in dry PMMA/PVC polymers blend electrolytes.

Ionic conductivity vs. thickness on the cast Nafion® polymer

Mayte Gil-Agustí, Leire Zubizarreta, Jessica Calleja-Langa, Rosa Iserte

Instituto Tecnológico de la Energía (ITE), Avenida Juan de la Cierva, 24 46980 Paterna, Valencia, Spain
Instituto de Tecnología Eléctrica, Universidad Politécnica de Valencia, Spain

e-mail: mayte.gil@ite.es

1. Introduction

Perfluorosulfonic acid membranes such as the Nafion are currently used as the electrolyte due to their favourable chemical and mechanical stabilities together with their high proton conductivity [1]. The conductivity of fully hydrated Nafion® membranes plays a key role in the performance of PEM fuel cells.

Many groups have previously studied the conductivity of Nafion® membranes and a large quantity of data has been published. The main difficulty in the analysis and comparison of these works is related with the utilization of different measuring methods. It is very difficult to rationalize all these data, but it appears clear that conductivity measurements are influenced by a number of parameters such as: (a) cell geometry, (b) technique employed, (c) electrolyte and (d) sample preparation method [2]. Moreover, the hydration of the material has also introduced differences that are well known in the conductivity measurements. So, the method to obtain the conductivity has to be taken into account.

On the other hand, there are several strategies to provide satisfactory proton conductivity and fuel cell performance. In the optimization to reduce the resistance of the membranes is usual to reduce the thickness.

The purpose of the present work was to study and to rationalize the experimentally observed increase of Nafion conductivity with membrane thickness that has also been obtained by other authors [2-4].

2. Materials and methods

Nafion polymer iso-propanol solutions were obtained from Ion-Power (USA). Adequate amounts of the solution were cast on Petri dish in order to obtained adequate thickness of the membranes. Solvent evaporation at 70ºC during 24 h, and annealing of the membrane at 125 ºC during 90 min were followed.

To measure the ionic conductivity of the membranes, they were conditioned by washing with water, H2O2 and diluted HCl, in hot conditions.

Ionic conductivity measurements were performed in a Zahner IES, in a frequency range of 1 Hz – 499 kHz, by sandwiching of the sample between two gold electrodes of 20mm of diameter at 2 bars of pressure and 90 ºC.

3. Results and discussions

Ionic conductivity of one-hundred membranes was studied. Measurements were obtained following Eq. 1,

$$\sigma = L / (R * S) \qquad Eq.1$$

where, σ (S/cm) is the conductivity, L (cm) is the thickness of the membrane, R (Ω) is the resistance, and S (cm2) the measured area.

Obtained results are in agreement with those recently published by Tsampas *et al*. [4]. They were found that the conductivity of Nafion contains two components, one due to proton migration in the aqueous phase, the other due to proton tunneling between adjacent sulfonate groups in narrow pores.

In the present study, several membranes with different thickness were synthesised and their ionic conductivity was measured. In Fig.1 is shown the correlation between ionic conductivity and thickness of cast membranes. Results were fit to a liner regression with a coefficient of adjustment of R = 0.94.

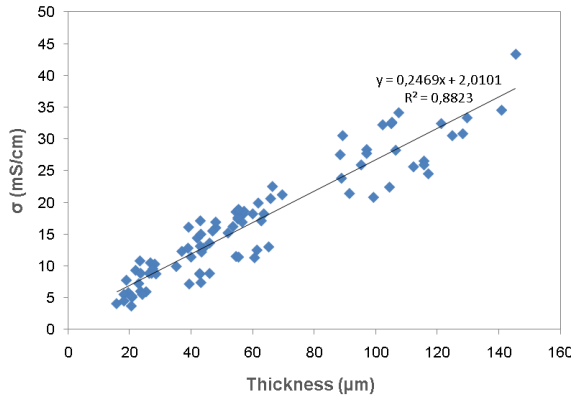

Fig.1. Variation of ionic conductivity with the thickness of the Nafion cast membrane.

4. Conclusions

The ionic conductivity value of Nafion cast membranes increases linearly with the membrane thickness in the range of 20 to 150 µm. This effect shows that a skin conductivity layer could be produced.

smadriga@una.ac.cr

Introduction: Collagen is the most abundant extracellular matrix (ECM) constituent of nature, dermis and scaffolds made from collagen exhibit weak antigenicity, biodegradability, and superior biocompatibility (haemostatic and cell-binding properties) by comparison to the synthetic polymers, such as poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and polyethylene terephthalate (PET). As a scaffold, collagen-based materials in the form of a sponge have been considered the most popular 3D scaffolds for dermal regeneration. Recently, much attention has been given to utilize chitosan in biomedical applications, for example, a wound healing agent, bandage material, skin grafting template, hemostatic agent, hemodialysis membrane and drug delivery vehicle. Chitosan has been applied to conduct ECM formation in tissue regenerative therapy. The superior tissue compatibility of chitosan may primarily be attributed to its structural similarity to glycosaminoglycan in ECM. Chitosan has been reported to be biocompatible, bioabsorbable and particularly, is considered a good wound-healing accelerator. Importantly, the oligomers of chitosan degraded by tissue enzymes were found to be of benefit to regeneration of the skin tissue of wound areas.
We isolated chitosan from native shrimp waste streams and collagen from tilapia skin waste; composite materials were successfully obtained by mixing chitosan with collagen at different molar ratios. Chitosan-collagen composites were formulated as a 3D sponge-like scaffold, applying previously developed methodologies involving solvent casting and freeze drying. Chitosan-collagen 3D scaffolds were characterized according to its water uptake capacity, thermal behavior (DSC) and morphology (SEM).

Materials and Methods: *Scaffold preparation:* Chitosan solution (2%, w/v) was slowly dropped into collagen suspension to make a chitosan-collagen composite mixture with a final chitosan concentration of 10% (wt chitosan/wt collagen). After driving out the air bubbles under vacuum, the collagen-chitosan blend was poured into glass molds and then freeze-dried to produce a porous composed matrix of collagen and chitosan.

Results: Chitosan binds physically to collagen by hydrogen bonding interactions, driven by their available amino and hydroxyl groups. This interaction allows for developing stable biomaterials, such as nanoparticles biomembranes, biofoams and tissue scaffolds. Figure 1 shows a picture, for illustrative purposes, of a chitosan-collagen sponge-like 3D scaffold. Thermal analysis of the chitosan-collagen 3D scaffolds by TG showed that chitosan-collagen biocomposite behavior was intermediate between both of its constituents (figure 1).

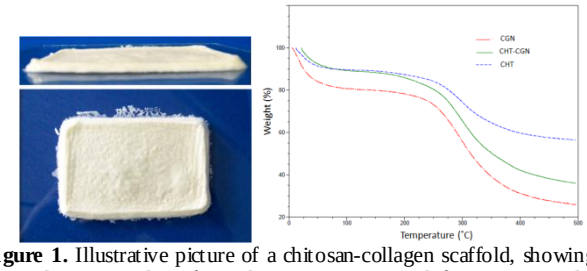

Figure 1. Illustrative picture of a chitosan-collagen scaffold, showing its crossed (top) and surface (bottom) sections (*left picture*) and TG thermogram for chitosan (CHT), collagen (CGN) and CHT-CGN composite 3D-scaffold (*rightfigure*).

SEM micrographs showed a change on the surface morphology of chitosan biomembranes when conjugated to collagen (figure 2), as evidence by the irregular surface appearance and the increase in porosity of the composed 3D-scaffold. Chitosan bioconjugation to collagen may provide a greater crosslink density; this effect may be driven by the higher number of potential interactions available between both macromolecules (hydrogen bonding and/or electrostatic interactions).

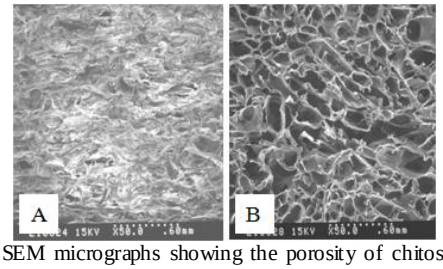

Figure 2. SEM micrographs showing the porosity of chitosan (A) and chitosan-collagen (B) 3D-scaffolds.

Conclusions: Chitosan-collagen 3D porous scaffolds for tissue engineering have been successfully optimized and characterized according to its thermal behaviour (TGA and DSC), porosity and morphology (SEM). We are currently starting cell growth studies on the scaffolds using model epithelial cells. On the other hand, chitosan-collagen hydrogels have been formulated with different active agents (drugs, natural and cosmetic compounds). Results obtained so far indicate that chitosan-collagen sponge-like bioconjugates can be considered as suitable 3D scaffold systems for tissue engineering and drug delivery. In general, biopolymers research by POLIUNA allows concluding that shrimp and tilapia waste streams are suitable sources for added-value derivatives with potential for innovative biomedical applications.

Studies on toughening of polylactic acid by melt-blending with thermoplastic polyurethanes

khhsieh@ntu.edu.tw

Poly(lactic acid) (PLA) is a widely used polymer in our daily life which has received increasing attention in the recent decade for its originating from renewable resources and its potential biodegradability. PLA exhibits high tensile strength (~58MPa) fulfils the packaging industry's requirements for most of the rigid objects but its low elongation at break (4~7%) limited the polymer to be utilized to form bags from blow-molding process or used as tough materials.

In this study, a series of thermoplastic polyurethanes (TPUs) were synthesized from reacting 1,6-hexamethylene diisocyanate (HDI) with three different types of polyols (Poly(ethylene glycol) adipate (PEA), Poly(butylene glycol) adipate (PBA) and Polycaprolactone (PCL)) and 1,4-butanediol. The obtained TPUs were utilized to toughen the commercial polylactic acid (PLA) through melt-blending process in the Brabender at 175°C. Mechanical properties, thermal properties and toughening mechanism of the polymer blends were investigated. The polymer blends were characterized as an immiscible system due to their two separate glass transition temperatures obtained from the differential scanning calorimeter (DSC) analyzer. The mechanical properties of the PLA/TPUs blends were found to be influenced by the crystallinity and crystallization speed of the added TPUs. The PLA/TPUs blends were more flexible and tough materials during the tensile testing and the necking-formation also can be observed.

When PBA derived TPUs was blended into the PLA at 10wt% content, the tensile strength and elongation at break was increased from 58MPa to 81.6MPa and 7% to 144% respectively. Therefore, the proposed PLA/TPUs blends were almost promising for fabrication of biodegradeable blow-molding bags and tough materials.

Keywords: Poly(lactic acid) (PLA), thermoplastic polyurethanes (TPUs), biodegradeable, melt-blending process

Multifunctional PDMS-PEG Coatings for the Finishing of Cotton

Ramona Ronge, *A. Körner*, *M. Möller*

DWI an der RWTH e.V., Aachen (Germany)

ronge@dwi.rwth-aachen.de

Their extraordinary combination of hydrophobic properties with low glass temperature, high elasticity and chain flexibility distinguishes silicones significantly from other synthetic polymers. Due to these properties they provide surfaces with low surface tension, low adhesion and high dewetting potential and therefore, they are widely used in the textile industry to improve the garments´ performance and to enhance soft handle, silk like gloss, soft and graceful flow and water repellence. Furthermore, silicones can improve sewability, abrasion resistance and crease recovery of the treated textiles.[1] Classical silicone softeners provide an unmatched soft handle but they also contribute to the water repellency of the surface and impair the moisture management of the garments. Another important aspect is the permanence of the silicone finishing both on textiles.[2],[3]

Aim of this work therefore was to design hydrophilic polydimethylsiloxanes (PDMS) endowed with reactive groups to provide a covalent attachment to the surfaces of cotton fibres. Commercially available PDMS with a comb like structure bearing hydrophilic ethylene- and propylene oxide side chains with hydroxyl end groups were used to implement the combination of hydrophilic properties and provision of soft handle. Functional groups were inserted in a polymer analogous reaction into the side chains by reaction with isocyanatotriethoxysilane.[4] Triethoxysilane groups are then available to react either with the hydroxyl groups on the cotton surface or with other triethoxysilanes to build a network at the fibre surface (see figure 1).

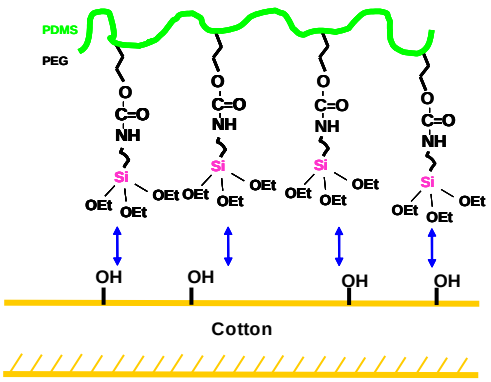

Figure 1: Concept of covalent attachment.

The successful conversion of the commercially available PDMS-PEG copolymers with isocyanatotriethoxysilane was confirmed by infrared spectrometry. ^{1}H-NMR spectroscopy proved that the degree of functionalization was nearly complete.

Cotton fabrics were finished with the functionalized silicone. For this purpose, an aqueous emulsion of the silicone with the surfactants Imbentin T060 and T120 was prepared. The cotton fabric was immersed in the emulsion for 20 min at 60°C with a liquor ratio of 1:20.

To check the permanence of the treatment the fabrics were twice washed with water. The composition of the elements on the fibre surface was analyzed by XPS. The results before and after washing are shown in figure 2. The data shown were corrected by subtraction of the blank values.

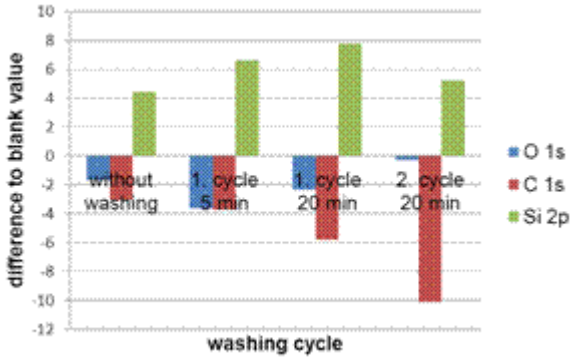

Figure 1: Permanence of the functionalized silicone on cotton.

The silicium content on the surface serves as a measure of both the presence and the permanence of the finishing. A decrease in the silicium content after washing was not determined. Thus a permanent modification was achieved.

The hydrophilic characteristic of the finished cotton were proved in a wetting test. Depending on the portion of PDMS in the copolymers, an increase of the hydrophobic character after washing was found.

The PDMS-PEG copolymer functionalized with isocyanatotriethoxysilane was proven to achieve a covalent attachment on the cotton surface. It is possible to apply the reactive silicone from aqueous emulsion. The functionalization of silicone with triethoxysilane has a positive impact on the substantivity and permanence of the finishing. However the desired hydrophilic character of the functionalized PDMS-PEG still has to be designed by variation of the PEG portion.

(email: jean-marie.raquez@umons.ac.be)

Introduction

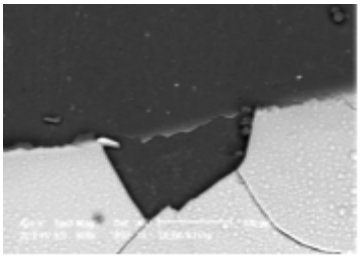
In osseointegration applications, pseudowollastonite (psW), a silica-based polycrystalline ceramic (α-$CaSiO_3$)[1,2] has been suggested as a bone substitute material for bone regeneration. psW is bioactive in physiological solutions as SBF or in cell-culture media by forming a bioactive HA layer onto its surface. However, during the dissolution of psW in physiological medium, a fast alkalization of the medium occurs due to the important release of Ca^{2+} and $(SiO_4)^{4-}$ ions, being harmful for the *in-vitro* or *in-vivo* applications. Hence, **this contribution aims at reporting the osseointegration studies composites made of psW and poly(L,L-lactide) (PLLA) in osseointegration**[3]. Design of such composites combining a bioresorbable semi-crystalline PLLA with psW offers an exceptional opportunity to tailor the release of the bioactive ions and also their physical and mechanical properties. These composites were straightforwardly prepared by melt-blending in a microcompounder. To modulate their bioactivity, amphiphilic poly(ethylene oxide-*b*-L,L-lactide) (PEO-*b*-PLLA) block copolymers were added to these composites. The bioactivity of the composites was evaluated by soaking them in a physiological fluid, followed by *in-vitro* and *in-vivo* studies.

Results & Discussion

Bioactivity Studies

The bioactivity and osteoconductivity of PLLA/psW(20%)-based composites is studied in view of a future application in osseointegration. Initial psW-based composites (20 wt% psW) were successfully prepared from PLLA and psW by a melt-blending process. These composites are found to be bioactive as they form an HA-like layer at the composite surface after 16 weeks of immersion in SBF. Hence, an amphiphilic copolymer was added to the initial composites to increase the hydrophilicity of the composite surface and to accelerate the HA formation and adhesion. The compatibilization of PLLA/psW(20%)-based composites with 15 wt% PEO-*b*-PLLA block copolymer **(**M_{nPEO} = 5000 g/mol; M_{nPLLA} = 7000 g/mol**)** allows to significantly reduce the time to form in vitro an HA top layer (~10µm) to 1 week (Figure 1). The enhanced hydrophilicity of the composites also improves the adhesion of the HA layer.

Figure 1. SEM image of a cross-section of the PLLA-based composite with 15 wt% PEO-b-PLLA block copolymer after



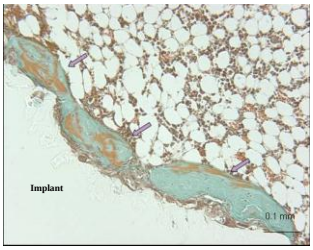
In vitro Studies

The PLLA/psW(20%) composite added with 15wt% PEO-*b*-PLLA block copolymer nor its degradation products are not toxic for osteoblastic SaOS-2 cells under the studied experimental conditions. Only a limited number of dead cell are observed, attesting that the presence of the by-products of degradation has no negative effect on cell viability *in-vitro*.

In vivo Studies

The effect on bone growth was studied *in vivo* using a rat tibia model, showing that the PLLA/psW(20%) composite added with 15wt% PEO-*b*-PLLA block copolymer is a biocompatible material as no inflammation occurs when implanted *in vivo*. Moreover, the composite shows to be permissive as it supports the formation of new bone (Figure 2).

Figure 2. Histological section of the composite when implanted in tibia's of rats (the implant is highlighted).



Conclusions

In conclusion, these composites show to be permissive for bone-regeneration results. These promising in vitro and in vivo results are encouraging to perform further studies to improve these bioactive

Onion-Like Superabsorbent Microspheres with PS-DVB Core and PAA-b-Crosslinked(PMMA) Capsules via SI-ATRP

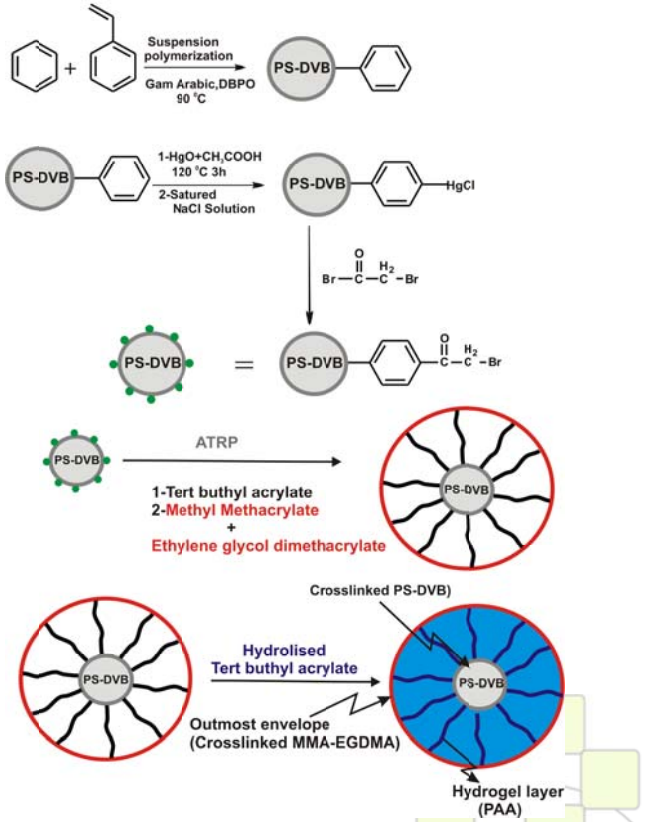
Ahmet Ince, Bunyamin Karagoz, Niyazi Bicak

Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

ahmetince85@gmail.com

Introduction: Superabsorbent hydrogels are loosely crosslinked polyelectrolyte's capable of water sorption as high as 100-1000 times of their own weights[1]. Having extensive use in our day-life, these materials found billion dollars of global market. Although sanitary napkins and baby diapers are the main areas of their use, these also have many potential applications in other fields. Production these materials is largely based on poly (acrylic acid)'s or its salts. Optimization of water diffusion and gel-blocking effects are problematic and crucial issues in their large-scale manufacturing. To avoid these difficulties in the present work, we have targeted to prepare crosslinked PS-DVB (10%) microspheres surrounded by bilayer-capsules consisting of poly(acrylic acid)-*b*-crosslinkedpoly(methyl methacrylate). Such a structure was generated by the reaction sequences outlined in Scheme-1.

Swelling ratios of the hydrogels is inversely proportional to the crosslinking densities. In this work we have targeted to attain maximum swelling ratios without using additional crosslinker for the poly (acrylic acid) segments. The resulting structure so obtained was expected to behave as micro-pools accommodating large amounts of water.



Scheme-1 Reaction sequences for preparing onion like water sorbent.

Result and Discussion: In the first step bromoacetyl groups were introduced to ST-DVB microspheres as ATRP initiator to create non-hydrolysable linking with surface brushes[2]. Sequential ATRP of *tert*-butyl acrylate and MMA and following selective hydrolysis of PBA block yielded superabsorbent capsules.

Experiments showed that, swelling of the resulting material is pH-dependent and equilibrium swelling ratios in neutralized form is proportional to thickness of PAA block and reaches to 200-220. Swelling rate of the onion-like superabsorbent did not change practically, upon standing in air atmosphere, indicating anti-gel blocking effect of the outmost PMMA layer.

Conclusion: Since block lengths of the poly(acrylic acid) layer can tuned up by surface density of the initiation sites and polymerization time, one can attain onion like superabsorbent materials with predetermined swelling capabilities.

marian.corres@ehu.es

The improvement of polymer matrix properties based on synergetic advantage that offer the addition of fillers of nanoscale dimensions is an area of primary interest. In the field of polymer fillers, clays have an outstanding position, because they have a structure of parallel layers that, in suitable conditions, can be delaminated into layers of nanometric size (1). The extent of compatibility between clay and matrix seems to be the most important factor that determines the delamination degree. For this purpose the inorganic surface of the clays can be organically modified to have more affinity with the organic polymeric matrix. In these sense the organic modifier has a double role, for one side it can expand the interlaminar space providing polymer chains diffusing into clay galleries and for other side it can favour specific interactions with polymer matrix. Consequently, the election of organic modifier is of primary importance to reach a good degree of dispersion and finally, to achieve improvement of properties derived of extremely high surface contact between filler and polymer resulting of nanoscale dispersion.

Attending to the above request the poly(hydroxy ether of bisphenol A) also known as phenoxy resin was selected as polymer matrix. It is an amorphous thermoplastic of linear chain containing a pendant hydroxyl group in its repeat unit, so phenoxy resin exhibits proton donor characteristics when interacting with fillers.

As layered clay was selected the vermiculite (VMT) and as organic modifier methyl, tallow, bis-2-hydroxyethyl, quaternary ammonium salt (known as Ethoquad) with the aim of promote specific interactions with host polymer.

Nanocomposites of phenoxy resin and VMT/Ethoquad with different clay content (2, 5, and 10 wt%) were prepared by melt extrusion using a co-rotating twin-screw extruder-kneader. The rotating speed of the rotor, the mixing time, and the temperature were fixed, respectively, at 200 rpm, 10 min, and 180 ºC.

Differential Scanning Calorimetry (DSC) of VMT/Ethoquad and nanocomposites was carried out to understand the clay dispersion in the polymer matrix. The quaternary alkyl ammonium salt exhibits endothermic peak, corresponding to melt transition during first heating (2). Therefore, analysing the thermal behaviour of the surfactant could aid to prove if the organic modification has taken place.

The DSC scans corresponding to Ethoquad sample show multiple endothermic peaks that confirm the heterogeneity of surfactant crystalline structures. Regarding the scans of the organically modified vermiculite the melting transition persist; indicating the possible intercalation of ETO into the clay layers where the tallow chain remain in a ordered packing (form). However the scan corresponding to matrix filled with 2%, 5% and 10% of organically modified vermiculite do not show any melting peak. This behaviour can be explained assuming that some exfoliation has been reached in the phenoxy matrix and Ethoquad is not constrained into vermiculite layers.

In order to prove the level of dispersion of VMT-Ethoquad within phenoxy matrix, a phenoxy/VMT-Ethoquad nanocomposite prepared by melt extrusion and a simple mixture of phenoxy and VMT were dissolved in chloroform, respectively. Whereas the simple mixture exhibits a precipitated phase, the nanocomposite shows a more transparent dispersion, proving that VMT-Ethoquad is well dispersed within the matrix.

Nanocomposite morphology was directly observed by Transmission Electron Microscopy (TEM). Microphotographs show that compositions of 2%, 5% and 10% of VMT-Ethoquad were homogeneously dispersed in the phenoxy matrix. Intercalated and exfoliated morphology were observed indicating that abundant delamination has taken place, however some tactoids were also present principally in 10 wt% composition nanocomposite. Probably the organic modifier containing hydroxyl groups promote the compatibility

The freeze-fractured surfaces of pure phenoxy and the nanocomposites were comparatively examined using SEM. Pure phenoxy resin exhibits a relatively smooth fracture surface. The SEM pictures of nanocomposites show a rougher surface, indicating that the presence of nanoclay layers forced the cracks to propagate along a very tortuous path. This result indicates that there is good interfacial adhesion between the clays and polymer and the transfer of stress to the clay layers.

Quantum-chemical study of the low molecular polyethylene fluorination

*Lidia Ignat'eva, Vyacheslav Bouznik

[a]Institute of Chemistry, FEB RAS, pr. 100-letia Vladivostoka 159, Vladivostok, 690022 Russia A.A. Baykov Institute of Metallurgy and Material Science RAS, Moscow, Russia

ignatieva@ich.dvo.ru

Fluoropolymers occupy an important place among polymer materials and are assigned to functional materials due to their many applications. The low molecular specimens, that already have practical applications for coatings, nanofilms, composites and nancomposites, have attracted considerable interest among varying fluoropolymers. One of ways to obtain the low molecular fluoropolymers is fluorination of hydrocarbon materials, such as paraffin and low molecular polyethylene. Quantum chemical calculations can be a good tool to study the processes of formation of these polymers. With a high degree of confidence you can get information on how to modify material, topological parameters of these systems, the preferred configurations and, finally, to a great extent help in the interpretation of experimental data obtained by the methods of vibration spectroscopy, NMR, and XPS which are commonly used to control the process of preparation of such polymers and study the molecular structure of the resulting materials. The results of quantum chemical calculations of the model system $C_{10}H_{22}$ with successive substitution of hydrogen by fluorine atoms are presented in this work. The energy of fluorination process, topological parameters, $NMR^{19}F$, $NMR^{13}C$, $NMR^{1}H$ and vibration spectra of model systems of $C_{10}F_nH_{22-n}$ (n = 1-22) were calculated. The nature of the signals in the $NMR^{19}F$, $NMR^{13}C$ spectra and band assignments in IR spectra of the calculated model molecules were made. *Ab initio* Hartree-Fock (HF, basis of 6-31G)
and density functional (DFT (B3LYP, basis of 6-311+G(d)) methods was used for calculations. The calculation method was adopted by the carried out test (molecules with known parameters) calculations. The obtained results are very close to experimental data for compounds which these molecules simulated.

Conclusion

The obtained calculations showed.
- At the fluorination of the polymer chain the intrachain substitution of hydrogen to fluorine gives the most stable configuration and the both fluorine atoms belong to the common carbon.
- At a partial fluorination of the polymer the new bands corresponding to vibrations of the CF, CF_2, and CF_3 groups appear in the vibration spectra. The structure and position of the bands, that characterize the vibrations of hydrocarbon groups, change due to redistribution of electron density in the whole molecule at substitution of hydrogen to fluorine. Noticeable changes in the IR spectrum occur even in the region of stretching vibrations of C-H at 3000-2800 cm^{-1} (Fig.1), therefore, one can easily discern whether the system has formed by a composite of the core-shell, or modified form of the polymer is created.
- $NMR^{19}F$ and $NMR^{13}C$ spectra differ at changing in number of substituted hydrogen atoms and the place of substitution in the polymer chain. Differences are rather obvious and in the $NMR^{19}F$ spectra and $NMR^{13}C$ spectra (Fig.2), therefore the NMR spectra can be an indicator of the configuration of the studied system and degree of chain fluorination.

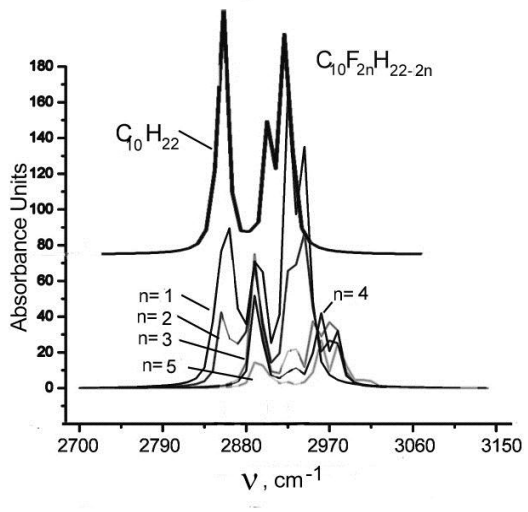

Fig.1. Calculated IR spectra of model molecules: $C_{10}H_{22}$ and $C_{10}F_nH_{22-2n}$

The poly(L-lactide) (PLLA) is a biodegradable and a biocompatible material that can be produced from renewable resources, and that exhibit mechanical properties comparable to those of commercial thermoplastics. PLLA is a semicrystalline polymer whose bioresorption and mechanical properties depend on the crystalline morphology and crystallinity degree (1). One of the most interesting ways to modify the polymer properties is the addition of nanoclays. This addition improves polymer properties, and in some cases, it leads to a unique combination of properties. The property improvement is highly dependent on the degree of dispersion in the polymeric matrix (2). However, the organophilic character or many semicrystalline polymers prevents sufficient interaction between the polymer and clay resulting in poor dispersion of the naturally polar clay within the hydrophobic polymer matrix. The increase of the clay dispersion degree can be achieved by means of organic modification of the clay. The election of the organic modifier is of primary importance to obtain a good level of matrix-clay interactions. These interactions affect chain mobility and consequently, the crystallization kinetics can be strongly affected (3). In addition to the nature of both, clay and polymer, components the obtained nanocomposite morphology depends on the preparation conditions.

In this study, nanocomposites based on poly(L-lactic acid) (PLLA) and an organomodified vermiculite (OMVMT) were prepared by melt processing. The effect of melt processing conditions on the degree of dispersion and thermal properties of the nanocomposites was analyzed. The melt processing was carried out at two different rotating speeds: 80 and 150 rpm.

The morphology of nanocomposites was analyzed by X-ray diffraction (XRD) and transmission electron microscopy (TEM) and their thermal properties by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA).

The XRD pattern of the nanocomposites were interpreted taking into account the position of the basal peak which depends on the distance between two adjacent layers. The basal peak of the OMVMT appears at 2θ=2.08 º, whereas the nanocomposite basal peak shows a shift to lower angle degree and in adition the peak decreases in intensity and broadens in peak breadth. This result suggests that there are interactions in between the polymer and clay that can lead to intercalation or exfoliation.

The morphology of OMVMT within the polymer matrix was characterized by TEM. The TEM micrographs reveal a mixed intercalated-exfoliated morphology without significant differences in the nanocomposites obtained at the two melt-mixing processing conditions.

The thermal stability of neat PLLA and its nanocomposites was analysed by TGA. The nanocomposites showed a slight increase in thermal stability comparing with neat PLLA. The enhancement of the thermal stability could be attributed to the exfoliated OMVMT layers dispersed randomly in PLLA matrix at nanoscale level, which are impermeable to volatiles, rendering more difficult the diffusion of volatiles from thermally decomposed products. DSC scans reveal that T_g and T_m are not influenced by the presence of clay. However, the nanocomposites show a significant increase in the enthalpy of crystallization and melting comparing with the pure PLLA (Fig.1). The fact that the crystallization is favoured by the organomodified clay can be a consequence of the good dispersion level achieved that enhances the nucleant effect promoted by the clay. No significant differences were observed in crystallization and melting enthalpies with the different melt-mixing processing conditions employed.

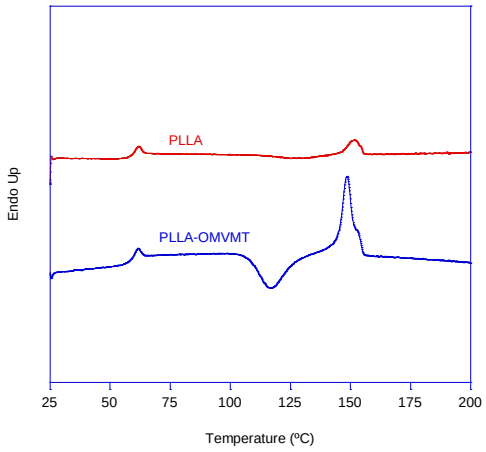

Figure 1. DSC heating scan of pure PLLA and PLLA with OMVMT.

cedric.cochrane@ensait.fr

Introduction

The aim of this work is to develop a smart flexible sensor adapted to textile structures, able to measure strain deformations of a parachute canopy during a drop test. It is therefore important that the integration of this sensor does not modify the general behaviour of the parachute.

Materials and Methods

A piezoresistive sensor based on a Conductive Polymer Nano-Composite (CPC), fully compatible with a textile substrate and its general properties, has been developed in our laboratory. The material used for the sensor is based on a thermoplastic elastomer (Evoprene)/carbon black nano-composite.

The optimized preparation procedure of the sensor and its deposition on a parachute canopy (Polyamide 6.6 lightweight fabric, Figure 1) are fully described.

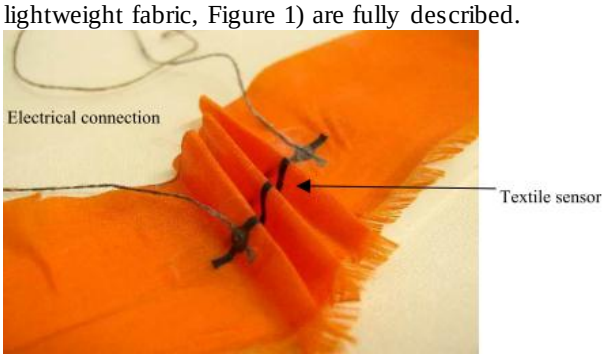

Figure1: CPC sensor on fabric.

Results and discussion

The electromechanical characterization (i.e. electrical response to mechanical stress) is performed to demonstrate the adaptability and the correct functioning of the sensor as a strain gauge on the fabric. In particular the effects of strain rate (ranging from 10 to 1000 mm/min, Figure 2) and of repeated elongation cycles (up to 5) on the sensor behaviour are investigated. The results show that strain rate (up to 1000 mm/min) seems to have only little influence on sensor response.

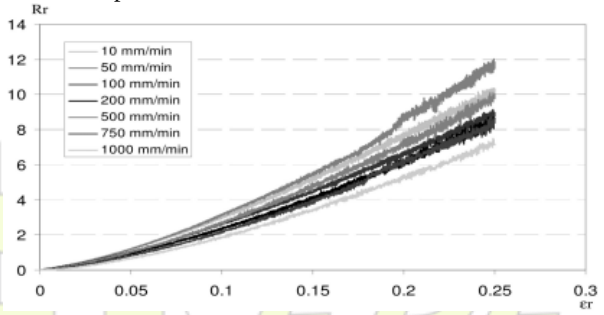

Figure 2: Relative resistance of sensors vs. elongation for different strain rates.

The average (linear) gauge factor K obtained in the strain range $0<\varepsilon r<0.1$ is 31. This is a very high value for a piezoresistive sensor. Recorded data can be fitted with better accuracy by a simple power law relation (Equation 1):

$$Rr = r.\varepsilon r^{p} \qquad \text{Equation 1}$$

Where Rr is relative electrical resistance of the sensor (Equation 2) and εr, elongation of the sensor.

$$Rr = (R-R_0)/R_0 \qquad \text{Equation 2}$$

Where R_0 is initial electrical resistance of the sensor.

This calibration law (Equation 1) will be used to evaluate the canopy fabric deformation during the real drop test.

As expected, when submitted to repeated tensile cycles, the CPC sensor is able to detect accurately fabric deformations over each whole cycle, taking into account the mechanical behaviour of the textile substrate.

Finally, the influence of environmental factors, such as temperature and atmospheric humidity, on the sensor performance is investigated. The results show that the sensor's electrical resistance is particularly affected by the humidity factor. Complementary information is given concerning the non-effect of aging on the global resistivity of the CPC sensor.

Finally, our sensor was tested on a parachute canopy during a real drop test: the canopy fabric deformation during the critical inflation phase was successfully measured.

Conclusion

The use of the CPC sensor in a real flight test has demonstrated that the deformation of a parachute canopy could be successfully measured with CPC sensor. This flexible sensor proved to resist the particularly drastic packing conditions of the parachute, the drop, the inflation, and the landing phases. Data from the CPC sensor were coherent with data provided by other conventional sensors and with literature. The results showed that elongation of the fabric during inflation was less than 0.09 mm/mm.

Influence of the aminopropylisobutyl POSS nanoparticles on the thermal behavior of isotactic polypropylene

R. Bouza, C. Ramírez, L. Barral, B. Montero, R. Bellas

Grupo de Polímeros, Dpto. de Física, E.U.P. Ferrol, Universidad de A Coruña, Avda. 19 de Febrero s/n, 15405 Ferrol, Spain

labpolim@udc.es

Introduction

Design of new composites based on polyhedral oligomeric silsesquioxane (POSS)/thermoplastic nanostructure blends is receiving a great attention from the plastic industries. The use of POSS cages as reinforcement into thermoplastic matrixes is very interesting; hence it allows obtaining new materials that may result in increase temperature usage, surface hardening or increased flame resistance. These enhancements have been found to apply to a wide range of thermoplastics and some thermosets systems [1].

Material and methods

In this work, the aminopropylisobutyl POSS was added by melt blending with isotactic polypropylene (iPP) at several concentrations and the dynamic crystallization behavior was studied by means of differential scanning calorimeter. Nevertheless, the poor interfacial adhesion between the matrix and the filler makes get worse the final properties of the nanocomposites. In order to improve this behavior, a coupling agent was added to the formulations. The maleic anhydride – modified PP (MAPP) was used as coupling agent to increase the affinity between the POSS and the matrix and improve the dispersion of the filler.

Results and discussion

The figure 1 shows the non-isothermal crystallization behavior of iPP and iPP/POSS composites as function of POSS content at a cooling rate of 10 ºC/min. It was observed an increase in the crystallization temperature in composites. The POSS acts as nucleating agent when it is incorporated into the iPP matrix in small amounts.

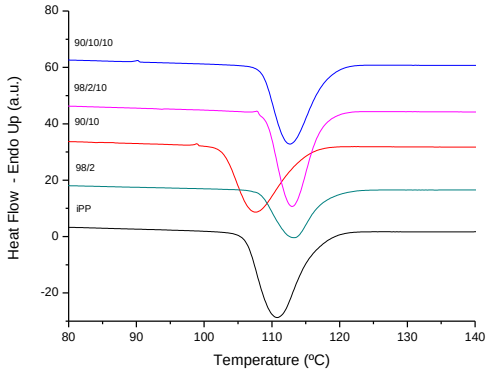

Figure 1: Crystallizations exotherms for the indicated samples.

However, the incorporation of greater amounts of POSS means to loss of nucleating effect. This may be due to the formation of clusters in the 90/10 binary system, as can be seen by SEM. In ternary systems with MAPP, this coupling agent does not affect the nucleation effect, since the crystallization temperature in the cooling rate studied, does not vary with respect to binary mixtures. But, it is important to note, that the MAPP provides more regular and stable morphologies, so that the POSS is better distributed in the polypropylene matrix and thus, there is an effect of nucleation in the sample 90/10/10. In this sense, several authors [2] indicated that a good dispersion of POSS was obtained particularly at low loadings of POSS.

The evolution of the crystallization process from the melt state to the organized state was followed by means of the variation in conversion, figure 2.

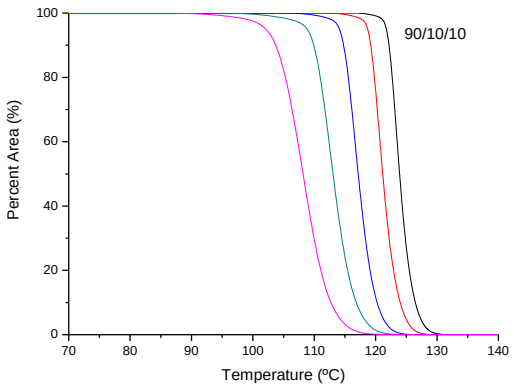

Figure 2: Variation of the conversion for 90/10/10 blend at the cooling rate specified.

The tendency of the conversion curves shows a much accelerated primary crystallization even at the lowest cooling rates. In the ternary blends the presence of the MAPP induces the compatibilization of iPP and POSS acting as an interfacial agent.

Conclusions

The crystallization of the iPP is affected by the presence of the compatibilizing agent. This presence leads to a slightly reduction in the crystallization temperature, indicative of an increase in compatibility.

Introduction

Recently, there is a large scientific and industrial interest in the development of rubber nanocomposites with layered silicates as reinforcements. Due to the nanometric scale of the layered silicate with high aspect ratio and high surface area, good reinforcement is possible at low filler loading compared to conventional fillers. In general, there are two idealized morphologies that can be developed using nanosilicate fillers: (a) intercalated (i.e., silicate layers are partially separated by polymer chains but ordered structure is still retained, and (b) exfoliated (i.e., silicate layers are totally delaminated and disordered). The basic principle of the formation of rubber/clay nanocomposites is that the rubber should penetrate into the intergalleries of clay, so the space between the galleries of the silicate should be accessible to the rubber chains. This is usually achieved by replacing the interlayer cations with ammonium salts. The distance between the silicate layers is greatly enlarged, and the clay becomes organophilic and more compatible with the rubber matrix.

In this work the state of intercalation and exfoliation in styrene-butadiene rubber (SBR) nanocomposites was investigate using infrared spectroscopy (IR), transmission electron spectroscopy (TEM) and X-ray diffraction.

Materials and methods

SBR 1502 (Dow Chemical) and Nanomer® I.30E (Nanocor, USA) were used as the elastomeric matrix and nanoclay, respectively. Nanomer® I.30E contains 70-75% montmorillonite and 30-25% octadecylamine. The curatives used for vulcanization (stearic acid, zinc oxide, 2-mercaptobenzothiazole and sulphur) were of analytical grade.

SBR nanocomposites with 2.5, 5, 10 and 15 phr nanoclay were prepared by compounding procedure followed by a compression-molding at 160ºC. The optimum cure time was determined by rheometry.

Infrared spectra were obtained using an *i*-Series IMAGE infrared microscope coupled to a Spectrum GX 2000 FTIR spectrometer. The spectra were obtained using an attenuated total reflectance (ATR) objective.

Transmision electron microscopy images were taken with a JEOL 1010 microscope with an accelerator voltage of 80 kV.

XRD analysis was carried out with a Siemens diffractometer using a Cu target, with a tube voltage of 40 kV and current of 30 mA.

Results and discussion

The infrared spectra of SBR and its composites contain information both of the component of vulcanized styrene butadiene rubber system as well as the clay filler. The most strongly absorbing region for the momtmorillonite corresponds to a broad feature between 1000 to 1200 cm^{-1} attributed to silicon-oxygen stretching modes. These bands in the Si-O region increase in relative intensity with increasing content of the nanofiller. However, the bands which appear to vary most significantly are three sharp features at around 1536, 1640 and 1397 cm^{-1} which can be attributed to zinc stearate. This component is originated from the reaction of zinc oxide with stearic acid and we have found some evidence that this component migrates during processing. No clear evidence for the formation of new component in the rubber was found, which suggest that the nanoclay does not form any new components. However, the spectral information from the nanofiller was different when it was located in the polymer matrix. A significant variation in the profile of Si-O stretching region was observed. This fact indicates strong evidence for significant exfoliation and intercalation [1, 2]. X-ray patterns and TEM microphotographs confirmed these results. For the SBR/nanoclay composites the diffraction peak corresponding to the clay shifted to lower angles as a result of an increase in the interlayer distance attributed to the intercalation of SBR into the organoclay galleries. Partially exfoliated structures and the formation of aggregates were also observed from TEM micrographs. The length and the thickness of the clay structures were measured as 123 and 8 nm, respectively.

Conclusions

Infrared spectroscopy provided clear evidence for clay exfoliation and migration of zinc stearate to the surface of the samples. The dispersion of the clay and the spacing between the silicate layers revealed the presence of intercalated, aggregated and partially exfoliated structures.

Preparation and characterization of polyethylene nanocomposites including titanium oxide nanoparticles

Paula A. Zapata [a], *Franco M. Rabagliati* [a]

a) Grupo Polímeros, Facultad Química y Biología, Universidad de Santiago de Chile, USACH. Casilla 40, Correo 33, Santiago, Chile.

Introductions

It has been reported that polymer with inorganic materials is considered a powerful method to produce new materials called polymer composites or filled polymers. However, due to the significant development in nanotechnologies in the recent years, nanoscale inorganic materials such as SiO_2, Al_2O_3 and ZrO_2 have brought much attention to this research field. [1] So nanocomposites usually have improved properties compared to neat polymers, such as better mechanical, barrier properties and higher thermal stability. [2,3]

Basically, there are three methods used to produce the polymer nanocomposites: (i) melt mixing; (ii) solution blending; and (iii) in situ polymerization. This late method is perhaps considered the most powerful technique to produce polymer nanocomposites with good distribution and dispersion of the fillers inside polymer matrix.

On the other hand metallocene catalyst has become an important class of catalyst for olefin polymerization of polyethylene, due to the possibility of modelling the molecular structure of the polymers and offers a great versatility and flexibility in the synthesis and control of the polyolefin structure.

In this study, we described the preparation of polyethylene nanocomposites by in situ polymerization using TiO_2 nanospheres synthesized by Sol-Gel method. TiO_2 nano-particles have unique properties such as higher stability, long lasting, safe and broad-spectrum anti-biosis. TiO_2 nano-particles have been especially the center of attention for their photo-catalytic activities. This makes TiO_2 nano-particles applicable in many fields such as self-cleaning, anti-bacterial agent, UV protecting agent and environmental purification. [4]

The TiO_2, monomer and catalyst system (metallocene/MAO) were added to the reactor at the same time, therefore the polymerization was made in the presence of the TiO_2. The effect of the different amount of TiO_2 on the catalytic activity, the thermal, mechanical and antimicrobial properties will be studied.

Results

STEM image and light scattering analysis (**Figure 1**) reveal spherical particles with average diameters of ca. 50 nm with relatively narrow size.

The polymerization results and polymer properties (viscosity, melting temperature) of the synthesized polyethylene with and without TiO_2 nanoparticles are shown in **Table 1**. The catalytic activity for ethylene polymerization in presence TiO_2 nanoparticles presented a slight decreasing in comparison with the resulting for polyethylene without nanoparticles.

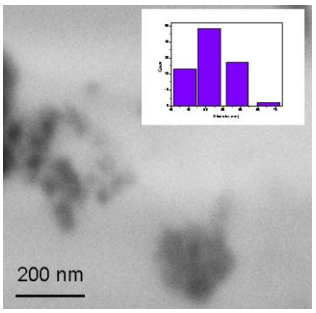

Figure 1. STEM image of TiO_2 particles.

Table 1. Results of ethylene polymerizations using TiO_2 as filler

Reaction	TiO_2 Nps (g)	Catalytic activity (kg mol^{-1} Zr^{-1} h^{-1}bar^{-1})	Tp (°C)	n (dL/g)
1	none	3100	65-68	1.31
2	0.2	1700	60	1.02
3	0.4	2600	60	--

Tp: polymerization temperature, n:viscosity, Polymerization conditions: mol Zr: $3x10^{-6}$; Al/Zr: 1400;T:60 °C. Pressure: 1 bar; reaction time: 30 min.

The incorporation of TiO_2 nanoparticles into polyethylene matrix can generated changes in the final thermal, mechanical and antimicrobials properties which will be studied.

A new way to improve PC/ABS blends: use of nano-sepiolite

Félix C. Basurto[1], *David García-López*[2], *Norky Villarreal-Bastardo*[2], *Juan Carlos Merino*[1,2], *José María Pastor*[1,2]

INTRODUCTION

Blends of PC and ABS offer a wide field of applications to automotive industry, as automobile parts: instrument panels, air-bag covers, consoles, door handles, mirror housings, etc. As a well-known fact, PC possesses interesting properties, such as high heat distortion temperature and impact strength, but shows poor results in strength at low temperatures, chemical resistance and processability; in turn, ABS could provide low cost, good processability and impact strength in a large range of temperatures[1]. The combination of the best properties of ABS and PC has resulted in the development of commercially available blends.

Sepiolite is employed as a reinforcing nanoparticle to improve the thermo-mechanical properties of the polymeric materials[2]. The idea of using sepiolite is to reduce the PC percentage and obtain very similar properties.

The aim of this work is to obtain the best methodology to obtain these nanocomposites. In particular, it is investigated the effect of the modification of sepiolite, the ABS and PC percentages and the best mixing order of polymers and nanoparticle.

MATERIALS AND METHODS

In this work, PC LEXAN 223R matrix was supplied by SABIC, ABS HI-100H matrix was supplied by LG Chem., and both sepiolites, standard without modification and modified with a quaternary ammonium salt (BM2TH) were supplied by TOLSA S.A. (Spain).

Characterisation of microstructural properties of nanocomposites has been carried out by means of microscopic techniques, such as optical and scanning electron microscopy (SEM). The morphology was related to thermo-mechanical properties such as Young's modulus, heat distortion temperature (HDT) and notched Izod impact strength at room temperature. Thermogravimetric analysis (TGA) has been done in order to know the residue left by clay in the nanocomposites.

RESULTS AND DISCUSSION

Several factors could affect the resulting morphology, and hence, the final properties of PC/ABS nanoblends: PC and ABS viscosities, percentages of both polymers in the blend, and processing conditions, among others[3]. These parameters are of great importance in phase inversion, and this phenomenon could be studied by means of scanning electron microscopy (SEM).

SEM microphotographs in sepiolite nanocomposites were also employed to elucidate the real location of clay, because sepiolite fibres could be located in ABS, PC or in the interphase, depending on the method followed during compounding.

Those different methods were designed to obtain PC/ABS nanocomposites, according to four different orders of mixing:

- (ABS + sepiolite) + PC
- (PC + sepiolite) + ABS
- (ABS + PC) + sepiolite
- ABS + PC + sepiolite

All these nanocomposites were elaborated and characterized, in order to define the best way to mix the raw materials, trying to reduce the PC percentage in the blend, with similar properties in nanocomposites.

Introduction

The magnetic nature of the polymeric material is closely associated to the magnetic nanoparticle size. In this scenario, special attention is given to superparamagnetic magnetite (Fe_3O_4) nanoparticles due to its remarkable features, such as biocompatibility, low susceptibility to changes due to oxidation, magnetic retention only when exposed to an external magnetic field and strong ferromagnetic behavior.[1-4]

It is well-known that in suspension polymerization processes each aqueous-dispersed monomer droplets behaves as a bulk microreactor.[5] For this reason, the surface modification of Fe_3O_4 magnetic particles with oleic acid permits a good dispersion of these inorganic nanocharges within the final polymeric particles, which leads to the formation of materials with uniform magnetic properties.

This work focuses on the synthesis of micro-sized polystyrene magnetic beads by *in situ* incorporation of surface modified Fe_3O_4 nanoparticles through suspension polymerization process intended for biotechnological applications.

Materials and Methods

Styrene (polymer grade) was used as monomer in the polymerizations. The suspending agent DENKA POVAL B-24 was kindly supplied by DENKA, Tokyo, Japan. The initiator LUPEROX® 78 (99.4%) was kindly donated by Arkema Química Ltda, São Paulo, Brazil. Nitrogen (99.5%) was supplied by White Martins Ltda, Rio de Janeiro, Brazil. Sodium hydroxide (97%) was provided by F. MAIA (Rio de Janeiro, Brazil), ferric chloride hexahydrate (97%) and ferrous sulfate heptahydrate (99%) were provided by VETEC (Rio de Janeiro, Brazil), hydrochloric acid (36.5-38.0% w/w) was provided by ISOFAR (São Paulo, Brazil) and oleic acid extra pure was provided by Merck (Rio de Janeiro, Brazil). All chemicals were used as received, without further purification.

Synthesis of Magnetic Nanoparticles

Magnetite (Fe_3O_4) nanoparticles were prepared by chemical coprecipitation of aqueous Fe^{2+} and Fe^{3+} salt solution and NaOH solution.[6] Initially, 6.1 g of $FeCl_3 \cdot 6H_2O$ and 3.1 g of $FeSO_4 \cdot 7H_2O$ were dissolved in 125 mL of distilled water and 5 mL of hydrochloric acid and heated to 60 ºC with bubbling of nitrogen gas. The salts and basic solution (60 g/L NaOH) were mixed under vigorous stirring. The temperature was kept constant and equal to 60 ºC for 30 min under atmosphere of nitrogen.

Surface Modification of Magnetic Nanoparticles

The surface of Fe_3O_4 nanoparticles was modified by using oleic acid.[7] 5 g of magnetic nanoparticles were dispersed in 170 mL of distilled water under nitrogen gas and heated to 85ºC. Then, 5.6 mL of oleic acid were added dropwise at a constant rate 0.5 $mL \cdot min^{-1}$ under an inert nitrogen atmosphere. The resulting mixture was maintained under stirring for 30 min at 85ºC.

In-Situ Formation of Magnetic Nanocomposites

The polymerization reactions were carried out in a 250-mL glass reactor (Quickfit®, England) at 85 °C, with a total organic load of 25 wt-%, 3.5 wt-% of initiator (in relation to styrene) and 0.5 wt-% of suspending agent (in relation to water), under an inert nitrogen atmosphere with a constant agitation of 1000 rpm for 4.5 hours. A hotplate IKA® C-MAG HS 7 (IKA® Works, Inc.) equipped with an integrated temperature control, including a Pt1000 temperature probe was used to heat the reaction medium.

Results and Discussion

The weight fraction of nanoparticles determined by thermogravimetric measurements (Shimadzu Scientific Instruments, Maryland, USA) was 1.7, 4.8 and 10.1 wt-%, respectively. It was observed that the thermal stability of the polymers was not improved by magnetic nanoparticles distributed in the polymeric matrix.

Based on the susceptibility classification (Johnson Matthey magnetic susceptibility balance, Pennsylvania, USA), the magnetic nanocomposites behave as paramagnetic materials. It was noted that the magnetic susceptibility increases as the concentration of Fe_3O_4 nanoparticles dispersed in the polystyrene matrix is increased.

It was also observed that the magnetic force is proportional to the amount of Fe_3O_4 nanoparticles dispersed in the polystyrene matrix. When the relative magnetic force is considered, one can observe that the polymeric sample with 1.7 wt-% of Fe_3O_4 nanoparticles presents the best response to the employed magnetic field.

Conclusions

Micro-sized polystyrene magnetic beads by *in situ* incorporation of oleic acid-modified Fe_3O_4 magnetic nanoparticles were obtained via suspension polymerization process. The obtained polymeric materials presented good magnetic behavior, indicating that the modified Fe_3O_4 nanoparticles were successfully dispersed in the polystyrene particles.

Introduction: Dynamics of polymers in ultrathin films is a long standing yet ever stimulating topic of polymer physics. Being inspired by unintentionally observed cracking of such films, we performed systematic studies of crack growth as a function of physical ageing at a temperature close to the glass transition temperature T_g. Cracking/ crazing occurred only after cooling from this elevated ageing temperature to room temperature. AFM inspection showed nano/micro-structures within the cracks consisting of voids and fibrils, indicating plastic deformation similar to crazing. The role of residual stresses was examined by following crack growth and dewetting dynamics through varying molecular weight (M_w).

Materials and Methods: Our results are based on experiments performed on thin polystyrene (PS) films of M_w ranging from 52 to 16800 kg /mol with a low index of polydispersity between 1.04 and 1.15 and of thicknesses varying between 40 and 100 nm. T_g of PS in the bulk is about 103°C. Thin films were obtained by spin-coating polymer solutions directly onto silicon substrates that were coated with PDMS, acting as a non-wettable layer. Cracking experiments were performed at room temperature after ageing at 90°C, i.e. T= T_g-13°C, under vacuum. Isothermal dewetting was studied at 125°C, i.e. T=T_g +22°C. Both processes were followed in real time by optical microscopy. Details of the craze microstructures were inspected by atomic force microscopy (AFM).

Results and Discussion: Cracking/crazing was taking place only after elevated temperature ageing. This has to be contrasted to freshly prepared films which never showed any cracks, even when stored at room temperature for several months. The morphology of voids and fibrils within the cracks largely resembles previous observations of crazes in deformed thin polymer films of similar thickness, probably related to the lack of plastic constraint along the film normal [1,2]. A clearly detectable tip of the craze (Fig. 1b) was found. A stripe-pattern orthogonal to the craze direction hints at periodic 'stiffening' tentatively attributed to heterogeneous stress distribution or possibly strain-hardening close to the craze boundary [3]. For low M_w (52 kg/mol), fibrils within the crazes were closely packed, without noticeable interfibrillar voids (Fig. 1d). In close agreement with previous results[4,5], a linear dependence with a slope of 0.28±0.05 of craze depth with film thickness was found (Fig. 1e) for 4060 kg/mol PS, while the short chain polymer (PS 52 kg/mol) exhibited a slope of about 1, implying that the craze cuts through the whole film. Craze depth and thickness were simultaneously measured by AFM [6], consistent with film thickness values determined by ellipsometry. Interestingly, an extrapolation of craze width vs. film thickness for the shorter polymer intersects the film thickness axis around 30 nm, coinciding with the threshold thickness below which our experiment never resulted in any crack formation, irrespective of molecular weight.

For the higher molecular weight PS (4060 and 16800 kg/mol), a systematic study of crack growth velocity showed a progressive increase with increasing ageing time while for the same films the dewetting velocity decreased with increasing ageing, consistent with earlier findings[7]. In contrast, for 52 kg/ mol PS a decrease in crack growth velocity with increasing ageing time was found while the dewetting velocity was unaffected by ageing, probably indicating the absence of residual stresses for such low molecular weight polymers.

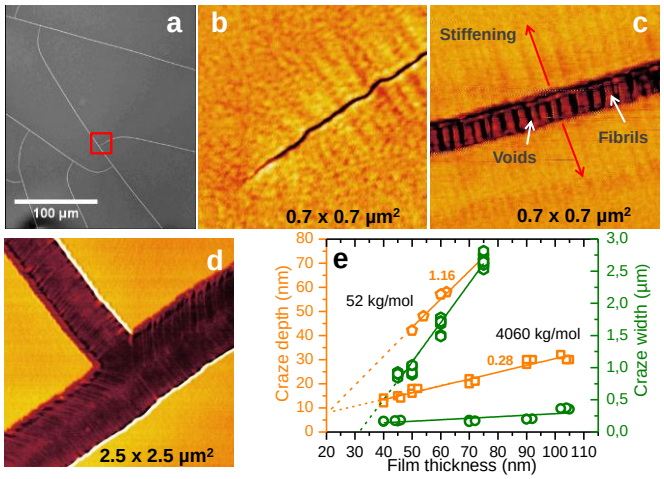

Fig. 1(a) Optical micrograph showing crack patterns formed in a 45 nm thick film of 52 kg/mol PS, aged for 24 hours at 90°C and 3 min at room temperature after quenching. AFM phase images of a 40 nm thick film of 4060 kg/mol PS, aged for 24 hours at 90°C and 2 hours at room temperature after quenching are showing: (b) a crack-tip, (c) that the two sides of a crack are interconnected by regularly spaced fibrils separated by voids and that this craze is bounded by 'stiffening' pattern of perpendicular stripes. (d) AFM phase image corresponding to the marked area in (a). (e) Plot showing the variation of craze depth and craze width with film thickness. Symbols are representing: Craze depth (□, □) and craze width (□, ○) for 52kg/mol and 4060 kg/mol PS, respectively.

Conclusions: We tentatively conclude that physical ageing of such films causes segmental relaxations of non-equilibrated polymer chains. Relaxations are easier and thus faster at the free surface. This introduces a gradient in lateral tension within the film in the direction normal to the film surface. Considering the possibility of generating strong mechanical tension at the film surface due to the formation of a 'crust' during film preparation [8], we may have to consider two antagonistic origins for crack growth: a gradient in stress induced by film preparation, with the highest lateral tension close to the free surface, and the building up of an inverted stress gradient after physical ageing and cooling the film to room temperature. Both gradients are potentially causing the formation of cracks.

Introduction

Exfoliated nanocomposites [1] formed by poly(3,4-ethylenedioxythiophene) and multilayer PEDOT/ poly(N-methylpyrrole), with different concentrations of non-modified montmorillonite or bentonite (MMT), from 1% to 50% w/w, have been prepared by anodic electropolymerization in aqueous solution. Analyses of the electrochemical and electrical properties reveal that the electroactivity of the nanocomposites is higher than that of the individual homopolymer, and that of the multilayer without bentonite. The exfoliated distribution of the clay in the polymeric matrix and the morphology of the prepared materials have been characterized using TEM, X-ray diffraction, SEM and AFM. Standard Sellotape Test [2] has been used to verify the improvement in the adherence of nanocomposites.

Materials and Methods

Monomers and MMT (bentonite) were purchased from Aldrich. Both nanocomposites were prepared by chronoamperometry (CA) under a constant potential of 1.10 V, on a VersaStat II potenciostat-galvanostat using a three-electrode two-compartment cell under nitrogen atmosphere at 25 ºC, from a 10 mM monomer solution in distilled water containing 0.1 M $LiClO_4$ as supporting electrolyte. Steel AISI 316 sheets (4 cm^2 area) were employed as working and counter electrodes, and the reference electrode was an Ag|AgCl electrode. The electroactivity of both the nanocomposites were determined by cyclic voltammetry (CV). A scan rate of 100 $mV \cdot s^{-1}$ was used. The structure and distribution of the clay in the nanocomposites were examined using a Phillips TECNAI 10 transmission electron microscope at an accelerating voltage of 100 kV. X-ray diffraction (XRD) spectra of PEDOT-MMT films were recorded using a Bruker D8 Advance model to 40 kV and 40 mA (λ= 1.5406 Å). SEM images were analyzed using a Focused Ion Beam Zeiss Neon40 scanning electron microscope at 3 kV. Topographic AFM images were obtained with a Molecular Imaging PicoSPM using a NanoScope IV controller in ambient conditions.

Results and Discussion

In the electropolymerization, the current density stabilizes at higher values for nanocomposites that for de polymers without bentonite, indicating that the flow of monomer during the electrogeneration process increases upon the addition of MMT.

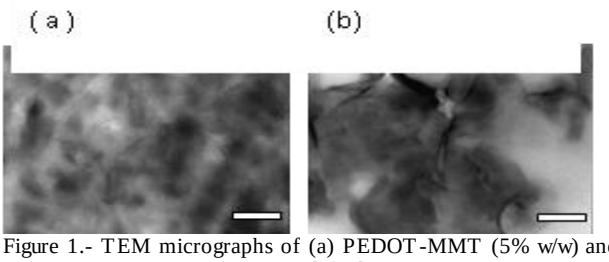

Figure 1.- TEM micrographs of (a) PEDOT-MMT (5% w/w) and (b) PEDOT-MMT (10% w/w). Line length: 100 nm.

TEM micrographs of the nanocomposites reveal that, independently of the clay concentration, MMT is exfoliated into individual platelets within the polymeric matrix. This is illustrated in Figure 1 for the PEDOT-MMT (5% w/w) and PEDOT-MMT (10% w/w).

In some cases, the electroactivity of the nanocomposite is higher than that of the homopolymer and that the multilayer PEDOT/poly(N-methylpyrrole), indicating that the addition of clay can enhanced the ability to store charge of the polymers. It has also been determined that the adhesion of the nanocomposites increases with the percentage of clay.

Conclusions

Conducting polymers-MMT nanocomposites have been prepared by anodic electropolymerization. Structural characterization indicates that the clay is exfoliated in the polymers matrix, which represents a significant improvement with respect to the intercalative structure usually found in conducting polymer-clay nanocomposites. The electroactivity and the adhesion of the nanocomposites, which increases with the concentration of clay, is higher than that of polymers without MMT. This fact indicate that PEDOT-MMT nanocomposites are potential candidates for the fabrication of devices able to store charge.

Introduction:

Polymeric nanocomposites exhibits improved physical proprieties compared to conventional materials as metals, polymeric alloys and thermoplastic composites. This new class of materials has large impact in various industrial segments, mainly in automotive sector due to its low density. This benefit is explained by the small amount of nanoclay added to the polymer matrix compared to common reinforced agents. Because of easy processing, most of the research activities have focused on preparation by melt compounding. Some parameters can influence nanocomposite formation, as: clay surface treatment, processing conditions and polymer matrix. ABS poly(acrylonitrile-butadiene-styrene) is a large volume engineering plastic and relatively low cost. Nanocomposites of ABS are being studied to improve mechanical and flammability properties[1,2]. The aim of this work is to investigate the effect of a binary mixture of organically modified montmorillonite (OMMT) on the properties of ABS.

Materials and Methods:

Two commercial OMMTs (Southern Clay), one with methyl, tallow, bis-2-hydroxyethyl quaternary ammonium (Cloisite 30B) and one with dimethyl, dehydrogenated tallow quaternary ammonium (Cloisite 20A) were used in single and binary mixture with ABS (Terluran GP35, BASF). The MFR measured was 10.5 g/10 min (ASTM D1238, 230°C/3.8 kg). All the materials were dried at 80°C for 4 h. The ABS/OMMTs (4 wt%) were prepared by melt intercalation on a co-rotating twin-screw extruder (Figure 1), Coperion ZSK 26Mc, L/D 44, screw speed 120 rpm (170 to 210°C), and two feeding rates 4 and 8 kg/h to obtain two levels of torque (40 and 75%, respectively). XRD analyses were done in a Rigaku DMAX 2200m Cu-Kα (40kV, 30mA), step of 0.05, 1s time and 2θ from 1.6° to 10°.

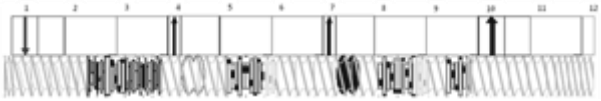

Figure 1: Twin-screw extruder design.

The factorial experimental design[3] (Table 1) for the binary OMMT mixtures study is a two block designs for screw torque factor (low and high level).

Table 1: Factorial experimental design for clay and torque.

Independent variables	Torque	C20A	C30B
Levels	-1	1	0
		½	½
		0	1
	1	1	0
		½	½
		0	1

Results:

Figure 2 shows XRD results of the OMMT (Cloisite 20A and 30B) and the two OMMT/ABS composites with a binary mixture of these organoclays, at 40% and 75% of screw torque. The XRD difratograms of the others OMMT/ABS, either OMMT 20A or 30B, were very similar. The interlayer spacing of the OMMT and for all the OMMT/ABS composites are shown in Table 2. These distances were significantly increased for all the OMMT/ABS, which is related to some intercalation of the polymer into the galleries of the clays. It seems that the torque did not have any significant effect on the dispersion of clay in the ABS matrix.

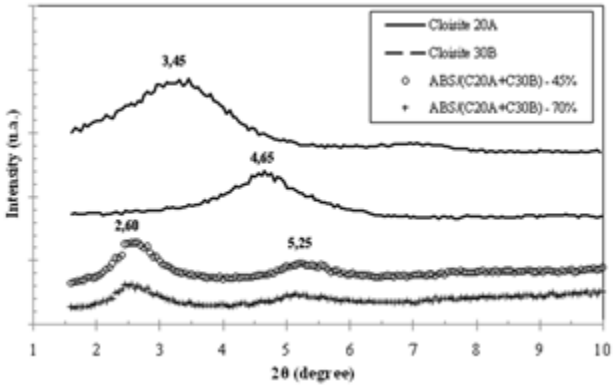

Figure 2: XRD analyses of OMMT and ABS/OMMT.

Table 2: Diffraction angles and interlayer spacing.

	2θ (°)	d001 (nm)
C20A	3,45	2,57
C30B	4,65	1,91
ABS/C20A - 45%	2,60	3,41
ABS/C20A - 70%	2,55	3,47
ABS/C30B - 45%	2,60	3,41
ABS/C30B - 70%	2,65	3,34
ABS/ (C20A+C30B) - 45%	2,65	3,34
ABS/ (C20A+C30B) - 70%	2,55	3,47

Conclusions:

The DRX analyses of the ABS/OMMT binary mixture presented the similar pattern observed in other works **¡Error! Marcador no definido.¡Error! Marcador no definido.** with the same commercial single OMMT, indicating that polymer intercalation was achieved. Rheological, TEM and DMTA analyses, as well flammability and mechanical tests are in progress.

Introduction:

It is strongly believed that the future optoelectronic and photonic devices will be comprised of organic-inorganic hybrid materials with nonlinear optical (NLO) response [1]. Most of the reported work refers to gold and silver nanoparticles embedded in organic matrices [2]. Palladium nanoparticles have been only rarely investigated towards their NLO properties [3].

Herein we report the synthesis, characterization and experimental investigation of the NLO properties of novel organic-inorganic hybrid materials based on functional amphiphilic block copolymers (ABCs) and palladium nanoparticles.

Results and Discussion:

Well-defined ABCs consisting of 2-(N-carbazolyl) ethyl methacrylate (CzEMA) and 2-(acetoacetoxy) ethyl methacrylate (AEMA) (Fig.1) were synthesized by RAFT controlled radical polymerization and their molecular characteristics were determined.

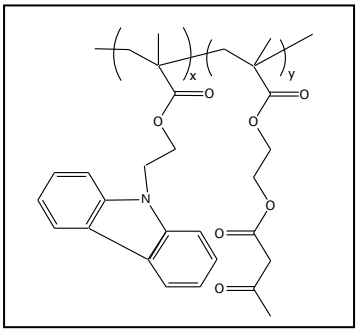

Figure 1: *Molecular structure of CbzEMA-b-AEMA ABCs.*

Micellar nanohybrids based on CzEMA-*b*-AEMA combined with Pd^o were fabricated in tetrahydrofuran (THF) as illustrated in Fig. 2.

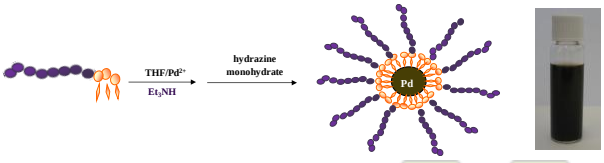

Figure 2: Schematic representation of the methodology followed for the preparation of CbzEMA-b-AEMA/Pd^o micelles.

Dynamic Light Scattering was employed to obtain information on the hydrodynamic size of the hybrid systems. In the absence of Pd^o, only unimers exist in solution; micellization is induced upon complexation followed by reduction.

Sample	λ (nm)	Conc. (mM)	$Re\chi^{(3)}$ 10^{-13} esu	$Im\chi^{(3)}$ 10^{-13} esu	$\chi^{(3)}$ 10^{-13} esu
$CzEMA_{104}$-*b*-$AEMA_{44}$ AEMA:Pd 2:1	532	1.43	0.795±0.033	-0.34±0.16	0.864±0.16
		1.067	0.502±0.033	-0.3±0.2	0.584±0.2
		0.72	0.185±0.0385	-0.23±0.13	0.294±0.135
		0.36	0.074±0.038	-0.134±0.068	0.152±0.077
		THF	0.24±0.022	-	0.24±0.022
	1064	4.096	0.121±0.0092	0.611±0.085	0.622±0.085
		1.68	0.045±0.015	0.242±0.034	0.245±0.037
		1.3	0.0037±0.015	0.212±0.057	0.212±0.059
		0.794	-	0.129±0.041	0.129±0.041
		THF	0.187±0.0072	-	0.187±0.007

Furthermore, their NLO response has been investigated by employing the Z-scan technique (35ps).

Table 2: Third-order NLO parameters of the $CzEMA_{104}$-*b*-$AEMA_{44}$/Pd^o measured in THF.

The originality of this work lies on the fact that it constitutes the first systematic work in which the NLO properties of novel hybrid systems consisting of carbazole-containing ABCs and Pd nanoparticles were investigated in detail.

Inducing Microdomain Orientation of Thermoplastic Elastomer in As-spun Electrospinning Fibers through Study Cases of SEBS Triblock Copolymer

Wonchalerm Rungswang[1], *Masaya Kotaki*[3], *Shinichi Sakurai*[4], *and Suwabun Chirachanchai*[1,2]

Thermoplastic Elastomer (TPE) isone the well-known block copolymers composing of soft and hard segments in a single chain.Due to immiscibility of those soft and hard parts, TPE simultaneously performs nano-phase separation, so-called microdomains. An orientation of those microdomains has been extensively studied in films and sheets, especially based on the stretching force. In the case of fibers, electrospinning is a good technique to generate the confined fiberat nanometer to sub-micrometer level under ultimate stress and at the same time in combining additional disk collector, it can control the fiber alignment[1] which allows us to understand the polymer at molecular level.In the past, electrospun TPEs were investigated and only peculiar and short shape of the microdomains as observed by TEM were reported [2]It comes to our question whether the ordered microdomainsand their orientation are existed in the TPEs, and how can we identify it? In addition, if the microdomain can be generated, is there any possibility to direct the microdomain orientation?

This present work, thus, for the first time, clarifies an existence of the short-range ordered microdomains including directing their orientation through the as-spun electrospinning fibers ofpolystyrene-*block*-poly(ethylene-co-butylene)-*block*-polystyrene triblock copolymer (SEBS).[3] Two dimensional small angle X-ray scattering (2D-SAXS) technique was applied to reveal the microdomain in details. The important result is that theelectrospun SEBS showed both elliptic pattern,referring to distorted lamella, and four-point patternobliquely oriented to the stretching direction (SD), regarding to the rapture of microdomain to tiny grains.

In our related work, we already reported about the molecular interaction betweenbenzoxazines monomer (BZ) and SEBSvia π-πstacking with PS segments.[4] Here, an addition of BZ in SEBS chain initiated the electrospun fibers to perform a unique orientation of which the microdomain is almost parallel to SD as evaluated from μ angle (the angle between vector normal to the lamellar microdomain and SD) ~ 80° and ϕ angle (the angle between vector normal the grain of lamellar microdomain and SD) ~90°.

The authors would like to acknowledge the Royal Golden Jubilee Program (the Thailand Research Fund (PHD/0058/2550)), and the Japan Student Services Organization (JASSO)for financial support. SEBS was kindly supported from Asahi Kasei Chemical Corporation, Japan and the SAXS measurements were conducted at Spring-8 under the approved number 2009A1153.

Computational Modeling of Nanocomposites' Mechanical Behavior at Different Environments Parameters (Moisture and Thermal Loadiing)

Katya Marinova Simeonova, PhD, Civil Engineer, Engineer-mathematician,

Associate Professor, Institute of Mechanics, Bulgarian Academy of Sciences,

e-mail: katyas@bas.bg

Discovering of carbon nanotubes (CNTs) by S. Iijima, [1] put the beginning of a revolution in nanoscience (nanomaterials). Carbon nanotubes, possess extraordinary physico-mechanical, electronic, electrical properties, transport, chemical, thermal etc. properties. These nanomaterials have nanoscale sizes and chirality structure. Moreover CNTs could be used as a very useful reinforcement for relatively novel materials, so called nanocomosites. In many cases nanocomposites have a matrix from different polymer materials (for example epoxy, resin, or other ones). Regarding nanocomposites, may be mentioned that because of so good properties of reinforcement (Carbon nanotubes), they are better than only CNTs. So, nanotubes and nanocomposites, find applications in many fields of technique, electronics, optoelectronics, transistors, engineering etc., [2]. Recently has been proved that these nanoscale materials are very good tool in molecular and cellular biology and clinic medicine too. The aim of the paper, presented below, could be formulated as follows: to develop a modified theoretical (computational) model for study of the effects of moisture and thermal loading on the stress state of nanocomposites at different types of reinforcements carbon nanotubes-single walled carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes and (MWCNTs). Computational model, has been developed on the basis of classical mechanics theories, and experimental data, [3]. Numerical algorithms and FORTRAN programs, designed by authors, have been presented as well in the work. Comparison of the results, obtained and experiments in literature, shows a good agreement.

Key words: carbon nanotubes, nanocomposites, moisture, shear stress, computational models, FORTRAN programs

e-mail: hideosaw@cc.hirosaki-u.ac.jp

Polyanilne (**PAn**)/inorganic composites have been considered as new class of materials due to their improved properties compared with those of pure conducting polymers and inorganic materials. For example, the combination of electrical conductivity of **PAn** and UV sensitivity of anatase TiO_2 are expected to find applications in electochromic devices, nonlinear optical system, and photochemical devises.[1] It is in general difficult to prepare conducting polymers/inorganic nanoparticle composites by conventional blending or mixing in solutions or melt form, because, polymers are not molten in nature and generally insoluble in common solvents.[2] On the other hand, partially fluoroalkylated polymers, especially fluoroalkyl end-capped oligomers are attractive polymeric surfactants, because they exhibit various unique properties such as high solubility, surface active properties, biological activities and nanometer size-controlled molecular aggregates which cannot be achieved by the corresponding non-fluorinated and randomly fluoroalkylated ones.[3] Therefore, it is in particular interest to develop novel fluoroalkyl end-capped oligomers/**PAn** nanocomposites, especially fluoroalkyl end-capped oligomers/**PAn**/titanium oxide nanoparticles composites have high potential applications imparted by not only fluorine but also **PAn** or titanium oxide toward a variety of areas such as conductive coating, charge storage, electocatalyst, electrochromic devices, and photovoltaic cells.

Here we report that fluoroalkyl end-capped acrylic acid oligomer [R_F-$(ACA)_n$-R_F]/, 2-methacryloyloxyethanesulfonic acid oligomer [R_F-$(MES)_n$-R_F]/, 2-acrylamido-2-methylpropanesulfonic acid oligomer [R_F-$(AMPS)_n$-R_F] /polyaniline [**PAn**] nanocomposites are prepared by the polymerization of aniline initiated by ammonium persulfate in the presence of the corresponding oligomers, respectively. These fluorinated oligomers were also applied to the preparation of the corresponding fluorinated oligomers/phenyl-capped aniline dimer (**An-dimer**: *N,N'*-diphenyl-1,4-diphenyldiamine) nanocomposites by the interaction of the fluorinated oligomers with **An-dimer**, which is considered to be an excellent model of **PAn**. In these nanocomposites, R_F-$(MES)_n$-R_F/**PAn** nanocomposites and R_F-$(MES)_n$-R_F/**An-dimer** nanocomposites were effective for the preparation of colloidal stable fluorinated oligomer/**PAn**/TiO_2 and /**An-dimer**/TiO_2 nanocomposites. These two types of fluorinated TiO_2 nanocomposites can exhibit quite different photochromic behaviors: R_F-$(MES)_n$-R_F/**PAn**/TiO_2 nanocomposites can exhibit a reversible wavelength change for polaron absorptions around 760 ~ 820 nm by alternation of UV-irradiation and storage in the dark; in contrast, R_F-$(MES)_n$-R_F/**An-dimer**/TiO_2 nanocomposites can exhibit a reversible color change from blue to colorless (a reversible absorbance change) by the similar treatment.

Hybrid materials based on unsaturated polyester resins and polyhedral oligomeric silsesquioxanes (POSS)

Floriana Constantin, Sorina-Alexandra Gârea, Horia Iovu

University POLITEHNICA of Bucharest, Faculty of Applied Chemistry and Materials Science, Department of Polymer Science and Technology, 149 Calea Victoriei, 010072, Bucharest, Romania

c_floriana2005@yahoo.com

Introduction:

The polyhedral oligomeric silsesquioxanes are hybrid molecules with the structure $(RSiO_{1,5})_n$.

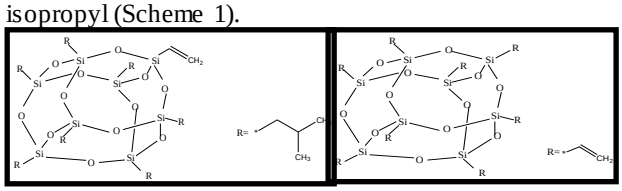
Unsaturated polyester resin is one of the most used thermosetting resins thanks to relatively low cost, adaptability to many fabrication processes and good properties, so it was used as matrix resin for polymeric composites [1-2].

The main purpose of this research was to study the influence of different types and concentrations of polyhedral oligomeric silsesquioxanes (POSS) on the thermal properties of unsaturated polyester resin (UPR) using several techniques like Dynamical Mechanical Analysis (DMA), Thermogravimetric Analysis (TGA) and Differential Scanning Calorimetry (DSC)[3-5].

Materials and Methods

The polymeric matrix was unsaturated polyester resin and benzoyl peroxide (5%wt. against UPR) was used as crosslinking agent.

As reinforcing agents two types of POSS were used, one with eight reactive vinyl groups and the other with one reactive vinyl group and seven unreactive groups, isopropyl (Scheme 1).



Scheme 1. The chemical structure of monovinylPOSS and octavinylPOSS

Results and Discussion

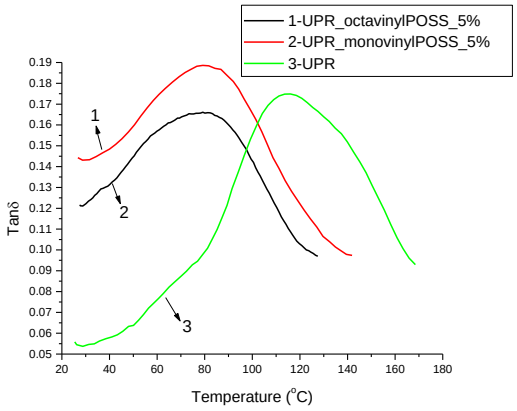


Fig.1 – The DMA curves of the (1) UPR – octavinylPOSS (5wt.%);
(2) UPR – monovinylPOSS (5 wt.%); (3) UPR.

From the DMA results (Fig. 1) it can be observed that the addition of the octa- and monovinylPOSS to the UPR decreased the glass transition temperature value with about 30°C which is probably caused by the plastifier effect of the POSS molecules.

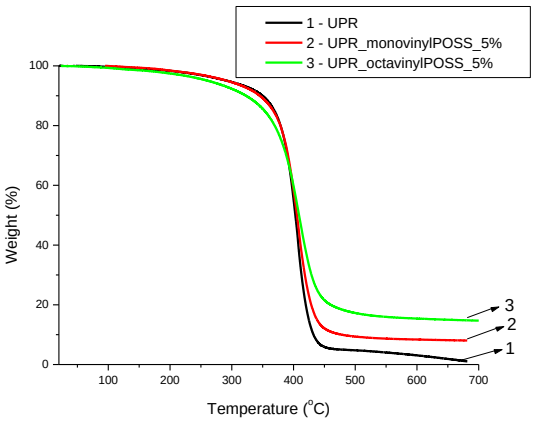

Fig. 2 TGA curves for the (1) UPR; (2) UPR – monovinylPOSS 5wt.%); (3) UPR – octavinylPOSS (5wt.%);

From the TGA curves (Fig. 2) one may observe that the thermal behavior of the UPR is not influenced by the addition of octa- or monovinylPOSS.

Also, the DSC tests confirmed that the addition of POSS compound to the UPR does not significantly modify the crosslinking temperature of the polyester resin.

Conclusions:

The glass transition temperature of the hybrid materials decreased due to the plastifier effect of POSS.

The termostability of the hybrid materials is not influenced by the POSS molecules.

Micellization and gelation of PEO/PPO block copolymers and their carboxyl-terminal derivatives

Jiří Dybal, Adriana Šturcová, Alena Braunová, Michal Pechar, Alexander Jigounov, Jaroslav Kříž

Institute of Macromolecular Chemistry AS CR, v. v. i.,
Heyrovský Sq. 2, 162 06 Prague 6, Czech Republic

e-mail: dybal@imc.cas.cz

Introduction

Micellization and gelation of water soluble tri-block copolymers PEO-PPO-PEO (Pluronics) is relevant in view of possible wide applications in pharmacy, bioprocessing and separation. Carboxyl-terminal derivatives were shown to micellize thermoreversibly and to bind multivalent cations. In the present work, Raman spectroscopy, attenuated total reflectance Fourier transform infrared (ATR FTIR) spectroscopy, NMR spectroscopy, and density functional theory (DFT) model calculations have been used to explore micellization and gelation processes in Pluronics at molecular level.

Materials and Methods

ATR FTIR spectra were collected on a Nicolet Nexus 870 FTIR spectrometer purged with dry air and equipped with a horizontal micro-ATR Golden Gate unit (SPECAC). Raman spectra were obtained on a Renishaw In-Via Raman micro-spectrometer with Ar^+ ion laser with excitation line at 514.5 nm. At given temperature, vibrational spectra of pure water were subtracted from spectra of Pluronic/water solutions. ^1H and ^{13}C NMR spectra and relaxations were measured with a 600 MHz Bruker 600 Avance III spectrometer. PFG diffusion experiments and dynamic relaxation experiments were done on a 300 MHz Bruker Avance DPX300 spectrometer. The model calculations were carried out at the density functional theory (DFT) level employing the Gaussian 03 program package.[2] All the structures were fully optimized with the B3LYP functional and the 6-31G(d) basis set.

Results and Discussion

We have studied a series of macromolecules with the same length of more hydrophobic PPO block (31 structure units) and varying length of more hydrophilic PEO blocks (5 to 84 structure units)[3,4] together with Pluronic P85 (EO26–PO39–EO26) and its carboxyl-end modification denoted as CAE-85 and low-molecular-weight model compounds.

Vibrational spectra of Pluronics in water and quantum chemical calculations showed that analogous coordination types of water molecules are detected in interacting water as in bulk water. Hydrophobic contacts prefer tetra-coordinated water and hydrophilic contacts induce di-coordinated water.[5] PPO chain was shown to reversibly coil in the pre-association stages as a result of its partial dehydration and this process is shifted to higher temperatures by the hydrophilic pull of PEO blocks.

While gelation of Pluronic P85 takes place when the concentrations are above the critical gelation concentration, carboxyl-terminal derivative CAE-85 displays significant differences. Formation of micelles corroborated by the shifts of the CH_3 deformation and C-O stretching vibrational bands due to dehydration of both hydrophobic and hydrophilic groups. Micelles of CAE 85 may be further stabilized by negative charge appearing at temperatures above critical micellization temperature, and it probably prevents the micelles from forming gel.

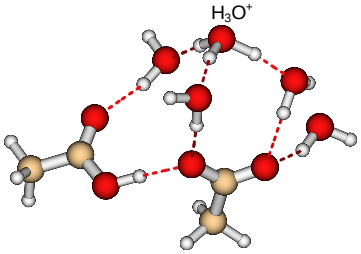

Figure 1. DFT optimized geometry of the dissociated carboxylic group.

DFT model calculations indicate that dissociated ion pair $COOH \rightarrow COO^- + H^+$ may be stabilized due to hydration and interaction with other carboxylic groups (Figure 1). The effects of multivalent cations on the CAE-85 micellization and micelle stability were also studied.

A Plasma reactor for the surface modification of silica based fillers: description and the apparatus and EPR investigation of reactive intermediates

Armando Buttafava, Daniele Dondi, Damiano Grassi, Fabio Pepori, Antonio Faucitano

Dipartimento di Chimica Generale, Università di Pavia, V.le Taramelli 12, 27100 Pavia (ITALY)

armando.buttafava@unipv.it

Introduction

Low pressure plasma in nonthermal conditions, possess an high temperature of electrons while conserving a low temperature for atoms and ions. In these conditions, it's possible to generate highly reactive species (radicals, ions) while studying the primary radical reactions having low or no activation energies. This permits either to investigate the thermal behavior of generated radicals or to study the reaction with suitable radical traps. For this purpose, an RF inductive plasma apparatus was designed for the EPR study of radicals at liquid nitrogen temperature. The radical chemistry of polymer fillers (silica, polybutadiene-coated silica and organoclays) and some polymers (polybutadiene, SBR and polystyrene) was studied with this method.

Materials and Methods

The inductive plasma apparatus consist of a radiofrequency generator at 13.56 MHz with a maximum power of 300W (Dressler Cesar III 133) coupled with a impedance matching unit (Dressler VM 1500W-ICP). The whole apparatus was shielded in order to avoid environmental radiofrequency dispersion. The plasma was generated in a specially-designed glassware (Figure 1) suitable for transferring the sample in a quartz EPR tube while keeping the sample at 77K. The internal gas pressure was set up in the range (0.1- 0.5 Torr). Nitrogen, oxygen and argon were used for the plasma generation.

Silica Zeosil 1165 with a surface area 160 m^2/g was used as received from Rhodia. Polibutadiene-coated silica was obtained according to literature data [1]. Organically modified montmorillonite with alkyl ammonium salts were purchased from Nanocor.

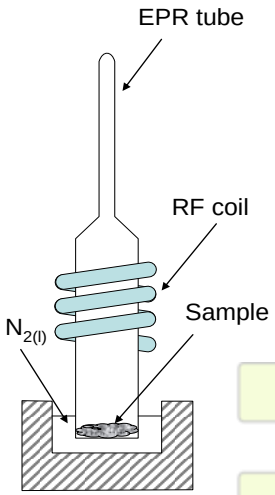

Figure 1. Schematic representation of the RF-plasma apparatus used.

Results and Conclusion

Plasma irradiation of silica lead to the formation of E' centres (b, Figure 2) and paramagnetic species attributed to zeosil impurities (c). The plasma treatment under nitrogen atmosphere lead also to the formation of H atoms (a), feature not visible in the oxygen plasma-treated sample. The presence of H atoms is an indirect evidence of the low temperature maintained by the sample. In fact, these signals usually decay, in the χ irradiated zeosil, at a temperature of 177 K [1]. Moreover, the EPR spectrum of silica treated in oxygen plasma shows that E' centres are produced in higher yields, as described for silica glass implanted with oxygen ions [2]

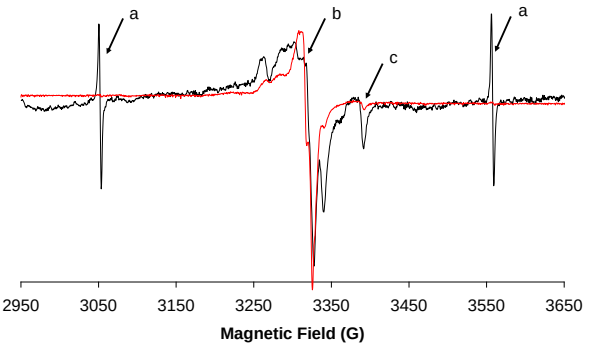

Figure 2. EPR spectrum of Zeosil silica plasma-treated with nitrogen (black) and oxygen (red).

The evolution of paramagnetic centers was investigated by recording EPR spectrum at different temperatures. Their thermal stability will be discussed and compared between different experimental setup.

The reactions of generated radicals in silica, clays and polymers with radical traps (volatile olefins, oxygen) were studied by introducing the reactants at low temperature and then increasing the temperature in the EPR cavity.

Effect of Sodium Dodecylbenzene Sulfonate on Carbon Nanotubes Dispersion

Ghamgosar khorshidi V., Bakhshandeh G.R., Salimi A., Naderi Gh*

Iran Polymer and Petrochemical Institute, P. O. Box: 14965/115, Tehran, Iran

a.salimi@ippi.ac.ir

Introduction

To achieve the best properties of Carbon Nanotubes (CNTs) in polymer matrixes, the filler must be dispersed effectively. Due to the strong van der Walls interactions in CNT, there is tendency to CNT agglomerations especially in non-polar polymer matrix [1]. A wide variety of surfactants have been used for dispersion of CNTs in aqueous media [2, 3]. In this work, we study the effect of sodium dodecylbenzene sulfonate (SDBS) as surfactant for dispesion of functionalized and non-functionalized Multi walled carbon Nanotubes in aqueous media.

Materials and Methods

Functionalized and non-functionalized Multi walled carbon Nanotubes (diameter 10-30 nm, length 10 µm, purity 95%) was supplied by Institute of Petroleum Industry (Tehran, Iran). The surfactant SDBS from Fluka was used as received. All dispersions were prepared in deionized water for constant 1wt% of each CNT. The samples were ultrasonicated for 5 minutes using (Bandelin HD 3200, Germany) and then filtered after centrifuging at 3000 rpm for 20 min. The dispersion of CNTs was characterized using UV-vis spectrophotometer model UV-1650 PC (SHIMADZU, Japan).

Results and Discussions

The UV spectra of non-functionalized and functionalized MWNTs are shown in Fig 1a and b, respectively. As shown in Fig. 1 a, the absorption increases as the surfactant concentration increases from 0.5 g/L to 1.5 g/L. This indicates that the SDBS can be adsorbed on CNT surface resulting to more dispersion of the CNTs in media. Besides, the existing benzene ring in SDBS structure provides higher attraction to CNTs surface [3]. As shown in Fig.1 b, the increase in absorption is more pronounced for the functionalized CNTs. Due to hydrogen bonding between the hydrophilic head of surfactant and the existing –OH group of functionalized CNTs, higher dispersion for CNT-OH can be obtained for the same level of surfactant loading.

Conclusions

The use of SDBS for CNT dispersion in aqueous media is an effective way. The increase in SDBS loading resulted to higher dispersion may be due to attraction of existing benzene ring in SDBS to CNT surface. The increase in dispersion was more pronounced for the functionalized CNTs mainly because of the hydrogen bonding between the hydrophilic head of surfactant and the existing –OH group of functionalized CNTs.

The original thermo-gas-dynamic (TGD) method of nanofluoropolymers (Forum®) synthesis based on the thermal destruction of bulk polytetrafluoroethylene (PTFE) under special gas-dynamic conditions was developed in the Institute of Chemistry FEBRAS [1]. PTFE FORUM® is the material consisting of polymer molecules of various molecular weights (Fig. 1).

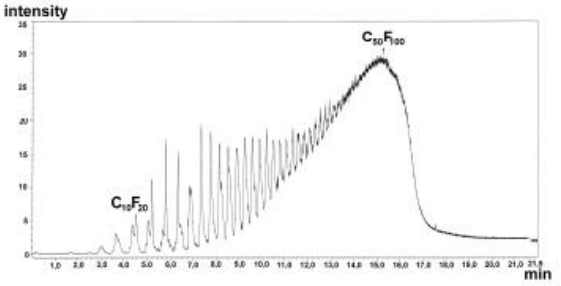

Fig. 1. Chromatography-mass spectrometry of PTFE low-molecular phase up to 400o C. At the temperature up to 400o C the molecules with molecular weights from 338 to 3000 transfer into the gas phase.Heating FORUM® powder in the defined temperature ranges allows generating fractions with defined molecular weights. Researches show that these fractions have different physical-chemical properties of practical interest. For example, film which is transparent in the optical band and generated from the PTFE FORUM® powder is able to absorb ultraviolet radiation. The degree of absorption is inversely proportional to the fraction's molecular weight (Fig. 2).

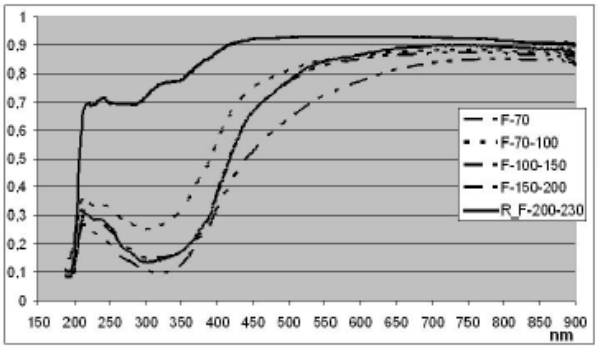

Fig. 2. Experimental light-spectrums of PTFE Forum® temperature fractions' reflection.

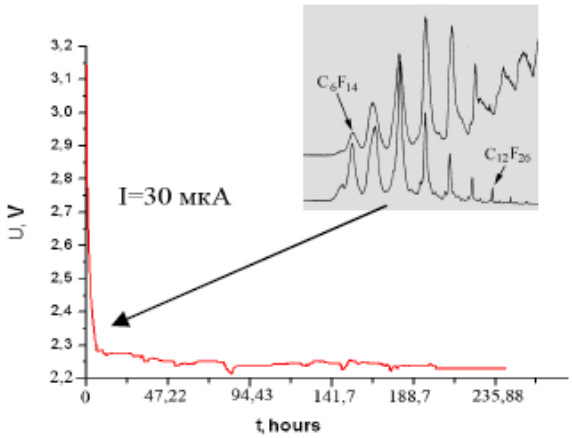

Fig. 2. The LCB discharge curve on the C_8F_{16} cathode

This paper contains the results of physical-chemical, structural and morphological researches of different PTFE FORUM® temperature fractions.

During the last decades, polypyrrole (PPy) has been one of the most studied conducting polymers because its easy synthesis, good electrical conductivity, redox properties, and environment stability make it a very promising material for technological applications.

The aim of this work was to study the influence of different dopants on the morphology and structure of composites of PPy coated polystyrene-co-methacrylic acid (PS-MMA) spherical particles.

Spherical particles of PS-MMA were prepared form surfactant free emulsion as it was described in [1]. PPy was chemically synthesized and deposited onto PS-MMA particles (PPy/PS-MMA) using different dopants such us $FeCl_3$, sodium p-toluensulfonate hexahydrate (NaTS), 5-sulfosalicylic acid dehydrate (SSA). The PPy amount in the samples was determined by elemental analysis. The influence of the dopant anion on the PPy morphology observed by scanning electron microscopy at the particle surface and the electric conductivity, at room temperature, of pellets obtained from dried suspensions are discussed. X-ray photoelectron and infrared spectroscopy were also used to analyze the structure of the samples. Their conductivities were also measured.

Uniform and continuous PPy coating is deposited on the samples with MMA. A relationship between morphology and size and conductivity was found. Samples with the highest sphere size and a smooth PPy coating showed higher conductivity than those smaller and with an irregular PPy distribution.

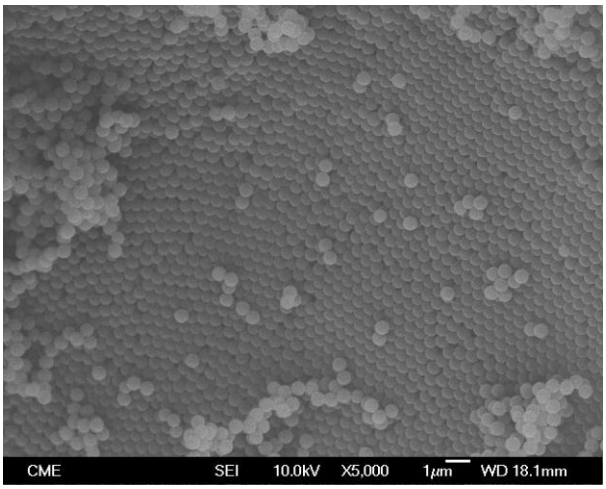

Figure 1. Scannning electron micrograph of (Ppy/PS-MAA) doped with FeTS.

Conductivity values from 5.84 S cm^{-1} for the most conducting coated latex to 0.50 S cm^{-1} for the less one have been found.

XPS experiments allow us to determine the contribution of C, O, Cl and S to the surface composition. The fraction of nitrogen atoms with positive charge excess (N_{ox}/N_{tot}) is equivalent to the doping level. One positive nitrogen atom to four (or three) total nitrogen was found in all the studied samples.

PPy deposition onto MMA/PS samples was followed by infrared spectra. FTIR spectra showed the strong high frequency absorption characteristic of conducting polymers in addition to bands assigned to latex and PPy vibrations. No signals of carbonyl group bands appear in the spectra indicating that degradation of PPy was low or non-existent.

Effect of Silane Grafting and Post Cross-linking of HDPE on Compatibilization and Oxygen Barrierity of HDPE/Clay Nanocomposite

Ali Sharifpakdaman, Jalil Morshedian, Yousef Jahani

Iran polymer and petrochemical institute

a.pakdaman@ippi.ac.ir

Introduction:

Due to several advantages, polyethylene is the most widely used polymer in food packaging industries. However, the use of neat PE is restricted because of some of its inherent properties such as relatively high oxygen and aroma permeability which weakens long shelf life property required for these applications.[1-3] Recently, polymer-clay nanocomposite materials have attracted attention as alternative route to improve polymer barrierity as well as other properties.[2] It has been found that these superior properties of nanocomposites are attributed to the dispersion and orientation of clay and interactions between clay and polymer. Consequently, in the case of PE because of its non-polar backbone, modification of clay surface or polyethylene molecules is highly required.[3,4]

In this work silane grafting of HDPE is done by reactive extrusion to improve hydrophilic property of polymer molecules. Furthermore other objective of this modification was creation of post cross-linkability of composite matrix for further enhancement of barrierity as well as stabilization of microstructure. As a result HDPE-g-silane/montmorillonite nanocomposites were successfully prepared by melt compounding with acceptable exfoliation and considerable reduction of oxygen transmission rate (OTR).

Materials and methods:

The polymer (HDPE–BL3) with MFR of 1.2 g/min (5Kg, 190^{o}C) and density of 0.954 g/cm^{3} was purchased from Jam Co., Iran. Vinyl trimethoxy silane (VTMO) with commercial name of Silfin-25 was supplied from Evonik (Degussa). Dicumyl peroxide 99% (DCP) from concord Co. was used as an initiator. And finally nano clay (org-MMT) was Cloisite 15A from Rockwood Co.

Appropriate amount of DCP was dissolved in silane (4 phr) and this solution was adsorbed in polyethylene granules in turbo mixer during about an hour. These granules were fed into twin screw extruder (Brabender) where grafting reaction was done. Then the prepared HDPE-g-silane was blended with org-MMT and again melt compounded in twin extruder. Finally cast film by Thermo Haake Reomix (200 micron thickness) and sheets by compression moulding (1 mm thickness) were prepared as test specimens. The samples were exposed to moisture whenever the cross-linking required.

Results and discussion:

The silane grafting of HDPE was examined using FTIR by visiting a peak around wavenumber1080cm^{-1}. In addition decreased MFR of grafted samples and attaining about 38 percent gel content after moisture curing confirmed successfully grafting of silane on PE backbones.

The XRD data obviously demonstrated the effect of grafting on compatibilization of HDPE and org-MMT (Fig 1). Intercalation occurred as a result of insertion of polymer chains between the clay layers. This could be seen in curves by shifting diffraction peak to smaller 2Θ which implied higher d-spacing according to Bragg equation.[5] Exfoliated morphology could be achieved by smaller amount of MMT in highly grafted PE. TEM micrographs also confirmed the XRD results by visiting good dispersion and widely intercalated systems.

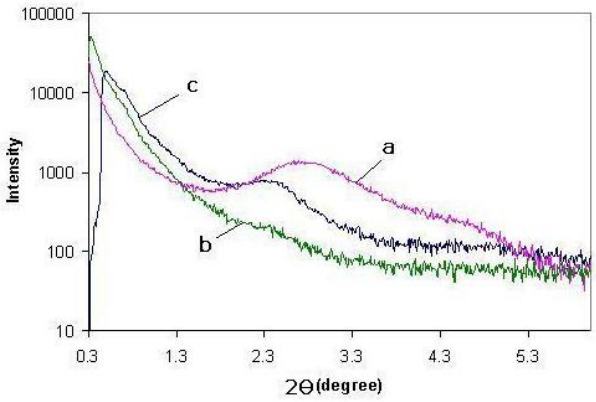

Figure 1. XRD patterns of (a) MMT (b) HDPE-g-silane (2 phr clay) and (c) HDPE-g-silane (4 phr clay)

Finally the oxygen transport properties of samples were measured. These data showed that barrierity of HDPE against oxygen was strongly improved in intercalated and exfoliated nanocomposite samples. In addition a slight improvement was observed by cross-linking of all specimens. Whereas, the crystallinity remained almost unchanged in compounding (examined by DSC), the changes of permeation were attributed to incorporation of nano clay and also cross-linking of final products.

Conclusions:

Silane grafting of HDPE was successfully performed to improve the miscibility of clay with PE. The oxygen permeability was strongly decreased in compatibilized nanocomposites. Furthermore, cross-linking of samples showed further improvement in barrierity.

v.vascotto@nanofab.it

Nowadays, biopolymers have attracted great attention by industry due to the more and more growing interest for environment and the possibility to replace the conventional polymer produced by petroleum sources.

Poly(lactic acid) (PLA) is a biodegradable thermoplastic material characterized by good barrier properties to gases, and it could be used in different fields, ranging from packaging to agriculture or medicine. PLA is usually hard and brittle and for this reason its fracture properties can be improved by adding a ductile polymer, like Poly(ε-caprolacton) (PCL). PCL is a biodegradable polymer too but PLA and PCL are immiscible, with formation of phase separation. Moreover, PCL is characterized by poor barrier to gases, which limit some industrial applications of the blend. In order to overcome this drawback, we studied the possibility to add layered silicates to the PLA/PCL blend.

In the last years, the utility of inorganic nanoparticles as additives to enhance the polymer performances has been well established. Of particular interest are polymers added with small amount (1-5 wt%) of organically modified layered silicates (OMLS); these nanocomposites demonstrated significant enhancement, relative to an unmodified polymer, of a large number of physical properties, including barrier to gases and vapour, flammability resistance, thermal and environmental stability, solvent uptake, and rate of biodegradability of biodegradable polymers.

In the case of PLA/PCL blends, the possibility to use nanoclays for the increase of the barrier properties in particular of PCL is of particular interest.

The aim of this paper is to study the preparation and the characterization of PLA/PCL/nanoclay composites for packaging applications. The materials were all prepared by melt blending the polymers and the nanoclays in a Brabender discontinuous mixer. Before the mixing process, PLA, PCL and the clays were dried under vacuum. Nanocomposites were obtained by melt blending polymers with nanofillers in the Brabender discontinuous mixer at 190 °C for 15 min.

Because PLA and PCL are not miscible, the study of the phases distribution in the blend is fundamental; for this reason Raman spectroscopy and Atomic Force Microscopy were used. In particular the confocal μ-Raman spectrometry was used to study the distribution of the phases, with and without nanofiller. The 514.5 nm line of an Ar-ion laser was used as excitation source; the spectrometer used is a 300mm focal length, equipped with a 600 lines/mm grating and images are collected by means of a 100x microscope objective (0.90NA). Phase mapping has been performed by measuring μ-Raman spectra during surface scanning of the sample over a selected area of a sample (40 μm x 16 μm). Since the μ-Raman spectra of the two components are quite similar, we exploited a characteristic peak of the PLA at 380 cm^{-1} (absent in the PCL spectrum) to map its distribution in the material. Another peak at 1430 cm^{-1} was chosen for comparison, being present in both materials (Fig. 1). The comparison between the distribution of the two peaks on the surface is used to tentatively identify phase separation of matrix and dispersed phase.

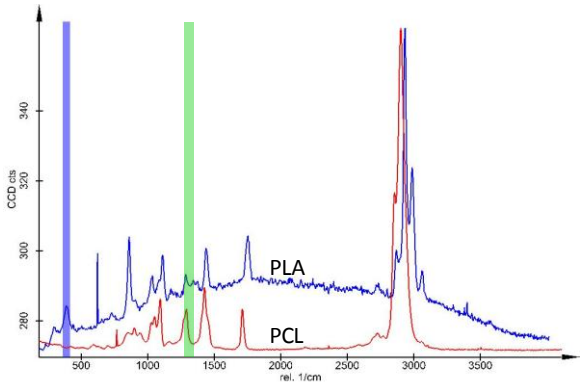

Fig. 1. μ-Raman spectra of PLA and PCL .

AFM topographic and phase images reveal the presence of small aggregates of few μm inside the polymer matrix, that could be attributed to the PCL dispersed phase. This is consistent with what we observed in μ-Raman maps, where the resolution is of the order of 0.5 μm. The results can suggest that modified montmorillonite preferentially forms aggregates of 1-2 μm inside the Poly(ε-caprolacton) domains.

Mechanical characterizations were performed and gas and vapour barrier properties were evaluated.

The addition of PCL on PLA caused, even at low amount, a decrease of tensile and barrier properties, in agree to the plasticizing effect of poly(ε-caprolacton).

However, by using nanoclay it was possible to overcome this drawback and in some cases it was possible to increase the properties of pure PLA.

Synthesis and Characterization of Superparamagnetic and Thermoresponsive Hydrogels Based on Functional Methacrylates and Oleic Acid-Coated Magnetite Nanoparticles

Theodora Krasia-Christoforou[1], *Petri C. Papaphilippou*[1], *Antonis Pourgouris*[1], *Oana Marinica*[2], *Alina Taculescu*[3], *George I. Athanasopoulos*[1] *and Ladislau Vekas*[3]

Introduction: Magneto-responsive composites belong to the broad category of "intelligent" materials capable of responding to external stimuli such as temperature, pH, the presence of an electric or a magnetic field etc. Among others, magnetic polymer conetworks in which magnetic (nano)particles are embedded, is a new class of "soft" composite materials, exhibiting great interest in nanotechnology and in biomedicine since they could be potentially used in magnetic drug delivery, cell sorting, catalysis, as sensors and actuators [1]. This study deals with the preparation of novel magnetoresponsive and thermoresponsive nanocomposite conetworks consisting of: (a) oleic acid coated magnetite nanoparticles ($OA.Fe_3O_4$) and (b) hydrophilic/thermoresponsive and hydrophobic (ligating) units namely hexa(ethylene glycol) methyl ether methacrylate (HEGMA) and 2-(acetoacetoxy)ethyl methacrylate (AEMA), respectively [2].

Materials and Methods:

Oleic acid-coated magnetite nanoparticles. The oleic acid-coated magnetite nanoparticles ($OA.Fe_3O_4$) were prepared by following an experimental procedure developed by Bica *et al.* [3]. Briefly, magnetite nanoparticles, Fe_3O_4, were obtained by the chemical co-precipitation of Fe^{2+} and Fe^{3+} cations in an aqueous solution in the presence of NH_4OH, at 80–82 °C.

HEGMA-co-AEMA/EGDMA random conetworks and $OA.Fe_3O_4$-containing nanocomposite conetworks. Free radical copolymerization was employed for the synthesis of the conetworks. Random cross-linking copolymerizations of HEGMA and AEMA were performed in either ethyl acetate (EA) or tetrahydrofuran (THF) in the presence of 2,2'-azobis(isobutylnitrile) that served as the radical initiator. For the preparation of the magnetoresponsive polymer conetworks the same synthetic methodology was followed in the presence of $OA.Fe_3O_4$.

Results and Discussion: Two series of hydrogel nanocomposites have been prepared in EA (Series A) and THF (Series B) in which the organic content was kept constant and only the inorganic content varied. In Fig. 1 a schematic presentation of the synthetic pathway followed for the preparation of the nanocomposite magnetoresponsive conetworks is given. The degrees of swelling (DSs) of all conetworks (in the absence and presence of $OA.Fe_3O_4$) were determined in organic (EA, THF) and in aqueous media. Deswelling kinetic studies that were carried out at ~ 60 °C in water, demonstrated the thermoresponsive properties of the nanocomposites, attributed to the presence of the hexa(ethylene glycol) side chains within the conetworks.

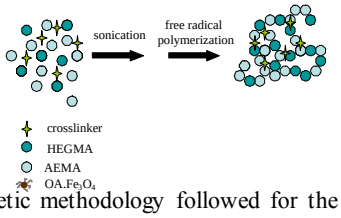

Fig. 1: Synthetic methodology followed for the preparation of $OA.Fe_3O_4$-containing nanocomposite conetworks [2].

Furthermore, the nanocrystalline phase adopted by the embedded magnetic nanoparticles was investigated by X-ray diffraction spectroscopy. The obtained diffraction patterns indicated the presence of magnetite (Fe_3O_4). Thermal gravimetric analysis (TGA) measurements showed that the $OA.Fe_3O_4$-containing conetworks exhibited superior thermal stability compared to the pristine conetworks. Further to the characterization of compositional and thermal properties, assessment of magnetic characteristics by vibrational sample magnetometry (VSM) disclosed tunable superparamagnetic behavior, depending on the magnetic content within the conetwork as presented in Fig. 2.

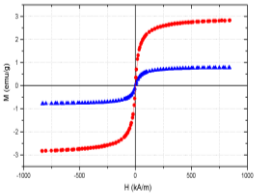

Fig. 2: Magnetization curves of $OA.Fe_3O_4$-containing nanocomposite conetworks measured at 300K [2].

Conclusions: A novel approach for the fabrication of nanocomposite conetworks exhibiting temperature- and magnetoresponsive behavior is reported. The tunable superparamagnetic behavior demonstrated by these materials combined with their thermoresponsive properties may allow for their future exploitation in the biomedical field.

Biosensory Function of Self-Assembled Fluorescent Nanotubes

Chulhee Kim, Jeonghun Lee, Sang Kyu Park, Hyun Soo Kim

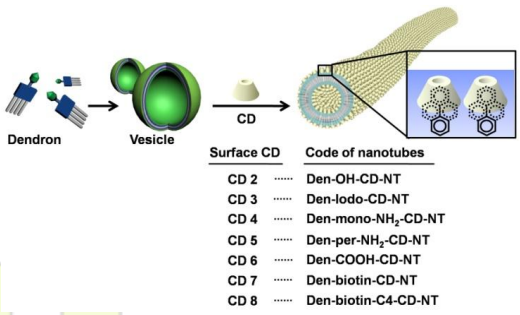
Department of Polymer Science and Engineering, Inha University, Incheon 402-751, Korea

chk@inha.ac.kr

Nanotubes have been a subject of great interests due to their innovative properties and potential applications in a variety of areas of nanoscience. In particular, for organic nanotubes, the precise functionalization and interconnection of the building blocks provided a vision that they could exhibit not only unprecedented architectures but also valuable functions for applications such as electronics and biomedicine.

Even though various self-assembling building blocks for nanotubes have been developed, a molecular recognition motif has not been employed for controlling the self-organization of building blocks into organic nanotubes. Recently, we have reported that the cyclodextrin (CD)-covered dendron nanotubes (Den-CD-NTs) were obtained by a hierarchical self-assembly process derived from a host-guest complexation between the amide dendrons with the focal pyrene moiety and cyclodextrins.[1,2] The smaller rim of CD is exposed to the surface of the nanotube upon inclusion of the focal pyrene groups into the cavity of CD. We reasoned that this type of hierarchical self-assembly approach would provide a facile methodology for the construction of diverse nanotube architectures via the host-guest interaction between the dendron and the C-6 modified CDs. The tunability in the surface functionalization would enable us to construct the hybrid of the nanotubes with metal nanoparticles. Furthermore, we also reasoned that the fluorescence characteristics of the nanotube in response to the change of the surface environment for the application of the nanotube as a biosensory vehicle.

In the primary building block, amide Dendron, the focal pyrene group was introduced not only as the guest moiety for a CD host but also as a fluorescent probe. Dendron self-organizes into vesicles in aqueous solution. Upon addition of CDs into the vesicular solution, the CD-pyrene complexation occurs through the inclusion of the hydrophobic focal pyrene unit into the cavity of CD. This supramolecular recognition transforms the self-assembled structures from the vesicle to the CD-covered nanotubes.



The fluorescent nature of Den-CD-NTs with the tunable surface functionality described in this work provides an opportunity for utilizing the nanotubes as a biosensing platform when the surface functional groups of the nanotubes are designed to interact specifically with the analytes. The sensitive emission property of the pyrene unit in the cavity of CDs of the nanotube toward the change in local environment would allow such binding of the biomolecules on the nanotube to trigger the change in the fluorescence emission of the nanotubes. For that purpose, we prepared the biotin-covered nanotubes (Den-biotin-CD-NT and Den-biotin-C4-CD-NT) as a biosensing platform for utilizing the specific binding of biotin with receptor proteins such as streptavidin and avidin. When streptavidin-AuNP conjugate (SA-AuNP) was added to the Den-biotin-C4-CD-NT solution, the fluorescence was quenched due to proximity of the pyrene moiety to the AuNP of SA-AuNP which binds to the biotin unit on the tube surface. These fluorescence characteristics of Den-CD-NTs along with well-defined surface architecture suggest that Den-CD-NTs can be utilized as a biosensor. To demonstrate the possibility of Den-CD-NT as a biosensory vehicle, an inhibition assay was carried out between streptavidin, avidin, and biotin as a proof-of-concept experiment.[3]

In the inhibition assay with Den-biotin-C4-CD-NT, SA-AuNP, and avidin, the fluorescence intensity of pyrene in Den-biotin-C4-CD-NT increased with increasing the concentration of avidin, because SA-AuNP binds less strongly to biotin than avidin so that the concentration of SA-AuNP bound on Den-biotin-C4-CD-NT decreases with increasing the avidin concentration. As shown in Figure 6e, the I_t/I_0 ratio increased with increasing the avidin concentration. I_0 denotes the fluorescence intensity of Den-biotin-C4-CD-NTs, and I_t is the fluorescence intensity of SA-AuNP/Den-biotin-C4-CD-NT depending on the avidin concentration. The detection limit for avidin was in the range of ~ 1 nM.

The tunability of the structure and function of Den-CD-NTs demonstrated the substantial advantage of our supramolecular approach for development of unique biomaterials.

e-mail : jayhkim@yonsei.ac.kr

We report the facile synthesis, formation mechanism, and photoluminescent (PL) properties of gold–poly(thiophene) (Au–PTh) nanoaggregates. They were prepared by one-step oxidative polymerization, in which Au3+ ion was utilized as an oxidizing agent for the polymerization of thiophene. Transmission electron microscopy (TEM) and high-resolution TEM (HR-TEM) analyses demonstrated that the raspberry-like Au–PTh nanoaggregates consist of individual Au NPs covered by PTh and stabilized by Tween 80. For Au–PTh nanoaggregates, a clear red shift in the SP peak was observed in the UV absorption spectra as compared with pristine Au nanoparticles (NPs). This red shift of the SP band is a consequence of the location of p-conjugated PTh on the surface of Au NPs, resulted from a strong binding between sulfur atoms of PTh and the Au NPs (sulfur–gold interaction). The strong interaction between the gold and sulfur atoms of PTh in the Au–PTh nanoaggregates was observed by X-ray photoelectron spectroscopy (XPS) analysis. The SP effect contributes to the PL intensity enhancement of the Au–PTh nanoaggregates and was confirmed by confocal laser scanning microscopy (CLSM).

aliram@rambler.ru

The present abstract is devoted to the investigation of hyperbranched macromolecules behavior dependence on thermodynamic quality of solutions.

In our work we study the hydrodynamic and conformational characteristics of hyperbranched polydi(allyl)carbosilanes with butyl (PCS-But) and tris-γ-trifluoropropyl (PCS-F) terminal groups and polydi(undecenyl)carbosilane (PCS-Und). All samples were characterized by equal degree of branching DB = 0.5. The dilute solutions of unfractionated polymers in toluene were examined by viscometry and light scattering methods. The intrinsic viscosity [η] and second virial coefficient A_2 values were determined in the range of temperature from 15 to 60°C. The hydrodynamic radius $R_{h[\eta]}$ magnitudes were computed using Einstein equation:

$$R_{h[\eta]} = \left(\frac{[\eta]M}{2.5\, N_A \frac{4}{3}\pi} \right)^{1/3}$$

Although rather significant changes of the A_2 magnitudes were found in the case of PCS-But, we did not see increase or decrease of intrinsic viscosity for hyperbranched PCS-But and PCS-Und.

It is expected the fluorinated substitutes can make the hyperbranched macromolecules more sensitive to thermodynamic quality changes. Our previous work [1] shows the role of thermodynamic quality of solvent in conformational and hydrodynamic properties of PCS-F. The decrease of molecular sizes and its asymmetry in poor solvent was found. We hoped to discover dependence of [η] and $R_{h[\eta]}$ on thermodynamic quality of solution under different temperature. However, PCS-F displayed the same behavior as unfluorinated PCS. This fact can be linked with relatively small temperature range, and the coil swelling effect could be observed at higher temperatures.

Colloidal Crystallization of Poly(*N*-isopropylacrylamide) Microgels

H. Takeshita, S. Nakano, M. Miya, K. Takenaka and T. Shiomi

Nagaoka University of Technology, Japan
takeshita@mst.nagaokaut.ac.jp

Introduction: Colloidal particles with monodispersed size distribution can form *crystal* at a volume fraction beyond a certain level. When colloidal particles are formed from thermosensitive gels such as poly(*N*-isopropylacrylamide) (PolyNIPA), colloidal crystallization can be caused by temperature-controlled reversible size change of the particles. In such systems, because gels have almost the same density with solvent, crystallization of microgel colloids can be a good model for colloidal crystallization of hard spheres in a microgravity condition. In this study, crystallization and glass transition behavior of PolyNIPA microgels were investigated by using ultraviolet-visible spectroscopy (UV-Vis), optical microscopy, and light scattering techniques.

Experimental: PolyNIPA microgels were synthesized by a precipitation polymerization technique. In the presence of sodium dodecyl sulfate (SDS), NIPA and *N*,*N*'-methylenebisacrylamide was polymerized at 40 °C using potassium persulfate as an initiator. The resulting aqueous microgel dispersion was dialyzed in deionized water for a week. The size and the size distribution of the microgel, which can be controlled by the amount of SDS, were measured by a dynamic light scattering technique. Colloidal crystallization behavior was measured by UV-Vis spectroscopy, in which crystal diffraction reduces intensity of transmitted light at a characteristic wavelength depending on lattice spacings of colloidal crystals.

Results and Discussion: The PolyNIPA microgels reduced their diameter with increasing temperature especially at around 40 °C, which coincides with the volume phase transition temperature of the ordinary PolyNIPA gels. The aqueous dispersion of the microgels with appropriate concentration formed colloidal crystal. The crystallization process was monitored by UV-Vis spectroscopy. Diffraction by the crystal structure formed causes absorption peaks at wavelengths corresponding to the lattice spacing. Crystallization temperature, T_c, and melting temperature, T_m, were determined from the behavior of the absorption peaks in cooling and heating processes. Concentration dependence of T_c and T_m is shown in Fig. 1. Based on this phase diagram, crystallization kinetics was investigated. Fig. 2 shows the double logarithmic plots of the time evolution of the degree of crystallization estimated from the peak heights of the absorption spectra. The slopes of the plots are about 2 for all T_c's, which coincides to the colloidal crystallization behavior of hard spheres under microgravity. Crystallization rate was estimated as an inverse of time for the transmission to decrease by 1%. In Fig. 3, T_c dependence of the crystallization rate is shown for microgel concentration of 4.53tw %. The bell-shaped dependence indicates that, the dispersion may become glassy state when quenched below 25 °C.

Introduction: The development of polypropylene (PP) composites and composite fibres containing inorganic fillers with nano-size of primary particles such as montmorillonites, boehmites, carbon nanotubes (CNT) and others is focused in particular on improving their mechanical properties [1], barrier properties, electrical conductivity and thermal stability [2].

Experimental: The commercially available kinds of polypropylene (PP), organically treated montmorillo-nites Cloisite 15A (C15A) and Cloisite 30B (C30B), boehmites Disperal 40 (D40), Disperal 60 (D60) and modified Disperal (DUN and DAM), further multiwall carbon nanotubes (MWCNT) Nanocyl 7000, as well as the non-reactive compatibiliser-dispersants based on polyoxyalkyl-enoxide and polyalkylsiloxane, were used in the experimental work. The PP multifilaments were prepared by spinning of PP and PP masterbatch blend using a laboratory spinning plant. The spinning temperature was 250-280°C. Fibres were drawn using a laboratory drawing machine at various draw ratios λ at a draw temperature of 120°C.

Method used: The DSC analysis was performed using Perkin Elmer DSC 7. The measurements were carried out with the cut fibres with length 1-2 mm using conventional method (CM) and with the fibres with constant length, which was achieved through winding of fibres on a small spool, later placed in a DSC pan – constant length (constrained) method (CLM) [3]. The Instron (Type 3343) was used for the measurements of the mechanical properties of fibres. The average factor of orientation of fibres (fα) was evaluated by sonic velocity measurements. Wide-angle scattering (WAXS) method was used for evaluation of total crystallinity Xα and the content of the mesophase Xm. Small-angle scattering (SAXS) method was used for evaluation of the d-spacing of organoclay in PP fibres.

Results and Discussion: Majority effects of nanofillers on supermolecular structure, thermal and mechanical properties of polypropylene fibres were very similar for layered silicates (plates), boehmites (more spherical) and CNT (fibrous) particles. To obtain high dispersion degree (exfoliation of silicates) the treatment with organic phase and/or suitable compatibiliser-dispersant was needed. Besides, the mechanical forces at drawing were helpful in this process (Figure 1). Similarly, the same conditions were convenient also for mechanical properties of fibres. The maximum tenacity and Young's modulus were achieved for nanofiller concentration about 0.1 wt% regardless of filler nature. DSC-CLM method showed as very sensitive for evaluation of thermal properties of oriented fibres. The melting temperature of constrained fibres significantly increased proportionally with orientation of fibres compared with CM method (Figure 2). It corresponds with their draw ratio (Figure 3). Nanofillers act as weak nucleation agents in PP; the highest effect was found for CNT. Unambiguous straight-line dependence was found for melting temperature vs. tensile strength (Young's modulus) of composite fibres (Figure 4). The analysis of the width and asymmetry of DSC-CLM thermograms related to non-uniformity of mechanical properties and processing are discussed in the paper as well.

Abstract

Kinetics of thermal degradation of chitin and chitosan using thermogravimetric technique (TGA) in dynamic mode were studied.

TGA analysis was carried out in an inert atmosphere of nitrogen, using a range of temperatures from 30 to 600ºC, in addition to rapidly heating values (β) of 5, 10, 15, 20, 25 and 30 degree/min.

Kinetic models were applied degradation *Ozawa*, *Friedman*, *Kissinger* and *Broido*. For the degradation of chitosan all models applied presented good adjustment, on the other hand for the chitin behavior was different, as the only model that presented a good adjustment linear was that of *Broido*.

From the termogramas obtained was determined that the decomposition temperature is higher for the chitin that for the chitosan, this is due to the greater crystallinity and a lower level of polymerization of the chitin.

However, in the values kinetic, was obtained greater activation energy for the chitosan, a product of interbreeding led by the group amino free. In the implementation of the model of *Ozawa* for chitosan expressed the effect of compensation kinetics, so that to be an increase of the activation energy, the factor preexponencial increases, maintaining the value of the rate constant change.

Hybrid Block Copolymer Precursors Carrying Reactive Triethoxy Silyl Side Groups : Synthesis, Micellar Behaviour and Hydrolysis-Condensation

beyou@univ-lyon1.fr

Among the several ways to obtain organic–inorganic hybrid materials, the sol-gel process, which relies on base- or acid-catalyzed hydrolysis and condensation reactions of metal alkoxides, is frequently used. This technique can be easily combined with organic polymerization to produce a variety of organic/inorganic nanostructured materials. Along this line, block copolymers with reactive alkoxysilyl groups has recently attracted much interest within the polymer community.[1-4] Herein, a series of poly(acryloxy propyl triethoxysilane)-*b*-poly(styrene) (PAPTES-*b*-PS) diblock copolymers of various compositions and molecular weights was prepared by nitroxide-mediated polymerization. We observed two clearly distinct T_gs for all the block copolymers, with values close to those of the corresponding pure homopolymer segments, suggesting that the PS and PAPTES blocks are phase-separated into two distinguished domains. Then, micelle formation was carried out by first dissolving the PAPTES-*b*-PS diblock copolymer in a solvent suited to both blocks (dioxane) and then adding methanol as a precipitant of the PS block. As seen in Figure 1a, the scattered light intensity suddenly increased when the methanol content reached a critical amount for which the PS block started aggregating.

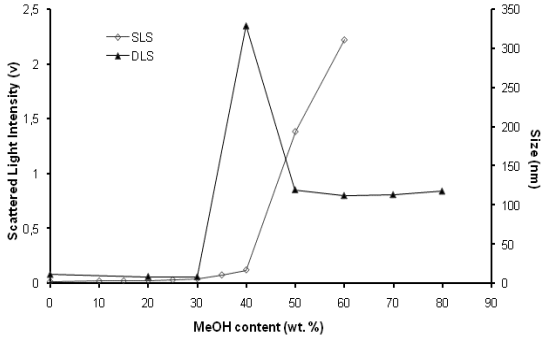

Figure 1. *a) Scattered light intensity as a function of added methanol content in $PAPTES_{91}$-b-PS_{175} / 1,4 dioxane solutions at different concentrations and b) Dynamic light scattering measurements and scattered light intensity as a function of added methanol content in a $PAPTES_{91}$-b-PS_{175} / 1,4 dioxane solution at a concentration of 2 mg.mL^{-1}.*

The micelle diameters, determined by dynamic light scattering, were in the range 50-109 nm depending on the PS molar fraction and the copolymer molecular weight. Regular spherical micelles were clearly seen in the TEM image (Figure 2).

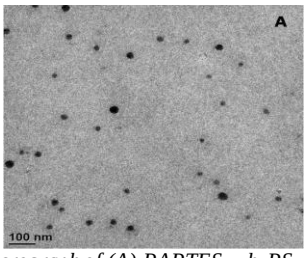

Figure 2. *TEM micrograph of (A) $PAPTES_{91}$-b-PS_{34} micelles in 40/60 (w/w) dioxane/MeOH solutions (C_0=30 mg.mL^{-1}).*

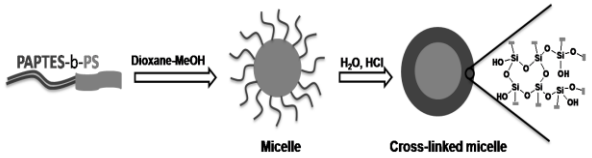
In order to permanently fix the micellar morphology of the aggregates, the PAPTES chains in the shell were cross-linked through hydrolysis/condensation of the alkoxysilyl groups in acidic medium (scheme 1).



Scheme 1. *Crosslinking of the PATES-b-PS micelles through hydrolysis-condensation*

A decrease of the hydrodynamic diameter of 10-15 nm was observed after the cross-linking process whatever the copolymer composition which was tentatively attributed to shrinkage of the corona induced by cross-linking. Similar particle sizes were observed by TEM before and after cross-linking suggesting that the cross-linking reaction mainly involved silanol groups located at the periphery of the corona on polymer chain ends. SAXS and SANS experiments carried out on these cross-linked core-shell particles will be also discussed.

Introduction: Recently, there has been increasing interest in the use of PP as matrix for the preparation of PP/MWCNTs nanocomposites [1-5]. This is due to the fact that PP has a good balance of mechanical and thermal properties, as compared with other polyolefins, which has made it a fast growing commodity. It has been observed that the mechanical and other properties of PP/MWCNTs depend on the degree of the dispersion of the MWCNTs in the polymeric matrix [1-5]. Strong interaction between nanotubes results in the formation of large aggregated bundles preventing their homogenous dispersion in the polymer matrix and therefore composites with poor mechanical properties are obtained due to the poor load transfer from the polymer matrix to the nanotubes [1-5]. The modification of MWCNTs reduces these interactions allowing a better degree of dispersion of the nanotubes in the polymeric matrix. The aim of this work was to study the effect of the modification of MWCNTs with IA and its derivative MMI on the morphology, mechanical and thermal properties of PP/MWCNTs nanocomposites.

Materials and Methods: MWCNTs were Baytubes® 150 CP from Bayer, Germany. High impact polypropylene copolymer with melt flow index of 0.8 g/10 min at 230 ºC and 2.16 kg was obtained from Petroquímica Cuyo, Argentina. IA was perchased from Sigma-Aldrich, USA. MWCNTs was oxidized by refluxing for 1 hour in a mixture of 2:1 of HNO_3 (58%) : H2SO4 (98%) followed by washing with water and drying under reduced pressure. FTIR and TGA were used to characterize the functionalized nanotubes.

The nanocomposites were prepared by melt mixing using a Brabender-Plasticorder batch mixer at 190 °C during 30 minutes at a rotor speed of 75 rpm and under nitrogen atmosphere to prevent polymer oxidation. The resulting composite was grinded and then pressed at 200 ºC to form a plaque of 1.5 mm thickness. The specimens for tensile mechanical measurements were obtained from the plaque as 1.5 x 90 x 120 mm according to the ASTM D 638-95.

Results and Discussion: The oxidation of MWCNTs mainly resulted in nanotubes with hydroxyl groups as well as carboxyl groups. The oxidized nanotubes were functionalized by using either IA or MMI and characterized by FTIR and thermogravimetric analysis (TGA). New absorption bands from MMI Carbonyl ester and acid at 1744, 1726 and 1716 cm^{-1} were observed, respectively. The vinyl C=C absorption band of MMI is also observed at 1633 cm^{-1}. An absorption band due to the carbonyl groups from IA was also observed in the FTIR spectrum of the IA-functionalized MWCNTs at 1695 and 1710 cm^{-1}. Figure 1 shows TGA of unmodified, oxidized and functionalized MWCNTs with IA and MMI. Considerable weight loss is observed at around 200 °C corresponding to the loss of functional groups from oxidized and functionalized nanotubes. All nanocomposites showed better thermal stability than polypropylene due to presence of carbon nanotubes. This major stability was attributed to the capacity of the nanotubes to restrict the thermal agitation of the polymer as well as to the major stability and thermal conductivity of the carbon nanotubes. The mechanical properties of PP was improved when 0.5 wt.% of MWCNTs was incorporated, specially nanotubes functionalized with itaconic acid, where an increase of up to 40 % of the elastic modulus was observed.

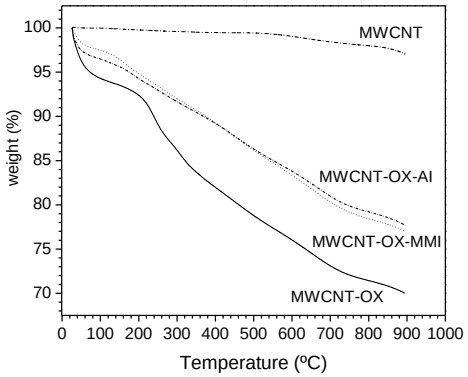

Figure 1. TGA thermograms of MWCNTs, oxidized MWCNTs and functionalized MWCNTs with IA and MMI.

Conclusions: The mechanical and thermal properties of PP were improved by incorporation of MWCNTs, especially those functionalized with IA, where a 40% increase of tensile modulus and higher thermal stability of PP was observed.

Microspherical Aniline Oligomers and their Nitrogen-containing Carbon Analogues

Zuzana Rozlívková, Miroslava Trchová, Elena N. Konyushenko, and Jaroslav Stejskal

Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, Heyrovsky Sq. 2, 162 06 Prague 6, Czech Republic

E-mail: rozlivkova@imc.cas.cz

Introduction

Polyaniline is probably the most studied conducting polymer because of a variety of morphologies that are displayed [1], nanotubes being the most interesting [2–4]. Aniline oligomers are generally believed to be responsible for the self-assembly that guides the growth of polymeric structures [3]. The chemical nature of such oligomers is still open to discussion.

The oligomers are produced at the early stages of aniline oxidation at higher pH [4]. Only at lower pH < 2, polymeric products are produced in addition to oligomers originated earlier. The oxidations, which are started and finished above pH 2.5, produce aniline oligomers only [5].

Methods

Oligomers were dissolved in various solvents, dropped on silicon wafers and left to dry.

In the present study aniline oligomers prepared at alkaline conditions have been studied by FTIR and Raman spectroscopy in combination with UV–visible spectroscopy, gel-permeation chromatography, and electron microscopic techniques.

Conclusions

Aniline oligomers have ion-exchange and redox properties that can have a potential usefulness. In some cases the self-assembling is observed. We illustrate that they may also be used as carbonization precursors in the preparation of nitrogen-containing carbons.

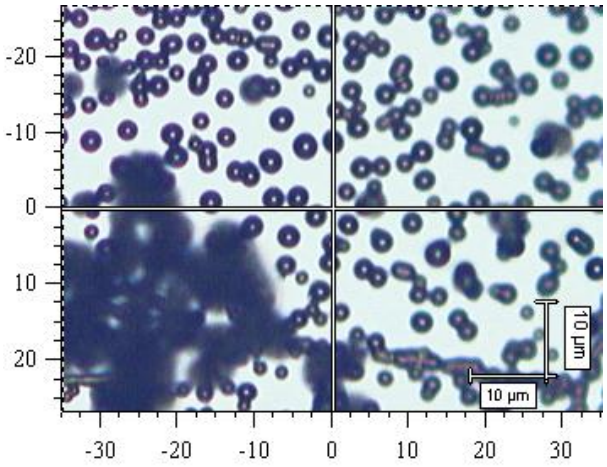

Figure 1. A drop of methanol-soluble part of oligomers evaporated on silicon support.

Porous titanium dioxide nanocomposite materials

O. Gaer, J. U. Wieneke, M. Ulbricht

Universität Duisburg-Essen, Lehrstuhl für Technische Chemie II, 45177 Essen, Germany
oxana.gaer@uni-due.de

To meet the future energy needs in an appropriate way and to prevent further climate damage, new environmentally friendly alternatives are in demand. Fuel cell technology provides an alternative energy; however, for the everyday consumer it has so far been too expensive. By linking fuel technology with nanotechnology innovations, it is intended to extend the life span of fuel cells and to reduce their production costs.

Here we present a concept for the synthesis and characterization of porous composite materials comprising nanoparticles (NPs) and styrene copolymers which are cross-linked with divinylbenzene (DVB). The materials are intended to be further pyrolyzed to yield new NP carbon composite materials. Here, polystyrene as reference and a copolymer obtained from 90 % styrene and 10 % 1,4-cyclohexanedimethanolmonovinylether were used. As starting material latex particles were synthesized by suspension polymerization of the monomers according to *Goodwin et al.* [1]. By swelling the latex particles with DVB and dilution with organic solvents and thinner (*Ugelstad* method [2]), it was possible to obtain porous copolymer particles. Pore sizes and pore size distributions and the resulting specific surface area were controlled by the systematic changes of process parameters (crosslinker and thinner composition). Characterization of the products was carried out by ATR-IR spectroscopy and BET measurements. In parallel to the polymer synthesis, dispersions of titanium dioxide NPs, for instance in toluene, were produced using an ultrasonic sonotrode. The quality of the dispersions was investigated using dynamic light scattering. The composites were prepared by impregnation of the styrene copolymers with the stable dispersion of titanium dioxide nanoparticles. The morphology of the materials and the distribution of titanium dioxide NPs were investigated with scanning electron microscopy. Overall, titanium dioxide nanoparticles could be incorporated into the porous polymer matrix in well defined distribution and relatively high loading. However, further studies are needed to find suitable pyrolysis conditions to achieve NP carbon composite materials for the use in fuel cell technology.

Introduction:

The nitrate ion in groundwater is becoming an environmental problem of major concern due to its high toxicity that causing cancer and nethemoglobinemia [1,2]. The important sources of nitrate can be inorganic fertilizer, industrial and sanitary waste waters, vegetable residues and compost, as well as rainfall and spontaneous nitrification of atmospheric nitrogen by nitrification bacteria. The dissolved nitrates filtrate through the ground by rainfall or irrigation and contaminate phreatic waters that feed wells from which drinking water is taken. Nitrates consumed with drinking water can be converted into nitrites in human body and may cause health problem. The increasing rigorousity of the drinking water quality standard, 50 mg/L in the European Union or 25 mg/L in USA, generates the urgent need to develop a new technology for nitrate removal from aqueous solutions. Recently, the catalytic reduction of nitrate by platinum and palladium metals is attracting considerable interest [3] **Experimental and Methods:**

The nanocomposites of polymers/MWCNTs were synthesized via in situ chemical oxidation polymerization method. These nanocomposites synthesized in different mass proportions of monomer to MWCNTs.

Results and Discussion:

In this research, we prepared nanocomposites of multiwalled carbon nanotubes (MWCNTs) with different polymers (such as: polyaniline (PANI), polypyrrole (PPY), poly(1,8-diaminonaphthalene) (poly(1,8-DAN)), poly (3,4-ethylenedioxythiophene) (PEDOT)) and poly (vinyl pyridine) (PVP), as effective and reusable nanocomposites for nitrate removal from drinking water. The nitrate removed from water with toxic concentration using ion-exchange mechanism with synthesized polymers counter ions without any toxic byproducts. We used different dopants as polymers counter ions and results shown that effective exchange of nitrate with Cl^- ions.

The different experimental parameters such as pH of the sample, polymers ion-pairs or dopants, temperature, nanocomposite loading, and ratio of polymer versus MWCNTs in nanocomposites, affect the amount of nitrate removal.

In order to examination of different nanocomposites in nitrate removal, every nanocomposite with different proportion in mass of polymer/MWCNTs was used. Results shown that effective nanocomposite with lower concentration of polyaniline is 3:1 and 4:1 nanocomposite. Since the pH of the aqueous solution is an important analytical factor in nitrate ions removal, the influence of pH on removation was examined in the pH range of 2-12 for each nanocomposite.

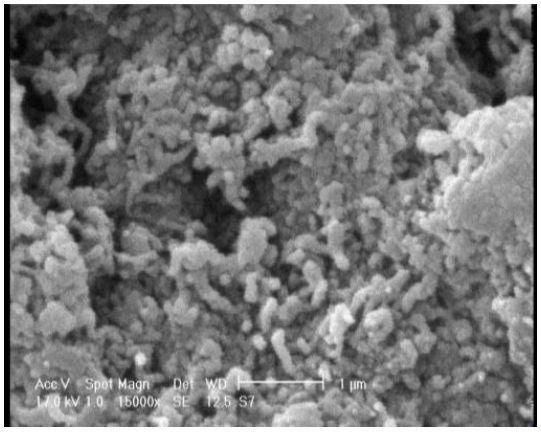

Fig. 1. SEM image of PANI/MWCNTs nanocomposite in 3:1 proportion.

In nanocomposite with higher concentration of PANI more remove percent has never been seen. For optimization of other factors that affecting nitrate removal the 3:1 portion selected because of higher physical stabilization in reusing for several times. In higher polymer concentration in nanocomposite the processability shows decrease.

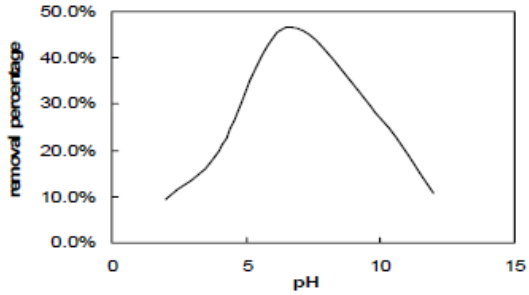

Fig. 2. Effect of water acidity on nitrate removal percent with PANI/MWCNTs.

Since the pH of the aqueous solution is an important analytical factor in the nitrate ions removal, the influence of pH on removing was examined in the pH range of 2-12 for each nanocomposite. The effect of solution acidity was investigated under prior found optimum condition. The results for PANI nanocomposite are shown in figure 2. It is obvious that the best removal of nitrate was done in pH= 6.5.

Conclusions:

The better performances explain by high degree of doping for PANI that allows the more exchange between nitrate and dopant anion of the conducting polymer.

By adding small amounts of nanoparticles relevant modifications of the polymer behaviour can be obtained justifying the extraordinary research in the field of nanocomposites during the last years [1]. It is well known today, although not completely understood, that these fillers can change the main polymer properties such as: crystallization, mechanical strength, electrical and thermal conductivity, melt processing, permeability, thermal degradation, and viscoelasticity, among others [1,2,3]. In this context, the addition of spherical silica nanoparticles modifying the crystallization and crystal morphology of the polymer matrix is highlighted as any final property of the material depends on these characteristics.

Despite several articles showing that silica nanoparticles produce both faster crystallization rates and an nucleating effect, an opposite effect has been recently published with outstanding consequences in the polypropylene properties [4,5]. Nitta et al. showed that the spherulite growth rate is drastically reduced when silica nanoparticles are added becoming zero at higher filler content [5]. These results stress the need of more studies about how the kind of nanoparticles and its dispersion affect the morphological behaviour of the matrix.

The main goal of the present article is to study the effect of adding spherical and tube-like silica particles on the spherulite formation of polypropylene under isothermal conditions. The effect of the particle size and morphology, and of the presence of a compatibilizer is further characterized.

Spherical (15 and 80 nm) and tube-like silica nanoparticles were melt blended with an isotactic polypropylene matrix and its effect on the isothermal spherulite growth rate was analyzed by polarized optical microscope. The addition of low amount (~ 1 wt%) of either 15 nm spherical or tube-like particles raises the spherulite growth rate and the nucleation density (see Figure 1), the latter in more than one order of magnitude. Samples prepared with silica spheres of 80 nm otherwise do not show any change in the crystallization behaviour. By adding a compatibilizer, both the nucleation density and the spherulite growth rate of the pure polymer are increased. Noteworthy, although the nanoparticles do not further increase the nucleation density of the polypropylene/compatibilizer blend, independent of its form and size, they cause a decrease in its spherulite growth rate. Therefore, the kind of nanoparticles and the compatibilizer are relevant variables controlling the spherulite formation processes of polypropylene composites.

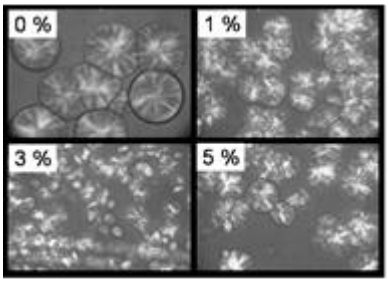

Figure 1. Optical micrographs showing the nucleating effect of S15 particles on polypropylene crystallization at 135 ºC. The number in the left-up corner represents the filler content in wt%.

Based on our results, we can conclude that by adding silica nanoparticles is possible to modify the spherulite growth of a polypropylene under isothermal conditions. The size and aspect-ratio of these particles are relevant variables controlling the crystallization processes.

junehuh@yonsei.ac.kr

Introduction: Supramolecular assembly of functionalized polymers, capable of forming block copolymer-like molecular clusters, has emerged as a promising alternative for creating nanoscopically ordered structures. Here, we demonstrate that nanospheres, which have intriguing internal nanodomains and controllable surface functionality, can be fabricated by supramolecular assembly of complementarily end-interacting two species of mono-end-functionalized polymers using the self-organized precipitation (SORP) method.[1,2] An exotic internal morphology, hierarchically organized structure of perforated spherical layers, was formed inside the nanosphere prepared from the stoichiometric mixture of the end-functionalized polymers, which is due to the formation of diblock-like supramolecules and their packing frustration in the spherically confined nanospace. When the mixing ratio of the two end-functionalized polymers differs from the stoichiometric ratio, the nanoparticle surface is enriched with excess of unpaired functionalized groups, which therefore provide us with a useful way to precisely control the surface functionality of the nanoparticles.

Materials and Methods: Our method for preparing nanospheres is based on the SORP of mono-end-sulfonated polystyrene (SPS) and mono-end-aminated poly(1,2-butadiene) (APB) at room temperature. A mixed solute consisting of SPS (M_n=10.5 kg/mole, polydispersity index =1.05) and APB (M_n=15.0 kg/mole, polydispersity index =1.05) with a weight fraction of SPS (Φ) is first dissolved in tetrahydrofuran (THF) chosen as a good solvent for both polymers. Subsequently, water drops are slowly added to the end-functionalized polymer solution, which provides a driving force for the polymers to form temporal aggregates nearby each of water droplets. The formation of these fluctuating, temporal aggregates become stabilized more and more by the steady addition of water droplets and the simultaneous evaporation of volatile THF. While the added water gradually becomes a majority solvent, the minority THF solvent, miscible both with polymers and water, plays a role similar to colloidal stabilizer preventing polymer aggregates from excessive growth. During this gradual change of solvent quality leading to the polymer assembly into nanospheres, the 1:1 end-associations between SPS and APB chains occur due to strong ionic interaction between a proton-donating sulfonic acid group of SPS and a proton-accepting amino group of APB ($SO_3^-\cdots NH_3^+$), which determines the morphological structure within the nanoparticle in combination with other interactions including the nonspecific repulsion between styrene and butadiene segments.

Results and Discussions: The transmission electron microscopy (TEM) images of the nanoparticles prepared from mixed solute of SPS and APB with Φ = 0.40 and their cryotommed section are shown in Figure 1, where the darker phase corresponds to the APB domains stained by osmium tetraoxide (OsO_4) and the lighter phase to SPS domains. The TEM image and its simulated morphologies reveal that the dashed circle-like SPS domains shown in Figure 1 are spherical layers perforated by several APB struts connecting concentric APB layers at different level.

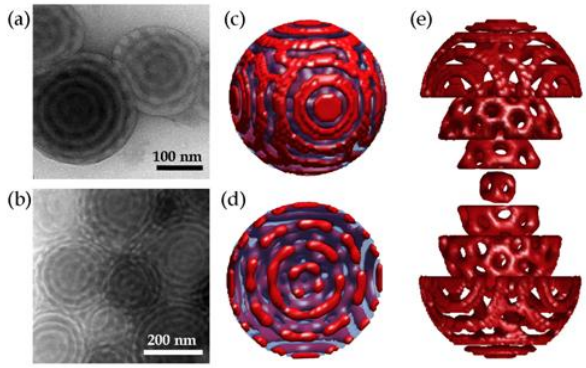

Figure 1. Nanoparticles prepared from mixed solute of SPS and APB with Φ = 0.40. (a) TEM image of the produced nanoparticles and (b) TEM image of cryo-sectioned nanoparticles. (c) The simulated nanosphere and (d) its internal structure represented by a radial cross section. Regions of high density of SPS and APB are colored opaque red and transparent blue, respectively. (e) The decomposed representation of hierarchical perforated spheres.

Conclusions: Nanospheres comprised of complementarily end-interacting two species of polymers have been fabricated by the SORP method. An exotic internal morphology, hierarchically organized perforated spheres, was formed inside the nanosphere prepared from the stoichiometric mixture, resulting from the formation of diblock-like supramolecules and their packing frustration in the spherically confined nanospace.

Introduction: As well known, graphene, two-dimensional graphite, exhibits remarkable, electronic properties that quantify it for applications in future optoelectronic devices. To date, most of researches concerning the applications of graphene have been poured into the evaluation of natural properties of graphene itself, mass production of well crystalline graphene nanosheets or the two-dimensional device applications, such as transparent conductive films. Recently, our group found that the simple modification of graphene surface without loss of the conductivity can be adapted to fabricate three-dimensional functional materials such as conductive micro/nanospheres, which have been highly requested due to the environmental problems induced by highly toxic chemicals during the metal-plating process.
Herein, we present a simple approach for the fabrication of monodisperse nanospheres with outstanding electro-conductivity, as an alternative to the conventional metal-plated conductive particles.

Materials and Methods: Negatively charged graphene sheets were prepared through chemical oxidation of expandable graphite flake (Graftech) using a modified Hummer's method, followed by reduction using hydrazine hydrate as noted in references [1, 2]. Positively charged polystyrene beads of two different sizes (cationic microsphere and nanosphere) were prepared by emulsifier-free emulsion copolymerization. The mixture of styrene (10.42 g, 0.1 mol) and MATMAC (0.05 mol) were added into the reactor, followed by addition of 0.1 g KPS dissolved in 10 ml deionized water. The polymerization was carried out under mechanical stirring at 400 rpm under nitrogen atmosphere at 70 oC for 8 hrs. Products were purified through dialysis. Positively charged PS spheres (0.08 g) and negatively charged graphene sheets (0.05 g), respectively dispersed in deionized water, were mixed on sonicator for 30 min and then were vigorously shaken for 12 hr at room temperature on vortex shaker (Maxi Mix II, Fisher). Subsequently, the coagulates were collected by centrifugation of 5000 rpm and dispersion in water at least three times, and finally dried on freeze dryer for 24 hrs.

Results and Discussion: In order to obtain hybrid spheres of electrical conductivity, assembly of graphene sheets containing anion charge with cationic polymer spheres (micro and nanospheres, respectively) was performed by simply mixing them together in deionized water medium. We found a spontaneous change of dispersion from respective colloidal states of graphene and polymer spheres to irreversible agglomerates, indicating the formation of graphene-polymer sphere assembly accompanied by spontaneous anion-cation coupling reaction. Electron microscopic examination was performed to analyze the assembly behavior between polymer spheres and graphene sheets. In Figure 1, SEM images obviously show that the polymer spheres were successfully decorated by graphene nanosheet patch. While the pristine colloidal polymer spheres don't exhibit any notable feature except smooth surface, the surface of polymer spheres after assembly with graphene sheets showed very rough texture, as shown in Figure 1(a), implying that there are adsorbed layer of texturing molecules on polymer spheres. In this system, the ionic interaction drove the graphene sheet to anchor on the polymer surface. Deposition of graphene sheets on polymer sphere is supported by transmission electron microscopy examination, showing that thin layer of graphene sheet was well deposited on the surface of polymer spheres to thickness of 5 to 16 nm, as shown in Figure 1(b).
In order to assess the electrical conductivity of graphene-wrapped hybrid spheres, the suspension of hybrid spheres in ethanol medium was sprayed on a fresh slide glass heated at 150 ^{o}C to form a translucent cell coated with the hybrid spheres, which exhibited an electrical conductivity of 1.33 S/m under four-probe method. For comparison, a pristine graphite-coated cell was fabricated and evaluated with the same procedure, showing an electrical conductivity of 15.5 S/m. The somewhat lower electrical conductivity of the cells made with graphene-wrapped hybrid spheres might be possibly due to the partial lack of ohmic contact in the cell as well as the electronic interfacial change. Nevertheless, it can be told that the electron transfer behavior found in graphene sheets is preserved even after the formation of hybrid with insulating polymer spheres.

Introduction

The inorganic nano-sized particles (1 to 20 nm) into polymer matrix at very low concentrations (<10 wt%) can lead to obtain composite materials with superior properties[1]. The nanoparticles have high surface area and develop more contact with the polymer matrix[2]. In this study, nanoparticles, ZrO_2/SiO_2 were introduced in the blends PVC/ABS (70/30) in order to obtain a composite material of high mechanical performance.

Materials and methods

Nanoparticles of zirconia/silica (ZrO_2/SiO_2) ratio at 80:20 were synthesized by the sol-gel process. Later it was incorporated into the PVC/ABS (70/30) polymer matrix to obtain a composite material. Nanoparticles treated at 400 °C were added to the matrix PVC/ABS (70/30) at 1, 2.5 and 5 wt% and processed in a two-roll mill. The film was obtained compression molded. Subsequently, we studied by DSC and DMA, tensile test and Izod impact strength.

Results and Discussion

By DSC showed a glass transition temperature (T_g) in the blend PVC/ABS, approximately 125.24 °C, corresponding to the rigid SAN phase present in the ABS and a melting temperature (T_m) to 188.4 °C. The decomposition temperatures (T_d) of PVC and ABS were observed at 282.85 and 305.64 °C, respectively. The variation of T_g of all material PVC/ABS-ZrO_2/SiO_2 (80/20) with respect to the T_g of the matrix PVC/ABS pure was at least ± 1 °C. Also the T_d was great than PVC/ABS pure matrix with 1%. However the events greater T_m shows the concentration effect when reach 5% of ZrO_2/SiO_2. In DMA, the use *E''* (loss modulus) and tan δ (loss factor) decided displays maxima at T_g[3]. In between-mixtures can be T_g detected two, one from each phase, but it shows shifts in their positions if some miscibility is present[4]. Figure 1 show the pattern of loss factor for mixing PVC/ABS (70/30) with ZrO_2/SiO_2 to different percentages and heat treated at 400 ºC. Noted that is the introduction of ZrO_2/SiO_2 (80/20) treated at 400 °C, produces an increase in T_g and at the same time a approach to the T_g present in the polymer matrix, improving the homogeneity in the composite.

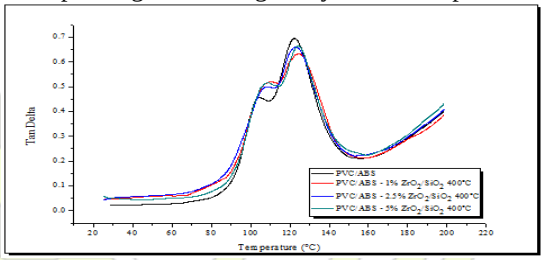

Figure 1. Loss factor matrix PVC/ABS (70/30) with ZrO_2/SiO_2 treated at 400 ° C.

Figure 2 show the tensile and impact strengths of the PVC/ABS with ZrO_2/SiO_2 to different concentrations. Figure 2(a) indicated the maximum resistance and the matrix increases slightly to 2.5% of the system. This can be due to greater compatibility between phases promoted by the system. With 1% is not a significant change in the maximum resistance of the matrix. On the other hand with 5% decrease slightly possibly due to overcrowding of the system ZrO_2/SiO_2 in the matrix.

Figure 2(b) show the impact strength of PVC/ABS blends as a function of ZrO_2/SiO_2 content. It could be seen that with the presence of 1% of the system treated at 400 °C gives an increase in impact strength with 258.50 J / M. The difference was 66.23% compared to the resistance of the pure matrix, indicating that there is a better interaction with the phases with the presence of 1% ZrO_2/SiO_2. It was noted that the presence of this system, the impact gradually decreased strength with more incorporation of ZrO_2/SiO_2.

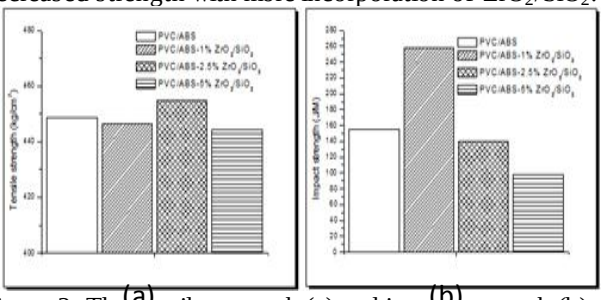

Figure 2. The tensile strength (a) and impact strength (b) of ABS/PVC (70/30, wt%) blends as a function of ZrO_2/SiO_2 content treated at 400 ° C.

Conclusions

According to the results of the DMA, the ZrO_2/SiO_2 system can act as a coupling agent for mixing PVC/ABS (70/30).A small amount of system has an influence on the tensile strength and impact. The tensile and impact of the blends increases with 1% of the system treated at 400 ° C due to the good dispersion and high degree of interaction between the nanoparticle and the polymer matrix.

P.zza Leonardo da Vinci, 32 - 20133 Milano, Italy

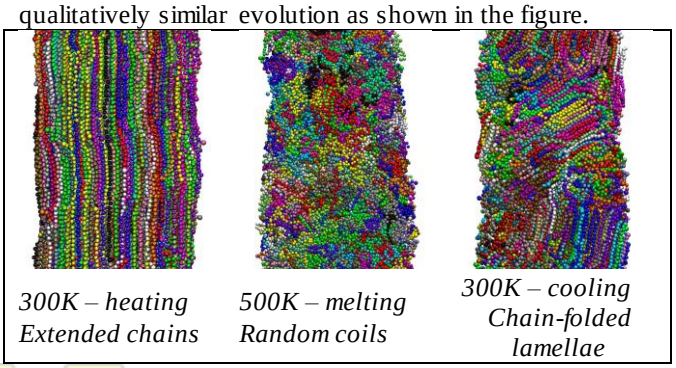
alberto.milani@polimi.it

Introduction In recent years, the electrospinning technique has been shown to provide a promising route to the production of nanostructured polymeric materials and nanofibers in particular[1]. These nanofibres have found applications in many fields such as template materials synthesis, catalysis, active filtering, nanocomposites, cell growth, tissue engineering and controlled drug release. There is currently a lot of interest in gathering information about the properties and the internal structure of electrospun nanofibers. Experimentally, it has been found that these depend crucially on processing conditions and post-processing treatments. Molecular simulations (MD or MC) have already been successfully applied to this aim[2].

Materials and Methods Because of the large size of nanofiber model systems, we carried out coarse-grained (CG) MD simulations of nylon-6 (NY6) nanofibers by means of the GROMACS 4 package [3]. Using the MARTINI force field by Marrink et al.[4] for the description of all intermolecular non-bonding interactions, we represent NY6 as an alternating copolymer consisting of apolar (C1) and polar (P4) spherical beads, respectively representing the $-(CH_2)_4-$ and the $-CO-NH-CH_2-$ units. As for the intramolecular stretching and bending terms, we generated our potentials by Boltzmann inversion of an all-atoms simulation of a short NY6 model chain.

We simulated isolated NY6 nanofibers of different radii and infinite length by suitably adopting full three-dimensional periodic boundary conditions. Initially, the chains were fully extended along the fiber axis. The simulations have been carried out at different temperatures until the occurrence of melting and each nanofiber was subjected to a whole heating-cooling cycle.

Results and Discussion All the fibers show a qualitatively similar evolution as shown in the figure.



300K – heating Extended chains | *500K – melting Random coils* | *300K – cooling Chain-folded lamellae*

The initial configurations (extended chains) are retained almost completely when running the simulation at 300 K. The fiber surface itself is quite uniform and does not show any appreciable disordering during the simulation. When the temperature is raised up to 500 K, the fibers undergo a very substantial disordering: they loose their preferential orientation and adopt a random coil conformation, thus indicating a molecular level melting. A kind of re-crystallization takes place upon cooling to 300K, without leading back to the original oriented chain-extended order; indeed lamellar-like domains are formed by chain-folded molecules. The folds appear to be fairly regular and tight, without long loops between the crystallized segments and there seems to be a fairly well-defined characteristic thickness for the lamellae. These domains do not have a well-defined orientation but they are randomly oriented with respect to the fiber axis. Finally, at intermediated temperature, the fibers may be in a nematic liquid-crystalline state or in an undercooled amorphous state. The structural and conformational features observed can be confirmed quantitatively by analysing density profiles, radial distribution functions, end-to-end distances, radii-of-gyrations and P2 orientation parameter for all the systems investigated.

The dynamics of the polymer chains have been also discussed by analysing the mean-square displacements of the chains along the fiber axis: the polymer chains do not diffuse at 300 K, both in the original chain-extended state and in the final chain-folded one, thus confirming that these states are indeed "solid". At 500 K, the chains are fairly free to translate along the fiber axis, despite of their mutual entanglements while at intermediate temperature a "liquid-like" state is obtained. Furthermore, the dynamics depends strongly on the radius of the oriented fibers during heating: the chains in the thinnest fiber are much more mobile than those in thicker ones as a result of different dynamics at the core and on the surface of the fibers.

Conclusions A coarse-grained force field has been implemented for the simulation of nylon-6 nanofibers. Similarly to the experimental evidence, in our simulations the nanofiber structure depends markedly on the thermal history and phase transitions are observed during heating and cooling from a melted state. In particular, a recrystallization in chain-folded crystalline domains takes place upon cooling as observed experimentally [5].

Testing 'Double Percolation' of Carbon Nanotubes in Copolymer Latexes by means of Reverse Addition Fragmentation Transfer Polymerisation.

Gavin TH Hill[1], *Guy Van Assche*[1], *Bruno Van Mele*[1], *Cor E. Coning*[2] *and Marie-Claire Hermant.*

Gavin.hill@vub.ac.be

Introduction Polymer composites containing carbon nanotube (CNT) networks have undergone extensive study over the last few years[1,2]. Electronic conductance in these films relies on a connected network of nanotubes or by saturation of CNT's into the polymer matrix. Recent studies on latex systems and polymer blends have revealed that conductivity at lower NT loadings can be achieved by a concept known as 'Double Percolation'(figure 1) where the threshold is controlled by the composition and morphology of the polymers. In this way the percolation threshold may be reduced by preferentially dispersing the NT's into the more compatible minor phase.

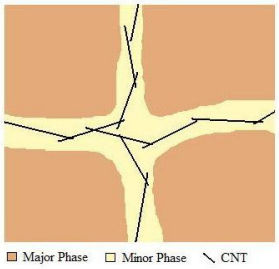

Figure 1 illustrating a percolated network in a copolymer.

This concept of double percolation is being applied to copolymers where the major and minor blocks can be produced in a latex (controlled morphology) using controlled radical polymerisation methods such as RAFT (Reverse Addition Fragmentation Transfer) followed by dispersion of the CNT's therein. Owing to studies by Van den Brande and Van Mele[3], Koning et. al.[4,5] and Hermant[6]; several candidate co-polymers have been identified, notably copolymers containing blocks of polystyrene (PS), poly-t-butylmethacrylate (PtBMA), polymethylmethacrylate (PMMA), polydimethylsiloxane (PDMS) and poly(2-dimethylamino)ethyl methacrylate (PDMAEMA).

Experimental Block Copolymers are prepared using emulsion RAFT polymerization and bulk RAFT polymerization. ATRP was carried out for some PDMAEMA-co-PS or PMMA copolymers.

Block copolymers and composites are analysed using Differential Scanning Calorimetry, Thermal Gravimetric Analysis and Gel Permeation Chromatography utilizing Universal Calibration and Triple detection. Latexes and solutions are analysed by Dynamic Light Scattering and UV-vis spectroscopy. Percolation thresholds are acquired by 2 and 4 point conductivity measurements on Nanocomposite thin films.

Discussion RAFT polymerization offers a flexible route to well defined block copolymers latexes. A significant challenge was using PDMS in emulsion systems, which was unrealistic for R-ATRP due to emulsion stability and catalyst/ligand problems. In the case of blocks where block A and block B are both miscible phases for CNT's 'Double Percolation' does not hold and a higher threshold is obtained (Figure 2).

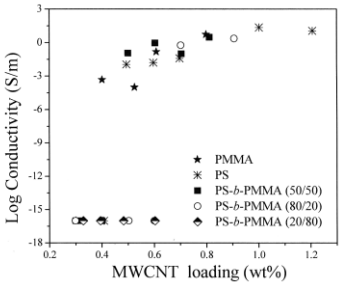

Figure 2 Conductivity measurements of films of PS, PMMA and PMMA-*b*-PS.

Co-polymer blocks consisting of PDMS-*b*-hydrophilic polymer can be used as a CNT dispersing surfactant. MWCNT's can be dispersed by these surfactants at lower concentrations than sodium dodecyl sulfate, SDS can have undesirable effects on compression molded films. Aqueous dispersion directly into a block-copolymer can offer an improved compatibility route to CNT dispersion into latexes or a direct route to nancocomposite polymer films.

Aqueous Microgels Modified by Wedge-Shaped Amphiphilic Molecules:Hydrophilic Microcontainers with Hydrophobic Nanodomains

Lei Li; Cheng Cheng; Xiaomin Zhu; Andrij Pich; Martin Möller

DWI at RWTH Aachen University, Aachen, Germany

Email: li@dwi.rwth-aachen.de, cheng@dwi.rwth-aachen.de, zhu@dwi.rwth-aachen.de,pich@dwi.rwth-aachen.de, moeller@dwi.rwth-aachen.de

Introduction: In the field of biology and pharmaceutics, various polymeric drug delivery and drug targeting systems are currently developed or under development in order to improve the specific delivery of drugs with low therapeutic index. In recent years, micelles self-assembled by amphiphilic polymers are the most used carriers for the encapsulation and transport of hydrophobic molecules[1].Meanwhile, the superior colloidal stability and flexible chemical composition of polymer-based microgelsalso attract more attention[2, 3]. Recentlywe developed a simple route to design hydrophilic microgels comprising inner hydrophobic nanodomains by complexationwithwedge-shaped amphiphilic molecules containingcomplementary functional groups[4]. Poly(N-vinylcaprolactam-co-acetoacetylethyl methacrylate) (PVCL/AAEM)-based microgel systems functionalized with vinylimidazole (VIm) groups were transferred into an organic medium, where they were neutralized by water-insoluble wedge-shaped sulfonic acid molecules. The loading of the wedge-shaped molecules into microgels can be controlled by varying the amount of imidazole groups integrated into the microgel network as well as the neutralization degree. In this work, a series of hydrophobic wedge-shaped sulfonic acid molecules with different alkyl chain length weresynthesized and used to modifythe PVCL/AAEM/Vimmicrogels. The structures as well as the uptake ability of the hydrophobizedmicrogels were addressed.

Materials and Methods: The synthesis of 4-N-[3',4',5'-tris-(dodecyloxy)benzamido]benzene-4-sulfonic acid (C12-H), 4-N-[3',4',5'-tris-(decyloxy)benzamido]benzene-4-sulfonic acid (C10-H) and 4-N-[3',4',5'-tris-(octyloxy)benzamido]benzene-4-sulfonic acid (C8-H)wasdescribedelsewhere[5].PVCL/AAEM/VImmicrogel was prepared using a literature procedure[6].VCL/AAEM/Vimmicrogelswith5mol-%vinylimidazolegoupswere separated from water bycentrifugationand dispersed in THF, where the complexationwith C12-H, C10-H and C8-Htook place. Afterwards the modified microgels were re-dispersed in water. Different amountsof Nile Red (0.97 mg/ml in a 1:2THF/acetone mixture) were added to eachmodified microgel solution (0.2 mg/ml in THF) to evaluate the dye uptake capacity.The dye uptake by the modified microgel particles was proved by means of fluorescence microscopy.The optical properties of the dye-loaded microgelsand the loading capacity were studiedusing UV-vis spectroscopy.Hydrodynamic diameter and zeta-potential were measured with Zetasizer Nano Series. Scanningforce microscopy (SFM) andtransmission electron microscopy (TEM) wereemployed to study the distribution ofhydrophobic domains formed by wedge-shaped moleculeswithin the microgel particles.

Results and Discussion: Independently on the degree of neutralization and the alkyl chain length all modified microgelparticles showed excellent colloidal stability and narrow size distribution after re-dispersion into the aqueous phase. Microscopicinvestigations confirmed the presence of nanodomains formed by wedge-shaped sulfonic acid molecules inside the microgel.At room temperature the microgelparticles modified with C12-Hat 100 % degree of neutralization exhibited smaller size than the original particles, while the modification with C10-H and C8-H increased the particle sizes.Note that after the complexationwith C12-H and C10-H the microgels lost completely their thermal sensitivity. However, the microgel modified with C10-H showed a slight linear shrinkage from the size of the C8-H microgel to the one with C12-H, while the temperature increased from 20 to 60 °C. This is possibly due to the different thermal behavior of the nanodomains formed by different wedge-shaped molecules. On the other hand, all the modified microgels lost their pH-sensitivity and exhibited strong negative surface charge even at degree of neutralization as low as 10 %. When hydrophobic Nile Red dyemolecules were loaded in the modified microgels, strong absorption and fluorescence in the visible range was observed. Meanwhile, all of them exhibited a clear temperature dependence of the maximum absorption wavelength.

Conclusions:A series of wedge-shaped sulfonic acid molecules with different alkyl chain length were incorporated into the PVCL/AAEM/Vimmicrogels. The modified microgelscontaining hydrophobic nanodomains in their interior could retain their colloidal stability in water. The varied structure affects both the particle size and the environmental sensitivity. The ability of the modified microgels to encapsulate hydrophobic molecules in water was confirmed by the uptake experiment of a hydrophobic dye monitored by UV-visspectroscopy and fluorescence microscopy.The dye-loaded microgel particles showed a thermochromism that allows them to be used as a temperature sensor.

Design of commercial polymer composites is based on combining different species to tailor material properties. One of the most promising strategies is the reactive compatibilization, when copolymers are formed *in situ* at interfaces just where they are needed to improve thermodynamic and mechanical properties of a composite.

In this work, an end-coupling between immiscible melts of two monofunctionalized macromonomers (Fig. 1) is modeled by dissipative particle dynamics starting from a flat interface and up to the formation of a mature microstructure (Fig. 2). The study is focused on understanding reasons of interface roughening and describing the subsequent self-assembling process. Influence of the reaction rate, chain length and polydispersity, blend composition and incompatibility of its components on the kinetics of copolymer formation and morphology development is investigated.

Simulations are performed with DPDChem freeware package [2] combining coarse-grained molecular dynamics with probabilistic treatment of chemical reactions. Time scales are attained that are two orders of magnitude as large as the interface saturation time making it possible to study the development of interface roughening in detail. Regimes of linear and logarithmic conversion growth are observed before the flat interface becomes unstable (Fig. 3), as predicted in theory [3].

It is demonstrated that overcrowding the interface with the copolymer product causing its phase separation plays the main role in spontaneous interface distortion. The instability leads to autocatalytic interface growth with exponential kinetics, when each new portion of the product creates more area for further reactions. It is followed by a slower terminal regime including formation and ripening of the lamellar microstructure. The late stage kinetics of end-coupling is strongly influenced by depletion of reactants and formation of ordered product layers. At certain conditions, it becomes asymptotically diffusion controlled in agreement with experimental data [4].

The role of diffusion is revealed in polydisperse systems, where the dependence of the copolymer average length on conversion goes through a minimum due to the competition of macromonomers of a same kind but different lengths. If the length ratio of dissimilar macromonomers is varied, self-assembling into different non-lamellar structures takes place. However, increasing this ratio results in a pronounced slowdown of the process at the autocatalytic stage, presumably, due to the formation of dense layers by longer blocks of the copolymer. Thus, an interfacial instability appears to be quite common in reacting melts of end-functionalized polymers but it does not ensure spontaneous formation of an ordered microstructure.

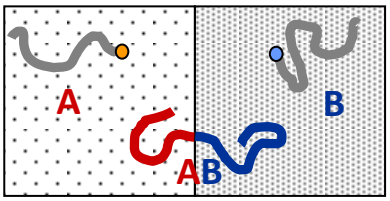

Fig. 1. Model melt of macromonomers A and B with an initially flat interface. Shown are active ends A (orange) and B (light blue), copolymer blocks A (red) and B (dark blue).

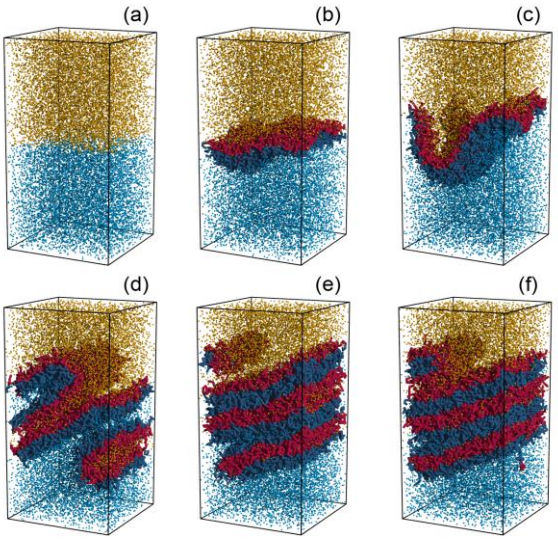

Fig. 2. Interface evolution: (a) the initial equimolar system, (b) saturated layer, (c) perturbed interface, (d-f) forming lamellar microstructure. The macromonomer lengths $N_A = N_B = 5$, reaction probability at contact $p_R = 0.25$, repulsion parameter $a_{AB} = 50$ [1].

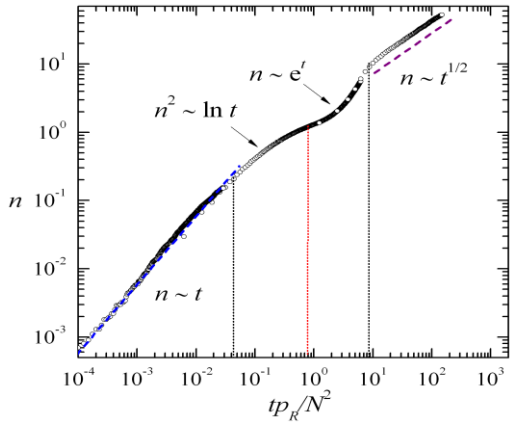

Fig. 3. End-coupling kinetics: the copolymer interfacial coverage n versus time t. $N_A = N_B = 2$, $p_R = 0.025$, $a_{AB} = 50$.

On the way towards wide-spread flexible large-area electronics, several features are of particular interest. With focus on low-cost applications, the manufacturing requires high throughput, preferably realized by simple methods on large-area flexible substrates, for example spin coating, inkjet-printing or roll-to-roll techniques.

For solution processed ZnO field-effect transistor (FET) devices, the highest electron mobility values are currently 1.65 cm^2/Vs, however obtainable only after annealing at temperatures >300 ℃. Here we report our investigation on the formation, characterization, room temperature processing and inkjet printing behavior of a molecular precursor and adherence of such films in an FET device. ZnO nanoparticles were synthesized using a facile sonochemical method with modification of previously conditions. The ZnO active channel layer was patterned with drops using a piezo ink-jet device. A single piezo-dispenser with a 50 μm orifice was used for ink-jet printing.

The appropriate active channel region was successfully formed on the substrate at a resolution of 200 dpi and a head frequency of 300 Hz. For film synthesis, inkjet printed ZnO was annealed at 150 ^oC for 30 min in air. The TFTs device has a channel width (W) of 100 μm and a channel length (L) of 10 μm. The I_{DS}-V_{DS} curves showed well-defined transistor characteristics with saturation effects at V_G>-10 V and V_{DS}>-20 V for the inkjet printing ZnO device. The carrier charge mobility was determined to be 0.162 cm^2 V^1s^{-1} with FET threshold voltage of -4 V and on/off current ratio 10^4

Electrospinning of poly(γ-benzyl-L-glutamate) nanofibres: the effect of polymer molecular weight and spinning conditions in various solvents

Jana Svobodová, *František Rypáček*

Institute of Macromolecular Chemistry AS CR, Heyrovsky sq. 2, Prague 6, 162 02, Czech Republic

jsvobodo@imc.cas.cz

Introduction: Natural and synthetic polypeptides belong to important biocompatible and biodegradable materials, which are being studied for biomedical applications. While the natural polymers, including proteins such as gelatin, collagen and silk fibrinogen are difficult to electrospin, because of their high viscosity and low solubility in organic solvents, the synthetic poly(α-amino acid)s can be prepared with properties suitable for this type of processing. In the presented work, the electrospinning of poly(γ-benzyl-L-glutamate) (PBLG), as an example of versatile poly(α-amino acid)s with many options for post-processing modification of spun fibres, was studied.

Current electrospinning research effort has focused on understanding the formations and morphology of electrospun fibres depending on process parameters as well as on finding suitable application of nanofibrous matrix. The main experimental parameters for successful electrospinning include applied voltage, tip-to-collector distance, solution concentration, viscosity, solvent conductivity and surface free energy. The feasibility of electrospinning often depends on the molecular weight of polymers, concentration and viscosity of polymer solutions and these parameters have also a dominant effect on the diameter and morphology of resulting fibres [1,2].

In this work three solvents (tetrahydrofuran (THF), dichloromethane (DCM) and dichloromethane/ trifluoroacetic acid (DCM/TFA) mixture) were used to prepare PBLG nanofibres. Electrospinning of all solutions was carried out at identical conditions to reveal the effects of molecular weight, solution concentration and viscosity on the PBLG fibre formation and morphological features of the electrospun material.

Materials and Methods: The PBLG samples were prepared by the ring opening polymerization of γ-benzyl-L-glutamate *N*-carboxyanhydride in dry dioxane, initiated with sodium methoxide [3]. The degree of polymerization was determined by viscometry in *N*,*N*-dimethylformamide, using Mark-Howink equation $[\eta] = 2.9 \times 10^{-7} M_v^{1.7}$. Intrinsic viscosities [η] of PBLG solutions were measured using Ubbelohde viscometer VS2004 (Vistec, Czech Republic) at 25 °C.

The electrospinning was performed using a standard jet apparatus with stainless steel nozzle having an inner diameter of 0.6 mm and copper plate with aluminum foil as the collector. The electrospinning parameters such as flow rate, applied voltage and tip-to-collector distance were fixed at 1 ml/h, 12 kV and 12 cm, respectively.

The morphology of the electrospun fibres was observed with scanning electron microscope VEGA Plus TS 5135 (Tescan, Czech Republic).

Results and Discussion: The molecular weights of the synthesized PBLG samples were 50 000, 120 000 and 270 000 g/mol. Bead-free, uniform fibres were successfully prepared of all the tested solvents from the PBLG samples with higher molecular weight (120 000 and 270 000 g/mol). The highest molecular weight (270 000 g/mol) produces thinner fibres with narrower fibre diameter distribution at the lower concentrations. The PBLG with the lowest molecular weigh (50 000 g/mol) did not produce uniform fibres.

The intrinsic viscosity of PBLG solutions decreases in the order DCM, THF, DCM/ TFA mixture. This is due to the fact, that DCM and THF are known as helicogenic solvents, in which the rod-like α-helix PBLG molecules aggregate to larger head-to-tail complexes [4]. The higher PBLG viscosity in these solvents lead to formation of thicker electrospun fibres (average diameters were higher than 1 μm) with broader diameters distribution. As the content of TFA in DCM/TFA mixtures increases (DCM/TFA = 90/10, 80/20, 70/30), the head-to-tail aggregation of chains decreases with PBLG conformation changing single α-helix and random coil, the solution viscosity decreases and the electrospun fibres become thinner and more homogeneous.

This results indicate, that for successful preparation of PBLG nanofibres, not only the molecular weight, and solution concentration and viscosity is important, but also the chain conformation of PBLG in electrospun solutions must be considered.

Investigation of Structure and Resistance of Electroless Copper Sulfide NanoParticles in Different Deposition Time

NSC 99-2221-E-036-002-MY3

Chi-Yuan Huang[*], *Yu-Min Fan*, *Ching-Shan Tsai*, *Keng-Yu Tsao* and *Chien-Pang Chang*

Department of Materials Engineering, Tatung University, Taipei, Taiwan

E-mail: cyhuang@ttu.edu.tw

In this investigation, the conductive filler of copper sulfide nanoparticles (CSNP) were prepared by the method of electroless deposition. Results showed that the CSNP transformed from flake-like columnar to ball shape from 0 minute to 60 minutes by SEM morphology analysis. The XRD analysis showed that the powder of CSNP fit in JCPDS card (PDF 11-0240) as Chevreul's salt at deposition time of 0 minute. When the deposition time increased from 20 to 40 minutes, the CSNP had the production of phase transitions. After deposition of 40 minutes, the phase of CSNP changed to Cu_2S, and the surface resistances of CSNP decreased from $>10^9$ Ω to 10.33 mΩ.

Experimental

The cupric source was from Copper Sulfate $CuSO_4 \cdot 5H_2O$ made by Wako, Japan. The weak reducing agent was Sodium Bisulfite $NaHSO_4$ made by Wako, Japan, and the strong reducing agent was Sodium thiosulfate $Na_2S_2O_3 \cdot 5H_2O$ made by Wako, Japan. The electroless bath carried on 75°C with nitrogen stir, separated to 0、20、40 and 60 minutes. After complete deposition, the precipitation carried on the steps of water wash、filtration and dry. The powder was measured by field emission scanning electron microscope (JEOL JSM-6700F and Hitachi S4700), the surface of the sample was coated with platinum and viewed with FESEM at voltage 3.0 KV. The powder was carried out by X-ray Diffractometer utilizing CuKα radiation of wavelength 1.54 angstrom. The resistance of powder was measured by 4-point-probe method (QT-50, Quatek, Taiwan), the precipitation of powder was pressed by 400 kgf/cm^2 as circular ingot (diameter 5mm) by compression machine.

Results and discussion

Fig.1 showed the SEM photographs of CSNP in different deposition time was from 0 minute to 60 minutes. The particle morphology at 0 minute was flake-like columnar shape of Chevreul's salt [1~2], and then 20 minutes the particle morphology was changed to laminated and ball-like shape coexisting. When the deposition time was 40 minutes, the flake shape was nearly vanished. At the deposition time of 60 minutes, the ball-like shape was decreased from 400 nm to 100 nm. Fig. 2 showed that the electroless plating time was longer, the phase of the copper sulfide was stronger. When the deposition time was 40 minutes, the phase was nearly Cu_2S. The powder at 0 minute fit in JCPDS card (PDF 11-0240), and powder at 40、60 minutes fit in with JCPDS card (PDF 02-1284). There were three characteristic peaks (2 Theta) at 46.29°、32.30°、27.99° which was (220)、(200)、(110) plane of Cu_2S (PDF 02-1284) [3]. Fig. 3 showed that the precipitation at deposition time of 60 minutes could be obtained the optimum surface resistances value of 10.33mΩ.

Study of the film formation and mechanical properties of the latexes obtained by miniemulsion co-polymerization of the butyl acrylate, methyl acrylate and 3-methacryloxypropyltrimethoxysilane.

José Manuel Ramos-Fernández, Celia Guillem, Ángel Lopez-Buendía

AIDICO, Polymer research unit C\ Camí de castellan Nº4 Novelda (Alicante) 03660

Water-based emulsion polymers are used in many applications such as latex paint, paper coatings and adhesives. Thermoplastic polymers are commonly selected because these kinds of materials can easily deform, coalesce and form coherent films. These kinds of films usually have low performance because, high glass transition temperature (Tg) (high cross-linking degree) polymer particles do not give coherent films at room temperature, (the coalesce and polymer chain interdiffusion is restricted) and low Tg (low cross-linking degree) polymer particles do not give hard and strength films. Therefore, high performance films based on waterborne thermoplastic polymers synthesis still remains a challenging issue. For many applications, the mechanical properties can be increased by introduction of cross-linking chemistry into latex-based coating. Thus, the latex particles remain with relatively low cross-linking degree in the dispersion but undergo the cross-linking once they have formed the coating on the substrate. Among the different alternatives, the incorporation of alkosysilanes into latex particles is an interesting alternative.

The general formula for an alkoxysilane shows two different kinds of chemical groups attached to the silicon atom. One is a nonhydrolyzable organic group, this group provides the functional group which reacts with the monomers commonly used in the coating formulation, and the second one represents the alkoxy moieties, which can react with hydroxyl groups and liberate methanol or ethanol. The alkoxy moieties provide the self-cross-linking ability to the copolymer. Thus after the film formation, the hydrolysis and condensation reactions of the alkoxysilane moieties, at room temperature, would lead to the film cross-linking.. Thus, premature hydrolysis and the subsequence cross-linking must be avoided during the latex synthesis in order to obtain the desired cross-linking degree after the film formation. Several strategies can be tackled to reduce the premature cross-linking: the use of sterically hindered alkoxysilane would produce a reduction in the hydrolysis rate, besides, good pH control is required since the lower hydrolysis rate occurs at neutral pH. On the other hand, the selection of an adequate polymerization technique can be a powerful tool to avoid the premature cross-linking. Semicontinuous addition of the alkoxysilane in the late states of polymerization reaction would avoid the prolonged contact between the alkoxysilane and water and therefore the hydrolysis can be efficiently avoided. One different approach is to carry out a miniemulsion polymerization instead of conventional emulsion polymerization. Miniemulsion polymerization consists of the polymerization of a stable dispersion of monomer droplets in the aqueous phase. The dispersion is formed by using an adequate dispersion device in order to break down the monomer droplets and reduce their size to the required value, usually below 500 nm. In properly

formulated miniemulsion, the alkoxysilane monomers are protected from the aqueous phase by a waterproof oil droplet, therefore the hydrolysis reactions can be dramatically reduced.

This work will be focussed in the miniemulsion co-polymerization of butyl acrylate, metyl acrylate and two different alcoxysilanes. The influence of the experimental parameters in the latex features will be evaluated. These latexes will be used to protect natural stone against external physical and chemical attacks; therefore the mechanical properties of the film obtained using these latexes will be evaluated, focussing the studies in the influence of the alcoxysilane in the mechanical properties.

Nanoindentation test will carried out to select the adequate amount of alcoxysilane. Under our knowledge, few nanoindentation tests have been carried out to evaluate the mechanical properties of this kind of cross-linked latexes. It is now widely recognized that the composition and properties of the material near the surface of a given coating may be quite unlike the composition and properties of the bulk of the film. Surface physical properties can have major effects on important coating performance properties such as appearance, adhesion, mar and scratch resistance, and wetability. Therefore an important effort will be made in order to asset the mechanical properties of the coating over the substrate (marble tiles).

Investigation of porous structure and thermal properties of sulphur containing copolymers

Beata Podkościelna

Faculty of Chemistry, MCS University, pl. M. Curie-Skłodowskiej 5,

Introduction

Porous polymers have been used in several applications like HPLC packings, catalysis, enzyme immobilization, as adsorbents and many others. These applications are a consequence of their physico-chemical and morphological properties such as dilution and cross-linking degree, porosity, pore volume, capability of modification, thermal resistance etc. Polymeric packing materials especially the most popular styrene/divinylbenzene copolymers seem to be great alternatives to silica based supports and to the alkyl bonded phases. These polymeric sorbents are chemically stable in solvents in the entire pH range, but have also drawbacks associated with the presence of micropores in the polymeric matrix. For this reason, the attention of scientists and producers is focused on designing their porosity.

Materials and Methods

Copolymerization of two pairs of tetrafunctional monomers bis[4(2-hydroxy-3-acryloyloxypropoxy)-phenyl]sulfide with divinylbenzene S.A-DVB and bis[4(2-hydroxy-3-methacryloyloxypropoxy)-phenyl]-sulfide with glycidyl methacrylate S.M-GMA are described. Porous microspheres were obtained by suspension-emulsion copolymerization in the presence of pore-forming diluents: toluene and decan-1-ol, using α,α'-azoiso-*bis*-butyronitrile (AIBN) as an initiator. In the syntheses constant concentrations of toluene in the mixture with decan-1-ol (1:1, w/w) were used. Porous structure of the obtained microspheres in dry (calculated by the BET method from the nitrogen adsorption-desorption measurements) and swollen (the inverse SEC method) states was studied and compared with that of bis[4(2-hydroxy-3-methacryloyloxypropoxy)phenyl]-sulfide with divinylbenzene S.M-DVB copolymers previously studied [1]. Swelling properties of the obtained copolymers as well as thermal properties studied by differential scanning calorimetry (DSC) and thermogravimetric analysis (TG) were discussed in detail. The surface texture of the obtained microspheres was controlled by the AFM analysis.

Porous structure characterization

In the dry state, porous structure of copolymers was characterized by nitrogen adsorption at 77K using an adsorption analyzer ASAP 2405 (Micrometrics Inc., USA). Before measurements the copolymers were outgassed at 150 ^{o}C for 2 h. Specific surface areas were calculated by the BET method, assuming that the area of a single nitrogen molecule in the adsorbed state is 16.2 Å^2. Pore volumes and pore size distributions were determined by the BJH method. In a swollen state the beads were characterized by the inverse size exclusion chromatography (SEC) technique introduced by Halász and Martin [2].

Results and Discussion,

The copolymer (S.A-DVB) has the narrowest pore size distribution with most probable pores of a diameter ~ 200 Å (calculated by the BET method from the nitrogen adsorption-desorption measurements) (Fig.1). Compared with the reference S.M-DVB both copolymers are characterized by monodispersive pore size distribution. Porous structure of these copolymers was also studied by the inverse SEC. Pore volumes determined by the inverse SEC method are significantly larger for all the studied copolymers. Additionally, the inverse SEC method reveals micropores in the internal structure of polymeric beads. The results obtained from the DSC and TG data indicate that the highest thermal resistance is found for the copolymer S.A-DVB which has the most crosslinked chemical structure. To investigate swelling behaviour microspheres were swollen in typical solvents, in all polar solvents the swellability coefficients vary from 16 to 40 %. The largest swellability coefficient in THF is observed for the S.M-GMA copolymer.

"Unexpected Enhancement of Polymerization Rate in Solution Polymerization with nanoCeO$_2$ particles "

Miren Aguirre, Maria Paulis, J.R. Leiza

POLYMAT

miren.aguirre@ehu.es

Introduction

Wood has the potential for being a competitive and sustainable material. However, for outdoor use it is necessary to enhance its performance and long term durability. The main problem is its high sensitivity to UV degradation. It is common knowledge that wood is affected by light either by color change or by degradation of the surface.

To protect wood from sunlight spectrum, UV-VIS (250-440nm), the light should be cut off or filtered before it reaches the wood surface. Traditionally, organic UV absorbers were used but these substances tend to degradate upon outdoor weathering. Several inorganic fillers, such as TiO_2, ZnO and CeO_2 have been proposed as alternative candidates.

The aim of this work is to synthesize clear-coat wood coating based on hybrid acrylic/nanoCeO$_2$ latexes by miniemulsion polymerization. In this work however, the effect of the nanofiller in the solution polymerization of the typical acrylic monomers used in the coating applications was be investigated.

Materials and Methods

The solution polymerization reactions were carried out batchwise at 70ºC. The solids content of the reactions was 25 wt%. The solvent (Toluene), the monomers (MMA/BA/AA) and the nanoceria (0-3 wt% with respect to the monomer) were charged in the reactor and after reaching 70ºC a initiator (AIBN) shot was added to start the polymerization.

Homopolymerizations of MMA and BA and copolymerizations of MMA/BA with and without AA were carried out, under the presence or not of the nanoceria.

The evolution of the conversion was followed gravimetrically and the molecular weight by GPC.

Results and Discussion

Figure 1 presents the time evolution of conversion for three different runs carried out with MMA monomer, for different nanoceria amounts. According to the data in Figure 1 the polymerization rate increases with the presence of 1% of nanoceria in the polymerization medium. However, increasing the concentration of nanoceria from 1 wt% to 3 wt% did not have an additional effect on the polymerization rate.

Table1. Conversion, molecular weight and polymerization rate results. *With respect to the monomer.

Run	nanoCeO$_2$ (%)	Conversion (%)	Mw (g/mol)	Rp (mol/s)
1	0	76.7	62000	0.205
2	1	99.6	28200	0.284
3	3	100	29300	0.291

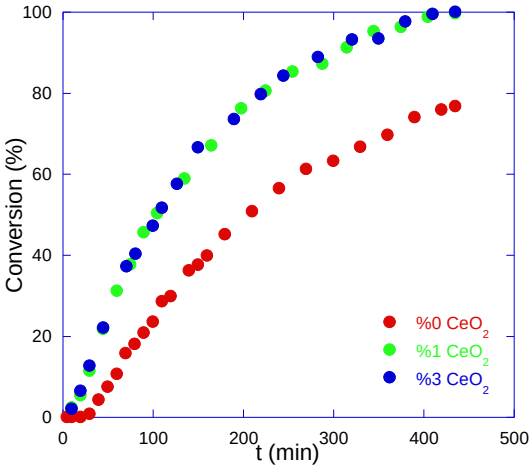

Figure 1. Time evolution of conversion for the batch solution polymerization experiments of MMA carried out with and without nanoceria.

The molecular weights of PMMA produced significally decreased in presence of nanoCeO$_2$. This was expected because in classical free-radical polymerization, increasing the polymerization rate the molecular weights of the polymer decreases. That might be due to the fact that more (AIBN) radicals are generated in the presence of the nanoceria, producing shorter polymer chains. Similar effect in the polymerization rates and molecular weights were also observed for the homopolymerization of BA and the copolymerization of MMA/BA. Nevertheless, the presence of small amounts of AA in the polymerization counteracts the enhancement effect provided by the nanoceria.

Whether the enhanced radical concentration is due to an increased decomposition of the AIBN in the presence of nanoceria or to the formation of new radicals is being investigated.

It will be investigated if this effect is similar in a compartmentalized system as miniemulsion polymerization.

Acknowledgments

Introduction

Stimuli-responsive hydrogels are subject of great scientific interest due to their unique properties and rich field of applications. Among thermoresponsive hydrogels one of the most popular are those based on Poly(N-isopropylacrylamide). They are highly swollen at temperatures below the so-called lower critical solution temperature and shrink at higher ones. This strong volume trermo-responsivity makes from Poly-NIPA hydrogels a very attractive matterial for many applications. Most popular uses are drug delivery systems, enzyme immobilizations, nano-valves, electrophoresis or mechanical actuators. Our attention is focused on the latter application.

Results and discussion

In the first part of this contribution, we modified our previously developed highly porous, silica-filled poly-NIPA nanocomposite hydrogels [1,2], characterized by a short time of response to temperature. Our goal was to obtain materials with markedly higher moduli as well as with fast and strong force response to external stimuli, while keeping the fast responsivity and the original volume ratio of the swollen and deswollen states. This type of material could be potentially used in mechanical actuators. We managed this by synthesizing new highly porous gels with thicker pore walls and also by variation of nanofiller: silica nonopaticles, titanium dioxide nanopowder and hectorite clay were tested. The mechanical properties, the morphology, the kinetics of the volume- and force-response to temperature and to pH will be discussed.

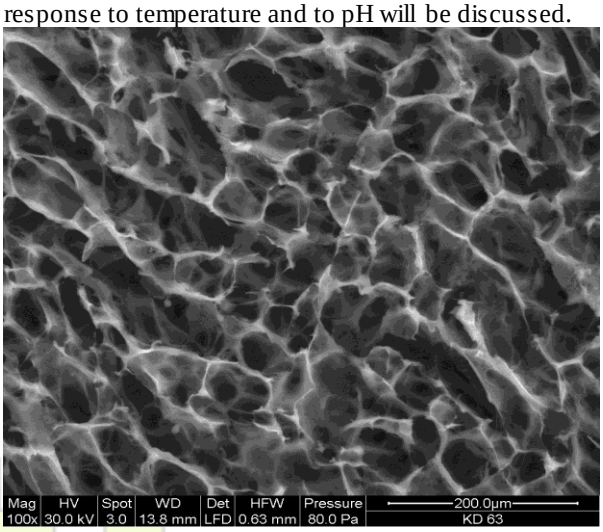

Figure 1. SEM picture of porous gel sample with 14 % of monomers concentration

Secondly, we prepared conductive hydrogels composites based on N-isopropylacrylamide and polyaniline (PANI). Polyaniline is one of the most

famous conducting polymers. It displays high electrical conductivity, environmental stability, ease of preparation from common chemicals, good processibility, in addition to a relatively low cost [3]. Highly porous specimens of poly-NIPA based hydrogels containing varying amounts of sodium methacrylate were covered by polyaniline via oxidation of aniline hydrochloride with ammonium peroxydisulfate, in aqueous medium at room temperature. To obtain homogenous distribution of the polyaniline in pore system, the gels were at first swollen with peroxodisulfate for five days and then subsequently treated with an aniline hydrochloride solution. The final products display a dark green color typical for PANI. Morphology, conductivity and mechanical properties of those composites will be presented.

Instantaneous Electric Dipole Moment in Conjugated Polymers

Luiz F. Roncaratti, Ricardo Gargano, Pedro H. de Oliveira Neto, Wiliam F. da Cunha, Geraldo Magela e Silva

Instituto de Física, Universidade de Brasília, Brasil

gargano@fis.unb.br

Introduction

Conjugated polymers has two degenerated ground states called A and B phases. The kink is a defect where these two phases have a "misfit". This is the basic signature of a soliton state [1]. We consider a zero charge spin ½ soliton on a thermalized one-dimensional lattice. In this case we found an oscillatory electric dipole at the kink induced by the thermal phonons on the lattice.

Methods

Our system is defined by a model Hamiltonian containing an interaction potential that depend on relative atomic coordinates [2], plus a Tight-Binding term as approximation for the π electrons-phonons interaction [3]. The last term includes also a modified hopping term to take into account an external electric field [4]. Each atom is also coupled to a set of reservoir oscillators representing a thermal bath.

To time evolve the system, we prepare a stationary state fully self-consistent with the degrees of freedom of electrons and phonons. To perform the dynamics we solve the Schrödinger one-particle equations coupled with the Euler-Lagrange equations to treat the lattice. Since our main objective is to characterize the dynamics under a temperature regime we eliminate the reservoir degrees of freedom in the usual way and obtain a quantum Langevin equation [5]. These equations are defined by an exponential correlated noise and its respective memory kernel [6]. The set of equation of motion was integrated numerically [7] using a fourth-order Runge–Kutta method.

Results and Conclusion

We used the parameters of a perfectly dimerized *trans*-polyacetylene [2] and characterized the instantaneous electric dipole at the kink as function of the lattice temperature. Our results shows a stable oscillating dipole over a large range of temperature values. This unveils a new and unexpected characteristic of solitons in conjugated polymers.

Abstract

Polyaniline (PANI) as a conductive polymer was successfully synthesized via inverse microemulsion polymerization. The effect of four main reaction parameters including aniline (AN, as monomer) concentration, molar ratio of dodecylbenzenesulfonicacid (DBSA, as surfactant) to AN, molar ratio of ammonium peroxydisulfate (APS, as oxidant) to AN and reaction temperature were well studied on the PANI volume conductivity. For this purpose, an experimental schedule was made according to Taguchi experimental design. SEM and TEM images of the prepared PANI showed a spherical morphology having less than 70 nm particle size diameter the all samples. The analysis of experimental results indicates that volume conductivity of PANI particles increases with increasing of AN concentration and APS/AN molar ratio. The PANI conductivity decreases continuously with increasing DBSA/AN molar ratio while the reaction temperature does not show a distinct trend on the conductivity of nano PANI particles.

Introduction

Intrinsically conductive polymers have been attracted much research especially due to their applications such as rechargeable batteries, solar control, optical property and anticorrosion coatings. Among these polymers, PANI has been greatly investigated because of its low cost, easy synthesis and environmental stability compared to the other conductive polymers. Indeed, electrical conductivity of PANI is resulted from its structural conjugated double bonds that can easily change from oxidized to reduced state and vise versa. Many parameters such as polymerization method, particle size, morphology and reaction parameters can affect the electrical conductivity of PANI[1]. However, according to our knowledge, there is no comprehensive investigation in this field.

In this work, the effect of four main reaction parameters all in four levels (Table 1.) was well investigated on the PANI conductivity which is the most important property of PANI. To do this, an experimental design was utilized according to Taguchi approach suggesting a standard L_{16} orthogonal array. Subsequently, the analysis of results was performed with analysis of variance (ANOVA) technique.

Table 1. Chosen reaction parameters and their levels for Taguchi experimental design

Parameters	Level 1	Level 2	Level 3	Level 4
AN (mol/lit.)	0.05	0.1	0.15	0.20
DBSA/AN	1.5	2.0	2.5	3.0
APS/AN	0.2	0.4	0.6	0.8
T (°C)	0	10	20	30

Materials and methods

AN, APS and hexane (as reaction environment) were purchased from Merck and DBSA was received from a local company. The AN was distilled twice in reduced pressure while the other chemicals were used as received. PANI was well synthesized through inverse microemulsion polymerization according to literature[2]. In this procedure, DBSA and AN were consecutively added into the hexane and the solution was kept under sonication which was leading to formation of nano micelles (as nano reactors). At the end, water dissolved APS was introduced drop wise into the system to initiate the polymerization reaction.

Results

SEM and TEM images showed a spherical morphology having less than 70 nm diameter indicating the nano size of the micelle structures.

The relative influence of each parameter on the PANI conductivity take into account with the ANOVA technique and the results are shown in Fig. 1. As can be seen, the electrical conductivity is improved with increasing AN and APS/AN ratio due to formation of longer PANI polymer chain and more oxidation of PANI, respectively. However, the conductivity decreases with increasing DBSA/AN molar ratio. This behavior could be related to the excess protonation of PANI polymer chains. This is because of the fact that the half doped structure of PANI is the most suitable structure for charge transfer through the polymer chains.

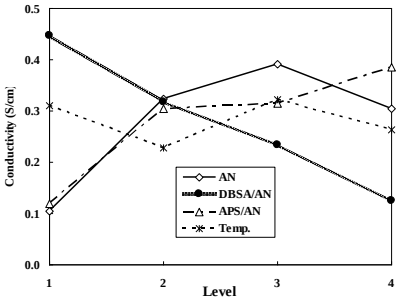

Fig. 1. Average influence of four reaction parameters on the electrical conductivity of PANI particles

Conclusion

The reaction parameters could be greatly affected the conductivity of PANI. Furthermore, they could be easily controlled during the PANI polymerization. To increase the conductivity of PANI, one can increase AN and APS/AN ratio and decrease DBSA/AN ratio.

Influence of Different Nanofillers on the Phase Behavior of Epoxy/Polystyrene Blends

Mario Culebras, Isidro S. Monzó and Clara M Gómez

Dpertment of Physical Chemistry/ICMUV, University of Valencia, Burjassot (Valencia) Spain

clara.gomez@uv.es

Introduction

Brittle thermosets materials, like epoxy resins, can be toughened by the incorporation of an elastomer or thermoplastic additive [1,2]. This modifier forms a homogeneous solution with the epoxy precursor. Addition of a curing agent increases the molar mass of the thermoset and a liquid-liquid phase separation occurs at a certain level of conversion [2]. The ultimate properties of these materials depend on the morphology generated during the build-up of the epoxy matrix. In order to predict or explain morphologies and properties, we must begin with a reasonable phase separation thermodynamic description of the system. The lattice theory of Flory and Huggins [3] is the best known theory used to describe the phase separation of polymeric solutions and blends and has been applied to study phase separation in thermoset/thermoplastic blends. A detailed phase-separation thermodynamic description of the system, starting with the thermoset precursor, thus establishing the basis of the thermodynamic treatment aids to better understand morphology development and final properties.

In the last years, there has been significant interest in the effect of nanoparticles on the properties of polymer systems. Nanoparticle addition can dramatically change the properties of polymers or polymer blends, or act as potential nanocompatibilizers for mixtures of immiscible blends. Much work has been devoted in obtaining improved matrices with very well-dispersed nanoparticle. However, the factors that control the formation of such hybrids are not well-understood. It is not clear under what conditions the different components will become intermixed to yield thermodynamic stable materials. An intense research can be carried out in this direction since the properties improvement will depend on the thermodynamic stability of the mixture and on the overall morphology of the material.

The aim of this paper is to study the influence of different nanoparticles on the phase separation and morphology development of an epoxy/polystyrene blend before curing and after polymerization with a diamine. The aspect ratio of the nanoparticles has been varied thus employing, fiber-like particles like sepiolite, spherical particles as silica and platelet like particles as montmorillonite.

Experimental Part

The epoxy prepolymer DER336 is based on diglycidyl ether of bisphenol A, kindly provided by Dow Chemical Company. The polystyrene Lacqrene PS1450N supplied by Atofina. Unmodified (S9) and organically modified (B5) sepiolite, different montmorillonites and modified SiO_2 were used as nanofillers.

Cloud-point temperatures of the different mixtures were determined using a light transmission device that detects the light transmitted as a function of temperature.

Results and Discussion

Figure 1 shows as an example of the experimental data the cloud point temperatures for epoxy/polystyrene in presence of different montmorillonite (MMT) type laminar silicates. It is observed that the organic modification of the MMT increases the cloud point temperatures of the epoxy/polystyrene blends, thus decreasing miscibility.

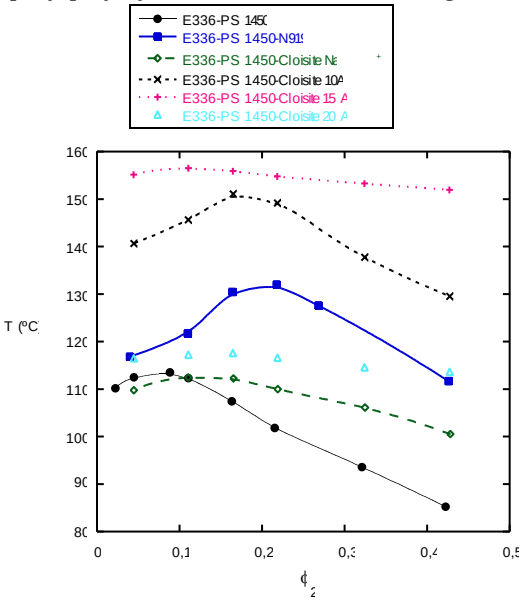

Figure 1. Phase diagram of epoxy DER336 and polystyrene in presence of different laminar nanofillers.

Systems modified with sepiolite show a decrease in miscibility when using organically modified one, however in the case of the silica the epoxy modified one increases miscibility.

Addition of an aromatic diamine as a curing agent decreases considerably the cloud point temperature, thus increasing the overall compatibility.

The Flory-Huggins theory has been used to theoretically represent the experimental cloud point curves. Binodal, spinodal as well as critical temperatures and interaction parameters concentration and temperature dependent have been determined.

Successive AGET ATRP of Cationic Methacrylate and PEO Macromonomer Yielding Water Soluble Stiff Cylindrical Molecular Brushes with Cationic Tail

C.Visnevskij, A.Baceviciute, R.Makuska

Vilnius University, Naugarduko 24, LT-03225 Vilnius, Lithuania

ricardas.makuska@chf.vu.lt

Introduction. One of the most successful controlled/living radical polymerization (CRP) techniques is atom transfer radical polymerization (ATRP) which allows the synthesis of copolymers with different architecture, such as block, gradient and brush, between others [1]. Activators generated by electron transfer (AGET) is an initiating process for ATRP in which the active Cu^{1+}/L_m complex is formed by the reaction of reducing agents, such as ascorbic acid or tin(II) 2-ethylhexanoate, with an oxidatively stable Cu^{2+}/L_m precursor prior to normal initiation with the added alkyl halide initiator [2].

In the present work, we aimed to synthesize diblock copolymers in which one block is charge carrying and composed of [2-(methacryloyloxy)ethyl]trimethyl ammonium chloride (METAC) units, and the another one is molecular brush and composed of poly(ethylene oxide) methyl ether methacrylate (PEOMEMA, M_n = 2080) units. Such diblock copolymers are envisaged as polymeric brushes containing cationic tail through which they could adsorb effectively to negatively charged surfaces and modify surface properties in extreme manner.

Materials and Methods. Components of AGET ATRP system was ethyl 2-bromoisobutyrate (EBrB), copper (II) chloride ($CuCl_2$), tris[2-(dimethylamino)ethyl] amine (Me_6TREN) and ascorbic acid (AscA). AGET ATRP was carried out at 35 °C in closed cells under mixing by magnetic stirrer. Poly-METAC was purified by double precipitation to acetone, and poly-PEOMEMA and diblock copolymers METAC$_x$-*block*-PEOMEMA$_y$ by ultrafiltration and freeze-drying. ^{1}H NMR spectra of the copolymers in D_2O or $CDCl_3$ were recorded at 30 °C using UNITY INOVA VARIAN 300 MHz spectrometer. For monitoring of the progress of polymerization, WATERS 600 series SEC instrument equipped with TSK-GEL column GMPW$_{XL}$ and RI detector Waters 410 was used. Molecular weight of the polymers was determined by both ^{1}H NMR spectroscopy and SEC combined with WYATT DAWN-DSP light-scattering photometer.

Results and Discussion. Under ATRP of METAC in methanol-water mixture (85/15 wt/wt), hydrolysis of the monomer was very fast far bypassing polymerization process. The AGET system containing Cu^{2+} and AscA helped to avoid hydrolysis and prepare pure poly-METAC. Reproducibility of the results of AGET ATRP of METAC in methanol-water (85/15 wt/wt) was improved significantly by automatic injection of the reducing agent using chromatographic pump. Optimal conditions for AGET ATRP of METAC were established from which the most important was periodic dosing of the reducing agent AscA. High conversion of METAC was achieved (more than 80%), and poly-METAC with degree of polymerization (DP) 15, 30, 50 and 100 (molecular weight M_n up to 20 000) and low polydispersity was synthesized. These polymers with living chain ends were used as macroinitiators for the synthesis of diblock copolymers.

AGET ATRP of PEOMEMA from EBrB was very slow and lasted 1–2 weeks. Moreover, the polymerization proceeded only in the presence of a certain excess of the ligand Me_6TREN (2-fold) and reducing agent AscA (1.75-fold) in respect to [Cu^{2+}]. Although maximal conversion of PEOMEMA was 40% only, poly-PEOMEMA with DP 15, 30, 50, 100, 160, 210 and 240 (molecular weight up to 500 000) and low polydispersity was synthesized.

Previously synthesized poly-METAC was used as macroinitiators for AGET ATRP of PEOMEMA. Conditions of polymerizations of PEOMEMA from poly-METAC were similar to those described before, i.e. a certain excess of the ligand and the reducing agent. Two series of diblock copolymers METAC$_x$-*block*-PEOMEMA$_y$ were obtained (Fig. 1), one with varying length of the cationic block, and another one with varying length of the brush block.

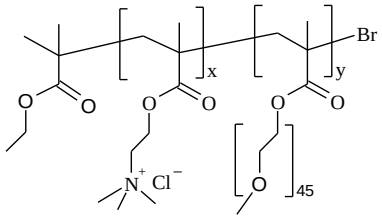

Fig. 1. Diblock copolymers METAC$_x$-*block*-PEOMEMA$_y$

Although diblock copolymers METAC$_x$-*block*-PEOMEMA$_y$ were soluble in water, they had a tendency to self-association (aggregation). The most intense aggregation in pure water was characteristic for the long-chain poly-PEOMEMA. The presence of the block of poly-METAC reduced aggregation of the molecular brushes or even removed it at all. Aggregation of the molecular brushes was removed also by addition of strong electrolytes, e.g. in 0.8 M $NaNO_3$.

Conclusions. Two series of diblock copolymers METAC$_x$-*block*-PEOMEMA$_y$ differing in the length of the both blocks were synthesized and characterized. Molecular brushes containing cationic tail will be tested as surface modifiers providing friction-reducing or protein-repelling properties.

Introduction.

Recently, nano- and microsphere assemblies with crystalline morphology found applications in various optical devices. It was revealed that the colloidal crystal arrays diffract visible light according to the Bragg law.[1] Diameters of microspheres in this kind of materials should be in a range 100-400 nm and their dispersity should be narrow. The high uniformity of particles allows to avoid defects in the colloidal crystals. Our studies were directed towards preparation and characterization of core-shell hydrophilic microspheres containing α-tert-butoxy-ω-vinylbenzyl-polyglycidol in the surface layer with properties needed for formation of colloidal crystals with thermoresponsive properties.

Materials and Methods.

Microspheres were prepared by a soap free emulsion polymerization of styrene and α-tert-butoxy-ω-vinylbenzyl-polyglycidol macromonomer (PGL) in water and initiated by $K_2S_2O_8$.[2] PGL (with M_n=2700, M_w/M_n=1.05) was prepared by anionic polymerization of 1,1-ethyl-ethoxyglycidyl ether and terminated by p-chloro-methylstyrene with potassium *tert*-butoxide and subsequent hydrolysis of ethyl ethoxy groups by oxalic acid.[3]

Diameters of microspheres (D_n and D_w/D_n) were determined by analysis of scanning electron microscopy (SEM) microphotographs registered using a JEOL 5500LV apparatus.

Chemical composition of interfacial layer of P(S/PGL) microspheres was determined by X-ray photoelectron spectroscopy.[4]

Hydrodynamic diameters of P(S/PGL) microspheres were determined by photon correlation spectroscopy measurements (PCS) in the range of temperatures from 15 to 65°C. The colloidal assemblies were prepared by gentle deposition of the suspension of P(S/PGL) particles (around 0.1 ml) onto the glass plates and subsequent drying at various temperatures.

The angle-resolved UV-VIS spectra were recorded using SPECORD S600 Analytik Jena spectrophotometer equipped with a variable angle reflectance attachment, operated in the range 20-60°. Water drop static contact angles were measured by Rame-hart NRL goniometer.

Results and Discussion.

The emulsion polymerizations yielded particles with very uniform diameters in the range 230-400 nm, depending on the concentration of macromonomer used in polymerization. It was found that particles are composed from polystyrene cores, and shells enriched with hydrophilic polyglycidol.

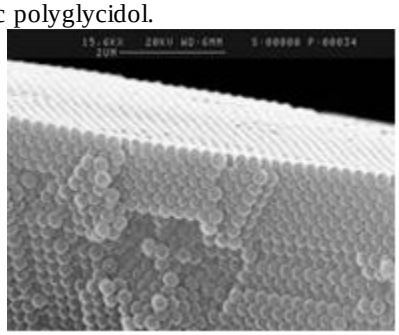

Figure 1. Colloidal array of P(S/PGL) microspheres The dependence of hydrodynamic diameter of particles suspended in water on temperature indicated that shells of particles shrank above the critical temperature equal 45 °C. This critical temperature did depend on composition of particle interfacial layer and on the ionic strength of solution.

The microspheres were used for preparation of colloidal crystals. Studies of light diffraction revealed that colloidal crystals formed above 45°C were composed of particles with diameters smaller than diameters of particles in crystals formed below 45°C. We found that with increased temperature the refractive index of material in colloidal crystals also did increase. Presumably, above the critical temperature polymer chains in the interfacial layer do collapse what leads to expulsion of water and to the higher hydrophobicity of the crystals (water contact angles increased from *ca*. 50° at 25°C to *ca*. 110° at 70°C.

Conclusions.

We did show that optical properties of colloidal crystals from P(S/PGL) particles could be tuned by changing temperature. Such crystals containing particles with ─OH groups are superior to thermosensitive crystals from poly(*N*-isopropylacrylamide) and poly(ethylene-glycol) particles with only functional end groups.

email: jrsouza@ipen.br

Abstract: This project proposes the development of microspheres (**MS**) size raging between 20 to 50 microns of biodegradable polymer poly(3-hydroxybutyric acid) (PHB) and its copolymer, the poly(3-hydroxybutyric acid-co-3-hydroxyvaleric acid) (PHB-HV), loaded with ^{165}Ho, as holmium acetylacetonate (**HoAcAc**), to be used in brachytherapy procedure to liver cancer treatment. At the first glance this study aims to confirm both the feasibility of the microsphere formation with these biopolymers and their ^{165}Ho incorporation capability. Further ahead, the influence of the amount of co-3-hydroxyvaleric acid in the in the PHB-HV-**MS** loaded and unloaded with Ho, will be evaluated in terms of thermal degradation, holmium encapsulation efficacy, microspheres size and morphology and resistance to the neutron irradiation. Therefore, initially, we are testing PHB-HV with HV contents of 8 and 5% (wt). Initial attempts to use the homopolymer PHB failed due to its lack of solubility in the process used to form the microspheres.

Introduction: The polyhydroxyalkanoates (PHAs) comprise a family of biodegradable and biocompatible polyesters produced by wide variety of microorganism. The general PHA chemical structure is depicted in **Figure 1**.

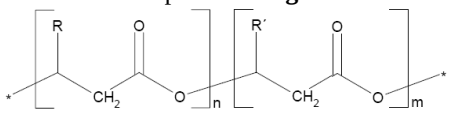

Figure 1: PHA chemical structure

The HoAcAc is depicted in **Figure 2**.

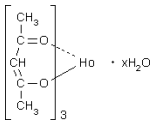

Figure 2: Holmium acetylacetonate (HoAcAc)

Brachytherapy is an internal radiotherapy treatment and presents an alternative treatment with promising results in relation to the usual procedures of chemotherapy or radiotherapy The brachytherapy treatment with yttrium-90 microspheres (^{90}Y-MS), with a glass matrix is well established in the treatment for patients with unresectable liver malignancies. Like ^{90}Y, ^{166}Ho is a high energy beta-emitter. However, considering its physical properties, ^{166}Ho is the ideal radionuclide for such therapies. Namely, holmium is the only element that can be both neutron-activated to a beta- and gamma-emitter with a logistically favorable half-life and visualized by MRI. Microspheres formed for some biopolymers have being found to be the best candidates to overcome the glass matrixes inherent problems. The microspheres of some biopolymers are capable to resist the neutron radiation from the atomic reactor and moreover they are biocompatible and after the irradiation treatment they can be further biodegraded.

Stable ^{165}Ho can be incorporated into the biodegradable microspheres and irradiated later in a nuclear reactor to be converted into the high-energy negatron emitter. The radioactive holmium-166 loaded PHB or PHB-HV microspheres are promising systems for the treatment of liver malignancies.

Results and discussions: The microspheres have been prepared by solvent evaporation technique, where through out a microemulsion stabilized by polyvinyl alcohol (PVA), the HoAcAc is incorporated into the polymer matrix, then subsequent sieving in order to separate the microspheres in the required sizes and further drying by lyophilization. In order to check the size and morpholoy the microspheres were analysed by confocal laser scanning microscopy (CLSM) and scanning electron microscopy (SEM), **Figures 3 and 4**, respectively.

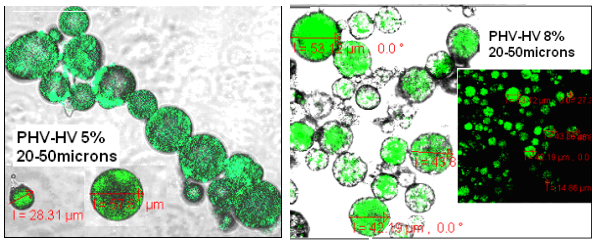

Figure 3: CLSM of PHV-HV loaded with HoAcAc

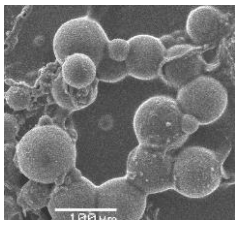

Figure 4: SEM of unloaded PHB-HV.

We are reporting the first results of this project which attempts to show the feasibility of microspheres formation using the PHB-HV through the o/w emulsion, stabilized by PVA by the solvent evaporation technique, a well established approach for the system widely studied poly(L-Lactic acid) HoAcAc. The results of CLSM and SEM confirm the formation of microspheres by the process used. Moreover, the images of CLSM show the incorporation of HoAcAc in the PHB-HV microspheres by the fluorescence of HoAcAc (the green areas of the figure). Although, this project is in its early stages of development, one has not seen yet significant differences between the HV content in the PHB-HV, just slight difference in the yield of microspheres preparation. Thus, the overall microspheres yield (between 70-20microns) was practically the same, however the PHB-HV 8% has shown about 13% more of microspheres sizing between 20-50 microns, which are the ones of interest. The presence of HV in the PHB it is well established and has remarkable influence in the PHB properties as, for instance, the crystallinity. Therefore, in the course of this project, the HV influence on the PHB will be evaluated more properly.

Abstract: This study describes the development of poly(lactide) (PLA) microspheres by an emulsion method for brachytherapy. The effects of both PLA and PDLA polymers on holmium encapsulation efficacy were evaluated. Microspheres containing holmium were prepared and characterized by thermal analysis, X-Ray diffraction, Scanning Electron Microscopy, FTIR spectroscopy and zeta potential measurements. Experimental data show that both polymers were converted into microspheres. However, PLLA1 with small inherent viscosity has formed higher amount of microspheres with size distribution smaller as compared with PLLA2 and PDLA.

Introduction

Three different types of material substrates have been investigated, i.e., biodegradable polymer-based, glassbased and resin-based microspheres. Currently, there is a project being developed at the IPEN coordenated by the radiopharmacy department, related to the labeling of three materials with ^{166}Ho. The nuclide ^{166}Ho($t_{1/2}$=26.8h) is a beta particle emitter (E_{max}=1.84 MeV), with suitable properties for radiotherapy and it can be produced with the relatively low neutron flux from the Brazilian Nuclear Reactor IEA-R1m. As an initial experience we used resin-based microspheres, a cation exchange resin labeled with ^{166}Ho, which showed the essential characteristics for liver cancer therapy.

Preliminary results concerning the preparation of glassbased microspheres labeled with ^{165}Ho showed that 5% of Ho_2O_3 was incorporated in an aluminosilicate glass, through the process of spheronization by flame, which produced spherical microspheres with 20-40 μm particle size. The preparation of biodegradable material, polymerbased microspheres, is in its initial stage and the objective is to prepare and label with 165Ho different polymer-based microspheres. These combined efforts have been done to offer a radiotherapeutic product for the Brazilian nuclear medicine community at reasonable cost and also to offer a viable possibility of treatment for patients affected by liver malignances [1]. In the present study, we report the effects on the PDLA e PLLA polymers after the Ho encapsulation efficacy and the characterization of the materials by different techniques: SEM, Thermal analyses, EDX, zeta potential, porosity and infrared spectroscopy (IR) [2].

Experimental

The PLLA1 (M_w 101,700), PLLA2 (M_w 152,000), PDLA polymers, and polyvinyl alcohol (PVA, MW = 31 KDa, hydrolyzation degree = 88%) were provided by Sigma Aldrich. Holmium acetylacetonate trihydrate (HoAcAc) was prepared as described previously [2]. The microspheres with HoAcAc were prepared by solvent evaporation as described previously (Fig.1) [2]. The HoAcAc and the polymer were dissolved in chloroform. The resulting homogeneous solution was added to an aqueous solution of PVA. The mixture was stirred at 500rpm, and the formed microspheres were were separated by sieving.

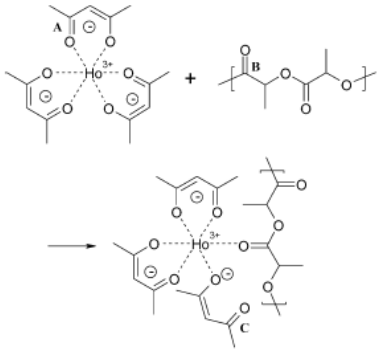

Fig. 1. Reaction of the formation of holmium microspheres.

Results and discussions

Microspheres were prepared by solvent evaporation and sieved to retain particles in a suitable size range. Fig. 2 shows the SEM micrographs of microspheres without holmium in different polymers. As it can be seen, they are spherical with a relatively small index of polydispersity according to the zeta potential results.

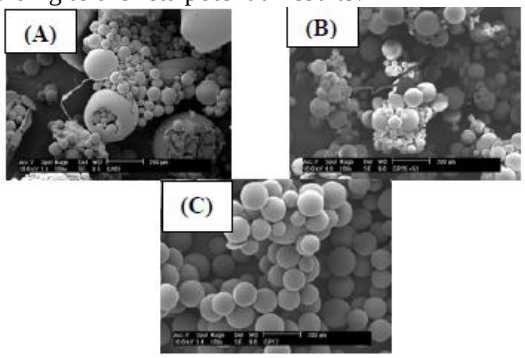

Fig. 2. SEM of PDLA (A) PLLA1 (B) and PLLA2 (C) microsphere without holmium.

The results showed that there was significant difference between the FTIR spectra of the microsphere-Ho when compared to the spectra of individual components. Thermal analysis curves showed that both PLLA samples have the characteristic melting points of the crystalline polymers, indicating that the crystallinity was maintained. EDX analysis showed the concentration of Ho in the material.

Conclusion

This study showed that microspheres were formed with and without holmium, and that the microspheres containing holmium present promising results for brachytherapy application.

Exciton Diffusion Length in Conjugated Polymers

P. H. O. Neto, W. F. da Cunha, L. F. Roncaratti, F. V. Moura, R. Gargano and G. M. e Silva

University of Brasilia

pedrohenrique@unb.br

Introduction:

Recently, optical electronic devices based in semiconducting conjugated polymers are attracting a huge attention of scientific community. Particularly, the formation, transport and recombination process of excitons are fundamental when concerning performance. It is known that the presence of triplet excitons further enhances solar cell efficiency over singlet-state-only cells [1]. However, the direct optical studies of triplet states are very difficult once singlettriplet transitions are forbidden. In this sense, this work investigates the dynamic of both singlet and triplet excitons in conjugated polymers samples under a presence of thermal effects to determined the diffusion length and to estimate the diffusivity. Our approach consists on a semi-empirical tight binding method with lattice relaxation in a first order expansion. Concerning the Ehrenfest molecular dynamics, the lattice degrees of freedom was treated by Euler Lagrange equations while the pi-electrons are described by the time dependent Schrodinger equation.

Thermal effects are incorporated on the method by means of a typical Langevin equation.

Methods:

The used hamiltonian was:

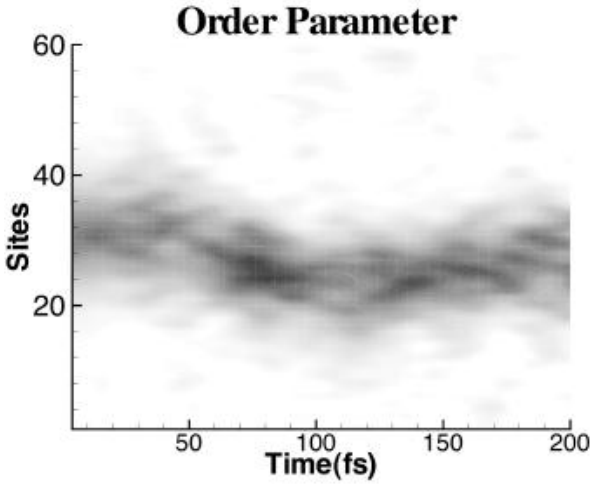
$$H = -\sum_{n,s} t_{n,n+1}(C^{\dagger}_{n+1,s}C_{n,s} + H.c) + \sum_n \frac{K}{2}y_n^2 + \sum_n \frac{p_n^2}{2M},$$

with $C_{n,s}$ being the annihilation operator of a pi-electron with s spin in the nth site; M isthe isthemassofaCH group; K is the harmonic constant; $y_n \equiv u_{n+1} - u_n$ where u_n is the displacement coordinate of the molecule site from the completely non dimerised configuration; p_n is the momentum conjugated to u_n. The hopping integral is $t_{n,n+1}$, given by $t_{n,n+1}=[1+(-1)^n D_0](t_0-ay_n)$ where a is the electron-phonon coupling; t_0 is transfer integral betweem nearest neighbor site in the undimerized chain; and D_0 is the Brazovskii-Kirova symmetry breaking parameter responsible for simulating a cis conjugated polymer symmetry.

In the scope of the Unrestricted Hartree-Fock Approximation, we first prepare a stationary state fully self consistent with the degrees of freedom of both the electrons and phonons.

Results and Discussion:

The parameters values used in this work are the usually adopted for cis-polyacetylene chains [2] and the results are expected to be valid for other conjugated polymers[3]. The systems are composed of 100 sites of cis-conjugated polymer under several temperature regimes. The figure presents the time evolution of bonding pattern order parameter at 300 K. It is observed



a phenomenological quasi-one-dimensional random walk of a polaron-exciton on the first excited state. The occupation electrons were chosen to set a triplet polaron-exciton. Our results are in good agreement with photo absorption spectroscopy data [4].

Conclusions:

In this work we studied the exciton dynamic on cis conjugated polymers. Specifically, we determined the diffusion length of both triplet and singlet polaronexciton under several temperature regimes. The used method was a semi-empirical tight binding with lattice relaxation. In the scope of the Unrestricted Hartree-Fock Approximation we performed the Ehrenfest molecular dynamic. Our results are in good agreement with experimental observations.

Bamboo Charcoal Supported Silver Particle by Polyol Process

Tzu Hsuan Chiang[1], Guan-Ting Lai*

[1]Department of Energy and Resources, National United University, Taiwan

thchiang@nuu.edu.tw

Authors Instructions

The structure of 1500°C carbonization bamboo charcoal approach face-centered cubic (FCC) of graphite that had excellent electric and thermal conductivity. For enhance thermal and electric conductivity of materials and the investigation was utilize bamboo charcoal supported silver particle by polyol process.

Introduction

Bamboo charcoal have electric and thermal conductivity when carbonization temperature upper 1000°C. Increase with carbonization temperature cause decrease proportion unregulated carbon structure that can form regulated graphite structure. Ishihara [1] reported the carbonization temperature with 600°C the electric resistance as 10^{12}-$10^{8}\Omega$, 600-800 °C is 10^{8}-10^{1} Ω, upper 800°C is $10^{-2}\Omega$. Many studies reported to synthetize silver particle [2-4] and CNT supported metal [5-6] by polyol process. But there is not study to about bamboo charcoal supported silver particle by polyol process. Therefore, the study used 1500°C carbonization bamboo charcoal that investigate influence on silver particle for different reaction temperature, reaction time and content of silver nitrate.

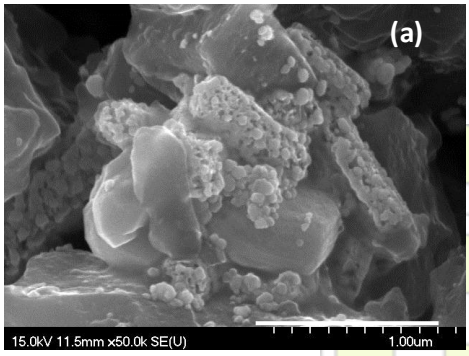
Materials and Methods

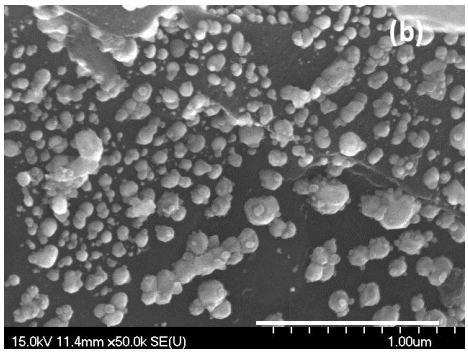
The study used materials such as 1500°C carbonization bamboo charcoal, silver nitrate and reducing agent as tripropylene glycol.

The 1g silver nitrate dissolved to tripropylene glycol then put 0.5g bamboo charcoal (modified by nitrate acid) and heating 120°C at 1hr.

Results and Discussion

Different reaction temperature was effect form silver particle size on bamboo charcoal as shown in Figure 1. The reaction temperature at 100°C formed smaller silver particle onto bamboo charcoal and larger silver particle as reaction temperature with 120°C. In the other hand, the increase with content of silver nitrate react with reducing agent that formed more silver particle which help enhance thermal and electric conductivity of bamboo charcoal.





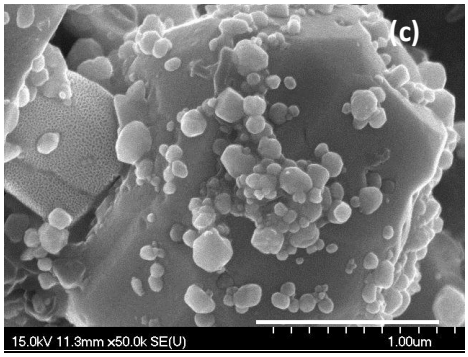


Figure 1: Bamboo charcoal supported silver particle for reaction temperature with (a) 100°C (b)110°C (c)120°C

Conclusions

The bamboo charcoal supported silver particle by polyol process which enhance thermal and electric conductivity.

Theory of Polyelectrolyte Solutions

Argyrios Karatrantos

Department of Chemistry, University of Durham, Durham DH1 3LE, United Kingdom

argyrios.karatrantos@durham.ac.uk

Soft matter systems, such as polymers, membranes, and proteins, usually contain objects that are electrically charged. The driving force behind the different physical phenomena that appear in charged materials such as liquid crystal ordering, self-assembly, and macroion complexation is the electrostatic interaction. For instance, in a solution it is possible to have a mixture of polyelectrolytes ranging from weak to very strongly charged (Fig. 1). From a theoretical point of view, salt free polyelectrolyte solutions have been studied greatly over the last years [1-4]. However, all these theories fail to qualitatively and quantitatively predict the properties of systems with strong correlations (strong coupling regime).
A theory for salt free polyelectrolyte systems is proposed based on a modified Debye-Huckel approach. The electrostatic interactions are inserted through random phase approximation. Moreover, counterion condensation is accounted for to determine the effective number of charges along the polyelectrolyte as well as of free counterions. The theory is applied to predict the thermodynamic behaviour of flexible polyelectrolytes, such as the osmotic coefficient of a salt free solution in weak and strong coupling regimes. The theory is in agreement with Monte Carlo simulations [4].

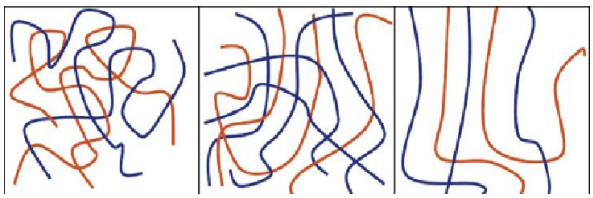

Fig. 1: Charged polyelectrolytes of different coupling strengths. Increasing coupling strength from left to right.

A New Method for Size Controlled Synthesis of Zinc Oxide Nanocrystallites and Their Nanocomposite Films

Bunyamin Karagoz, Niyazi Bicak

Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

karagozb@itu.edu.tr

Introduction: Control of particle size is critical issue in preparing nanostructured materials. A number of methods, such as controlled-nucleation growth and microemulsion techniques have been developed to attain desired particle sizes[1]. These approaches, however have limited success for precise control of the particle sizes. The inorganic nanoparticles such as ZnO nanoparticles generated by these methods are generally amorphous. The most common method of crystalline nanoparticles is the hydrothermal technique, in which the nanospecies are generated from dissolved reagents[2].

In this work, we described a chemical method, "ligand exchange method", for size-controlled synthesis of zinc oxide nanoparticles in crystalline form at ambient temperatures.

Result and Discussion: In the present procedure size-controlled synthesis of ZnO nanoparticles was achieved by slow exchange of ammonia of the zinc complex with dodecylamine (DDA) in alcohol-water solution.

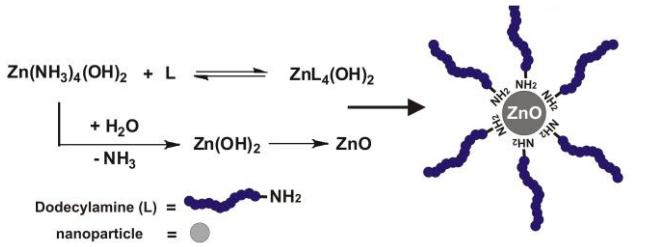

Fig-1 : size controlled ZnO nanoparticle formation in aqueous alcohol solution by simultaneous ligand exchange with DDA

The overall process gave ZnO nanoparticles with surface tethered amine molecules (Fig-1). A series of nanoparticles was prepared using various [DDA] /[Zn (II)] ratios (1/3-1/15 and characterized by UV, FT-IR, TGA, DLS, PL and ESEM techniques. Those investigations implied that, the particle size is directly proportional to M/L ratio (Fig-2).

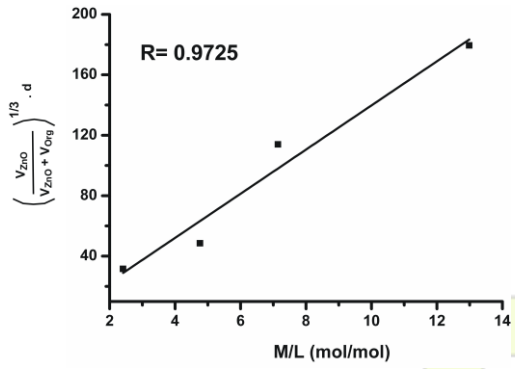

Figure-2: The particle size- M/L relationship for ZnO nanocrystals.

Surprisingly, XRD patterns indicated 30-200 nm size of rod like nanoparticles having hexagonal crystalline (Wurtzite) structure for ZnO nanoparticles.

The resulting nanoparicles were reacted with poly (glycidyl methacrylate)-*block*-poly(methlymethacrylate) in toluene solution to encapsulate in a crosslinked matrix.

The PMMA block was considered as shell forming component to provide miscibility in organic matrix. DLS measurements of the resulting core-shell nanoparticles with L/M: 0.44 indicate considerable increases their sizes (from 62 nm to 212 nm) after treatment with the block copolymer.

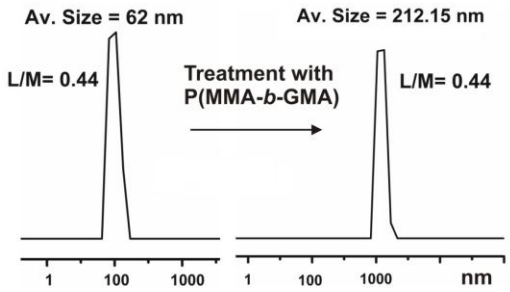

Figure-3: DLS of ZnO nanoparticle (with L/M:0.44) showing size increment after treatment with PMMA-*b*-PGMA

Nearly transparent dispersions of the resulting the core-shell nanoparticles in acetone solutions of poly (methylmetacrylate-*co*-butylacrylate) gave homogenous freestanding films (40-60 μm) with good homogeneities upon casting on glass substrates.

Conclusion: The ligand exchange method presented provides size controlled (60-210 nm) synthesis of ZnO nanoparticles in crystalline forms. Action of poly (glycidyl methacrylate)-*block*-poly(methlymethacrylate) in toluene solution yields core-crosslinked nanocrystallites with PMMA shells.

Polymer electrolytes are used in electrochemical devices such as batteries, fuel cells, super capacitors, and electrochromic devices. Some of the most attractive electrolytes for these applications are based on poly (ethylene oxide) (PEO) and its nitrogen analogue poly (ethylene imine) (PEI).

In a previous study [1], we discussed the influence of ion pair concentration and mobility on the molar conductivity of PEI-LiTFSI electrolytes. The influence of the segmental motion of the polymer chains was inferred from comparisons between molar conductivity, glass transition temperature and, viscosity of the electrolyte.

In the present study we used the same methods to investigate the ion conduction mechanism of PEI- LiTFSI electrolytes containing SiO_2 nanoparticles. The ionic conductivity of the electrolytes was examined at different salt concentrations and temperatures and with certain amounts of SiO_2 nanoparticles having a particle size of 7 nm. The electrolytes were characterized by impedance spectroscopy, differential scanning calorimetry, and viscosity measurements. The ionic conductivity was noticeably enhanced as a result of the SiO_2 nanoparticles. A comparison of the latter results with those of the previous study allows us to discuss the influence of ion pairs and the mobility on the conductivity as well as the temperature dependence of the ionic conductivity.

Introduction:

The atom transfer radical polymerization of styrene provides an efficient method for the synthesis of polystyrene with controlled number average molecular weight, molecular weight distribution, chain functionality, polymer topology and composition1. ATRP entails the reversible homolytic cleavage of a carbon-halogen bond of an alkyl halide initiator molecule in the presence of a transition metal/ligand catalyst complex, such as CuBr/2,2'-dipyridyl, followed by the successive monomer addition to form the resultant polymer1. The present research involves the extension of the ATRP method to the synthesis of chain end functionalized polymers by utilizing functionalized initiators based on substituted 1,1-diphenylethylene derivatives2.

Experimental:

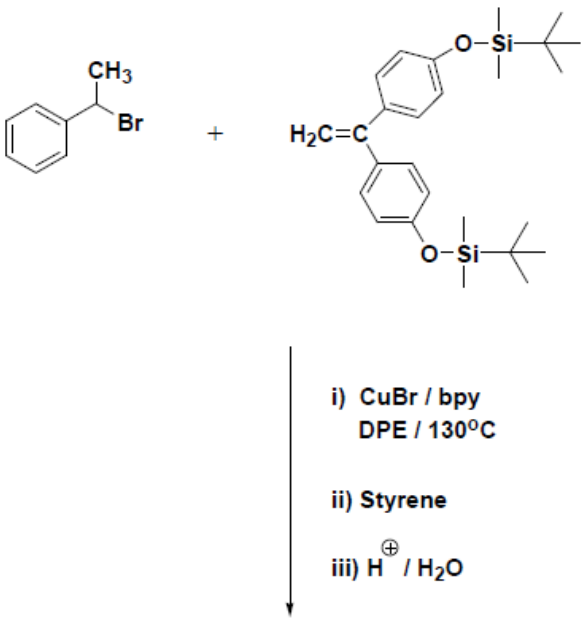
1,1-Bis(4-t-butyldimethylsiloxyphenyl)ethylene was prepared according to the procedure outlined by Quirk and Wang3. The preparation of α-disiloxyl functionalized polystyrene was performed according to the general ATRP method2. α-Dihydroxyl functionalized polystyrene was prepared by the acid catalyzed hydrolysis of α-disiloxyl functionalized polystyrene3. The initiator precursor and functionalized polymers were characterized by size exclusion chromatography, spectroscopy and non-aqueous titration measurements.

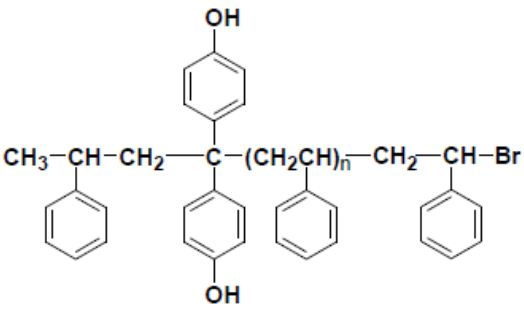
Results, Discussions, Conclusions:

By ATRP methods, the initiation of the polymerization of styrene with a functionalized initiator adduct, formed *in situ* by the reaction of (1-bromoethyl)benzene with 1,1-bis(4-t-butyldimethylsiloxyphenyl)ethylene in the presence of CuBr/bpy catalyst in solution, proceeded via a controlled/living fashion to afford α-disiloxyl functionalized polystyrene. Quantitative yields of α-siloxyl polystyrenes with predictable molecular weights and narrow molecular weight distributions were obtained in high initiator efficiency reactions.

Polymer kinetic measurements show that the polymerization reaction follows first order rate kinetics with respect to monomer consumption and the number average molecular weights of the polymers increase linearly with monomer conversion.

Deblocking of the siloxyl group by acid hydrolysis provides the corresponding α-dihydroxyl functionalized polystyrene in quantitative yields.





Similarly, preliminary results show that the use of functionalized 1,1-diphenylethylene derivatives as initiator precursors in RAFT polymerization methods produces well defined chain end functionalized polymers.

Authors Instructions: Hengrui Yang is a PhD student of institute of textiles & clothing, Hong Kong Polytechnic University. Her research focus on the smart multifunctional block copolymer for textile applications.

Introduction: In the last few decades, a lot of interest in both industry and academic circle has been directed towards the modification of the chemical and physical properties of cellulose-based nature fibers, with the aim of obtaining new functional materials or preparing highperformance composites based on renewable resources.1-5 For this purpose, great efforts have been devoted to control properties such as wettability, hydrophobicity, and adhesion of the cellulose fibers by surface modification.6,7 . ATRP has previously been utilized for surface modification of silicon, gold, silica and porous substrates, etc. In this work, ATRP "grafting from" technique was used to polymerize a stimuliresponsive, smart polymer, Poly(Nisopropylacrylamide) (PNIPAAm), from initiators immobilized on cotton fabric substrate.

Results: A temperature responsive homopolymer brushes poly(N-isopropylacrylamide) (PNIPAAm) were fabricated on the surface of cotton fibers by the typical surface-initiated atom transfer radical polymerization in water/methanol. The success of grafting was confirmed by fourier transform infrared spectroscopy (FTIR), Xray photoelectron spectroscopy (XPS). Scanning electron microscope (SEM) images (Fig. 1) was used to study the surface morphology of the bare cotton and cotton-PNIPAAm.1H solid-state NMR techniques were applied to characterize the molecular structure and covalent bond between PNIPAAm and cotton surface.

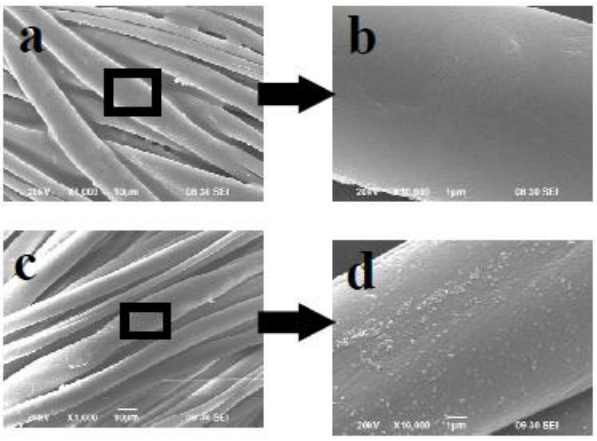

Figure 1. SEM images of (a) bare cotton fabric and (c) cotton-PNIPAAm. (b) and (d) are the magnified image of (a) and (c), respectively. The rectangles in (a) and (c) represent typical areas selected for magnification.

Raspberry–like silica particles to design superhydrophobic surfaces.

Raquel de Francisco, Nuria García and Pilar Tiemblo

Instituto de Ciencia y Tecnología de Polímeros (CSIC)

rdefranciscorivas@ictp.csic.es

Nowadays, the design of surfaces with special wetting behaviour such as superhydrophobicity[1,2] arises much interest because of their applications as self-cleaning and antifouling surfaces. Superhydrophobic surfaces are those with water contact angle (CA) over 150º and hysteresis of 10º or lower.

It is well known that for a surface to show superhydrophobic behaviour both the chemistry of the surface and its topography have to be controlled and roughness at the micro and/or nanoscale has to be introduced. On flat surfaces, a maximum CA of 120º can be achieved by chemical means. Lotus leaves[3], for instance, evidence the need for a dual size roughness to obtain superhydrophobic surfaces.

On the other hand, transparency is a desired property for many of superhydrohobic surfaces applications. However the requirements for transparency and superhydrophobicity are in conflict since the demand micro/nanoroughness for the particular wetting behaviour induces light scattering and therefore opacity. Thus, there are only few examples in the literature which manage both, optical transparency and superhydrophobic behaviour. These works are based on controlled rough structures smaller than the wavelength of visible light.[4]

In this work we present a strategy based on a combination of both low-surface energy compounds and hierarchical topographic features to try imitating raspberry structures.

First, silica particles of different sizes ranging from 50 to 800 nm in diameter have been synthesised by the Stöber[5] method. These particles are dispersed in ultra-pure water using mechanical stirring. Methyltrimethoxysilane (MTMS) was afterwards added to the dispersion to form the nanometric spheres which are grafted to the silica surface. This MTMS condensation reaction is catalysed by ammonium. The final whitish mixture was lyophilized to prevent the agglomeration of the decorated silica nanoparticles.

Reaction conditions such as reaction time, MTMS and catalyst concentrations and post-treatments were studied and optimized to render the raspberry-like structures. These particles were characterized by microanalysis to calculate the MTMS content, solid-state NMR to estimate the MTMS condensation ratio, dynamic light scattering to determine the particle size, specific surface measurement to evaluate the surface coverage, and microscopic techniques, SEM, TEM, and AFM, to elucidate the surface structure. A SEM micrograph showing the particular rough surface of the as-obtained silica particles is shown in Figure 1.

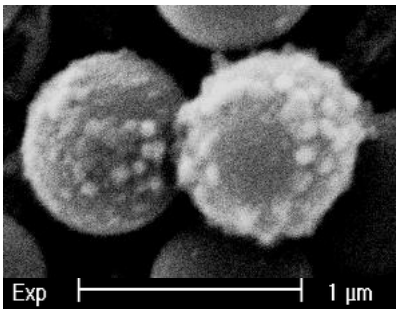

Figure 1: SEM micrograph of raspberry-like silica particles.

These decorated silica particles were dispersed in polymer matrixes of different nature (hydrophilic such as polymethylmethacrylate, PMMA, or hydrophobic as polydimethylsiloxane, PDMS). The dispersions were made using a high shear lab dissolver. The polymer/silica suspensions were used to prepare the final coatings on glass and silicon supports with a spin coater and bar coater. The wetting behaviour, optical transparency, surface roughness and scratch resistance of the resulting surface coatings were critically analyzed.

The results show that using these particular raspberry-like structures it is possible to improve the hydrophobicity of polymer coatings without detrimental effects on transparency and the mechanical properties.

catalina.salom@upm.es

In the last years the area of nanocomposites has received considerable attention with expectation that nanoclay filled polymers can be used as matrix material for high temperature composite application. In addition, unlike traditional filled polymer systems, nanocomposites require relatively low dispersant loadings to achieve significant property enhancements, which make them a key candidate for aerospace applications. These enhancements are primarily a consequence of the interfacial effects that result from dispersing the silicate nanolayers in the polymer matrix and the high in-plane strength, stiffness and aspect ratio of the lamellar nanoparticles. The clay known as montmorillonite (MMT), modified with organic onium ions with long alkyl chains, has been widely used in order to obtain nanocomposites. In previous works (1,2) it has been reported that the presence of reactive groups in organic onium ions can form chemical bonds with the polymer matrix which favours a very high exfoliation degree of the clay platelets in the nanocomposite. In this work nanoclays from MMT have been modified using cationic exchange and characterized. Then, polyester (PE) nanocomposites have been prepared from unsaturated polyester resin (UPE). The effect of the type of reactive alkyl ammonium ion clay modifier (RAA) on the microstructure and on the thermal mechanical behaviour has been analyzed. The results are also compared with PE/C30B MMT previously studied.

Materials and Methods

The materials used in the preparation of PE thermosetting nanocomposites are listed in Table 1

Table 1 Materials used in PE nanocomposites

UPE	Norsodyne 44233
MMT	Na^+ montmorillonte
C30B	$CH_3T(CH_2CH_2OH)_2N^+Cl^-$
RAA1	Di-allyl-dimethyl ammonium chloride
RAA2	[2-(acryloyloxy) ethyltrimethyl ammoniun] chloride

Preparation of reactive nanoclays

Reactive nanoclays (RN) were prepared using the cationic exchange reaction between MMT and RAA´s modifiers. Thus, 3 g of MMT in 250 ml of distilled water was stirred at 300 rpm during 2.5 h (T=60 ºC). A separate solution with 1ml of RAA1 or RAA2 in 20 ml of water + ethanol was kept under vigorous stirring during 45 min at room temperature. The modifier solution was slowly added to MMT solution (1 h), stirred at 300 rpm and T=30 ºC. The ion exchange reaction was then carried out by stirring de mixture for 2 h at 60ºC and 15 h at room temperature to obtain the reactive nanoclay. The reactive nanoclay was washed repeatedly with distilled water. RN powder was obtained by freeze-drying the product.

Preparation of PE/RN nanocomposite. A mixture of UP resin+RAA1 or RAA2 (4% weight fraction) was stirred at 300 rpm at 50ºC during 7 h. In both cases, well-dispersed mixtures and stable suspensions of the RAA´s in UPE were obtained. Then, crosslinking reaction was initiated adding 1.5 wt% of benzoyl peroxide to UP/RAA mixtures. The mixture was achieved by stirring at 400rpm at room temperature. Next the reactive mixtures were pressed in aluminum moulds and cured in an oven at 80 ºC for 1 h. Postcuring was also performed for 3 h at 110 ºC.

Results and Discussion

Figure 1 shows the wide angles X-ray diffraction patterns (WAXD) of PE/RN nanocomposites

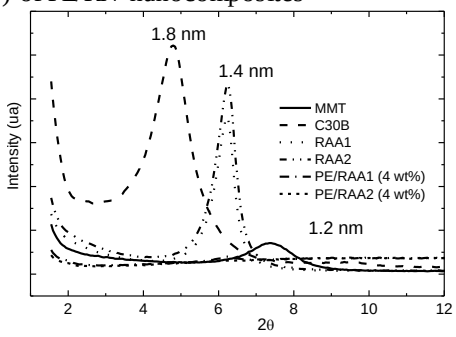

Figure 1. WAXD patterns for PE/RN nanocomposites

The reactive MMT (MMT-RAA1 and MMT-RAA2) shows an interlayer distance d_{001} of 1.4 nm placed between the corresponding ones to MMT-Na^+ and commercial organic modified MMT (C30B). This behaviour indicates that de reactive organic modifier RAA1 and RAA2 are less effective in diffusing into the clay gallery than the non reactive organic modifiers of C30B. However PE/RN nanocomposites show no peaks in WADX patterns in the $1.5º<2\theta<10$ region which is in accordance with a fully exfoliated structure for PE/RN nanocomposites.

The thermal characterization of the nanocomposites by means of DSC measurements (Mettler Toledo mod 821 DSC calorimeter) indicates that the glass transition temperatures, T_g, of RN nanocomposites are similar to those obtained for PE/C30B. However the thermo-mechanical properties determined by DMTA (DMTA V Rheometric Scientific instrument) are significantly improved. It has been observed an increase of 30% in the value of the elastic modulus, E´ in the glassy region, respect to the E´ value of PE/30B nanocomposites. This increment reaches up to 70% in the rubber region.

Conclusion

Exfoliated structures of polyester nanocomposites have been obtained using reactive nanoclays as organic modifiers. A significant improvement in the mechanical behaviour has been observed.

Introduction

This study is focussed on the use of a new class of organic-inorganic hybrid as modifier of epoxy networks. These hybrids, the polyhedral oligomeric silsesquioxanes, POSS, are nanosized cage structures, that can be chemically incorporated into linear or thermosetting polymers.[1] These compounds are based on a Si-O central cage, which have different organic chains linked on it. If some of these chains have any active group, it can react with the epoxy rings of the resin becoming covalently linked to the network structure.

Material and methods

Mixtures of diglycidylether of bisphenol A resin (DGEBA Araldite GY240, provided by Hunstman) and two different POSS, the glycidylisobutyl-POSS (GIb) and the glycidylcyclohexyl-POSS (GCh), provided by Hybrid Plastics were cured with methyltetrahydro-phtalic anhydride (MTHPA) from Sigma-Aldrich by means of a catalyzed mechanism using N,N-dimethyl benzylamine (BDMA) from Fluka.

Epoxy nanocomposites with 1, 3 and 5 wt% of both POSS were prepared. The curing procedure was studied by differential scanning calorimetry with a Mettler Toledo DSC-821e thermal analyzer and FTIR spectrophotometer FTIR-680PLUS from Jasco. This device is equipped with an attenuated-total-reflection accessory with thermal control and diamond crystal (Golden Gate heated single-reflection diamond ATR, Specac Tecnokroma).

Thermal-dynamic-mechanical analyses were carried out with DMTA 2980 from TA Instruments.

Results and discussion

The presence of both POSS slows down the reaction as observed by DSC. In mixtures containing GIb, the deceleration is higher with increasing of POSS content but, in samples with GCh higher contents of POSS this has a minor effect on the reaction rate. GIb shows a glass transition at -13 ºC and three melting points at 51 ºC, 112 ºC and 135 ºC respectively, while, GCh only shows a glass transition at -37 ºC. The curing of samples with GIb starts at a lower temperature than the third melting point of this POSS and therefore the delay in the start of curing with higher contents of GIb can be attributed to the presence of unreacted crystalline POSS agglomerates. In samples with GCh, the curing shows a slight delay in reference to the neat formulation because of the presence of the rigid cage structures of Si-O. However, the higher reactivity of epoxy cycloaliphatic groups and the greater size of these nanoparticles, which increases the free volume, lead to an improvement of the reactivity.

Isoconversional kinetic analysis and Coats-Redferns method were applied to DSC scans in order to determine the kinetic parameters and the kinetic model.

An autocatalytic procedure with reaction orders m + n = 2 was selected as the kinetic model that better explains the experimental results.

IR analyses at a temperature of 150 ºC is used to follow the disappearance of the bands corresponding to epoxy and anhydride groups and the appearance of the ester band produced during the curing process. The results obtained confirm that the reaction occurs even in the presence of POSS with the same trend than the observed by DSC. [2]

Finally, thermo-mechanical properties analyzed by DMTA show a decreasing of glass transition temperature, T_g, of the samples when POSS is added, (fig. 1). This fact is attributed to the higher free volume of mixtures when the cage of POSS is present in the structure.

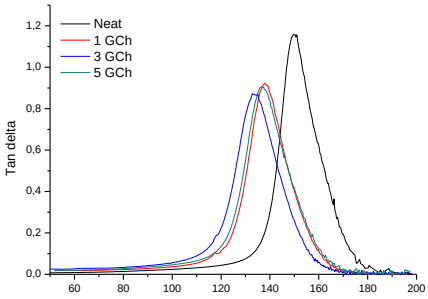

Fig.1. Tan δ determined by DMTA of thermosets modified with GCh.

The storage moduli in the rubbery state are higher in all the POSS modified thermosets, which is attributed to the rigidity that the inorganic nanoparticles provides to the structure.

Conclusions

The presence of POSS in the neat epoxy resin slows down the reaction in different ways, depending on the thermal behavior of the POSS used and its structure. However, the reaction can completed and the materials obtained have a higher stiffness than the neat material in the rubbery state.

Introduction

Synthesis of silver clusters and nanoparticle in solution of polymers and polymeric matrixes are en intensively developing direction of reception of nanostructures systems containing metal nanoparticles with unusual physico-chemical and medico-biological properties [1]. Researches in this area show, that macromolecules not only stabilize the disperse systems, but also participate in their formation, controlling the size and the form of growing nanoparticles [2-3].

The aim of this work is to obtain of biodegradable bactericidal polymer films, containing nanoparticles of silver on the basis of derivatives of cellulose.

Materials and Methods

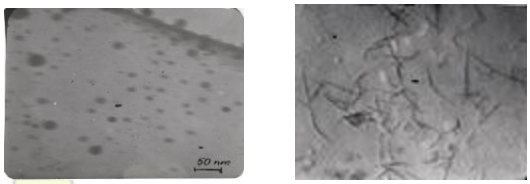
The following samples as research objects were selected: Na-carboxymetilcellulose (Na-CMC), microcrystalline cellulose (MCC) and nanocellulose (NC).

In 2% solution of Na-CMC and suspensions of MCC, NC solutions of polymers, under ultrasound dispersion 0,01-0,1M the solution of nitrate silver was added.

Films with the thickness of 20-40 microns were obtained by the method of overflow from the polymer, containing $AgNO_3$. The process of nanosized silver particles formation in polymer was initiated by ultra-violet irradiation.

Results and Discussion

The formation of spherical silver nanoparticles and clusters has been observed in the course of photochemical restoration of CMC salts the content silver ions. It has been established, that containing of free Ag^+ ions in a reactionary blend is no more than~5%, the formation of nanoparticle take place only at the expense of photorestoration of cations, connected with CMC carboxylate-anions. Therefore with rather high concentration of carboxylate-anions the complex of $Ag^+ \cdot$CMC represents as a nanoreactor at formation of silver nanoparticles. It has been established, that, at low 0.01 M concentration of silver nitrate the form of silver nanoparticles are spherical with diameter of 8-25nm. (fig. 1a)

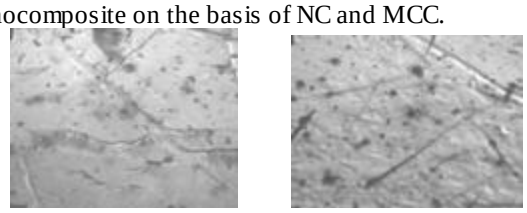


а) б)

Fig.1. TEM images of *films* CMC *containing spherical (a) and rod nanoparticles silver(b).*

At increasing the concentration of silver nitrate up to 0,1M solution CMC the nanoparticles silver.were formed in form of nanorods with length of 500 nm and thickness of 30-50 nm. (fig. 1b)

At fig.2 shows TEM images of the obtaining samples nanocomposite on the basis of NC and MCC.



а) б)

Fig. 2. TEM images of NC *(a) and* MCC *(b) films containing spherical and rod nanoparticles silver.*

The samples containing spherical nanoparticle of silver with the size of about 35-60 nanometers were obtained with the addition of 0,01 M aqueous $AgNO_3$ solution to 2 % water suspension of NC under ultra sound and UF-irradiations.(fig. 2a)

In the same concentration of $AgNO_3$ in the suspension of MCC it is observed more accurately rod silver clusters. In this case the range of the size and the form of particle nanosilver is very great. Spherical and linear forms of silver nanoparticles with various sizes are observed,.

The increase in concentration of a solution of nitrate of silver leads to transformation of spherical particles into nanorods having the length till several microns at width of 50-70 nanometers. (fig. 2b)

In this case on the surface layer of MCC elastic resistance of a matrix is possibly less, that, apparently, and it defines the formation of nanoparticle of big sizes.

Conclusions

The possibility of reception of the films containing nanoparticle of silver on the basis of biodecomposed polymers, such as CMC, MCC and NC is studied.

It is shown, that depending on structure and molecular characteristics of used polymeric matrix and concentration of silver ions it is possibility regulated the sizes and forms of silver nanoparticles. Obtained biodegradable, antimicrobic and bactericidal films can be used as a covering agent for the treatment of wound and burns.

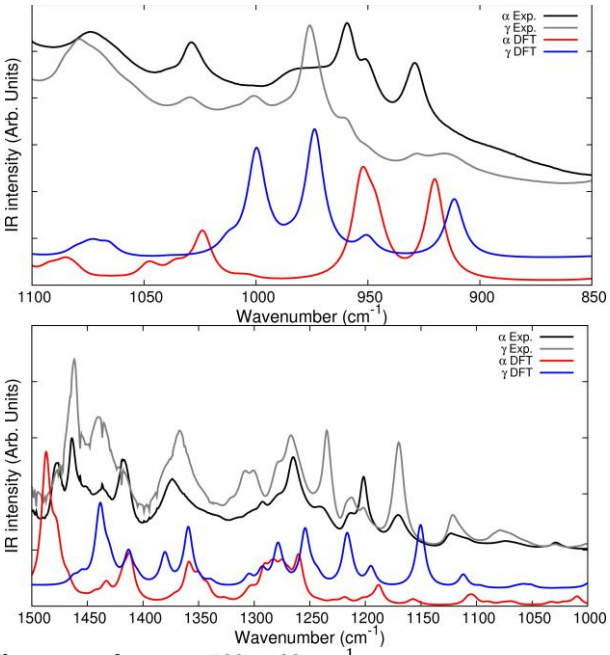
P.zza Leonardo da Vinci, 32 - 20133 Milano, Italy

alberto.milani@polimi.it

Introduction In addition to their use in the everyday life, many advanced applications in polyamides science and technology are still investigated: the development of nanocomposites, the application of the electrospinning technique and even applications in the field of biomaterial and nanomedicine are promising fields of research. Moreover, the detailed study of structure/property correlations is required in these perspectives. Polymorphism in particular is the key feature ruling at a nanoscale the properties shown by these materials and nylon-6 is probably the most significant example, due to the existence of two main crystalline forms (α and γ). The characterization of nylon polymorphs has been experimentally carried out by means of X-ray diffraction and IR spectroscopy and sometimes by molecular mechanics simulations. In the case of vibrational spectroscopy, however, a reliable simulation requires suitable first-principles techniques, which became available only in very recent years. Therefore, their spectroscopic characterization is often left to fully experimental works whose results are now routinely used also for the characterization of new systems based on polyamides. However, no validation of these results has been so far presented based on accurate molecular calculations. To this aim, we here present state-of-the-art first-principles simulations of the IR spectra of nylon-6 (NY6) α and γ polymorphs.

Materials and Methods Density Functional Theory (DFT) calculations of the NY6 polymorphs were carried out by using the CRYSTAL09 code [1]. The functional B3LYP was used with 6-31G** basis set; the correct description of Van der Waals forces was guaranteed by application of Grimme's correction. A full geometry optimization of the two crystal structures was carried out by taking into account properly the space group symmetry of the systems; based on the optimized structures so obtained, IR spectra were calculated and compared with the available experimental spectra for both the forms.

Results and Discussion We report in the figure the comparison between the DFT computed and experimental IR spectra of the two crystalline forms of NY6, showing separately the two frequency ranges where spectroscopic markers of the two structures can be found. A very good agreement is found between experimental and computed spectra: we can confirm that the bands at 930, 960 and 1030 cm^{-1} are indeed clear markers of the α form while the bands at 915, 973 and 1002 cm^{-1} are markers of the γ form. This conclusion is in agreement with previous experimental studies where these assignment are accepted on the basis of empirical spectral correlations [2]. It should be noted that some authors [3] assigned the band 973 cm^{-1} to the metastable β form: our investigation does not support this results.



The spectral range 1500-1100 cm^{-1} is even more interesting since some ambiguities are present in the previous studies and marker bands in this range have been rarely identified or used when investigating the different crystal phases of NY6. Based on our calculations, the band at 1170 cm^{-1}, sometimes assigned to the amorphous phase and sometimes to crystalline forms [3], should be attributed mainly to the γ form as for the bands at 1234 and 1440 cm^{-1}. On the other side, we can assign the bands at 1202, 1416 and 1478 cm^{-1} to the α form. For all these bands, assignments in terms of phonon eigenvectors can be now proposed unambigously. A deeper and complete characterization of the IR spectra of NY6 can be thus obtained based on DFT calculations, thus providing new basis for the characterization of NY6-based materials by means of vibrational spectroscopy.

Conclusions DFT calculations have been used to simulate the IR spectra of two NY6 polymorphs by using the state-of-the-art techniques of computational solid state chemistry. A very good agreement is found between experimental [2] and computed spectra: on this basis previous experimental analysis have been discussed, confirming some of the previous assignment, introducing new evidences and settling some of the existing ambiguities.

Introduction: Since their discovery, carbon nanotubes (CNT) have attracted particular attention for their unique structural, mechanical and electrical properties. However, thank to strong van der Waals interactions, CNT tend to aggregate and their not uniform dispersion limits their applications. Functionalization of CNT with long molecules and polymer chains enables suppressing the interactions between CNT and their aggregation.
In this work, Nanocyl multiwall carbon nanotubes (MWCNT) were covalently modified in order to achieve better dispersion and their location in one phase of styrene-isoprene-styrene block copolymer (Kraton). The modification is expected to cause significant changes in mechanical and electrical properties of final composite materials.
Materials and methods: Surface of MWCNT was modified by a) polymerization of styrene from MWCNT surface (MWCNT-PS), or b) covalent bonding of cholesteryl groups (MWCNT-chol). In both cases, MWCNT surface was first modified by 4-(2-hydroxyethyl)nitrobenzene to introduce hydroxyl groups onto MWCNT surface (MWCNT-OH). MWCNT-PS were prepared by reaction of MWCNT-OH with 2-bromopropionyl bromide and subsequent atom transfer radical polymerization of styrene from the surface of MWCNT by ATRP using CuBr/PMDETA as a catalytic system. MWCNT-chol were prepared by esterification of MWCNT-OH by reaction with cholesteryl chloroformate. The modified MWCNT were characterized by scanning electron microscopy (SEM), transmission electron microscopy (TEM), thermal gravimetric analyses (TGA), and Fourier transmission infrared spectroscopy (FTIR).

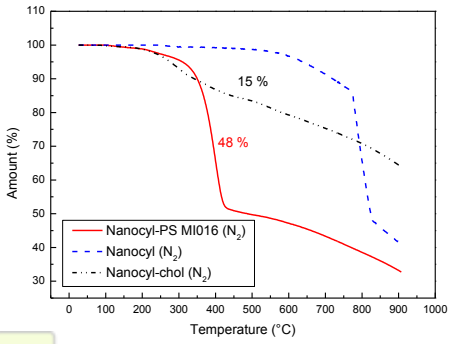

Figure 1: TGA of neat MWCNT, MWCNT-PS and MWCNT-chol under nitrogen atmosphere

Results and discussion: According to conversion determined by NMR and GC, the molecular weight of PS grafted from the MWCNT surface was 4500 g/mol. The average content of grafted PS determined by TGA in nitrogen atmosphere was about 48 ± 3wt. % (Fig. 1). FTIR spectra (ATR, Ge) proved the presence of peaks corresponding to PS. The modification was confirmed also by TEM, where white layer of PS was observed around the MWCNT (Fig. 2).

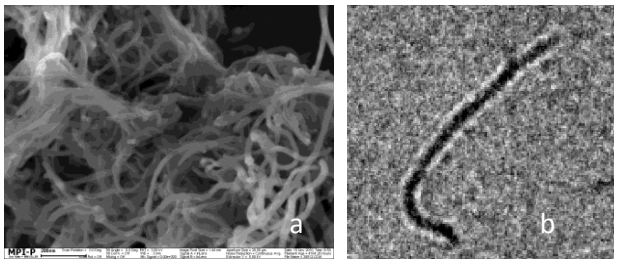

Figure 2 a) SEM image of MWCNT-PS b) TEM image of 0.1 wt. % MWCNT-PS/Kraton cast from chloroform, solution concentration 3mg/ml

The content of grafted cholesteryl groups in MWCNT-chol determined by TGA in nitrogen atmosphere was about 15 wt %. The modified MWCNT were used for composite preparation by casting from solution method.

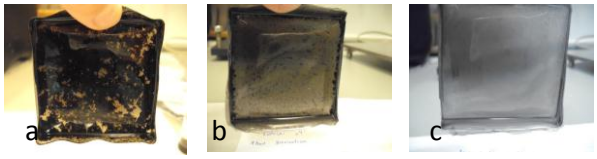

Figure 3 The composite films of Kraton containing 0.1 wt. % of a) neat MWCNT, b) MWCNT-chol, and c) MWCNT-PS.

The best films were obtained as follows: The carbon nanotubes were sonicated for 1 hour in chloroform and subsequently mixed with dissolved polymer matrix and sonicated for 10 minutes. The films were prepared by slow evaporation of the solvent.

Conclusion: MWCNT were successfully covalently modified. The modification significantly improved positive influence on carbon nanotubes dispersion, what was best observable at concentration of 0.1 wt. %.

Influence of montmorillonite (Cloisite 30B) content on water and oxygen barrier properties of polylactic acid films

nadine.tenn@univ-rouen.fr

Barrier properties of polymers are currently in great demand, particularly in packaging industry, where they are replacing many traditional materials [1]. However, in comparison with traditional materials (metals, glass and paper) plastic packaging are more permeable to gases, water vapor and aroma compounds. The ingress of water leads to a permanent change in the nature of food products. Thus, the protection of the packaged goods against oxygen and water vapor is an essential prerequisite for achieving a long shelf-life [2].

With growing environmental awareness, the use of biodegradable polymers is seen as one of many important strategies to minimize the environmental impact of petroleum-based plastics. Therefore, the research of biodegradable polymers has gained considerable attention in recent years. Among all biodegradable polymers, polylactic acid (PLA) is the most promising polymer which in addition to its biodegradable characteristics shows good mechanical, thermal and barrier properties, comparable to those of polystyrene or poly(ethylene terephtalate) [3,4]. However, PLA gives rise to degradation, mainly caused by hydrolysis reactions in the presence of water. Different solutions were proposed in order to solve this problem, for example melt blending with other polymers or nanoparticles.

In this work a serie of PLA based nanocomposites containing organomodified montmorillonite (Cloisite 30B) was prepared. The influence of montmorillonite content (5, 10, 15 and 20 wt. %) in the nanocomposite film on water and oxygen permeabilities, on phase morphology and on thermal behavior was investigated. Atomic force microscopy (AFM) images confirmed well the homogeneous distribution of montmorillonite nanoparticles in the composite films up to 15 wt. % of Cloisite 30B. The presence of Cloisite 30B agglomeration was observed for nanocomposite films with particle content higher than 15 wt. %. The dispersion of clay nanoparticles in composite films was revealed by X-ray diffraction measurements. Besides, the increase of the crystallinity degree with the increasing of nanoparticle content (up to 15 wt. %) was found by means of DSC measurements. An important decrease of water (about 70 %) and oxygen (about 60 %) permeabilities was observed for nanocomposite film with 15 wt. % of Cloisite 30B. This high barrier effect may be explained by good dispersion and orientation of nanoparticles and, also, by the increase of the crystallinity degree of the nanocomposite film.

Therefore, the obtained results show the interest of using such nanocomposites for packaging application, especially due to the important improvement of their barrier properties.

patsy@inti.gob.ar

Introduction

Polymer blending is an alternative approach to obtaining new materials with desirable properties based on available polymers rather than to design and synthesize completely new polymers. Blends obtained from polycaprolactone (PCL) and polyhydroxybutyrate (PHB) are immiscible polymer. Researchers show organo-modified clay changes blend morphology in different immiscible polymer blends [1,2]. In a previous work we studied the preparation of nanocomposite materials from PHB and organic modified clay [3].

In the present study, we evaluate blend nanocomposite films morphology, mechanical and barrier properties in order to study the effect of organic modified clay on PHB/PCL blends, as function of its composition. Films were obtained by cast film extrusion.

Materials and Methods

Commercial grade PCL FB 100 was supplied by Solvay Chemical and PHB homopolymer by PHB Industrial S.A.. "Cloisite^{TM} 30B"(MMT30B) was supplied by Southern Clay Products.

PHB /PCL (20/80 and 50/50 w/w) blends and their composites (5% MMT30B) were prepared in a Werner & Pfleiderer ZSK25 intermeshing twin screw extruder. Films were obtained in a Killion KL-100 single screw extruder with flat die and take off unit. PHB/PCL blend and nanocomposite films morphology (fractures surface) was studied by SEM (Philips 505). Mechanical properties were measured in machine direction using INSTRON 5569A (Test Method ASTM D882). Oxygen permeability was measured using OX-TRAN 2/61(MOCON) (Test Method ASTM D3985) and water vapor permeability (WVP) was determined using a modified ASTM E96 procedure at RH 52%.

Results

SEM images (Figure 1) show that incorporation of MMT30B organo modified clay to PHB/PCL (20/80) does not change blend morphology. The size of PHB disperse phase in PHB/PCL/MMT30B nanocomposite was smaller. For PHB/PCL 50/50 a co-continuous morphology was clearly formed (Figure 2). Occlusions of PCL within the PHB continuous phase and occlusions of PHB within PCL continuous phase were observed. MMT30B incorporation changes the blend morphology from a co-continue to a ¨disperse phase into matrix¨ morphology. The disperse phase domain size decreased drastically when MMT30B was incorporated to PHB/PCL blend, as it was shown for different polymer blends by other authors [2, 3]. MMT30B intercalation/exfoliation was effective due to a better interaction with the polymeric matrixes (PHB and PCL). The organic modified clay was localized at the interfacial polymer region [4]. Nanocomposite blend films mechanical and barrier properties are shown in Table I. For PHB/PCL 20/80 blend no significant difference was observed for the properties evaluated in this study, when MMT30B was added. For nanocomposites films obtained with PHB/PCL 50/50, better mechanical and barrier properties were observed. The change in blend morphology could explain the highest mechanical and gas barrier performance of PHB/PCL 50/50/ MMT30B nanocomposite film.

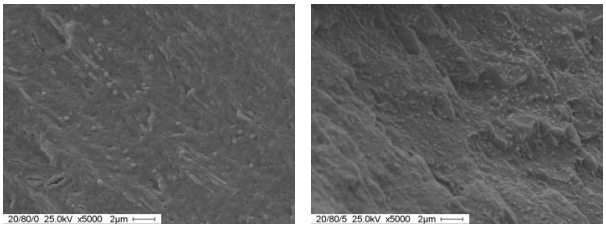

Figure 1:PHB/PCL 20/80 (left) and PHB/PCL 20/80/MMT30B (right)

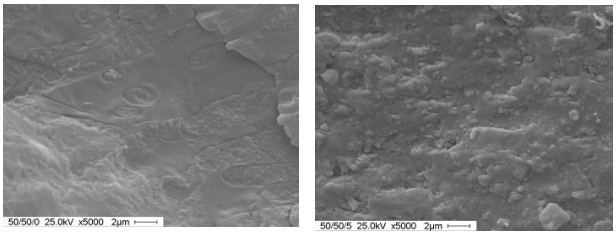

Figure 2:PHB/PCL 50/50 (left) and PHB/PCL 50/50/MMT30B (right)

Table I: Mechanical and barrier properties

PHB/ PCL/ MMT30B film	Elastic Mod (GPa)*	Tensile Max.(MPa)*	O_2 permeability**	WVP ***
20/80/0	0.7 (0.1)	19 (2)	202	--
20/80/5	0.9 (0.1)	17 (1)	167	--
50/50/0	0.9 (0.1)	11 (1)	112	3.1×10^{-14}
50/50/5	1.8 (0.1)	12 (1)	61	8.3×10^{-16}

*Crosshead rate 50mm/min. **(10^{-3}cm^{3}um/m^2/d/atm). ***(g/m/seg/Pa)

Conclusion

Nanocomposite films from PHB/PCL 50/50 and 20/80 (w/w) and MMT30B, were prepared by cast film extrusion. Morphology, mechanical and barrier properties were evaluated in order to study the effect of MMT30B incorporation for different blend composition. The incorporation of MMT30B changes the blend morphology and, as a consequence of this, PHB/PCL 50/50/5 films showed better mechanical and barrier properties.

We exploit the strong temperature dependence of dielectric constant of N-methylformamide to vary the Bjerrum length of a polyelectrolyte, sodium polystyrene sulfonate, and investigate the dynamic properties of salt-free solutions over a broad temperature range, from 54 to -58 °C.

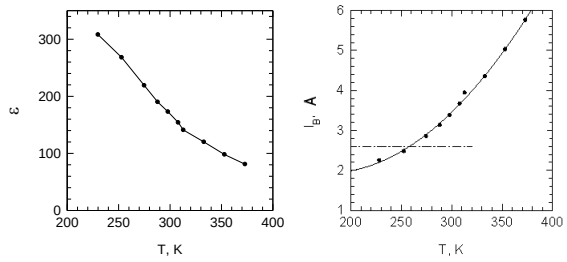

Fig. 1. (a).Temperature dependence of dielectric constant ε of NMF (b)Temperature dependence of Bjerrum length l_B for NaPSS. The dotted line indicates the distance of the neighboring charges on the polyelectrolyte chain.

Dielectric constant, ε for NMF (ε = 160 at 25°C) is much higher than that of water (ε = 85 at 25°C) and strongly depends on temperature (Fig. 1a). This feature of the solvent can be exploited to vary the Bjerrum length (Fig. 1b), to make it possibly larger or smaller than the charge spacing a of the polyion. The purpose of this paper is to investigate, by dynamic light scattering, whether the transition between the ordinary and extraordinary regime in salt-free polyelectrolyte solutions can be achieved only by a change of temperature.

For PSSA in salt-free solution in NMF, DLS experiments were performed in broad temperature range from -58 to 54 °C (Fig. 2). One can see that intensity correlation functions $g_2(t)$ are clearly bimodal with a fast and slow relaxation processes.

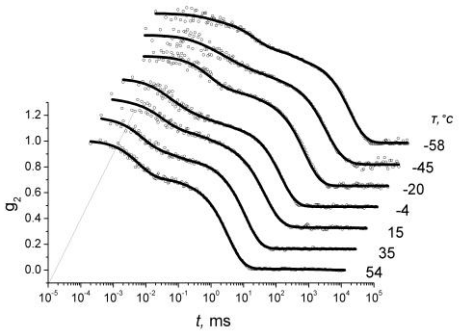

Fig. 2. Correlation functions $g_2(t)$-1 measured at a scattering angle of 90° together with the fitted curves, for the indicated temperatures T(°C).

Therefore we have selected the model of double Williams-Watts stretched exponential function to analyze the intensity correlation functions. The temperature dependence of the diffusion coefficients and the amplitude of the fast and slow modes is shown in Fig. 3a,b.

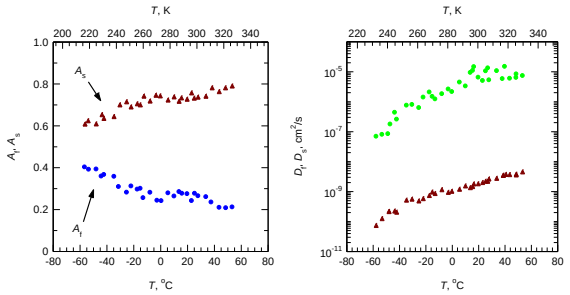

Fig. 3. (a)Temperature dependence of the amplitude of the fast (A_f) and slow (A_s) modes. Indeed the relative amplitude of the slow mode decreases from 0.8 at 54 °C to 0.6 at -58°C. (b)Temperature dependence of the diffusion coefficients of the fast (D_f) and slow (D_s) modes for a solution of NaPSS in NMF.

In order to suppress the effect of temperature variation of viscosity on diffusion, the ratio D_s/D_f of fast and slow diffusion coefficients was examined. As temperature is decreased from 54 to -58°C, D_s/D_f increases by a factor of 2, *i.e.*, follows a trend equivalent to adding salt to a polyelectrolyte solution at constant temperature (Fig. 4a). The same tendency is observed of the ratio A_s/A_f.

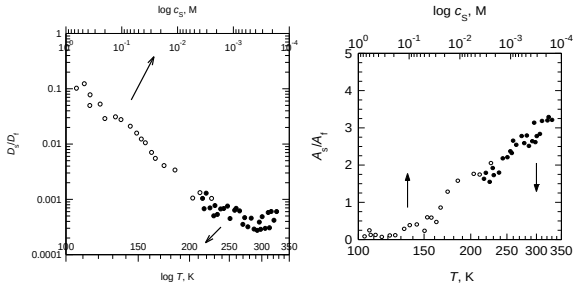

Fig. 4. (a) Dependence of the ratio of the slow and fast diffusion coefficients D_s/D_f (full symbols) on absolute temperature (logarithmic axis) and dependence of D_s/D_f (open symbols) measured on the same polymer/solvent system at 25°C as a function of concentration c_s of added salt (NaCl) obtained in a previous publication. (b) The same for amplitudes.

We conclude that the polyelectrolyte solution approaches the O-E transition as temperature decreases, but even at the lowest temperature that we could reach, A_s did not decrease below 0.5. Comparison with results reported earlier shows that a salt-free NaPSS/NMF solution at a temperature of -58°C corresponds to a solution with 0.001 M salt (NaCl) at 25°C. These results confirm the expected variation of the Bjerrum length of a polyelectrolyte chain.

The influence of nanoparticles on the crystallization behaviour and the local deformation mechanism of poly(ε-caprolactone)

Polymer nanocomposites have recieved a lot of attention over the last few years. The nano-sized fillers have, due to their large specific surface area, a potentional to influence the whole bulk of the nanocomposite already at very low filler content and could therefore induce changes in the properties of the polymer that are very different from conventional composites[1]. However, there is a lack of understanding on what the exact mechanisms behind these changes are. Fillers can affect the nanocomposites in different ways, a.o. they can act as nucleation agents for crystallization[2], change the entanglement density in the amorphous phase[3], give pure reinforcement[4] and/or change the morphology of the obtained composite[5].

The main objective of our study is to investigate the influence of different nano-sized fillers on the morphology and the crystallization behaviour of a semi-crystalline polymer, i.e. poly(ε-caprolactone) (PCL), and to link this to the mechanical properties and the local deformation mechanism of the obtained composites. Special focus will be on how the orientation of the polymer chains is affected by the presence of the fillers and their orientation upon deformation and an attempt will be made to indentify the different mechanisms that are responsible for the observed changes. The state of dispersion of the filler in the matrix, the aspect ratio and the surface treatment of the filler will be discussed. Next to the results of standard measurments like DSC, DMTA and tensile tests more indept studies of the crystallization and deformation behaviour via in situ SAXS and WAXD measurments will also be presented.

Two different systems will be discussed; PCL/silica nano-composites, prepared via solution dispersion of premade silica nanoparticles and PCL/cellulose nanowhiskers composites. The nanowhiskers are needle-like structures with a length of 150-250 nm and a diameter comparable to the radius of the silica particles, i.e. 15-20 nm[6]. These fillers can be more easily oriented in the direction of deformation and they have a very distinct effect on the polymer matrix, compared to silica particles. The matrix/filler interaction is changed via grafting of PCL of different length to the surface of the fillers, and its influence on the properties of the composite will also be discussed.

Introduction

Over the past years, the interest in polymeric materials from renewable sources has been continuously growing both in the academia and in industry, due to the increasing need for differentiation of energy resources and reducing their environmental impact. In this context, poly(lactid acid) (PLA) becomes highly attractive for a substitution of fully petrochemical based polymers.

On the other hand, the large scale application of PLA is often limited by its mechanical and its barrier to gases and vapours. The addition of small amounts of lamellar nanoparticles in a polymer matrix (polymer nanocomposites) can remarkably improve the mechanical properties of the matrix and enhance the barrier properties of these materials. However, the improvements of these properties depend on the nature of the final morphology of the material, the control of the dispersion and on the dimensions of the particles.

Among inorganic materials, smectite clays have received considerable attention because their structure exhibits the required stiffness, strength, and dimensional stability. However, very recently, attention has been turned to layer double hydroxides, also known as hydrotalcites (HT), as inorganic filler materials.

HT consist of brucite-like layers of zinc hydroxide, where some Zn(II) cations are isomorphically substituted with Al(III) cations to confer net positive charges to the layers. These charges are balanced by inter-layered hydrated anions, resulting in a multi-layer of alternating host layers and gallery anions [1].

The possibility of replacing these anions by simple ion-exchange procedures makes HT a unique class of layered solids to be used as hosts of polymers bearing a negative charge or polymers copolymerized with a small amount of a negatively charged monomer.

Aim of this work was to study the effect of the compounding methods on the morphology and on the properties of PLA-hydrotalcite nanocomposites prepared by melt extrusion. Moreover the influence of two different kinds of hydrotalcites – organically modified and not modified – and their concentration were evaluated too.

Materials and Methods

The polymer used in this work was an extrusion grade poly(lactid acid) (PLA Polymer 2002D) supplied by NatureWorks.

Two commercial hydrotalcites, supplied by AkzoNobel, were used as nanofillers: a unmodified type, Perkalite LD and an organically modified type, fully ion exchanged with fatty acid, Perkalite F100S.

The filled materials have been prepared using either a single screw extruder, a counter rotating twin-screw compounder or a corotating twin-screw extruder.

The top processing temperature adopted in all the extruders was 200 °C. The PLA has been compounded with both the hydrotalcites at different concentrations: 1%, 2% and 5% wt/wt.

Neat PLA was processed under the same conditions as the nanocomposites and used for all the further comparison with the other materials.

The prepared materials were characterized by SEM, mechanical and rheological measurements.

Results and Discussion

SEM analyses showed that the best morphology is exhibited by materials prepared with the corotating twin-screw extruder while the worse one by the samples processed with the single screw extruder. The increase of the hydrotalcite concentration led to a worsening of the morphology, i.e. an increase of aggregates and worse dispersion. However the materials containing the organic modified filler showed a better morphology. The rheological measurements revealed that the viscosity of all the materials containing the HT is lower in comparison with the viscosity exhibited by neat matrix in particular when the modified HT is used. It could be hypothesized that this behavior is due to degradation phenomena occurring during the processing of the materials. In particular, the products of the organic modifier degradation could act as a promoter/initiator of polymer degradation.

As regards the mechanical properties, the addition of HT caused only a slight increase of elastic modulus of filled materials even if the 5% of filler was incorporated. The tensile strength of the filled materials decreased if compared with the neat PLA, while the elongation at break is almost the same. Probably, the improvements that should be related to dispersion of the nanofiller in the systems are counterbalanced by degradation of matrix as reported for similar systems [2].

However, in full agreement with morphological analyses, the best performances were exhibited by materials prepared with the corotating twin-screw extruder while the worse ones by the samples processed with the single screw extruder.

Conclusions

PLA-hydrotalcite nanocomposites were prepared using either a single screw extruder, a counter rotating twin-screw compounder or a corotating twin-screw extruder.

The filled materials showed only a slight improvement of mechanical properties probably due degradation phenomena occurring during the processing of the materials.

Introduction: Recently, polymer/layered silicate nanocomposites have been studied in details, because of significant improvement in total properties. Also the effect of 2-acrylamido-2-methyl-1-propane sulfonic acid (AMPS), a reactive surfactant that has amido and sulfonic groups in the molecule in achievement and stability of exfoliated morphology of nanocomposites produced by emulsion polymerization have been studied[1]. In the current work we prepared some polymer nanocomposites with styrene and methylmethacrylate (MMA), AMPS as reactive surfactants and two amount of Na-MMT (4 and 8 weight percent) via emulsion polymerization and investigated relationship between morphology and thermal stability of nanocomposites.

Materials and Methods: Na-MMT was from Southern clay Co. MMA, styrene, AMPS and potassium persulfate (KPS) were purchased from Merck Co. Before polymerization step, Na-MMT was dispersed in deionized water and stirred at room temperature for 4days. Table 1 shows the sample codes. At first step, 10g of monomers, Na-MMT/water suspension, AMPS (0.6g) and deionized water was poured in the 1L reactor. Under nitrogen atmosphere and at 65^{O}C, KPS/water solution was injected. In second step the rest of the monomers were fed into the reactor at the rate of 19.2ml/h, using a syringe pump. In the last step, while keeping the temperature constant at 85^{o}C, the polymerization was continued to reduce un-reacted monomers for 2 hours. Finally the latex was dried under vacuum at ambient temperature for 5days.

Table1: Formulation of samples

Sample Code	MMA(g)	Styrene(g)	Na-MMT/Water(ml)
SAT4	-	40	40
SAT8	-	40	80
MAT4	40	-	40
MAT8	40	-	80

Results and Discussion: Figure 1 shows XRD patterns of samples. All PMMA/nanocomposites did not show any peak. Consequently they have the exfoliated structures. However, for polystyrene nanocomposites containing 4 and 8 Wt% Na-MMT, two peaks exist at 4.15^{o} and 5.5^{o}, respectively. This shows that polymerization of styrene in the presence of AMPS, has led to intercalated morphology. About thermal stability of nanocomposites (Figure 2) high weight residue and less thermal stability at temperatures below 385^{o}C for PS/nanocomposites can be observed. High amount of weight residue of PS nanocomposites which prepared with AMPS has been attributed to reduction of monomer conversion in emulsion polymerization [2]. When the monomer conversion decreases, relative amount of Na-MMT to monomer increases and intercalated morphology achieves. Different phenomena control thermal behavior of nanocomposites. Dispersed nanoscale Na-MMT layers can prevent the evaporation of small molecules

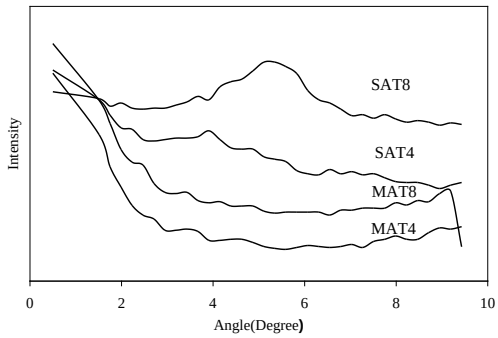

Figure1: X-ray diffraction patterns of samples

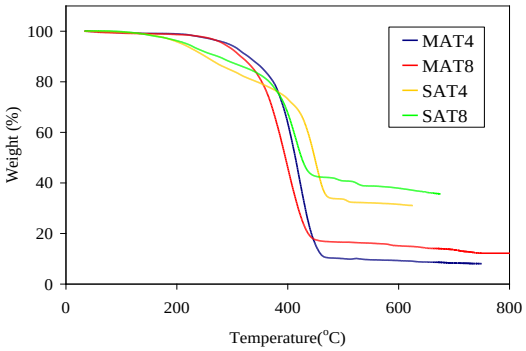

Figure2: TGA curves of samples

generated in thermo-oxidative degradation process and effectively inhibit decomposition of polymer molecules; therefore thermal stability of polymeric nanocomposites improves. In contrast, the stacked Na-MMT layers can hold accumulated heat that can be used as an internal heat source to accelerate the decomposition process, in conjunction with the heat flow supplied by the outside heat source; therefore the thermal stability is decreased [3]. Our results showed intercalated morphology may affect these two opposite phenomena on thermal stability, but the active temperature ranges are different: in temperature rang before 400^{o}C heat accumulation by Na-MMT layers is dominant factor to control thermal stability, but in temperature rang above 400^{o}C Na-MMT layers are more effective as gas barrier and thermal stability is improved.

Conclusion: Our results showed that AMPS has a significant effect on monomer conversion, especially in case of styrene, and monomer conversion reduction is a driving force to achievement intercalation morphology. From results of TGA analysis it can be concluded that intercalation morphology can considerably change thermal stability behavior of nanocomposites.

Introduction

We report the rheology of PDMS based suspensions with solvent-dispersed graphite oxide (GO) and decorated GO with 3-(acryloxypropyl) trimethoxy silane (GOM) sheets. The aim is to study both the dispersion of these carbon nanofillers in PDMS fluids from viscoelastic measurements (Rouse regime) and their rearrangement in terms of complex shear modulus recovery under non-linear deformation. Finally, the dispersion stability and aggregation/agglomeration structural formation of such 2D sheets is discussed.

Experimental

Graphite, graphite oxide (GO) and graphite oxide functionalized with 3-(acryloxypropyl) trimethoxy silane (GO-M) were dispersed in low molar mass PDMS (no entangled chains, viscosity: η = 0.6 Pa.s). These suspensions have been characterized from a linear and non-linear viscoelasticity point of view. First of all, Transmission Electron Microscopy and X-Ray diffraction showed an intercalated morphology of graphite and functionalized graphite oxide. In PDMS suspensions, GO-M and graphite oxide have been assumed to be exfoliated by the short PDMS chains.

Results and Discussion

Only the PDMS suspension filled with the graphite oxide showed a drastic change in the viscoelastic properties for weight fractions up to 6.5 wt % (Fig 1). Actually, for GO concentrations higher than 1.5wt%, the viscoelastic behavior does not show any terminal flow zone and the elastic character of this suspension becomes dominant at low frequencies with the appearance of a secondary plateau. Furthermore, the low percolation threshold of GO sheets is attributed to their macro-scale aggregation/agglomeration driven by their Brownian motion in these low viscosity PDMS suspensions. It was further concluded that the surface modification of graphite oxide by 3-(acryloxypropyl) trimethoxy silane prevents the aggregation of GO sheets.

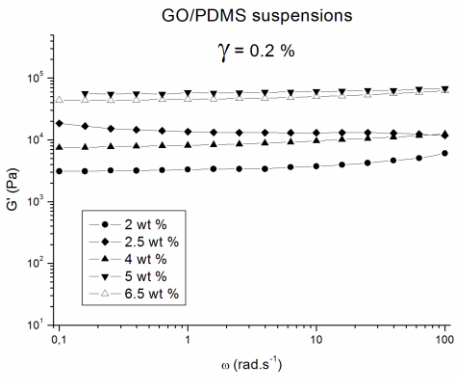

Fig 1: Storage modulus variation of GO/PDMS suspensions

The non-linear behavior of the GO/PDMS suspensions revealed that the increase of strain amplitude leads to a high modification of the network structure out of the equilibrium state. Nevertheless, the critical strain (transition between the linear and non-linear) regime was observed not to depend on GO concentration ($\gamma_c \approx 0.2$ %) as shown in Fig2. This result means that a fractal structure cannot be associated to the aggregation of GO sheets. Actually, GO sheets aggregate into agglomerates that span through the gap between the plates of the rheometer. Finally, recovery tests carried out by subsequent strain sweep proved that the initial equilibrium network structure can be completely and instantaneously restored, and this within the time necessary to start the subsequent non-linear test i.e., a few seconds. Compared with literature works, this particular behavior originates from the low viscosity of the suspension that allows Brownian motion of graphene oxide sheets within the magnitude order of a few seconds. Future work will consist in grafting polymethylhydrogenosiloxane onto APTMS-grafted GO sheets in order to check if functionalization with a polysiloxane backbone offers the possibility to tailor the viscoelastic properties of GO/PDMS suspensions.

Polyamides constantly attract much interest because of their unique property combination. Although they show exceptional thermal and oxidative stability, chemical resistance and low flammability, their insolubility in common organic solvents and high glass and softening temperature make these polymers difficult to process and fabrication [1,2]. Therefore, much effort has been concentrated on synthesizing soluble, processable polyamides without scarifying their desired properties.

In this research work new high thermal resistance polyamides, bearing naphthalene, sulfide, sulfoxide and sulfone units in the polymer backbone were prepared under microwave (MW) irradiation. Improved solubility together with retained high thermal stability could be achieved by introduction of bulky naphthalene rings. The thermal stability, solubility and viscosity of polyamides were obtained. The sizes of polymer species were evaluated using Scanning Electron Microscopy (SEM) images.

Synthesis of thermoresponsive nanocomposite hydrogels by alternative methods

Bernhard Ferse, Anna Große, Karl-Friedrich Arndt

Technische Universität Dresden, Physikalische Chemie der Polymere, 01062, Dresden, Germany

Bernhard.Ferse@chemie.tu-dresden.de

Introduction: In the last three decades, hydrogels have attracted increasing attention in many applications. The mechanical stability plays a decisive role to use hydrogels as actuators in microfluidics, tactile communication and others. HARAGUCHI *et al*. [1] synthesized novel polymer-clay nanocomposite gels (NC-gels), which possess very large deformability, amazing toughness, and high optical transparency. They consist of poly(*N*-isopropylacrylamide) (PNIPAAm), a temperatureresensitive polymer, and the synthetic clay Laponite. The inorganic clay, a synthetic hectorite, belongs to the 2:1 phyllosilicates.
The polymerization of NIPAAm using a free radical thermal initiator was studied extensively in the past. But this method cannot be used for the preparation of thin films or hydrogel structures. Patterned hydrogels in the µm-range or sensitive layers can find applications as sensors and actuators in microfluidic devices.

Materials and Methods: The here presented nanocomposite hydrogels were prepared by in-situ free radical polymerization of NIPAAm in the presence of inorganic, exfoliated clay without the need of an organic crosslinking agent. The initiation was carried out by UV-light ($\lambda < 360$ nm) using a photoinitiator 2-hydroxy-4'-(2-hydroxyethoxy)-2-methylpropiophenone. Irradiation through a mask results in pattern of a sensitive polymer with enhanced mechanical properties even in the swollen state. [2]

Results and Discussion: To understand the photopolymerization process of PNIPAAm-Clay nanocomposite hydrogels in aqueous solutions the gelation reaction was monitored by rheometry using oscillatory deformation tests. Tensile mechanical properties of photopolymerized NC-gels were investigated in order to get information about the gelation mechanism. Additional microscopic analyses (SEM, TEM, AFM) complete the results concerning the network structure of NC-gels

Conclusions: A discussion of the results of different analytical methods come to the realization, that the main process of network formation is the adsorption of the formed polymer chains on the clay surface. Consequently, a simple additive free mixing process of linear PNIPAAm and clay solutions leads to homogenous, thermosensitive mix-hydrogels without any chemical reaction. The obtained mix-gels show good mechanical stability and transparency.[3]

PVDF/Copper Nanocomposites: Preparation and Properties

J. Arranz-Andrés, E Pérez , M. L. Cerrada

Institute of Polymer Science and Technology, CSIC, Juan de la Cierva 3, 28006 Madrid, Spain,

jarranz@ictp.csic.es

Introduction

The insertion of nanometric inorganic compounds in polymeric matrices provides an interesting method to improve some polymers properties, such as electric, thermal, optic or the magnetic ones. On the other hand the resulting materials present the advantages from polymers regarding processability[1], flexibility or less weight and price in comparison with traditional metals. The nanometric structure sometimes shows properties different from those of the same material in a higher level structure[2,3]. For example, polymer composites with conductive metallic particles can be used as antistatic or in electromagnetic interference shielding applications[4]. As a result, this methology has a lot of applications depending upon the inorganic material incorporated within the polymers.

Materials and Methods

Composites of poly(vinylidene fluoride), PVDF, with copper nanoparticles (with a nominal average particle size of 25 nm) have been prepared at different compositions via melt blending. The films obtained were characterized from a morphological and thermal standpoint by transmission and scanning electron microscopies, synchrotron radiation, thermogravimetry and differential scanning calorimetry. Synchrotron X-ray measurements were performed at the CRG beamline BM16 of the ESRF (Grenoble, France). In addition, the molecular dynamic and mechanical properties of the samples have been evaluated.

Results and Discussion

Scanning electron micrographs of cryofractured specimens show a homogeneous dispersion of copper nanoparticles within the polymer matrix without significant aggregation.

An increase in the mechanical parameters related to rigidity, such as young modulus or microhardness, is found when the content of metal does. However, an opposite effect is observed for the properties related to the deformation of the polymer.

The effectiveness of a shield and its resulting electromagnetic interference attenuation depend on the frequency, the distance of the shield from the source, the thickness of the shield, and the shield material. In the present samples, shielding effectiveness is expressed as a function of the ratio of the incident and transmitted X-ray radiation (with a wavelength of 0.098 nm). Figure 1 shows a decrease in more than four orders of magnitude of the incident electromagnetic radiation when the sample with 20 vol% copper is used as shield.

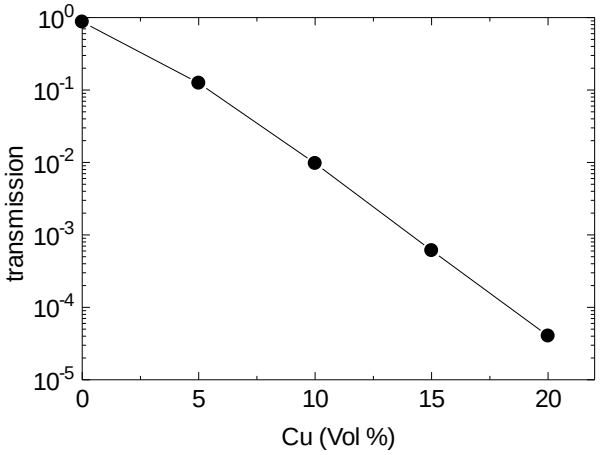

Figure 1. Normalized transmission of X-ray radiation as a function of Cu content in the PVDF/copper nanocomposites.

Conclusions

The dependence of different physical properties on copper nanoparticles concentration has been studied for poly(vinylidene fluoride) nanocomposites. A good distribution of nanoparticles is observed in these PVDF-based materials independently of their composition. On the other hand, a significant improvement is found in some of the properties evaluated.

The Effect of Organoclay Nature on the Nanostructure and Mechanical Properties of Polyamide-12 Nanocomposites

N. Aranburu, J. I. Eguiazábal, J. Nazabal

Dpto. de Ciencia y Tecnología de Polímeros and Instituto de Materiales Poliméricos, POLYMAT
Facultad de Ciencias Químicas, UPV/EHU, Paseo Manuel de Lardizabal 3, 20018 Donostia, Spain

e-mail: naramburu003@ikasle.ehu.es

Introduction

For the last decade, polymer/organoclay nanocomposites (NC´s) have attracted the academic interest, due to their clearly superior properties relative to those of conventional composites. Addition of low clay contents to a polymer matrix (2-5%) leads to the enhancement of different properties, such as mechanical properties, thermal stability, barrier properties or flame retardancy. The properties improvement of the NC´s is related to the high aspect ratio and rigidity of the silicate layers, and also to its degree of dispersion and delamination in the polymer matrix [1]. The affinity between the polymer matrix and the organoclay is the main factor achieving a good dispersion. It can be enhanced by optimizing the structure of the organoclay for a given polymer matrix [2].

Among the different NC´s, those based on polyamide matrices obtained by melt processing have been the most studied. For common polyamide/organoclay NC´s, montmorillonite modified with one alkyl tail has been shown to be the most effective achieving a good dispersion [3]. The highest exfoliation levels have been observed for polyamide-6/organoclay NC´s, while high dispersion levels have been observed also for other polyamide based NC´s. However, in polyamide-12 NC´s, where the aliphatic content is bigger, the role of the organoclay modifier is not still clear.

In this work, we have analysed the effect of the modifier structure of the organoclay on the phase behaviour, the nanostructure, and mechanical and thermal properties of NC´s based on polyamide-12 (PA12).

Experimental

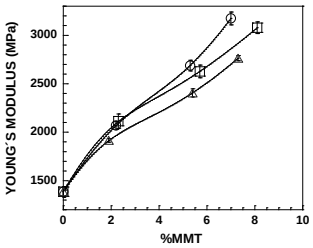
The PA12 was Rilsan AMNO-TLD from Arkema and the fillers were three montmorillonites (MMT) modified with dimethyl dehydrogenated tallow quaternary ammonium (Cloisite® 20A, Southern Clay Products), bis-2-hydroxyethyl methyl tallow quaternary ammonium (Cloisite® 30B, Southern Clay Products), and octadecylamine (Nanomer® I30 TC, Nanocor). The NC´s were prepared in the melt state using a twin screw extruder, and injection molded to obtain standard testing specimens. The phase behaviour and the thermal properties of the NC´s were characterized by differential scanning calorimetry (DSC) and dynamic mechanical-thermal analysis (DMTA). The nanostructure was determined by transmission electron microscopy (TEM) and X-ray diffraction (XRD). The mechanical properties were measured by tensile and impact tests.

Results and Discussion

The melting and crystallization temperatures and the crystallinity of the PA12 measured by DSC, as well as the glass transition temperature measured by DMTA, remained unaffected in the nanocomposites, regardless of the organoclay nature.

In Figure 1 it can be observed that the best results in terms of Young´s modulus improvement of the NC´s were achieved with the organoclay containing hydroxyl groups (30B) and the organoclay modified with two alkyl tails (20A). The Young´s modulus values of the NC´s obtained with one alkyl tail modified organoclay (I30) were unexpectedly lower than those of the other NC´s, regardless of the MMT content. These mechanical properties results are in good agreement with the TEM micrographs of the PA12 NC´s (Figure 2), where higher dispersion levels are observed for NC´s obtained using 30B and 20A organoclays as fillers.

It is suggested that, unlike polyamide-6 based NC´s, organic modifiers with higher molecular volume facilitate the organoclay dispersion in the PA12 matrix. This is related to the higher aliphatic content of the PA12.



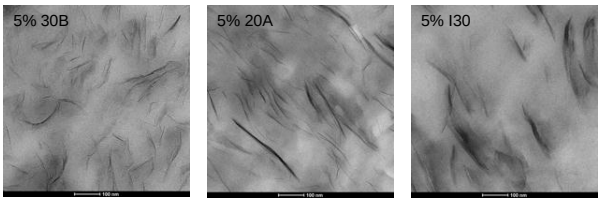


Figure 1. Young´s modulus of the PA12 NC´s as a function of the 30B (○), 20A (□) and I30 (Δ) organoclay content.

Figure 2. TEM micrographs of PA12 based NC´s containing 5% 30B, 20A and I30 organoclays.

Crystallization Studies on Clay Nanocomposites of Nylon 47

L. Franco, L. Morales, M.T. Casas, J. Puiggalí

Departament d'Enginyeria Química/Centre de Recerca en Nanoenginyeria, Universitat Politècnica de Catalunya, ETSEIB, 08028-Barcelona

lourdes.franco@upc.edu

The α and β crystalline structures of even-even nylons are based on a stacking of sheets composed of hydrogen-bonded molecular chains with a planar zig-zag conformation. The corresponding diffraction patterns are characterized by the presence of two strong reflections at spacings close to 0.44 and 0.38 nm. In general, a not completely well understood reversible phase transition is detected on heating/cooling processes. In the first case, the two indicated reflections gradually merge on a single one indicative of a pseudohexagonal arrangement at the so called Brill transition temperature. Peculiar structures based on the establishment of hydrogen bonds along two different directions have recently been postulated in some even-odd nylons, which fibers rendered also two strong equatorial reflections at similar spacings than reported for the α/β conventional structures. Synchro-tron radiation experiments (Figure 1) indicated that the new structure can also be found in nylon 47, which in addition showed complex polymorphic transitions.

Nanocomposites of nylon 47 and different organo-modified clays (i.e. C25A and C30B) were prepared by both melt mixing and solution intercalation film-casting methods. TEM micrographs (Figure 1) and X-ray diffraction data showed exfoliated and intercalated structures for nanocomposites with C30B (melt mixing) and C25A (film-casting) clays, respectively.

DSC calorimetric data indicated that the structure of the nanocomposite had a remarkable influence on both isothermal (Figure 3) and non-isothermal hot crystallization processes. Thus, the crystallization rate decreased or increased when the added clay adopted an exfoliated or an intercalated structure, respectively.

Nylon 47 crystallized from the melt giving rise to different types of morphologies with distinctive features than observed in conventional even-even nylons. Thus, spherulites with a fibrilar texture and a negative birefringence were always observed at low crystallization temperatures, whereas spherulitic aggregates were typical at high crystallization temperatures (> 228 ºC). These aggregates had a birefringence (positive or negative) that depended on the temperature of the sample and changed on a reversible way (Figure 3).

Overall crystallization rate depends on the primary nucleation density and the crystal growth rate. These two effects could be independently evaluated by means of optical microscopy. Thus, primary nucleation density increased and decreased respect to the neat polymer when clay particles gave rise to intercalated and exfoliated structures, respectively. The crystal growth rate was lower in both nanocomposite samples since clay particles had a disturbing effect that was more significant when an exfoliated organization was attained. The degree of crystallinity decreased also significantly in the exfoliated nanocomposite sample.

Characterisation and Cure Kinetics of Epoxy-Clay Nanocomposites Cured using an Anionic Initiator

F. Román, Y. Calventus, P. Colomer, J. M. Hutchinson

Thermodynamics Laboratory, ETSEIAT, Polytechnic University of Catalonia,
Colom 11, 08222 Terrassa, Spain

calventus@mmt.upc.edu

Introduction

One of the problems in the fabrication of epoxy polymer layered silicate (PLS) nanocomposites cured with diamines is that stoichiometric conditions cannot be achieved in the inter- and intra-gallery regions [1]. This has a detrimental effect on the nanostructure and properties of the cured nanocomposites. In the present work we investigate an alternative approach, which involves the anionic homopolymerisation of the epoxy monomer, which avoids the problems of stoichiometry. This approach will be shown to result in PLS nanocomposites with improved properties.

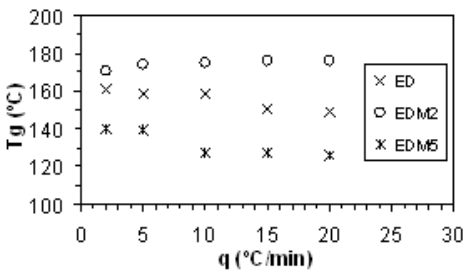
Materials and Methods

The homopolymerisation reaction is initiated by 4-N,N-dimethylaminopyridine (DMAP), which is added, in a proportion of 3 phr with respect to the resin [2], to the resin/clay mixture. The resin is diglycidyl ether of bisphenol-A (DER331, Dow Chemical Company) and the clay is a commercial organically modified montmorillonite (MMT) (I.30E, Nanocor Inc.). We investigate the influence of the MMT content on the homopolymerisation reaction and on the nanostructure and properties of the nanocomposite.

The cure reaction is studied by differential scanning calorimetry (DSC) under isothermal conditions at temperatures from 80ºC to 110ºC and under non-isothermal conditions at rates between 2 and 20 K/min. The glass transition temperature (T_g) and thermal stability of the cured material are determined by DSC and Thermogravimetry (TGA), respectively, and the nanostructure is assessed by Small Angle X-ray Scattering (SAXS) and Transmission Electron Microscopy (TEM). We present here the results for three different systems, with the following approximate wt% of epoxy, initiator and clay, respectively: 97, 3, 0 (ED); 95, 3, 2 (EDM2); 92, 3, 5 (EDM5).

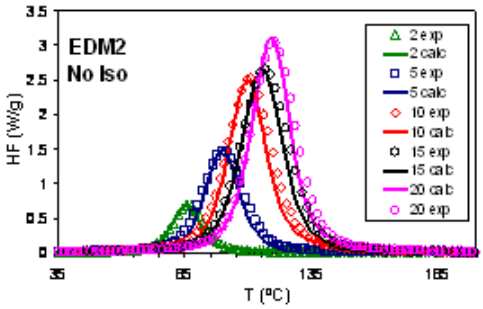
Results and Discussion

There are some important differences between the results obtained here and those obtained earlier for the same epoxy-clay system cured with a diamine [1]. First, whereas for the amine-cured system T_g decreases with increasing clay content, here the T_g of sample EDM2 is higher than that of the neat resin (ED), as shown in the Figure below. The reduction in T_g for sample EDM5, seen in the same Figure, could be due to a poorer dispersion of the clay in the resin.

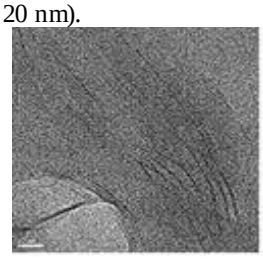


In addition to the increase in T_g, the TGA results also show that EDM2 has significantly improved thermal stability with respect to 2 wt% systems thermally homopolymerised without DMAP or amine-cured.

In the kinetic analysis, the experimental cure curves have been fitted with an autocatalytic model. For the non-isothermal experiments, a good fit is obtained, as can be seen in the Figure below, while for the isothermal experiments the cure curves can be fit only up to vitrification. The isoconversional activation energy for EDM2 is lower than for both ED and EDM5.



The DSC results have been complemented with nanostructural studies. SAXS indicates an improved degree of exfoliation for EDM2 compared with an amine-cured sample, but there remains some intercalation with a d-spacing of 1.5 nm. When examined by TEM, the 2 wt% sample presents a much greater degree of exfoliation than the 5 wt% sample. Typically it consists of some small agglomerates, about 2 μm in size, with layers separated by 1.5 nm, but with evidence of considerable exfoliation outside these agglomerations, as seen in the micrograph below (scale bar 20 nm).



Conclusions

In the light of these results, EDM2 presents an interesting possibility for the development of an optimum nanostructure.

Introduction

The use of nanofibers in tissue engineering is rapidly growing in several last years. The random nanofibrous structure is suitable to form three-dimensional scaffolds with selected seeding cells and/or various constructs with bioactive compounds or drugs. The main goal in tissue engineering is to regenerate a function or part of a damaged tissue. The combination of cell cultivation and control delivery of suitable drugs or bioactive motifs seems to be good way to fulfill requirements for this purpose. To assess the controlled release of model drugs from nanofibrous constructs we decided to study three different approaches: 1) incorporation of drug (model drug gentamycin) into multilayer nanofibrous construct; 2) binding of drugs to linear polymer carriers with increasing molecular weight; 3) control the release of drug by its solubility in aqueous environment (model drug cyclosporine).
The comparison of individual procedures (1-3) is shown and discussed in the presentation.

Materials and Methods

Recent advances in the preparation of nanofiber layers, especially using the Nanospider™ technology, allow the preparation of a sufficiently large area of nanofibrous layer with reproducible thickness and structure. Subsequently, it is possible to employ these layers as drug carriers and evaluate their efficiency in laboratory scale by physical and chemical methods and by *in vitro* tests in tissue culture.

Nanospider technology

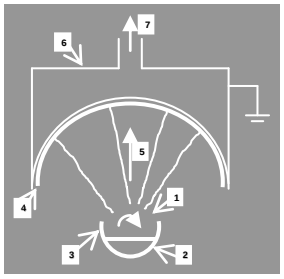

Photo picture of Nanospider TM

Scheme 1. Principle of NanospiderTM
1- electrode metal roller, 2 - fiber-forming polymer solution, 3 - reservoir, 4 - textile substrate, 5 - nanofiber formation direction, 6 –electrode earthing shield, 7 – air suction

Nanofibers were prepared from polycaprolactone (PCL), polylactide (PLA) and polyvinyl alcohol (PVA). Some of the PVA layers were covered from the both sides by polyurethane (PUR) nanofibrous layers of various thicknesses (PVA/PUR). Wide range antibiotic gentamycin and immunosuppressant cyclosporine were incorporated to the nanofiber samples.

The set of linear polyethylene glycols with molecular weights 2000, 6000, 10000 and 20000 was terminated by phenyl groups (detectable by spectral methods) by reaction of end hydroxy groups with phenylisocyanate.
Concentration of studied compounds released to the surrounding solution (water) was determined by HPLC/MS and UV spectroscopy.

Results and Discussion

PVA nanofibers containing 10 % (w/w) of gentamycin overlapped from both sides by PUR nanofibers of various thicknesses were immersed into 10ml of distilled water and shaken at 37°C. After a particular time period, 2.5ml of solution was withdrawn and replaced by fresh water. The concentration of gentamycin was determined by HPLC/MS.
Overlapping of the PVA layer containing gentamycin by layers of stable PUR nanofibers apparently decreased the influence of diffusion and convection in the process of gentamycin release and its washing out was prolonged.
Synthesized polyethylene glycols were incorporated into polymer nanofibers (PVA, PCL, PLA) in a amount of 3 wt%.
It appeared that the rate of release of model molecules is affected by their size (chain length) and the polarity of polymer nanofibers into which they were incorporated.
Samples of PLA nanofibers with incorporated 10 % (w/w) of cyclosporine were immersed to 10ml of distilled water and shaken at 37 °C. After a particular time period the concentration of cyclosporine in solution was determined by HPLC/DAD.
The concentration of cyclosporine increased at about 0.6-0.8 μg/ml within approx. 30 hours and than steadied. Apparently, the release of cyclosporine is considerably influenced by its low solubility in aqueous medium.

Conclusions

The retention of biologically active compound in the nanofibrous structure, kinetic of its release respectively, is affected by a number of factors such as thickness of the nanofibrous layer, interaction of the drug with polymeric nanofibers and the size of the molecules incorporated to the nanofibrous structure. The relationship of these factors and kinetics of the drug release was observed and evaluated for 3 different procedures. In all cases, the ability to control the rate of the release of model compounds was demonstrated.

Effect of Dispersed Phase Modulus on Brittle/Tough Transition of Toughened Polypropilene Based Nanocomposites

Introduction: The achievement of super-toughness in polymers that are ductile but notch-sensitive is clearly one of the most significant advances in the development of new polymeric materials [1]. Different theories are used to explain the brittle/tough (B/T) transition in rubber-toughened blends. Among them, those which relate the B/T transition with a particle size or with an interparticle distance or ligament thickness (τ) are the most used. However, the τ is increasingly used to asses the B/T transition in detriment of the particle size because similar impact strength values may be obtained when the particle size changes, whereas the relation between τ and impact strength is bidirectional.

The critical interparticle distance (τ_c) was firstly considered to be a characteristic of a given matrix, but subsequent studies showed that it depended both on extrinsic (impact speed, test temperature and mode of deformation) and intrinsic parameters (interfacial adhesion (γ), modulus of the matrix (E_m), type and modulus of the rubber (E_d)). However, the influence of the intrinsic parameters on the B/T transition, is often difficult to understand, since the change of one parameter usually supposes the change of at least another. For that reason, the true effect of E_d on τ_c is far from being understood [2].

Therefore, the aim of this paper is to examine the influence of the modulus of the rubber on the B/T transition of toughened polypropylene (PP) nanocomposites (PNs). Maleic anhydride modified poly(ethylene-octene) (mPEO) was mixed with a minority amount of organically modified montmorillonite (OMMT) (10%) in order to increase the modulus of mPEO from 10 MPa to around 90 MPa. This allows us to change the modulus of the dispersed phase without changing other intrinsic parameters.

Materials and Methods: The toughened PNs were obtained in two extrusion steps. Firstly, the mPEO was mixed with 10% OMMT in a twin screw extruder. Subsequently, this PN was added up to 30% to a PP matrix in a second extrusion step before injection moulding. The PP/mPEO blends were prepared as a reference in one step. The characterization of the nanostructure was carried out by transmission electron microscopy (TEM), the surfaces of cryogenically fractured specimens were observed by scanning electron microscopy (SEM) and the phase structure was analyzed by dynamic mechanical analysis (DMA). The mechanical properties were determined by Izod impact and tensile tests.

Results and discussion: The phase structure analysis indicated that both the high temperature glass transition (T_g), which corresponds to the PP phase, and the low temperature T_g, corresponding to mPEO, remained practically constant with the OMMT addition; indicating its pure nature.

The nanostructure analysis revealed that the clay layers stayed in the mPEO dispersed phase and that the additional processing, required to incorporate the rubber to PP, did not lead to any compaction of the widely dispersed layers. Moreover, the SEM micrographs showed that the particle size of the dispersed phase of the PNs was similar to that of the corresponding blends. This indicates that both the nature of the matrix and the interface were preserved and therefore, the addition of OMMT only influenced on E_d.

The impact strength values of the PNs and blends have been plotted against τ in Fig. 1. The B/T transition of PNs occurred at a τ_c smaller than that of the blends. Taking into account that the extrinsic parameters (testing conditions) that influence τ_c were the same both in PNs and blends, and among intrinsic parameters only the dispersed phase modulus varied, this lower τ_c value of the PNs, compared with that of the corresponding blends indicated that τ_c depends on the modulus of elasticity of the dispersed phase, and that a higher modulus leads to a lower τ_c.

gabriela.ambrozic@ki.si

The use of polymers as additives in the solution-phase synthesis of ZnO nanoparticles has been shown to be an excellent way of controlling the crystallites' size, shape and dispersibility. The polymers do not only prevent the agglomeration of the inorganic nanoparticles in the given solvent, but also control the particle growth by adsorbing selectively through functional groups on the surface of the ZnO crystals.[1, 2] However, in order to obtain pure ZnO, a follow-up removal of the polymer template by calcination or long-term UV-radiation exposure is needed.

On the other hand, the polymer can be used not only as an additive but also as a macromolecular ZnO precursor. In such a case the ZnO was obtained by a post-calcination of Zn-coordinated polymers.[3, 4]

In this investigation we focus on a simple, robust and low-temperature synthesis of pure ZnO nanoparticles and polymer-ZnO hybrid materials formed by the NaOH-mediated conversion of poly(zinc dimethacrylate) in 1-butanol, without a post-calcination.

Although the synthesis and properties of poly(zinc dimethacrylate) have already been the subject of some research investigations[5-7], there is, however, only one example reported on its conversion into ZnO particles incorporated inside the native polymer-forming nanocomposite.[8] ZnO/ZnS polymer nanocomposites were prepared by exposing the fibers of poly(zinc dimethacrylate), pre-synthesized by solid-state γ-ray polymerization, to 180 ^{o}C and a H_2S gas flow.

In our work for the first time we used poly (zinc dimethacrylate) to prepare neat ZnO particles. The polymer in this case acts as a template for controlling the crystal growth as well as a precursor of neat ZnO nanoparticles formed under defined reaction conditions, which ensure that the degradation of the polymer chain or the formation of insoluble $Zn(OH)_2$ does not occur.

The obtained single-crystalline ZnO nanorods show a low tendency to aggregate and can be effectively re-dispersed once they are isolated and dried (Figure 1).

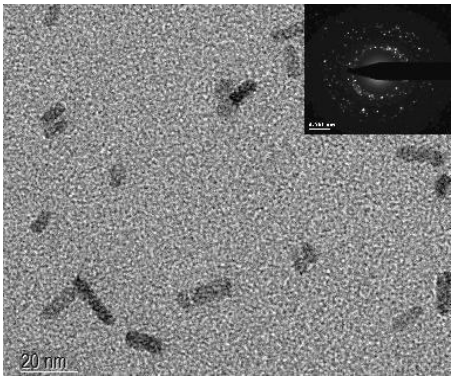

Figure 1: TEM image of ZnO nanorods formed by exposing poly(zinc methacrylate) to NaOH

Thermal stability of PMMA/ZnO nanocomposites

A. Anžlovar, Z. Crnjak Orel, M. Žigon

National Institute of Chemistry, Hajdrihova 19, SI-1000, Ljubljana, SLOVENIA

e-mail:alojz.anzlovar@ki.si

Introduction

Zinc(II) oxide - ZnO is a widely used semiconducting material with an exceptional combination of physical properties having a wide range of potential applications[1]. PMMA is widely used thermoplastic polymer well known for its optical properties. It is reported that inorganic nanofiller enhances the thermal stability of the polymer matrix in composite materials[1,2,3]. Therefore, by combining nano ZnO filler and PMMA polymer it is possible to prepare transparent composite materials which show, besides exceptional UV absorption and sun light resistance, also enhanced thermal stability of the PMMA matrix[4,5].

Experimental

Organophilic nano ZnO powders were synthesized by the hydrolysis of zinc(II) acetate in various diols[6,7] using p-toluene sulphonic acid - pTSA as an end capping agent and without pTSA. Particles were characterized by SEM microscopy, IR spectroscopy and XRD diffraction confirming the presence of crystalline ZnO. Thermal properties of PMMA/ZnO nanocomposites were studied by thermogravimetric analysis - TGA and differential thermogravimetry - DTG.

Results

It is known that nano ZnO can enhance the thermal stability of the PMMA matrix[1,2,3]. Results of TGA and DTG analysis showed that significant shift of T_d – 5% weight loss (20 – 40 °C) was achieved by adding 1 wt. % of nano ZnO. At lover concentrations of ZnO filler the thermal stability enhancement is much smaller. DTG curves also showed that nano ZnO particles have more intense effect on thermal stability enhancement than submicrometer ZnO particles (Figure 1) [8].

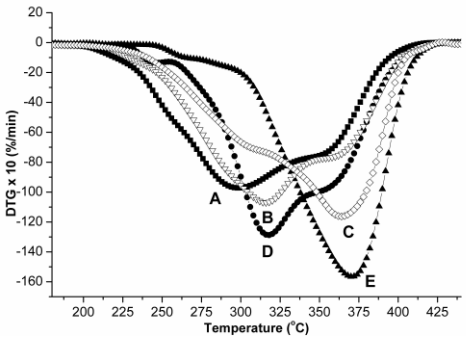

Figure 1: DTG curves of PMMA/ZnO nanocomposites in dependence of ZnO content and particle size:A) PMMA, B) 0.1%ZnO–340nm, C) 1.0%ZnO–340nm, D) 0.1% ZnO–75nm, E) 1.0% ZnO–75nm..

The thermal decomposition course of PMMA studied by DTG curves also indicates that the chemical structure of PMMA is changed (reduced concentration of vinylidene chain end double bonds) when MMA is polymerized in the presence of nano ZnO. This was confirmed by ^{1}H NMR spectroscopy which showed significant reduction of double bond signals at 5.54 and

6.18 ppm by increasing the concentration of nano ZnO, while by adding sub micrometer ZnO no changes were observed (Figure 2) indicating that the main mechanism of thermal stabilization is reduced concentration vinylidene double bonds[8].

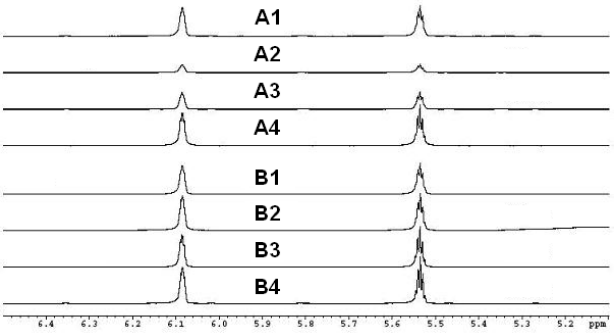

Figure 2: The intensity of vinylidene proton peaks in ^{1}H NMR spectra of PMMA in dependence of the ZnO concentration and size: A-ZnO(75nm); A1) 0%, A2) 1%, A3) 0.1%, A4) 0.01% and B-ZnO(340nm); B1) 0%, B2) 1%, B3) 0.1%, B4) 0.01%.

Conclusion

Themal stability of PMMA matrix in composite materials is enhanced by admixing nano ZnO in concentration of 1 wt. % and higher while submicrometer ZnO shows much less intense effect. DTG and ^{1}H NMR spectroscopy showed that the main mechanism of thermal stabilization of PMMA is changed mechanism of MMA radical chain polymerization causing reduced concentration of vinylidene double bonds

Influence of the epoxy /amine stoichiometry on the thermomechanical properties of nanocomposites based on high T_g epoxy and organophilic clays

MA. García del Cid, M.G. Prolongo, R.M. Masegosa, C. Arribas, C. Salom

Escuela de Ingeniería Aeronáutica y del Espacio. Universidad Politécnica de Madrid

mg.prolongo@ upm.es

In epoxy-layered silicate nanocomposites two main steps govern the morphology: the intercalation in which epoxy monomers diffuse into clay galleries, leading to an increase of the d-spacing and the exfoliation in which the silicate layers are delaminated and fully dispersed. Organic modification of the silicate layers makes it compatible with the polymer. The mechanical properties improvement of epoxy-organophilic clay nanocomposites and their correlation with the intercalated or exfoliated morphologies, are object of study nowadays. For epoxy thermosets having low glass transition temperature (T_g), improvements of the elastic modulus and increases in T_g have been reported, both when intercalated or exfoliated morphologies are formed. However, the effect of organophilic clay dispersion on epoxies of high T_g, that are cured using aromatic diamines, is not clear, thus increases as well as decreases of the epoxy T_g in the nanocomposite have been reported.

In previous works (1,2) we have studied the thermal and mechanical properties of epoxy-clay nanocomposites prepared with organically modified montmorillonites (Cloisites: C93A, C15A and C30B). The different effects of clays on epoxy curing are related to the chemical structure of the onium cations. Both C30B and C15A are modified with quaternary alkyl onium cations, C30B has two hydroxyls in the onium cations. C93A is modified with alkyl ammonium cations having one acidic hydrogen. Moreover epoxy/Nanomer I.30E nanocomposites were prepared, Nanomer I.30E is a montmorillonite modified with primary alkyl ammonium cations. The three epoxy/cloisite nanocomposites show intercalated clay structures. The epoxy/I.30E nanocomposites present exfoliated structures according to the catalytic effect of the acidic onium cations that promotes the intragallery curing.

The nanocomposites show improved mechanical properties i.e. they show higher elastic modulus than the neat epoxy thermoset. However all clay-epoxy nanocomposites have lower T_g than the neat epoxy thermoset, regardless of the clay used, with no significant differences between exfoliated or intercalated nanocomposites. The lowering of T_g is usually attributed to a plastizasing effect of the alkyl ammonium ions or sometimes to the formation of an imperfect -no totally crosslinked- network. If the homopolymerization of the epoxy is favored between the layers, this may cause a displacement of stoichiometry so that the T_g would be reduced. Another hypothesys is that there occurs thermal dissociation of the alquyl onium on curing at high temperatures.

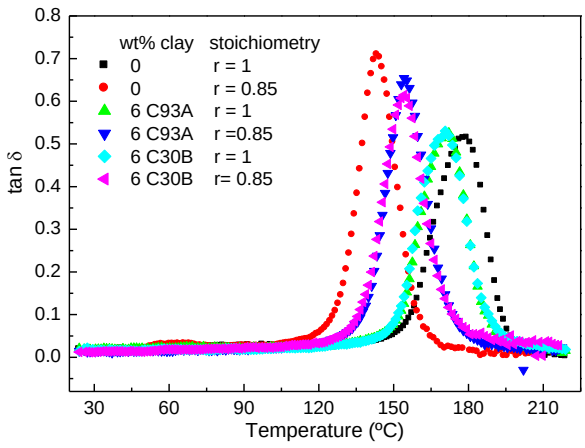
The objective of this work is to study if there is a relation between the decrease in T_g and a possible imbalance of the stoichiometry caused by the clay.

The epoxy resin was diglycidyl ether of bisphenol A (DGEBA) and the curing agent 4,4'-

diaminodiphenylmethane (DDM). Stoichiometric ratio: r = HN/-O- = 1 and non stoichiometric r = 0.94, r = 0.85 were studied. The nanocomposites were prepared with Cloisites: C30B, C93A and Nanocor I.30E. The clay was dispersed in DGEBA at 120ºC, the dispersion was degassed, mixed with DDM at 80ºC, sonicated and cured. The curing protocol was: 1h at 120º + 2h at 180ºC. The experimental techniques used were: DSC, DMTA, WAXD, FTIR, and Testing Machine.

Firstly the effect of the clays on the homopolymerization of DGEBA without DDM was studied . It was found that the clays act as catalysts for the self-polymerization. The effect is more pronounced for I.30, and C93A is less effective than C30B.Then the curing by DSC, the DMTA properties and the structure by WAXS of the nanocomposites having different stoichiometric ratios were investigated.

The figure shows tanδ-temperature isochrones obtained from DMTA for some of the nanocomposites studied. For nanocomposites having r=1, the T_g decreases with the clay content. For nanocomposites having r < 1, T_g increases with the clay content. This opposite behavior indicates that organophilic clay offsets the effect of the stoichiometry imbalance.



FTIR was used to confirm the presence of amine, glycidyl moieties in the nanocomposites. Mechanical properties obtained from DMTA and from testing mechanical tests were correlated with the nanocomposite structure.

Introduction: In recent years, the development of mechanically reinforced nanocomposites based on biodegradable polyester matrices has gained a strong incentive due to their potential use as biomaterials and to growing worldwide environmental concerns.

Objectives: This work aims to pursue this goal, and combines polycaprolactone matrices (PCL) with mesostructured silicas, by means of surface initiated acid-catalysed Ring Opening Polymerisation (ROP). Mesoporous silica materials are known as adequate carriers for hosting many types of molecules [1], and they were used here simultaneously as reinforcement filler and as carrier for ROP initiators. Metal-free ROP catalysts, based on organic derivatives of sulfonic acid, are used [2, 3] which will constitute an additional benefit from the environmental standpoint.

Methods: The reinforced polymers were prepared using high surface area SBA-15 and MCM-41 mesoporous silicas functionalised with OH groups (initiators). Methane sulfonic acid was used as catalyst for the surface-initiated ring-opening polymerisation of CL and LA.

Results and Discussion: Preliminary physical characterisation data show that for a PCL sample with moderate molecular weight (Mn~20000) and containing around 3.5% mesoporous silica (SBA-15), the mechanical properties are drastically improved, with the reinforced polymer being much tougher than neat PCL. Melt rheology measurements show that this reinforced PCL has a zero-shear viscosity nearly 5 times higher than for neat PCL, with shear-thinning visible at higher shear rates.
In spite of an expected initiation by the hydroxyl attached to the mesoporous silica framework, it was found that nearly all the PCL chains are not attached to the silica particles. MALDI-TOF results hint that this is due, in part, to the formation of cyclic PCL species by back-biting transesterification reaction.

Introduction: Nanosized fillers such as carbon nanotubes, clay and nanofibers have been considered suitable reinforcing materials for epoxy resins to produce high performance composites with enhanced properties. Carbon nanotubes (CNTs) are excellent candidates for improvement of thermo-mechanical properties of epoxy resins [1]. Raw CNTs have a tendency to aggregate because of their large surface area and strong resultant van der Waals forces. The dispersion of CNTs is very important in order to fully realize improvement in epoxy based CNT composites, this being improved considerably by functionalization [2] Aiming the enhancement of the dielectric properties and the moisture resistance of classic DGEBA epoxy resins, the present research proposes fluorinated epoxy nanocomposite systems reinforced with amine modified Multiwalled Carbon Nanotubes (*MWNT*).

Materials and methods: Fluorinated epoxy resin was synthesized from epichlorhydrine and 4,4′-(Hexafluoroisopropylidene)diphenol by a method described in the literature [3]. Amine modified nanotubes have been obtained by a two step reaction: first step is the interaction between carboxylated MWNTs and thyonil chloride ($SOCl_2$) to obtain acylated groups on the nanotubes surface, second step was the interaction between acylated MWNTs and the amines modifying agents: benzylamine (*BA*) and a polyetheramine (*B100*). Functionalization was proved by TGA, FT-IR, XPS and SEM analysis. The modified CNTs were dispersed in diglycidylether of hexafluorinated bisphenol A (DGEFBA) by tip sonication, cured with an aromatic polyamine (Poly(m-xylylenediamine-alt-epichlorohydrin) diamine terminated) by a two step temperature schedule to obtain the final composites. Composite samples were characterised by TGA, DMA, DSC and SEM analysis.

Results and disscusion: XPS surface characterization of functionalized MWNTs showed a decrease of the oxygen content for MWNT-BA and subsequent appearance of nitrogen bonds from the amine groups. Amine groups were present also in the MWNT-B100, but due to the ether groups from the B100 backbone, the O1s content was slightly increased as shown in table 1.

Table 1 XPS data for functionalized MWNTs

Nanotubes Type	At. C1s %	At. O1s %	At. N1s %
MWNT-COOH	83.8	16.2	0
MWNT-BA	88.3	9.7	2.0
MWNT-B100	81.8	16.9	1.3

Thermostability of the DGEFBA composites systems, defined as the temperature of 3% weight loss ($Td_{3\%}$), was obtained using TGA technique. Compared with the neat DGEFBA, the composites reinforced with only 0.3% of functionalized MWNTs showed a ~20°C improvement of $Td_{3\%}$ (figure 1), meaning that the epoxy network was strengthened by the one formed through the good dispersion of the nanotubes.

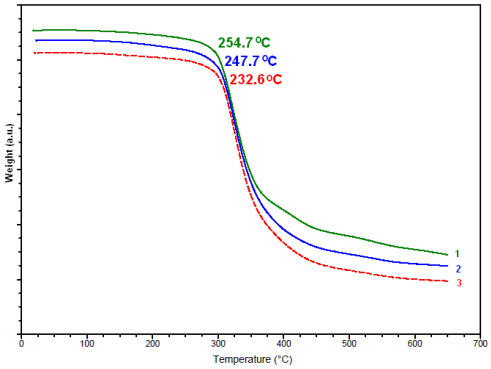

Fig. 1 TGA curves of 1) DGEFBA/MWNT-B100 2) DGEFBA/MWNT-BA; 3) neat DGEFBA;

The curing process of the initial composite systems was studied by dynamic DSC, resulting that 0.3% of functionalized MWNTs do not affect significantly the reaction enthalpy (~290 J/g) and the maximum cure temperature (~ 99°C).

Fluorinated epoxy resins are known as hydrophobic materials with high resistance to the moisture environment. Due to this fact it was noticed a low compatibility with the carboxylic groups from the MWNTs surface resulting in agglomerates. The SEM images for amine functionalized MWNTs (Fig.2.B) showed well dispersed nanotubes in the DGEFBA resin, which is responsible for the enhancement of the new composites.

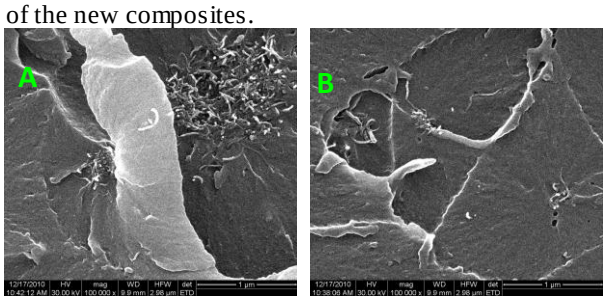

Fig. 2 SEM images of DGEFBA composites with A) MWNT-COOH and B) MWNT-B100

Conclusions: MWNTs were functionalized with two aromatic amines in order to improve their compatibility with fluorinated epoxy resin. The new composites showed improved thermal stability and good dispersion.

Fluorescent Polynorbornene/Oxazine-1 Loaded Fluoromica Nanocomposites by *In Situ* Polymerization for Solution Processable Electronics

Giuseppe Leone, Umberto Giovanella, William Porzio, Chiara Botta, and Giovanni Ricci

CNR-Istituto per lo Studio delle Macromolecole (ISMAC), via E. Bassini 15, I-20133 Milano (Italy)

giovanni.ricci@ismac.cnr.it

In the growing world of nanotechnologies, a particular interest has been given to the synthesis of hybrid supramolecular assemblies, arranged into ordered nano-scaled architectures embedding photofunctional dyes, for the development of optoelectronic devices. [1]

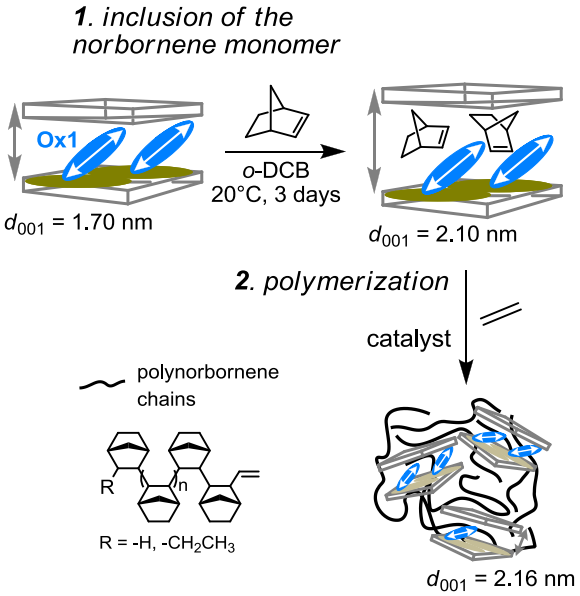
A common limitation of organic dyes is their susceptibility to chemical and photochemical degradation. Moreover, their tendency to aggregate induces multichromophoric interactions that alter the color quality and give unfavorable non-fluorescent species. In order to overcome these drawbacks, many researchers began investigating hybridization of the dye by addressing these molecules into different organic or inorganic hosts. Among host–guest assemblies, layered silicates belonging to the family of 2:1 phyllosilicate clays have proved to be very convenient hosts, especially because they offer unique two-dimensional expandable interlayer spacing to yield organized intercalated guest species. [2] To date, several luminous dye-clays have been extensively studied to prepare functional assemblies. However, the fabrication of optoelettronic devices with these hybrids is still a challenging task because of the still poor film quality.

We thought that a possible way to find a solution to the above critical points could have been the incorporation of dye doped clays into a flexible polymeric matrix, allowing to maintain the dye luminescence properties and to improve the film processability at the same time.

Following this idea, we have now prepared fluorescent polynorbornene/oxazine-1 (Ox1) loaded fluoromica nanocomposites by *in situ* polymerization via Ziegler-Natta catalysis.

Sodium-fluoromica is modified with cationic Ox1 dye by ion-exchange: at higher Ox1 loading the dye adopts a much more perpendicular orientation of the long-molecular axis with respect to the clay layer surface. As a result of this tilted geometrical arrangement the clay *d*-spacing increases and minimizes the area covered per a monolayer intercalated Ox1 molecules. These features facilitate the entry of the incoming polymerizable monomers (*i.e.*, norbornene and ethylene) in between the clay galleries, and thus the interlayer growth of the macromolecular chains (see Scheme 1). [3] When the polymerization is initiated within the layers, where the slabs of the inorganic host act as a template, an ordered and well-dispersed multicomponent polymeric hybrid, in which dyes are highly oriented in the inorganic framework, is formed.

Nanocomposites exhibit an improved solubility with respect to the dye/clay compounds, which made the polynorbornene composite easy processable by spin-coating technique. Absorption and photoluminescence studies show that the nanohybrids exhibit the presence of dye species having features of both Ox1 monomer molecules and J-dimers.



Scheme 1.

The nanocomposites show four main advantages: (*i*) a high dye concentration can be achieved avoiding non-fluorescent dye aggregate formation; (*ii*) the clay aggregation is hampered by the polymer chains that wrap the clay platelets; (*iii*) the solubility is improved with respect to the dye/clay compounds, making the polymer composites easy processable by spin-coating technique; (*iv*) the presence of the hydrophobic poorly–polar polymer in between the clay layers affords a phase segregation which drives the dye molecules to adopt less conformational degrees of freedom until to increase the head-to-tail interaction (J-aggregates) between them.

In conclusion, the results obtained open up unprecedented prospects for the synthesis of novel luminescent polymer hybrids which can be used to fabricate functional devices with unique photoluminescence properties.

Novel rheological and electrical results of polyamide/graphene nanocomposites

Jorge Canales[1], *Mercedes Fernández*[1], *Maria Eugenia Muñoz*[1], *Antxon Santamaría*[1]

1- Polymer Science and Technology Department, University of the Basque Country

antxon.santamaria@ehu.es

Introduction

The number of papers on polymer nanocomposites based on layered silicates and carbon nanotubes has increased exponentially in recent years. However, publications about the use of graphene to obtain polymer nanocomposites are still relatively scarce, although its number is also increasing[1,2,3]. Yet, the excellent electrical, thermal and mechanical properties of graphenes open sound prospects for the dispersions of such nano thin carbon sheets in thermoplastic or thermoset polymers. In this contribution we investigate rheological and electrical features of polyamide/graphene nanocomposites.

Results

A commercial amorphous polyamide, with a processing temperature in the range 220-290ºC, is used as the polymer matrix where carbon sheets are dispersed. For comparison purposes, graphite, a commercial graphene and graphene prepared in our laboratory are employed. With the aim of approaching to industrial processes, the dispersions are performed in the molten state, in a mini extruder which works either in corotational or contrarotational mode. Adequate mixing conditions are selected according to a feedback procedure involving rheological and electrical data of the dispersions Dynamic viscoelastic measurements are used to evaluate the effect of temperature on the complex viscosity of the nanocomposites. Besides, the analysis of the terminal zone, in particular the variation of the loss factor with frequency, allows determining the percolation threshold or the minimum volume fraction of nano sheets to constitute a physical network. These rheological results are linked with electrical conductivity results, leading to discuss the connection between rheological and electrical percolation. Pressure-Volume-Temperature experiments are also carried out to investigate the effect of pressure on viscosity, in concordance with rheological data obtained by dynamic viscoelastic measurements.

aolea@unab.cl

Introduction. Polymeric micelles are created by spontaneous self-assembly of individual amphiphilic polymeric molecules (unimers) at a critical micelle concentration (CMC) and above the critical micelle temperature (CMT). Most of the polymeric micelles used for drug delivery are spherically shaped core-shell structures where the hydrophobic segments of an amphiphilic polymer form the core of the micelle while the hydrophilic parts form the corona or outer shell. The hydrophobic micelle core serves as a microenvironment for the incorporation of lipophilic drugs, while the hydrophilic shell helps to avoid micelle aggregation and to ensure micelle solubility. The most commonly used hydrophilic blocks has been poly(ethylene oxide) (PEO) that has the monomer subunit –CH2-CH2-O-. Water-soluble triblock copolymers of PEO and poly(propylene oxide) (PPO) are commercially available in a range of molecular weights and PPO/PEO composition ratios. Commercial names for these copolymers are Poloxamers and Pluronic®. These molecules are widely used in industrial applications such as detergency, dispersion stabilization, foaming, emulsification, and recently in drug solubilization and controlled release. In aqueous solution, these amphiphilic copolymers form micelles with hydrophobic PPO blocks as the core and hydrated PEO blocks as the corona.
Therefore, in this work we have studied from a physicochemical standpoint, polymeric micelles formed by Pluronic® with the aim to get information on the factors that control the incorporation and delivery of antifungal agents.

Materials and Methods. Two different Pluronic®, F-127 and F-68, were used as received. Aqueous solutions, with polymer concentration in the range $1 \times 10^{-2} - 1 \times 10^{-3}$, were prepared by direct solubilization of polymer in distilled and deionized water. Polygodial extracted from *drymis winteri* was dissolved in acetonitrile and incorporated to the micelle solution by either injection or sonication methods. Antifungal activity was evaluated against *Saprolegnius*.
The micelle critical concentration, cmc, was determined by measuring the ratio monomer/excimer intensities in pyrene fluorescence spectra, as a function of polymer concentration.

Results and Discussion. The cmc of block copolymers was determined by fluorescence probing. Typical results are shown in figure 1. The obtained values are similar to those found in literature, i.e. 2.8×10^{-6}M and 4.8×10^{-4}M, for F127 and F68, respectively.

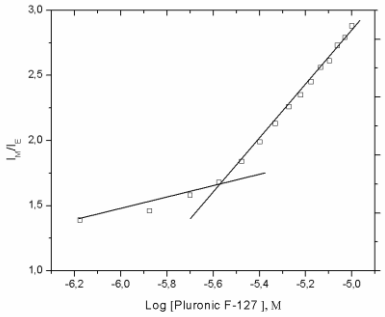

Figure 1. Plot of the ratio of monomer to excimer intensities, against log of Pluronic concentration.

The maximum amount of polygodial incorporated to these polymeric micelles is 0.69 mg/mL, and it is independent of the solubilization method. At this concentration the aqueous solution of poygodial in micelles exhibit large zones of inhibition growth for *Saprolegnius* (see figure2)

Figure 2. Growth of Saprolegnius in the presence of different concentrations of polygodial solubilised in polymeric micelles.

The results are interpreted in terms of the distribution constant and the liberation rate of polygodial.

Conclusions. Polygodial has been solubilised in aqueous solution of triblock copolymers. The anti-Saprolegnius activity of this agent is not affected by the polymer carrier.

qqryk@o2.pl

Introduction: Sodium cobalt bis(dicarbollide), COSAN, is water soluble despite the fact that the boron cluster itself is strongly hydrophobic. These and other features lead to peculiar behavior of the metallacarborane in water, such as aggregation and surface activity despite a lack of amphiphilic topology.[1] It is also known that metallacarboranes can interact with several biocompatible polymers that could be exploited in preparation of nanoparticles for drug delivery.[2,3] To obtain a deeper insight into the cobalt bis(dicarbollide) behavior in aqueous solutions and its interaction with water soluble polymers consisting of poly(ethylene oxide), PEO, and poly(2-ethyl oxazoline), PEOX, we employed isothermal titration calorimetry.

Materials: Sodium salt of metallacarborane anion [3-cobalt(III) bis(1,2-dicarbollide)](-1) was a kind gift of Dr. Bohumír Grüner and Dr. Jaromír Plešek (Institute of Inorganic Chemistry, ASCR, Řež near Prague). Poly(ethylene oxide) was purchased from Fluka (M_w is 41.5×10^3 and PDI 1.10). Poly(2-ethyl-2-oxazoline) was purchased from Aldrich (M_w is 50.0×10^3). Poly(ethylene oxide)-*block*-poly(2-ethyl oxazoline) was purchased from Polymer source, Inc. (Dorval, Quebec, Canada), (M_w of PEO and PEOX: 5.0×10^3 and 6.5×10^3, respectively, PDI 1.10).

Results and Discussion: The ITC results show fairly complex behavior even of pure sodium bis(dicarbollide). The heat of dilution is both endo- and exothermic depending on starting concentration of metallacarborane. When PEO solution is titrated by metallacarborane in 0.1 M NaCl solution, we observed exothermic contribution with the sharp exothermic peak (see Figure 1) that can be attributed to rearrangement of the boron clusters within the PEO matrix of the creating composite. We also observed that the interaction with PEOX and PEO-PEOX is more complex than simple one-binding-site approach and requires using of more sophisticated models. The binding sites of cobalt bis(dicarbollide) with PEO and PEOX chains were estimated by 2D NMR experiments. From appropriate fits of the experimental ITC curves we calculated heat of formation, stoichiometry and binding constants of the metallacarborane/polymer complexes.

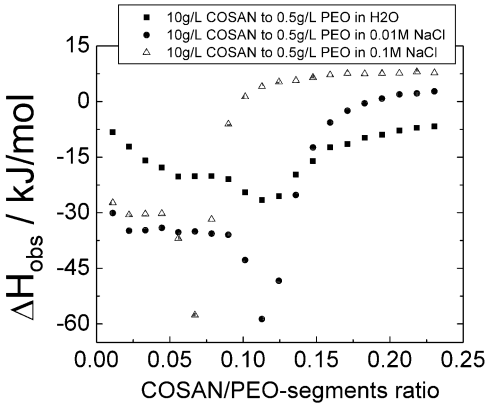

Figure 1: The ITC isotherms of PEO solutions titrated by COSAN as indicated.

*mmarinst@ugr.es

Introduction: Molecular oxygen is one of the most important gases in our environment. Oxygen sensors are usually based on the quenching of luminescent dyes by paramagnetic oxygen. Therefore, the incorporation of luminescent dyes into polymeric nanoparticles makes them an interesting platform for oxygen optical sensing. Miniemulsion solvent evaporation and the influence of different variables have been already studied by G. Mistlberger *et al.*[1] for the production of optical sensing nanoparticles. However, due to the complex medium and the multiple physic processes involved, the relation between all the variables is not yet clear. Statistical design offers a tool to find out this influence by using a minimum number of experiments. In this work a preliminary screening test has been carried out to choose which are the most relevant parameters leading to a monodisperse size distribution.

Materials and Methods: polymer nanoparticles were prepared by the emulsification of a water insoluble cocktail and the consequent evaporation of the solvent. Poly(styrene-co-maleic anhydride) of three different molecular weights and maleic contents, chloroform, polyvinyl alcohol (PVA) and sodium dodecyl sulfate (SDS) were used. The parameters studied to characterize the nanoparticles were size (d, in nanometers) and polydispersion index (PdI), both measured with a Zetananosizer (Malvern Instrument).

Results and Discussion: Factors able to affect the nanoparticles are related to either the processes or the raw materials. Main factors regarding to the process are time and amplitude of sonication. It seems clear that factors influencing size and polydispersity are also related with polymer weight and concentration, surfactant type and concentration and o/w relation. In other to evaluate the most relevant ones a screening test was proposed covering the range shown in Table 1 for each variable.

Table 1. Codes for the different variables and range selected

Codes	Variable	Range Min	Range Max
W	Molecular Weight ($g \cdot mol^{-1}$)	14400	240000
C_p	Polymer concentration (mg/ml)	10	160
V	Percentage of organic phase (%)	1	20
C_{SDS}	SDS concentration (mg/ml)	0.14	2.88
A	Amplitude of sonication	20	90
t	Time of sonication	5	10

Since one of the challenges is to produce small, monodisperse nanoparticles, the response function was designed to penalize the values of PdI and d over 0.2 and 200 nm, respectively. Therefore, three different response functions were proposed, and the effects were calculated. Following an analysis of variance criteria (ANOVA), the most significant variables were: polymer type and concentration, and organic phase percentage. This is in concordance to considering significant those variables whose effect exceeds the percentage of error, corresponding to a sample prepared in triplicate, as can be

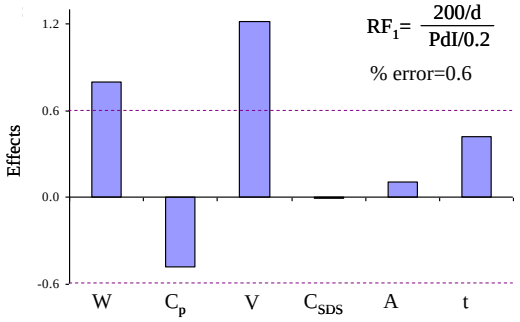

Fig. 1. Effects for the variables according to response function RF_1.

As expected, the most relevant parameters are those related to the raw materials. However, it is worth mentioning that although SDS does not appears as a significant variable, the surfactant role is very important in the particle formation. Thus, this variable has a significant effect over the particle size, but seems not to be so critical in the RF_1 defined above, for the range selected. In fact, two experiments were repeated using PVA instead of SDS and in both cases, the result was a highly polydisperse solution of nanoparticles exceeding 1 μm. This can be explained by the high molecular weight of PVA, which leads to the incomplete formation of micelles for the concentration used in the experience.

Conclusions: Miniemulsion evaporation was performed to study the effect of variables. The preliminary results show that for the range studied, the SDS amount does not affect size and size distribution, when both responses are combined in a function which represents the result considered as optimum: small and narrow distributed particles. Therefore, these parameters may be controlled by means of polymer type and concentration, and o/w relation. Further studies will be carried out to completely optimize the system.

frrvdiaz@usp.br

Introduction. Natural rubber (NR) is commonly reinforced with carbon black (CB) to produce vulcanized material. CB is derived from the oil refining process polluting the environment. Replacing CB by a little among of modified clays mixed with a complementary volume of some carbonous materials (CM) turns it into a new environmentally friendly nanocomposite. CB substitution in this industrial process must contribute to diminish the oil dependence and the environment pollution. This paper shows the application results of organophilic clay (OC) blended with CM substituting CB as rubber fillers. OC is the organic modification of smectite clay by ammonium quaternary (AQ). CM are very little sized particulate minerals obtaining as byproducts of the mining process with today poor economical applications because it's very little grain size. In the blend CM act as a supplement to volume and as reinforcers too.

Industrial rubber products commonly use, at least 40% of CB filler. Products tested in this work use 10% OC + 30% CM as maximum filler. Weights in % referring to the NR total mass.

Materials. Bentonites. An absorbent aluminum phyllosilicate generally impure clay consisting mostly of montmorillonite, $(Na,Ca)_{0,33}(Al,Mg)_2Si_4O_{10}(OH)_2(H_2O)_n$ Two types exist: swelling bentonite, or Na-bentonite and non-swelling bentonite or Ca-bentonite. Originated from weathering of volcanic ash often in presence of water. [1]. Some Ca-bentonites from the Paraiba State, Brazil were selected to modify them with sodium carbonate transforming the same ones into Na-bentonites that swell in water. These synthesized Na-bentonite were modified using AQ to produce hydrophobic OC. OC reacts with the polymer materials collaborating in its structure during the mass preparation and in the vulcanization, transferring to the end product technological properties the same or better than the traditionally CB filler.[2]

CM are finest grain of coal shale (black dust) with high-C level or of limestone (nearly white) with CO_3^{-2} from the mining excavation activities.

NR: Product obtained from the Hevea Brasiliensis tree.

Additives: Traditionally used substances for rubber vulcanization as sulphur (S), Zinc Oxide; Stearic Acid and the rubber accelerators: TMTD; MBTS; MBT.

AQ: Alkyl – Trimethyl - Ammonium chloride.

Methods. OC production: The clay fraction below 325 meshes characterized by X-ray diffraction, Foster swelling test, Scanning electronic microscope, Thermal Analyses, and others were modified by Na and AQ to OC trough a new "dry" process described by Silva (2006) [2]. It is a small water addition to the clay followed by homogenization, cure, addition of AQ, cure, homogenization, drying, milling and classification by a 200# sieve. Depending use / type of the end product, the CM is selected and blended with the OC.

Plates vulcanization, conformation and characterization of the test samples. OC+CM added to mass by a mixer. Plates were produced according the Esper Ltd. process and standard ASTM D 3182 for the carpet for cars and synthetic floors production.

For characterizations the reinforcement fillers were 0%, and 40% of CB; and 10% OC + 30%CM. After 2 min of lamination of sulfur with the rubber blanket, verified homogeneous visual aspect, being, directed for the plate vulcanization effected in steel form under action of Thermo-Hydraulic Press Marconi Mark Model MA098 warm to 160°C ± 5°C.

Universal test machine model EMIC DL3000 was used for **evaluation of the mechanical properties** of rupture lengthening and rupture tension according ASTM D412 standard [3]. Hardness was evaluated for each plate according to the ASTM D2240 standard [4].

Results.

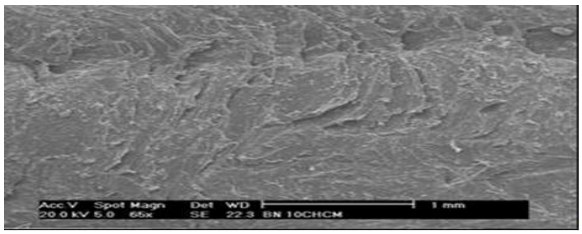

Fig. 1 Micrograph of a nanocomposite vulcanized plate

Table 1 – Results of the Mechanical assays

Sample	Rupture tension (MPa)	Rupture lengthening (%)	Shore A
NR	03,2	700,0	43
NR + 40% CB	11,2	315,0	52
NR+10%OC+30%CM	29,5	757,0	58

Conclusions: 1. The OC-CM/NR nanocomposites show normal aspect at the micrograph. 2. The OC-CM/NR nanocomposites mechanical results show greater values than the composite with CB as filler.

Hierarchical Structure and Its Formation Process in Liquid Crystalline Block Copolymers

Tomoo Shiomi, Hiroki Takeshita, Shunsuke Adachi, Shin-ichi Taniguchi, Katsuhiko Takenaka

Department of Materials Science and Technology, Nagaoka University of Technology

shiomi@vos.nagaokaut.ac.jp

1. Introduction

Block copolymers containing a side-group liquid crystalline (LC) block have a potential to exhibit hierarchical phase structure, which consists of several ten nanometers of microphase separation (MS) structure and a few nanometers of liquid crystalline (LC) structure. Such hierarchical structure may be formed in the interplay between microphase separation and liquid crystallization. Therefore, main interests are as follows: (1)[1,2] in liquid crystallization from microphase separated melts, whether the microphase separation structure is disrupted or kept, or how is the formation process, (2) how is the liquid crystalline structure within the microdomain, and (3) how is the orientation of the mesogen axis to the interface of the microdomain. In this paper, we will present the formation process as well as the hierarchical structure in liquid crystalline -amorphous block copolymers.

2. Experimental

Block copolymers composed of a cyanobiphenyl-type liquid crystalline block (PCB) and poly(*n*-butyl acrylate) (PBA), shown in Fig. 1, were prepared by atom transfer radical polymerization (ATRP). The length of spacer between the main chain and mesogenic group was controlled by the number *x* of methylene groups to be *x*=6, 8, 11. The characteristics of the samples employed are listed in Table 1. Phase structure and its formation process were observed using time-resolved small-angle X-ray scattering (SAXS) techniques employing synchrotron radiation at beam lines BL-10C and BL-15A for 1D and 2D experiments, respectively, at the Photon Factory in the High Energy Accelerator Research Organization in Tsukuba, Japan. The orientation of mesogenic groups was observed by 2D-SAXS together with polarized optical microscopy (POM), and LC-isotropic transition temperatures were determined by DSC.

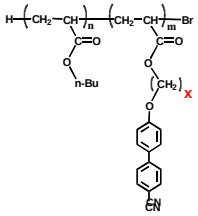

Fig. 1. Block copolymer

3. Results and Discussion

The liquid crystalline structure of the PCB homopolymer was bilayer smectic (Sm) for *x*=8 and 11 and nematic (Nm) for *x*=6.

For block copolymers, the MS structure and LC structure were characterized as shown in Table 1: Sm in the lamellar domain except for *x*=6 whose structure was Nm even for the homopolymer, while Nm in the cylindrical domain. Fig. 2a and 2b show SAXS profiles of the isotropic and liquid crystalline states and the temperature dependence of the peak position q_m of the 1st-order peak of the SAXS curve due to the MS structure, respectively, in the liquid crystallization from lamellar MS structure. The liquid crystallization process from cylindrical MS structure is shown in Fig. 3a and 3b. As shown in BA08OCB and BA11OCB44 of Fig. 2b, the peak position shifted discretely in the Sm formation. This suggests that the MS structure is reorganized by the liquid crystallization. Also, the coexistence of Sm and Nm is observed in the transition region, which means that Sm structure is formed via Nm formation. On the other hand, as seen in BA06OCB_35 of Fig. 2a and BA11OCB_20 of Fig. 3b, the peak position of MS structure is not discretely changed in the Nm formation.

The orientation of mesogenic groups was parallel to the interface of microdomain, regardless of LC structure and MS structure.

Fig. 2. In the liquid crystallization from lamellar structure, (a) SAXS profiles and (b) change of the 1-st order peak

email: chamciuc@icmpp.ro

Introduction

Polyimide/silica nanocomposites were extensively studied as materials with improved thermal, mechanical and electrical properties [1-2]. The compatibility between polyimides and silica generated in the sol-gel process is limited because of weak interactions between the pure organic and inorganic phases. A way to improve the compatibility between polyimide and silica is by functionalizing the polymer chains at their ends, including comonomers that contain appropriate functional groups or adding a coupling agent to bond the polyimide chains and inorganic oxide network. Introduction of polydimethylsiloxane segments into polyimide may prevent the phase separation of hybrid composites and the formation of high-molecular weight silicate. The siloxane segment interacts with silica because of the similarity of its structure with the sol-gel glass matrix of the silica precursor, indicating that polyimide-polydimethylsiloxane/silica might be a good material for organic/inorganic hybrid composites [3].

Materials and Methods

(3,4-Dicarboxyphenoxy)phenyl]phthalide dianhydride (DAFT) and α,ω-bis(3-aminopropyl)oligodimethyl-siloxane (PDMS) were prepared according to [4, 5]. Two series of polyimide nanocomposites thin films containing 10%, 20% and 30% silica were prepared starting from a poly(amic acid) and tetraethoxysilane via sol-gel technique and thermal cyclodehydration. The first series was obtained using a poly(amic acid) resulting from polycondensation reaction of 1,3-bis(4-aminophenoxy)-benzene (DAB) with DAFT, (molecular ratio: 10/11) in NMP as solvent. For the second series the poly(amic acid) was synthesized from 4,4′-oxydiphthalic anhydride and a mixture of DAB and PDMS in NMP/THF as solvent. 3-Aminopropy-ltriethoxysilane (APTES) was used as coupling agent.

Results and Discussion

The structure of the nanocomposites was confirmed by FTIR spectroscopy. The films, having the thickness in the range of tens of micrometers, were flexible and showed good thermal and mechanical properties. Effects of inorganic particles on primary and secondary relaxations and on the overall dielectric behavior were also studied. The surface morphology and the roughness were investigated by atomic force microscopy (AFM) and scanning electron microscopy. The AFM images of films having siloxane segments showed high light points related to the microphase-separated areas in the polymer. All samples exhibited good thermal stability having the initial decomposition temperature above 400°C. They showed high glass transition temperature in the range of 240-248°C for the first series of hybrid films, and 216-223°C for the second series of samples containing siloxane segments in the polymer matrix. The dielectric spectroscopy of the samples containing siloxane segments revealed a primary α_1 relaxation due to the siloxane segments, and three subglass transitions: γ, β_1 and β_2. At higher temperature an α_2-relaxation that corresponds to the upper glass transition and a conductivity process appeared. The dynamic mechanical analysis showed relaxation processes similar to those observed by means of dielectric spectroscopy (Figure 1).

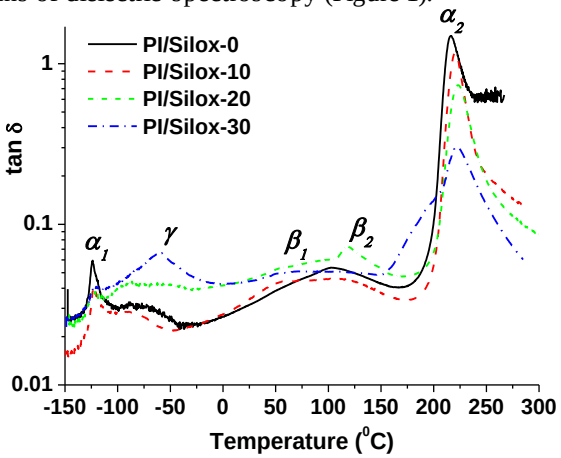

Figure 1. Temperature dependence of *tan δ* for samples having siloxane segments in the polymer matrix

Conclusions

Nanocomposite thin films containing different amount of silica were prepared by sol-gel technique, using a polyimide or a polyimide-polydimethylsiloxane as polymer matrix. APTES was used in order to obtain chemical bonding between silica and polymer matrix, and thus a better compatibility of the organic and inorganic phases. The influence of silica content on hybrid film properties was evidenced by dynamic mechanical analysis and dielectric spectroscopy.

Introduction

The main feature of polymeric nanocomposites, in contrast to conventional composites, is their immense reinforcement effect. The carbon nanotubes as reinforcing nanofibers affect the structure and consequently the properties of the polymer matrix. Dynamic Mechanical Thermal Analysis (DMTA) and Positron Annihilation Lifetime Spectroscopy (PALS) as methods for studying the polymer structure are adequate tools and complementary approaches for investigating the nanocompositions in a nanostructural level.

DMTA is most useful for studying the viscoelastic behavior of polymers, locating their glass transition temperature as well as identifying secondary transitions corresponding to other macromolecular motions, which can be attributed to the temperature-dependent activation of a wide variety of chain movements. Moreover, PALS is one of the most sensitive and non-destructive methods for investigation of the free volume in materials.

The aim of this work is to establish the structural changes in isotactic plypropylene (iPP) caused by addition of different quantities of carbon nanotubes in the presence or absence of maleic anhydride as compatibilizer.

Materials and methods

The materials investigated were the virgin iPP (density = 901 kg/m^3) and iPP nanocomposites containing multiwalled carbon nanotubes, MWCNTs, (diameter 10-15 nm, length 1-10 μm) as filler. Initially it was in the form of a masterbatch based on iPP and 20 wt.% of MWCNTs. This masterbatch was mixed with virgin iPP at 200°C, preparing compositions of different filler content. (0.05; 0.1; 0.5; 1, wt.% MWCNTs) The technology of sample preparation consists of extrusion, followed by calendering at 230°C. Therefore, the sheet about 1.5 mm thick was the experimental material including a control sheet of virgin iPP. A sample series with addition of maleic anhydride as compatibilizer was also measured.

DMTA measurements were carried out with a Polymer Laboratories MK II apparatus working in the tensile mode. The complex modulus and tan δ of the sample were determined at 1Hz over a temperature range from –150 to 150 ºC. The heating rate was 1.5 ºC min^{-1}.

The used PALS spectrometer was a standard fast-fast coincidence system. The source was $^{22}Na_2CO_3$ with activity of 30 μCi, between two 7.5 μm-thick Kapton foils. The analysis of the PALS spectra were performed by LT v.9.

Results and discussion

The composites with low contents of nanofiller (0.05 % and 0.1 %) show a shift of the alpha relaxation of iPP to lower temperatures and higher intensities. Further increases of filler concentration (0.5 % and 1 %) decrease the intensity of this relaxation and increase its temperature location. The values of storage modulus E' for all samples investigated almost coincide for temperatures higher than Tg (β relaxation). At lower temperatures also coincide E' values for pure PP and for composites with 1% filler. However, the composite with filler concentration 0.1% shows the highest values for E' (Figure 1).

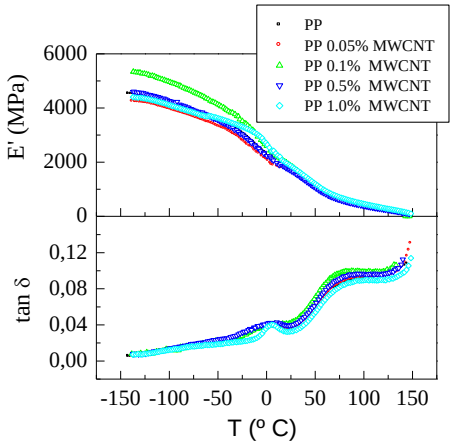

Figure 1. Storage modulus (E') and loss tangent (tan δ) as a function of temperature for virgin iPP and different iPP/carbon nanotubes composites.

Microhardness studies confirm the particular behavior of the sample with 0.1% of nanotubes, content near to the beginning of the strengthening mechanism [1].

Loss tangent exhibits a widened beta relaxation for compositions containing higher than 0.1% nanotubes. This could be interpreted in two ways:

a) Increasing nanotubes content leads to a rise of agglomeration and then the distribution of relaxation times is considerably broadened.

b) Nanotubes grouping leads to nanovacancies arising which could be reflected in easier motions of the PP macromolecular segments. As a consequence, the intensity of the low-temperature gamma relaxation, occurring at around -80 ºC, increases.

On the other hand, the addition of maleic anhydride (MAN) does not have a significant influence on DMTA results and does not influence the free volume holes (FVH) dimensions obtained from PALS measurements. Moreover, for these compatibilized samples the o-Ps intensity rapidly decreases, which could be due to the increase of the crystallinity degree or to the possibility that MAN acts as an inhibitor of Ps formation.

New nanocomposites based on unsaturated polyester resin and modified halloysite

A. Ghebaur[1], *S.A. Gârea*[1], *H. Iovu*[1]

[1]Polytechnic University of Bucharest, Faculty of Applied Chemistry and Materials Science, Department of Polymer Science and Engineering, 149 Calea Victoriei, 010072, Bucharest

ghebauradi@yahoo.com

Introduction

Halloysite in the natural state exhibits a high hydrophilic behavior and therefore shows a low compatibility with polymer matrix like epoxy resin, unsaturated polyester resin (UPR). The compatibilization step of inorganic compound with organic matrix was done by a cationic exchange process between silicate and protonated organic agents. This compatibilization method is not suitable for halloysite due to its low CEC value [1-3].

The goal of this study was to synthesize new hybrid materials based on UPR and modified halloysite with two different coupling agents which contain amine and vinyl functional groups.The hybrid materials were analyzed using different methods like FTIR, XPS, XRD, DMA, DSC and TGA.

Materials and Methods

Unsaturated polyester resin (UPR) was supplied by Vianova under the trade name VIAPAL UP 52 YE and used as received. Benzoyl peroxide (BP) was used as crosslinking agent (5 wt. % against UPR). Halloysite (HNT) was provided by Sigma–Aldrich and used without further purification. The HNT exhibit a diameter of 30 nm and a length between 0.25 - 4 μm. The specific surface area is 65 m^2/g and specific gravity 2.53 g/cm^3, the CEC being 8.0 meq/100g..

The silanization (coupling) agents, Triethoxyvinylsilane (TEVS) and Aminopropyltriethoxysilane (APTES) were received from Sigma-Aldrich. X-Ray Diffraction (XRD) analysis was performed on a XRD 6000 SHIMADZU diffractometer.

The DMA tests were run on a TRITEC 2000 equipment using 5°C/min heating rate at three different frequencies (0.316, 1 and 3.16 Hz) in the temperature range 25-240°C.

Results and Discussion

In case of modified HNT with coupling agents, the XRD results showed that the peak corresponding to the basal distance exhibits the same position as for unmodified HNT, indicating that the reactions of HNT with coupling agents occurred on the external surface. The results of dynamic mechanical analyses showed that the glass transition temperature value of hybrids was influenced by the halloysite's modifier agents.

Conclusions

The properties of the final hybrids based on modified HNT are influenced by the concentration and type of modifier. Thus Vinyl-HNT will lead to a higher T_g value and also a higher thermostability especially at lower concentration used which is caused by the direct involving of the vinylic groups from the HNT surface into the crosslinking process with UPR carbon-carbon double bonds. Amine-HNT lead to a low compatibility to the UPR matrix, the T_g value and thermostability of

the final composites decrease, the modified HNT act more like a plasticizer.

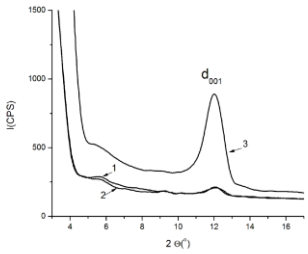

Figure 1. XRD spectra of 1-Vinyl-NHT, 2-Amine-HNT, 3-unmodified-HNT

Table 1. The T_g value of different HNT-based hybrid materials

System	T_g (°C)
UPR	116
UPR/Vinyl-HNT (1 wt. %)	120
UPR/Vinyl-HNT (2 wt. %)	118
UPR/Vinyl-HNT (5 wt. %)	112
UPR/Amine-HNT (1 wt. %)	107
UPR/Amine-HNT (2 wt. %)	101
UPR/Amine-HNT (5 wt. %)	103
UPR/Unmodified-HNT (1 wt. %)	116
UPR/Unmodified-HNT (2 wt. %)	117
UPR/Unmodified-HNT (5 wt. %)	117

Influence of Silane Treatment on the Filler-Coupling Agent Interactions

Adriana Lungu, Nicoleta M. Florea, Cristian Parvu, Eugeniu Vasile, Horia Iovu

University Politehnica of Bucharest, Romania

adriana_lungu2006@yahoo.com

Introduction:

Dental resins composites are composed of a polymeric matrix and a silane treated reinforcing inorganic filler. The filler usually consists of glass, quartz, or ceramic particles of different compositions and size distribution. Adhesion between the polymeric matrix and the inorganic particles is accomplished using a silane coupling agent. In the literature, two main silanization mechanisms for silica nanoparticles are described: direct condensation path and hydrolyzation and condensation path. According to the first mechanism, silane would chemically bond to the surface of filler particles via direct condensation of the $–OCH_3$ groups of the silane with the surface –OH groups of the filler, in an anhydrous environment. For the second mechanism, the presence of water is required in order to hydrolyze $–OCH_3$ groups from silane to silanol groups, and the silanol groups condense with surface –OH groups on the inorganic particles to form a covalent bond [1-3].

Materials and Methods:

The purpose of the present study was to compare the efficiency of the chemical grafting of fumed nanosilica with the same organosilane (methacryloxypropyl-trimethoxysilane (MPS)) using each mechanism already mentioned. The interaction of the MPS with silica particles was extensively studied but the best method or mechanism of silanization does not emerge from the literature.

Hydrophilic fumed silica having an average particle diameter of 7 nm and a specific area about 400 m^2/g was purchased from Aldrich. The advantage of fumed silica is that many chemical and spectroscopic analyses can be carried out because of the high specific area. Prior to silanization, silica particles were dried for 24 h at 150^{0}C in an oven and were used immediately.

Different solvents were tested, but anhydrous toluen and acetone were finally selected to perform the comparative grafting reaction of MPS on nanosilica. Fumed silica was silanated with 5% MPS either in toluene and acetone and triethylamine (TEA) was used as catalyst for both reactions. After sylanization, MPS physically adsorbed was removed by washing and UV-VIS spectroscopy confirms the gradually MPS removal. Particles sylanization was proved using FTIR, TGA and XPS. ^{29}Si-NMR and TEM were also performed.

Results and discussion:

FTIR spectra show the expected characteristic bands of the grafted silane (C–H stretching bands in the 2900 cm^{-1} region and free C=O stretching band at 1720 cm^{-1}). The peak at 1700 cm^{-1} attributed to C=O group hydrogen bonds with silanol groups is almost completely overlapped by the strong peak at 1720 cm^{-1}. The native silica exhibits the Si-OH and O-H stretching at 3400 and 1630 cm^{-1} and the Si-O-Si network vibration at 1090 cm^{-1}.

TGA curves prove that the weight loss at 800^{0}C is 23% for silica sylanized in acetone, and only 12% for silica sylanized in toluene. Both results are significantly greater than native fumed silica which exhibits 3% weight loss.

XPS wide-scan spectrum revealed that, after the sylanization occurred, C1s peak was detected, assigned to MPS covalently linked to silica surface. According to the XPS data, the carbon atomic percent is almost double for the silica sylanized in acetone than in toluene.

Fig. 1 shows the TEM images of silica nanoparticles whose surface had been coated with organosilane using the two methods. Native fumed silica exhibits a three-dimensional nano-scale chain-like aggregated structure, while sylanated silica is covered by a thin film.

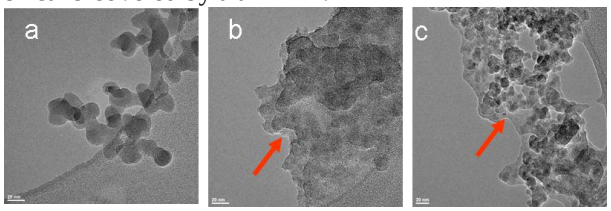

Fig. 1. TEM micrographs of native silica particles (a); silica sylanated in acetone (b) and in toluene (c)

AFM was carried out for further characterization of the silica nanoparticles. The AFM analysis reveal a slightly increase of the roughness for silica modified in toluene.

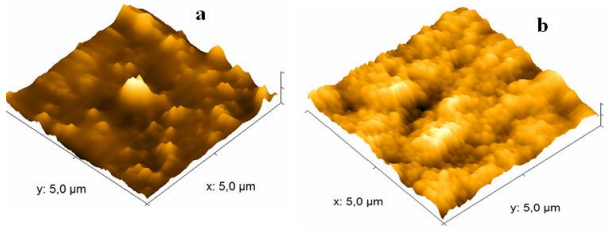

Fig. 2 AFM surface plot of unmodified (a) and modified silica particles in toluene (b)

Conclusions:

The chemical grafting of silanes at the surface of fumed silica is one of the main steps of the dental composites synthesis. The main aim of our future work is to obtain dental composite materials with improved properties.

e-mail: dominique.scalarone@unito.it; massimo.lazzari@usc.es

In recent years great efforts have been directed toward the synthesis of metal and metal oxide nanoparticles and their assemblies within block copolymer templates.[1,2]
In particular, polar compounds, such as metal oxide precursors, exhibit preferential interactions with hydrophilic blocks that, as a consequence, are able to guide metal oxides to a variety of structures according to the morphologies and dimensions accessible by block copolymers.
Among the variety of metal oxides, TiO_2 has been receiving much attention because of its non-toxicity, chemical stability, low cost, high refractive index and especially because of its photoactivity.
The research described in this contribution focuses on the preparation of mixed micellar solutions obtained by adding proper amounts of a polar solution of TiO_2 nanoparticles to benzene solutions of polystyrene-*block*-poly(ethylene oxide) (PS-*b*-PEO) copolymers. TiO_2 nanoparticles were synthesized by sol-gel reaction of titanium tetraisopropoxide (TTIP) in 2-propanol under acidic conditions (HCl, 37%).
The existence of specific interactions between TiO_2 nanoparticles and PEO guides the nanoparticle distribution within micellar solutions according to the block copolymer self-assembling. While benzene is a good solvent for both PS and PEO, HCl_{aq} and 2-propanol are non-solvent for the hydrophobic PS block. As a consequence PS-*b*-PEO molecules in solution self-assemble in direct or inverse micelles depending on the solvent/co-solvent ratio.
The inorganic content was varied in a wide range of compositions, focusing on micellar systems with PS cores and PEO/TiO_2 coronas, that in a further step were used as scaffolds in order to fabricate nanostructured titania films.
Micelle morphologies were mostly studied by Atomic Force Microscopy after spin coating of the micellar solutions. The spin coating conditions used, the composition and the low concentration of the solutions ensure fast evaporation of solvents and the freezing of micelles in the solid state.
Apart from fully spherical micellar structures (Figure 1a) also mixed morphologies (Figure 1b), mainly spheres with diameter of about 35 nm, but also some cylindrical micelles 200 nm long, were obtained.
In particular, micelle shape was tuned by adding small amounts of homopolymer of the same nature of the core forming block (PS), which surprisingly forced the sphere-to-cylinder transition (Figure 1c). This finding is especially remarkable because the formation of such micelles occurs for a limited range of compositions.[3,4]

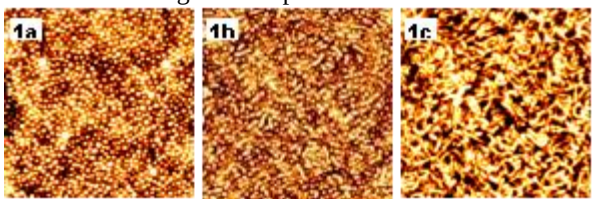

Figure 1. AFM images (2X2 mm) of different PS-*b*-PEO/ TTIP micellar morphologies

In a following step of the research thin PS-*b*-PEO/TiO_2 hybrid films with different morphologies were prepared by spin-coating micellar solutions and were transformed into the corresponding nanostructured titania, either in the form of nanoporous thin films or challenging worm-like shapes. The degradation of the polymer template in form of dried micelles and the simultaneous crystallization of TiO_2 was achieved by thermal treatments without collapsing the nanostructures.[5]

Microstructure analysis of the layers containing nanoparticles hybrids $ZnO-SiO_2$, TiO_2-SiO_2 on textile fabrics

SÓJKA-LEDAKOWICZ Jadwiga[1], WALAWSKA Anetta[1], OLCZYK Joanna[1], JESIONOWSKI Teofil[2]

[1]Textile Research Institute, 5/15 Brzezinska Str., Lodz, Poland
[2]Institute of Chemical Technology and Engineering, Poznan University of Technology, M. Sklodowskiej-Curie 2 Str., Poznan, Poland,

e-mail: ledakowicz@iw.lodz.pl

Keywords: *textile composites, nanoparticle hybrids, microstructure analysis, coating*

Introduction

The development of materials in the nano scale is a base of the production of many modern composite products. This kind of products based on textiles can be widely applied thanks to new properties imparted to them. Very interesting modifiers are micronized particles of metals, such as: zinc oxide (ZnO), titanium dioxide (TiO_2) [1]. Metal oxides have not got the chemical affinity for fibres. They can be incorporated into the textiles in the form of coatings containing appropriate binding agents based on organic compounds. The oxide composites TiO_2-SiO_2 and $ZnO-SiO_2$, characterised by high thermal stability and excellent mechanical strength, have been recently more and more used [2]. The addition of silica can improve the dispersion of metal oxide particles in composite as well as increase their adhesion, reduce tendency to agglomeration and also contribute to the increase of surface activity of a final product. The research works have focused on developing a methodology of obtaining nanostructured textile composites with barrier properties against UV radiation and microorganisms with the use of nanoparticles hybrids TiO_2-SiO_2 and $ZnO-SiO_2$. The aim of studies was the microstructure analysis of layers obtained on textile carriers as a result of modification with metal oxides. The impact of low temperature plasma pre-treatment of textiles on the chemical bonding of nanostructured layers with fibres was analysed.

Materials and Methods

Polyester non-woven obtained with aqua-jet technology and cotton and polyester fabrics were modified. The modifiers incorporated into the structure of textile products were: oxide composites TiO_2-SiO_2 and $ZnO-SiO_2$. In order to characterize their adsorption-desorption properties, the adsorption-desorption izoterms of nitrogen were determined as well as the specific surface area with BET method using AUTOSORB-1 apparatus was found. Morphology and microstructure of micronized particles of oxide hybrids were tested with TEM method (JOEL 1200 EX II microscope) while the assessment of modified surface microstructure of textiles was done using SEM method (SEM Zeiss VO40 microscope). The plasma pre-treatment of textile materials was carried out in TETRA 30 reactor (Diener Electronic) in the RF (frequency of 13.56 MHz) and AF (40kHz) discharge. Plasma was generated in the environment of Ar and CO_2. The preparations of metal oxides nanoparticles were incorporated into the textile structure by coating with pastes based on acrylic resins, characterized by homogeneous dispersion and suitable viscosity. Obtained textile composites were evaluated in the scope of protective properties against UV radiation and antibacterial effect for selected colonies of bacteria and fungi.

Results and Discussion

The analysis of the microstructure morphology and particle size distribution showed that the particles of TiO_2-SiO_2 and $ZnO-SiO_2$ hybrids have a nanometric size and are characterized by the shape resembling the spherical one. These preparations have a well developed specific surface area (especially $ZnO-SiO_2$) and are characterized by high homogeneity (especially TiO_2-SiO_2). Analysis of SEM microscopic images of modified textile products showed the presence of thin, often discontinuous coatings containing micronized particles of metal oxides on their surfaces.

Application of low temperature plasma pre-treatment of textile materials contributes significantly to the increased incorporation of coating pastes, especially it increases the amount of attached nanoparticles of hybrids (TiO_2-SiO_2 and $ZnO-SiO_2$) to textile surface.

SEM images of polyester fabric: a) unmodified b) modified with TiO_2-SiO_2

a)  b) 
Conclusion

Introduction of coatings containing TiO_2 nanoparticles-SiO_2 hybrids or $ZnO-SiO_2$ to textile surface is an effective way to obtain added value textile materials. Obtained nanostructural textile composites exhibit good barrier properties against UV radiation (UPF> 40) and the inhibition effect for selected bacteria and fungi colonies.

Abstract

The influence of starting carbon materials on the synthesis of carbon nanotubes (CNTs) is investigated. Comparisons are made between graphite rods and polycyclic aromatic hydrocarbons (PARs) as carbon sources in helium arc discharge. The major parameters are also evaluated in order to obtain high-yield and high-quality carbon nanotubes. The cathode deposits are examined using scanning electron microscopy (SEM) and scanning probe microscopy (SPM) in AFM mode to determine the microstructure and nanostructure of carbon nanotubes.

The SEM investigation of the carbon nanotube deposits formed on the cathode provides evidence that PARs can serve as building blocks for nanotube formation. The high-temperature graphitization process induced by the arc plasma enables the hydrocarbons to act as carbon sources and changes the aromatic species into the layered graphite structure of CNT. These polycyclic aromatic hydrocarbons not only act as the precursors but also enhance the production rate of carbon nanotubes. The PAR precursors thus play an important role in the mass production of carbon nanotubes.

2 Department of Chemical & Biological Engineering, Koç University, Turkey

alexandros.lamprou@chem.ethz.ch

Introduction: The synthesis of macroporous crosslinked polymeric resins has been extensively investigated for half a century, with numerous target applications, from solid-phase synthesis and ionexchange to chromatographic columns, pollutant adsorbents and catalysts. Irrespective of how sophisticated the procedure is, a pore-forming agent is typically applied, be it a template or a traditional porogen. Herewith we put forth a novel, porogen-free approach towards rigid macroporous microclusters combining the colloidal concepts of Controlled Aggregation and Breakage with the emerging "Reactive Gelation"[1] technique.

Materials and Methods: In our work, primary latex Poly(Styrene-co-Divinylbenzene) nanoparticles were produced by a 3-step core-shell semi-batch miniemulsion polymerization. Following swelling of the primary particles with monomer mixture containing radical initiator, salt was introduced under defined rates of addition and mixing. Aggregation was induced due to latex destabilization, while the resulting aggregates were simultaneously broken due to shear. After reaching equilibrium between aggregation and breakage the temperature was increased, inducing polymerization inside the monomer-swollen, interpenetrated particles, thus anchoring the structure of the formed aggregates. The resulting microclusters were thoroughly characterized by SEM, Dynamic Light Scattering, Nitrogen sorption and Mercury Intrusion Porosimetry.

Results and Discussion: These microparticles were found to be irregularly shaped, yet monodisperse in size and mechanically rigid, with compact internal structure, relatively small specific surface area, high internal porosity, with very large macropores and negligible amount of micropores.

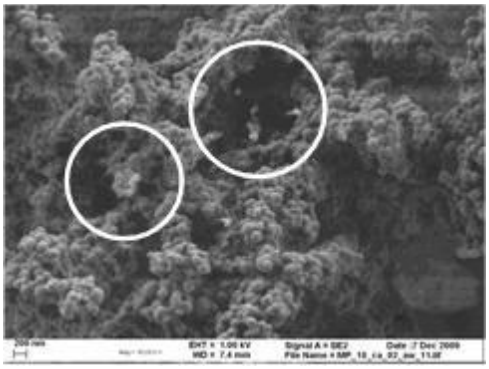

Figure 1: SEM image of aggregate produced.

The effects of initial latex properties and operating parameters on the final microclusters were investigated. Namely, the primary particle size, crosslinking density along the outer particle shell and shear rate during salt addition were varied. We concluded that it is qualitatively possible to control the final cluster size and pore size distribution, while the internal structure remains essentially unaffected. For the sake of comparison a monolith was also produced under static aggregation for one group of experimental conditions.

Conclusions: Alongside the fundamental conclusions, by introducing proper functionalizations, a vast range of applications may be addressed.

Crystallization Kinetics of Polypropylene Nanocomposites

Helton P. Nogueira[1], Evandro M. Alexandrino[2] and Maria I. Felisberti[3]

Chemistry Institute, University of Campinas (UNICAMP), P.O. Box 6121, Zip Code 13083-970, Campinas - SP, Brazil –

[1] helton.nogueira@iqm.unicamp.br;[2]evaalexandrino@iqm.unicamp.br; [3] misabel@iqm.unicamp.br

Introduction

The development of polymeric nanocomposites by the Toyota's Research group has opened a new dimension on materials science field, being the most different systems polymer/nanoparticles obtained.[1]

One of the most studied system is the polymer/nanoclay system. For instance, the use of montmorillonite as filler for polymer matrixes such as polypropylene, polyethylene, polyamide, and others, has resulted in nanocomposites with enhanced mechanical properties and improved characteristics such as gas permeability barrier, and thermal stability. [2]

The properties of semi-crystalline polymers depend on chemical structure, molecular weight, polydispersity and crystallization conditions. The crystallization conditions and the mechanisms involved in it directly influence the material properties. Therefore, controlling crystallization allows to control various characteristics of the material, such as crystallite size, degree of crystallinity, the molecular arrangement of the lamellae of the crystallites and interfacial interactions, *i.e.* the morphology of the semicrystalline material.[3] In this work the Hoffman-Lauritzen theory was used to describe the non-isothermal crystallization kinetics of polypropylene and its nanocomposites containing organophilic montmorillonite (OMMT). Differential Scanning Calorimetry analysis (DSC) provided the crystallization data for this purpose.

Materials and Methods

Polypropylene (PP) nanocomposites with OMMT were prepared by melt compounding in a twin screw compounder with or without poly(propylene-co-maleic anidryde) (PP-g-MA) as compatibilizer. Samples from the central region of the injection molded specimens (3 to 7 mg), were used in DSC experiments performed under non-isothermal conditions at constant cooling rate (β) from the molten state. Experiments were carried out at different cooling rates 2, 4, 6 and 8 °C min^{-1} allowing the construction of conversion or crystallization degree (α) curves as a function of temperature (T).

In order to determine the activation energy (Ea) for different crystallization degree of PP and its nanocomposites Ozawa-Flynn-Wall Isoconversional Method[4] (OFW) was applied (equation 1). Hoffmann-Lauritzen's parameters a constant U^* and the growing rate K_g, were determined from Ea x T curves using the method proposed by Vyazovkin's[5], (equation 2).

$$ln\beta = -1{,}0516\,\frac{E_\alpha}{RT} + constant \qquad \text{Equation 1}$$

$$E = U^*\frac{T^2}{(T-T_\infty)^2} + K_g R\frac{T_m^2 - T^2 - T_m T}{(T_m - T)^2 T} \qquad \text{Equation 2}$$

Results and Discussion

Ea curves as a function of the conversion degree (α) were obtained and the equations to describe the dependence of Ea on the conversion for each material were obtained by fitting these curves.

These activation energies were not constant in overall conversion range due to the complex crystallization process, which depends on a number of variables such as nucleation, growing rates and viscosity. These factors affect the polymeric chain mobility.

(E_a x T) curves were obtained from (α x T) and (E_a x α) curves. Hoffmann-Lauritzen's parameters (HF parameters were obtained from the non-linear regression method applied to (E_a x T) curves, according to Vyazovkin's method. Table 1 summarizes the HF parameters for polypropylene and its nanocomposites.

Table 1 – Hoffmann-Lauritzen's parameters

Cooling rate (8°C min^{-1})	U* (kJ mol^{-1})	K_g (K^2)
PP_{neat}	4.7±0.4	(3,31±0,03)x10^5
PP/OMMT (95/5) %wt	39.0±0.6	(5.70±0.04)x10^5
PP/PP-g-MA/OMMT (90/5/5) %wt	21.0±0.4	(4.00±0.03)x10^5
PP/PP-g-MA/OMMT (85/10/5) %wt	31.0±0.4	(5.00±0.03)x10^5

From table 1, it is observed that PP growing rate constant result was in agreement with the literature reports [6]. With the addition of OMMT, the Kg values were increased, showing that this filler influenced the PP crystallization kinetics.

Conclusion

Thermal analysis were successfully carried out to obtain the Hoffmann-Lauritzen parameters, which were mainly measured only by optical microscopy under isothermal crystallization conditions.

From the results it was possible to describe the crystallization kinetics of polypropylene nanocomposites in a non-isothermal condition, with a good precision.

Magnetite-Montmorillonite Hybrid Materials for Wastewater Treatment

Gema Marcelo, Iñigo Larraza, M. Mar López, Carmen Peinado, Teresa Corrales

Departamento de Fotoquímica. Instituto de Ciencia y Tecnología de Polímeros (CSIC), Juan de la Cierva 3, 28006 (Madrid)

gema.marcelo@ictp.csic.es

Introduction

During the last few decades, magnetite (Fe_3O_4) nanoparticles have attracted increasing attentions in the field of enviroment remediation due to the fact that magnetite can be easily separated and collected by an external magnetic field. However, one of its main limitations is the coaggregation of magnetite nanoparticles. Motmorillonite is a kind of natural 2:1 type layered clay mineral with high cation exchange capacity, swelling and high surface area. In nature MMT forms agglomerates, making delamination essential. In order to exfoliate it, it is necessary to swell it in water and make it react with a molecule that increases the interlayer space.

Montmorillonite has been shown to be a suitable support for the dispersion of magnetite nanoparticles and avoid the aggregation of the particles [1].

In the present study, Montmorillonite-supported modified magnetite nanoparticles with a polymeric shell were prepared. Positive charged hyperbranched polymers such as polyethyleneimine (PEI) was chosen for this work because PEI can change the magnetite nanoparticle surface and at the same time react with the clay platelets, exchanging with the metallic cations present between the layers. Among the different polymers used in order to modify magnetite particles and to exchange with the cations of Montmorillonite interlayer galleries we have chosen PEI because it has been established as a good adsorbent for removal of chromium from water. Therefore, Montmorillonite-PEI-magnetite hybrid material was further investigated for the removal of hexavalent chromium from aqueous solutions.

Materials and Methods

Magnetite nanoparticles were prepared as reported in bibliography [3] and characterized by TEM. They have a cubic shape and 40± 15 nm of diameter.

The characterization of the resulting hybrid material was performed through TEM, XRD, FTIR and gas diffusion through a polymeric membrane.

Chromium adsorption experiments were carried out in a Perkin Elmer spectrophotometer according to the determination procedure described in the literature [2].

Results and Discussion

Incorporation of magnetite particles in the Montmorillonite material yielded to a magnetic material easy to treat with a magnet. **Figure 1** shows two TEM images of the hybrid Montmorillonite-PEI-magnetite system. As it can be seen Montmorillonite sheets have been well exfoliated and magnetite particles are dispersed between Montmorillonite sheets.

Chromium adsorption experiments were performed at different pHs and Cr (VI) concentrations, the amount of Cr(VI) adsorbed per unit mass of the adsorbent, q and the removal efficiency of Cr (VI), *E* (%), for several pHs are shown in **Figure 2.** As can be observed removal of our material is close to 100% for a long range of pHs.

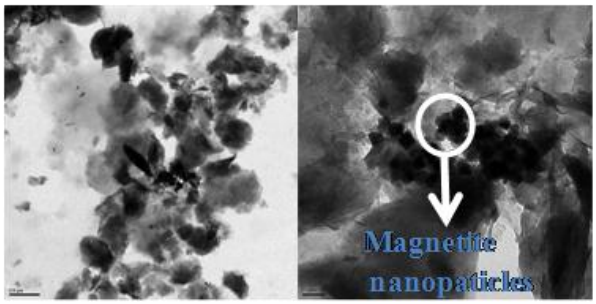

Figure 1. TEM images of montmorillonite-magnetite material.

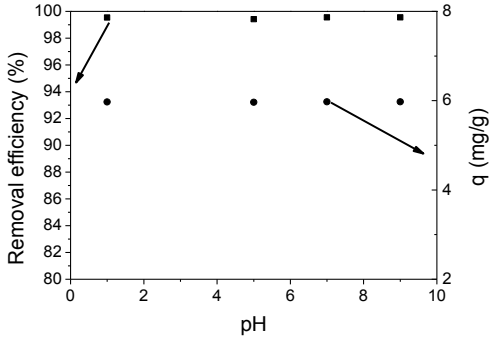

Figure 2. Removal efficiency and amount of Cr adsorbed per mass of the adsorbent.

Conclusions

The use of MMT as a support is useful to control the dispersion and the aggregation behaviour of magnetite nanoparticles. Also, compatibilization of magnetite nanoparticles with montmorillonite through PEI surface modification of magnetite nanoparticles provides a good exfoliation of montmorillonite sheets that increases the effective surface to interact with the magnetite nanoparticles.

Adsorption experiments seem not to be affected by pH and present high values of removal efficiency therefore showing promising applications for the removal of Cr(VI) from aqueous solutions.

claire.barres@insa-lyon.fr

Introduction

PVC plastisols are polymer particle suspensions in plasticizers. In such systems, PVC volume fraction, particle size and size distribution, plasticizer type and interactions among particles and between particles and plasticizers strongly influence the rheological properties of the plastisol. Plastisol processing involves the gelation of the material, which turns it into a homogeneous solid.

Polymer nanocomposites generally surpass conventional microcomposites, with same filler content, in terms of thermal and mechanical properties. Very few studies have been devoted so far to the dispersion of nanofillers in PVC plastisols. The present study is aimed at better understanding the effect of nanofillers on the final properties of gelled PVC plastisols, especially by characterizing the micro/nanostructure resulting from the nanofiller distribution among the PVC network.

Materials and Methods

Model PVC plastisols, i.e. simplified formulations, were prepared by mixing PVC resin in di-isononyl phthalate (DINP) so that to obtain polymer volume fractions ranging from 0.1 to 0.65.

Cation-exchanged montmorillonite with dimethyl benzyl hydrogenated tallow (MMT2MBHT), or untreated silica with a specific surface area of 200 m2/g were added to the plastisols, with variable volume fractions of inorganic material.

Measurements of viscoelastic and flow properties were carried out on controlled stress rotational rheometers (MCR300, Anton Paar; AR1000, TA Instruments) in cone-and-plate geometry. The gelation process was monitored using a parallel-plate geometry by multi-frequence analysis in the linear viscoelastic domain, while raising the temperature of the sample at 2°C/min from 45 to 120°C. Plots of tan δ (tan δ =G"/G') vs. temperature for different angular frequencies ω of the oscillations yield a single intersection point which, according to Winter [1],[2] or Aoki [3] defines the beginning of gelation. The temperature at which cross-over of all plots occurred was considered as the "pre-gel" temperature. It actually consists in a liquid-solid transition due to the formation of a percolated particles network, and must be distinguished from the complete gelation/fusion of PVC grains [4].

Complementary morphological characterization (by SEM and TEM), allowed to document the PVC and filler network(s) formation.

Results and Discussion

As displayed in figure 1, a clear yield stress appears upon nanofiller addition, which expresses the buildup of a physical network of particles. This network "rigidity" increases with filler fraction.

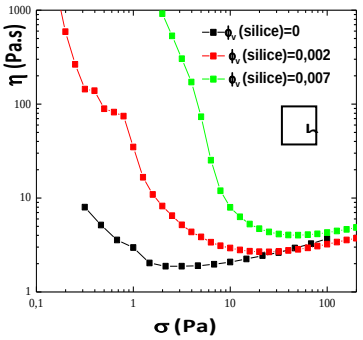

Fig. 1 : flow curves for the 65 vol% PVC plastisol with different volume fractions of silica.

The pre-gelation temperature of PVC suspensions is affected by volume fraction. The achievement of a good dispersion of the nanofiller and the buildup of a nanofiller percolated network significantly decreases the pre-gel temperature by comparison with PVC-only plastisols or with plastisols with lower nanofiller content (a drop of ~10-12°C can be observed).

Micrographs of gelated samples show specific features of the suspensions with percolated filler: the filler particles form a network which fills the "free" space left by the PVC particles after their percolation (example in fig.2). So, the pre-gel temperature reduction can the be interpreted as a consequence of the nanofiller promoting PVC particle-to-particle contact by a steric effect.

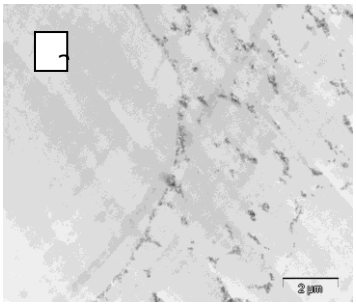

Fig. 2: TEM micrograph of a silica-filled, gelled plastisol.

Conclusions

Rheology and microstructural analysis are complementary in characterizing the structures of complex suspensions such as nanofilled PVC plastisols.

Different morphologies were obtained for the 2 types of nanofillers (organophilic MMT and silica), which reveals different dispersion and network formation mechanisms.

Introduction

Investigations of nonelectrostatic intermolecular interactions in polymers solutions are of considerable interest for understanding of interpolymer complexes formation mechanisms, including ones of biological origin [1]. Among objects emerging as a result of polymer-polymer interactions, are least studied hydrophilic associates [1], intermediate between noninteracting macromolecules and stable interpolymer complexes. Associates formed by the molecules of one definite polymer are even less studied. At the same time studying of such associates is interested for understanding of formation mechanisms of supramolecular structures, tertiary and quaternary structure of protein, etc. [1]. New approach to research of interactions between macromolecules of identical chemical nature, but essentially different on the molecular mass (MM) is proposed in present report. It is shown that intermolecular interactions influence even on parameters of such well studied systems as water solutions of polyacrylic acid (PAA).

Experimental

Behavior of water solutions containing PAA of two MM M_w=2000 (PAA_1) and M_w=750 000 (PAA_2) at various temperatures and total concentrations, as well as behavior of PAA in crosslinked form were investigated. Dependences of pH of solution from a parity of macromolecules concentration of two various M_w and total concentration, as well as dependences of swelling degree of crosslinked analogues on temperature at various neutralization degrees of crosslinked polyacid were registered.

Results

It is known that ionization ability of polyacids macromolecules decreases with increase in their molecular weight/3/. Really, direct pH measurements of PAA's water solutions, executed in the given work, have shown that transition from PAA with low molecular weight M_w=2000 to polyacid with M_w=750000 is accompanied by pH increase on 0,9÷1,1 units of pH-meter scale approximately. Examples of pH dependences of PAA's water solution of two various M_w from mixture composition x (x - ratio of [PAA1] mole concentration to total mole concentration [PAA1] + [PAA2]) for the various total concentrations of polyacids are presented on fig. 1 ($T=27^0C$). It is seen that noticeable deviation of the received dependences on additive straight line, which corresponds to a case of absence of intermolecular interactions takes place at rather high general total PAA concentrations.

pH dependences of the aqueous solutions of PAA of different MM and the swelling degrees of crosslinked PAA on the temperature were obtained also. These dependencies demonstrate opposite behavior of mentioned above systems. The measured pH value of solutions of PAA of high MM with increasing temperature is shifted to the alkaline region (decreasing of average concentration of hydrogen ions), and at the same time the swelling degree of crosslinked PAA increases (increase the degree of ionization polyacid.)

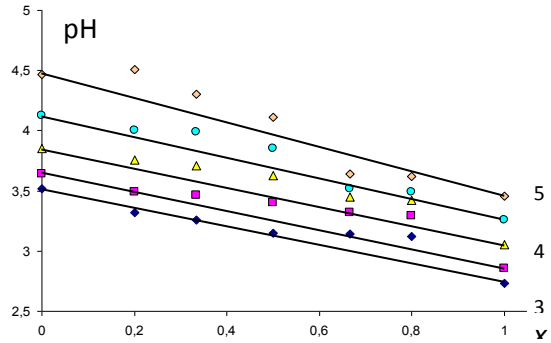

Fig.1. Dependences of pH of water solution of PAA_1 and PAA_2 mixture on composition of solution at different dilutions; curve 1: $c_{0\Sigma}$ = 0,05 mole/l, curves 2-5, $c = c_{0\Sigma}/2$, $c_{0\Sigma}/4$, $c_{0\Sigma}/8$, $c_{0\Sigma}/16$.

Discussion

The observed deviations from additivity are evidence of the existence of interactions both between individual molecules PAA and between their segments. The amplitude of these interactions increases with increasing of the local concentration of links in a certain region of the solution. These interactions, as shown in present report, make core of coils more compact, which leads to significant inhomogenity of solution. There are the areas filled relatively dense associates, and the regions corresponding to the periphery of the friable coils in the solution (a modified model "globule with a loose periphery" for a theoretical description of the observed phenomena was used).

Conclusions

Pronounceable interactions of non-electrostatic nature between both individual macromolecules and their segments take place in solutions of polycarbon acids proceed as expressed in the These interactions, particularly, lead to the anomalous behavior of acidity of polyacid solution, which shifts to higher pH values with increasing temperature, despite the fact that this factor increases the degree of ionization of carboxyl groups.

Polymeric Ionic Liquids: Homo- and Copolymers in Water

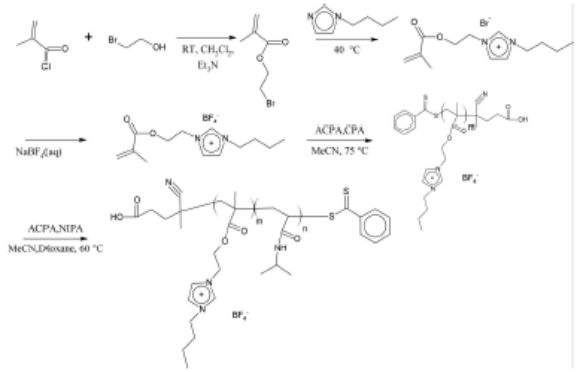
Erno Karjalainen & Heikki Tenhu

University of Helsinki, Finland

heikki.tenhu@helsinki.fi

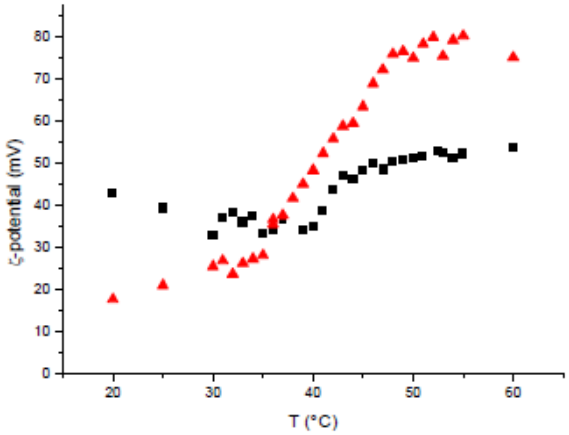
Introduction. A methacrylate substituted with an ionic liquid has been polymerised using RAFT. The obtained homopolymer has been further used as an macro chain transfer agent with which poly(N-isopropylacrylamide) (PNIPAM) blocks with varying lengths were constructed.

Scheme 1. Polymer synthesis



Results and discussion. The solubility of the polymeric ionic liquid (PIL) block depends on the counterion. In the case shown below, the PIL block is not soluble in water. However, both the homoPIL and the block copolymers may be transferred from an organic solvent into water. In aqueous surroundings all polymers form nanoscopic particles, micelles or aggregates. Block copolymers show thermal behaviour typical for micelles with an outer shell of thermoresponsive PNIPAM. The emperature dependence of the zeta potentials of the ationic polymers is most interesting. In the case of homopolymeric PIL the potential keeps more or less constant with temperature. On the other hand, the block copolymers show a considerable and discontinuous increase of the potential, the temperature range of which matches that of the collapse of the PNIPAM blocks. Because the change in the zeta potential probably results from the release of the counterions, the phenomenon has been further studied by fluorescence spectroscopy using a fluorescent probe 1,8-ANS. The detachment of the probe from the polymer with increasing temperature occurs differently in the case of homo and copolymers. A tentative way to rationalize the observations is that the BF4- counterions are more strongly bound to the homopolymer than to the thermosensitive block copolymer.

Figure 1. Zeta potential vs temperature for two block copolymers with varying PNIPAM block lengths.



Functional poly(vinylpyrrolidone)s for the controlled synthesis of Ag nanoparticles

A. Ledo-Suárez, I. Rielo-Rodríguez, M. A. López-Quintela, M. Lazzari

Department of Physical Chemistry, Faculty of Chemistry and Centre for Research in Biological Chemistry and Molecular Materials (CIQUS), University of Santiago de Compostela, 15782 Santiago de Compostela, Spain

M. G. Tardajos, H. Reinecke, A. Gallardo

Inst. de Ciencia y Tecnologia de Polimeros (CSIC), 28006 Madrid, Spain

e-mail: ana.ledo@usc.es

Synthesis of metal nanoparticles has been widely studied and many preparative methods have been developed in the last decades. Particularly, gold and silver nanoparticles have received a special attention because of their peculiar catalytic, electronic or optic properties.

One of the most frequently used protective agent for the synthesis of metal nanoparticles is poly(N-vinyl-2-pyrrolidone) (PVP), which has recently been demonstrated to act not only as protection against aggregation but also as reducing agent of the metal ions. Several synthesis of silver nanoparticles in presence of this polymer were carried out at low temperatures by means of a one-step process, without the presence of any reducing agent. Kinetics of the reaction, shape and size of nanoparticles could be tuned by changing PVP/metal salt ratio (R) or temperature. With high values of R, slow and well controlled reactions with formation of small and homogeneous nanoparticles take place, whereas lower values, or high temperatures, give the opposite situation, i.e. faster reactions, bigger dimensions and worse polydispersity [1].

In the framework of a comprehensive project aiming to investigate the effect of diverse functionalized polymers on the synthesis of noble metal nanoparticles in solution, herein we report preliminary results of a further investigation focused on the potential of functional PVP for the controlled synthesis of silver nanoparticles, namely poly(1-vinylpyrrolidin-2-one-3-carboxylate) (PVP-COONa), poly(3-(3-Sulfopropyl)-1-vinyl-2-pyrrolidone) (PVP-RSO3), and their random copolymers with PVP. The preparation of these polymers has been recently described [2,3].

Functional PVP-capped silver nanoparticles were produced in a controlled fashion in absence of any other reducing agent, working at rather low values of R (i.e. at low polymer concentration). PVPs containing lateral chains with -COONa or -SO_3Li groups, clearly provide a better stability to the colloids because of the interactions between the side chain groups, and nanoparticles. As a consequence, the rates of formation are slower and a better control of silver nanoparticle size and distribution may be obtained.

In particular, a better stabilization was observed in the case of PVP-SO3 due to the more effective electrostatic interactions with the nanoparticle precursors.

Study of Nanocomposites Processing containing Polyaniline and Carbon Nanotube as use with Radar Absorbing Structures.

Luiza de C. Folgueras and Mirabel C. Rezende

Departamento de Ciência e Tecnologia Aeroespacial / Instituto de Aeronáutica e Espaço / Divisão de Materiais

luiza@ita.br; mirabelmcr@iae.cta.br

Introduction: Due to the unique properties of the carbon nanotubes (CNTs), several new usage possibilities and applications have impelled the development of new materials. Among the attractive properties of the CNTs we may quote the good mechanical resistance and excellent heat conductors and are capable of transporting electricity [1]. The use of conducting polymers in the processing of radar absorbing materials is increasing due to the large chemical versatility of these polymers, especially polyaniline, which allows the control and the modeling of its physical-chemical properties [2]. The present work shows the processing of structural microwave absorbing materials. Polyaniline and carbon nanotubes formulations were used and a simulating the preparation of the structural material.

Materials and Methods: In the processing of absorbing nanocomposites, first, the substrates of glass fiber woven (20 cm x 20 cm) were individually impregnated with polyaniline formulations (PAni) (15% (w/w)), multiwalled carbon nanotubes (MWNT) (formulations with 0.1, 0.3, 0.5, 0.8, 1.0 and 1.2% (w/w), each one named of material 1 up to 6) in polyurethane matrix. The polyaniline was synthesized by using dodecylbenzene sulphonic acid, at chemical route; and the multiwalled carbon nanotubes were acquired from Bayer – Baytubes C 150 P. The impregnation of the PAni/NTC in the wovens was done using the conventional painting method. Aiming at forming the structural and radar absorbing composite, the impregnated wovens were piled up and then, the layers were positioned, beginning with the woven impregnated with the formulation 0,1% of NTC. For the electromagnetic characterization (frequency range of 8-12 GHz) were carried out using the Naval Research Laboratory (NRL) arch method. A flat aluminum plate was used as a reference for the measurements (100% reflectivity and 0% absorptivity).

Results and Discussion: Fig. 1 shows the aspects of the woven processed and the evaluation of the materials by scanning electron microscopy. Fig. 1(a-b) shows the aspects of the fiber glass woven impregnated individually with the different formulations; it can also be noticed that there has been a good dispersion of the PAni/CNT powders in the polyurethane matrix. Fig. 1(c-d) shows both the polyaniline dispersed in the polyurethane matrix and the region where the carbon nanotubes are agglomerated, respectively.

Fig. 2 shows the results of the absorption of the radiation of the materials processed (named from 1 to 6) and piled in two forms of multilayers, placed one above the other: materials from 1 to 6 (Fig. 2(a)), and materials from 1 to 5 (Fig. 2(b)). Then, one woven at a time was removed from the multilayer formation, reducing the total amount in the piling, and the electromagnetic behavior was evaluated.

This way, the performance of the materials concerning the quantity of polyaniline and carbon nanotubes present in each multilayer assembly can be evaluated. We observe that, as the impregnated fiber glass wovens are removed from the multilayer formation, the behavior of absorption of the radiation reduces, and it begins to behave as a transparent to radar material, for smaller concentrations of the formulation. In this case, it is a typical behavior of the materials formed with fiber glass and without any impregnation of absorbing center. The average attenuation of both materials is of up to 50% of the incident microwave radiation.

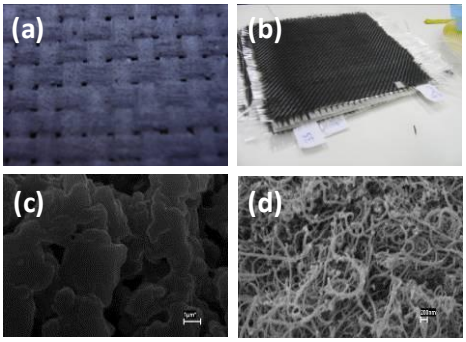

Fig. 1 – Aspects of materiais.

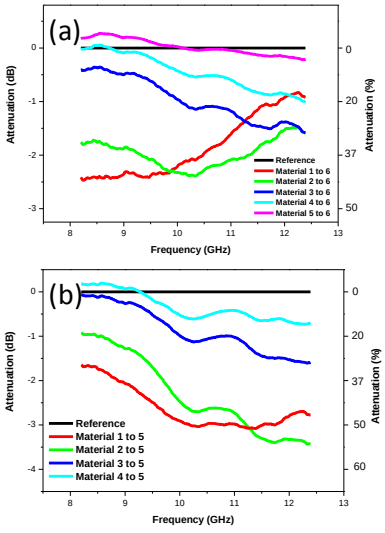

Fig.2 – Attenuation of materials.

Conclusions: The best multilayer formation aiming at processing structural absorbing materials is the composition that contains the materials from 1 to 5, because they attenuate the radiation and also have a behavior of broadband material in frequencies higher than 12 GHz.

esenych@yandex.ru

Introduction

Information aspects of polymer based systems behavior are of a considerable interest from both academic and practical points of view. The problem of "generation of information" during the evolution that preceded the biological one remains unresolved in many respects because of poor understanding of mechanisms of evolutionary transition toward the macromolecules able to store and process information. From the practical point of view, the data recording onto systems of macromolecular and submolecular levels are also of a considerable interest for development of qasi-biological base of nanoelectronics [1]. Accordingly, it is relevant whether an individual synthetic polymer molecule in a liquid phase can be considered "a memory cell" or its analogue. At first sight, it is unequivocally not, so as the macromolecular coils represents statistical and, moreover, strongly fluctuating system. However, viewing the macromolecule as analogue of the neural network reveals that synthetic hydrophilic macromolecules even of an elementary structure are capable both to store and process information.

Numerical modeling of a macromolecule as a neural network

Two versions of the structures modeling behavior of real macromolecules were generated numerically. The plane model structure was generated as sequence of random steps on a grid made of regular hexagons (fig. 1).

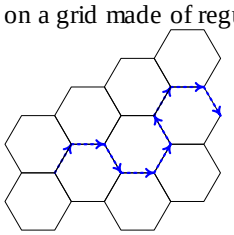

Fig.1. Plane model structure

The modeling 3D structure was generated similarly using the tetrahedral structures of C-C bonds. It is supposed, that each of the knots of the outcome structure can obtain individual electrostatic charge (which corresponds to the maximum simplified model of a partially dissociating polyelectrolyte). The point where the knot is located is impacted by the field generated by both the chain charges and the cloud of counterions (such potentials as dipole-dipole and Coulomb interactions are used at modeling). It is supposed, that the structure knots are also impacted by a heterogeneous external field, which physically corresponds to, for example, interaction of a macromolecule with other one or to internal interactions between macromolecular fragments.

It is shown that each knot of the structure can be considered as an element of the artificial neural network of Hopfield in present report. A Hopfield network is described by a formal Hamiltonian having the same structure as the functional whose minimization allows receiving distribution of charges along the model of polymeric chain. Comparison of the Hamiltonians allows obtaining mentioned above conclusion.

It is of importance, that each configuration of an external field corresponds to a certain set of input signals of the neural network. This brings along the conclusion that external fields impacting the macromolecule form definite set of images which the macromolecule as an analogue of a neural network is able to distinguish.

Results of numerical modeling

In searching of images distinguished by the macromolecular neural network, their representation in the form of a set of binary numbers, which then were translated into decimal form, was used. Reaction of the network to all the images totally was investigated using the method of consecutive search. The example of result for a case of 10 neurons (10 monomer units) is shown on fig. 2, the decimal number of an image N is on the axis of abscissas and frequency of its recognition f is on the axis of ordinates. The distinct peaks testifying the presence of stable image distinguishing (of charges sequence) are visible.

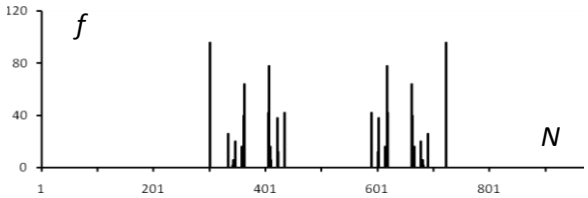

Fig.2. Images recognized by molecular neural network

With use of the various randomly generated structures, it is shown that there are certain steadily distinguished images whose character does not depend on conformation of the modeling macromolecule. The conclusion also remains true at transition to the 3D structures, as well as while using various modeling potentials of interaction between knots. In other words, **each macromolecule generates its own "alphabet" itself**; this **native** alphabet may be used for data storage and processing in quasi-biological nanoelectronics.

Conclusion

The isolated macromolecule in a liquid phase can be considered as an object able to store information, the statistical nature of the coil not being an obstacle for this purpose due to the well-known property of neural networks, namely, their tolerance to errors.

Introduction

Studies on fluorescence of high molecular weight atactic polystyrene (aPS) have been carried out by many authors since early 1960's. In addition to its monomeric fluorescence at 280 nm, aPS shows strong excimer fluorescence at 330 nm not only in solid state but also in fluid solution, because the excimer of aPS is formed between adjacent side-chain phenyl groups whose main conformer has been assigned to be tt in a meso diad [1]. Thus, most fluorescence of isotactic polystyrene (iPS) is of excimer since iPS consists of meso diads. On the other hand, the racemo diad of aPS and oligostyrenes are known to have quite low efficiency of excimer formation [1]. However, the fluorescence behavior of syndiotactic polystyrene (sPS) that consists of all racemo diads have not been published much.

Thus, we tried to show the novel fluorescence behavior of sPS solids and to explain the origin of the fluorescence by comparing it with the behavior of another syndiotactic polystyrene derivative, syndiotactic poly(*p-tert*-butyl-styrene) (sPTBS) in the present study.

Experimental Section

THF solutions of sPS, iPS, aPS and sPTBS were used for the measurement of uv/vis and fluorescence spectrum and the preparation of films (~3%). These films with various thicknesses were prepared by a spin-coating method on quartz disks or by casting the THF solutions on glass plates.

Results and Discussion

First, we measured the uv/vis absorption spectra of sPS, iPS, aPS and sPTBS in THF. The absorption peak of sPS was slightly red-shifted compared with aPS and iPS, but this is due to the change of the fraction of two vibrational bands.

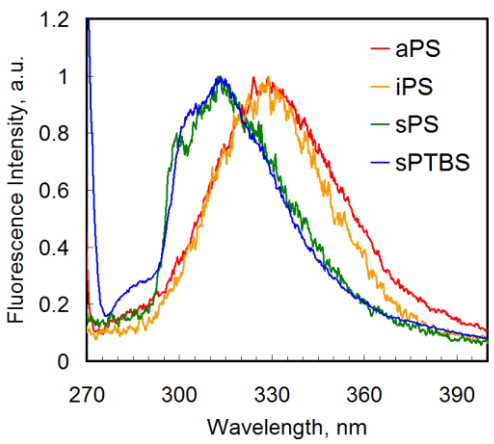

Figure 1. Fluorescence spectra of aPS, iPS, sPS and sPTBS thin films on quartz prepared from THF solutions by a spin-coating method. They are normalized to their peaks.

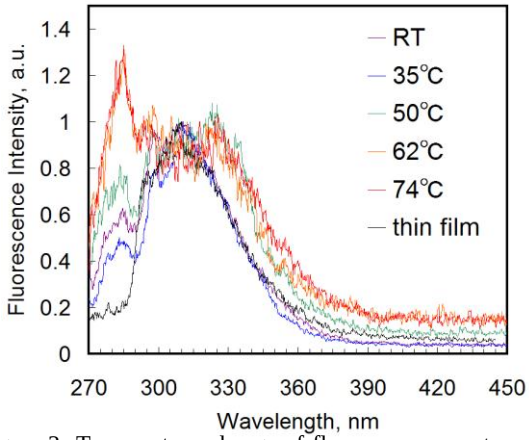

Figure 2. Temperature change of fluorescence spectra of sPS in THF when they were heated. All of them are normalized to the fluorescence peaks at 315 and 330nm.

Figure 1 shows the fluorescence spectra of each thin film. aPS and iPS demonstrated strong excimer fluorescence whose peak was at 330 nm. However, the fluorescence of sPS thin films showed one component whose peak was at 315 nm, which was different from phenyl monomer (at 280 nm) and excimer. The same fluorescence was observed for thick sPS films, so this was found to be of the main fluorescence of sPS solids. Interestingly, the similar fluorescence was observed for sPTBS, though it also showed its monomer fluorescence around 290 nm. Then, we examined the excitation spectra of sPS and sPTBS films of various thicknesses for 315-nm fluorescence. The absorption peak corresponding to the 315-nm emission was not the same as usual phenyl monomer, but did not change with film thicknesses. Consequently, the 315-nm emission of sPS and sPTBS was concluded to be of a ground state dimer formed between side-chain phenyl groups of different chains in solid state.

THF solution of sPS at higher concentrations turned out to form partially pre-gel at room temperature. The fluorescence of sPS was monitored during the pre-gel being gradually heated (Figure 2). Because the ground state dimer dissociate at higher temperatures, the peak at 315 nm was found to decrease while the phenyl monomeric fluorescence at 280 nm began to appear and increased with an increase in temperature.

Finally, we have succeeded to clarify the fluorescence behavior of sPS and sPTBS solids and to demonstrate that they are useful for monitoring their states such as aggregation or pre-gel.

Introduction

Porous carbons are attractive materials for adsorption, separation, catalysis, energy storage devices due to their characteristic properties like porosity, chemical stability, heat resistance and electrical conductance. Template method is advanced technique using ordered structure of inorganic materials for formation carbonaceous products with determined and homogenous porosity. In creating porous structure of the carbon choosing of appropriate type of template plays important role. Another important feature is surface chemistry. From practical point of view surface chemistry is equally important as porous structure, since functional groups have principal influence on interactions between solid surface and molecules in fluid phase.

Polymers are especially promising in this field, because their properties can be modified in wide range e.g. hydrophobic or hydrophilic character, thermal stability, ability to carbon formation.

In our work we have studied three polymers as carbon precursors and their influence on properties of the obtained carbon materials.

Materials and Methods

Nanocarbons were prepared using template method. Furfuryl alcohol (FA) – P1, 4,4'-bismaleimidediphenyl methane (BM) – P4 and its copolymer with divinylbenzene (BM-DVB) – P5 were used as a source of carbon. A hard template was silica gel. Acetone solutions of each precursor (FA, BM, BM-DVB) were applied to impregnate the template. After total pore volume was filled, an obtained composites were heated in order to polymerize precursors inside porous structure of the template. Then carbonization process was performed. Temperature was gradually elevated up to 800ºC and maintained for 30 min. To prevent oxidizing reactions heating was carried in argon atmosphere. The silica template was removed by dissolution in 40% HF. The obtained products were washed with water and dried.

Elemental analyses, nitrogen sorption experiments (at 77K), thermal analyses, FTIR spectra, Boehm titrations, and solid phase extractions (SPE) for phenolic compounds were performed to characterize porous and chemical structure of the obtained carbon products.

Results and Discussion

Some of the obtained results are presented in the Table. Elemental analysis reveal FA (P1) is the precursor that give product the richest in carbon, percentage contents of H, N and other elements (mainly oxygen) is rather poor. Then P1 has relatively small amount of functional groups. P4 and P5 possess chemically differentiated surfaces. The presence of DVB (P5) in the polymer structure caused that the obtained carbon has two times less basic functional groups, as showed results of Boehm titration. The differences in surface functional groups are also confirmed by FTIR analyses (not presented here). Polymeric precursor has influence on thermal stability of the carbon products, as well. Initial decomposition temperature for analysed samples (IDT) are in the range of 130-180ºC, but carbons (P4 and P5) are much more thermally resistant. They possess in their structures substantial quantity of nitrogen.

Table

Sample	%C	%H	%N	% other	S_{BET} m^2/g	V_{tot} cm^3/g	IDT ºC	Basic mmol/g	Acidic mmol/g
P1	93.54	0.48	0.33	5.65	1785	1.56	130	0.35	0.44
P4	85	0.71	4.43	9.86	1013	1.34	170	0.37	0.69
P5	86.3	0.85	3.03	9.82	836	1.26	180	0.14	0.54

Results of nitrogen sorption experiment, specific surface area (S_{BET}), total pore volume (V_{tot}) and pore size distribution (PSD) are shown in Fig1. Porosity parameters (S_{BET} and V_{tot}) decrease in the following order P1, P4 and P5. Very interesting information can be obtained from Fig1. Although the silica template in all cases was the same the differences in pore size distribution are visible. In the case of P1 pore width is 3 nm, whereas for P4 and P5 pore widths are identical and equal 3.7nm. High and sharp peak for P4 indicates a narrow range of pore sizes. Peaks for P1 and P5 have similar shapes. These peaks are a little wider than that for P4 peak, what means the structures of P1 and P5 carbons are more heterogeneous than P4.

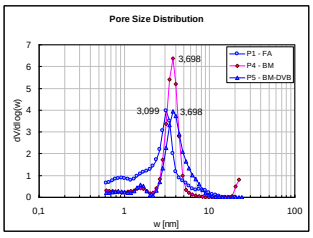

Fig1

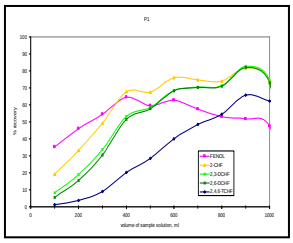

Fig2

In Fig2 example of sorption properties of P1 carbon in SPE method is presented. Different affinity of phenol and four its chlorinated derivatives towards the surface is proved. Breakthrough of most compounds takes place at volume of 1000mL and recovery reaches 80%.

Conclusions

These studies revealed that:

- the most homogenous porous structure was obtained from BM precursor
- the most developed surface was obtained from FA precursor
- the most thermally resistant product was obtained from BM-DVB precursor.

How affect the shape and modifier of clay on polymer blends?

INTRODUCTION

Nowadays, the development of new materials with balanced properties between stiffness and toughness are required in sector such as automotive to develop some parts like bumpers, hub cups, tail gates, doors handle, etc. Thus, the addition of an elastomeric phase to polymer nanocomposites usually could improve the toughness, but a detrimental of the stiffness properties will be obtained[1]. Then, the challenge is achieve a good balance between stiffness and toughness

From our knowledge, all studies based on polymer nanoblends used clay with a platelet-like shape such us smectite. Furthermore, the study of the microstructure and macrostructure of polymer blends with fibrilar clay shape, i.e., sepiolite, offers a unique opportunity to know how the properties are influenced by the clay shape.

In that sense, the main purpose of this work is to compare the effect of clay shape on polymer nanoblends based on PA6 and EPDM using montmorillonite and sepiolite modified with the same organic surfactant, in this case an ammonium salt. Also along this study we will explore the effect of change the surfactant employed in sepiolite, because the modification degree of clay could affect both the inorganic/organic compatibility and the dispersion of the sepiolite in the polymer matrix. In that sense, the sepiolite employed was organically modified with silanes, because of the high affinity between silane groups and amide groups of PA6[2]. Furthermore, in this paper we have used a theoretical relation EPDM-g-MA:Clay 5:1, where the amount of clay was 3 and 5 wt%, because blends with that relationship showed good balanced properties for automotive parts as can be seen in our previous work.[3]

MATERIALS AND METHODS

In this work, PA6 Akulon F130C matrix was supplied by DSM, mEPDM nordel IP3722P was supplied by Dupont, EPDMgMA Roylatuf 498 was supplied by Crompton, motmorillonite Nanofil® 8 was supplied by Süd Chemie and both sepiolites, standard without modification and modified with a quaternary ammonium salt (2M2TH) and a silane (HS06) were kindly supplied by TOLSA S.A. (Spain).

Characterization of microstructural properties of nanocomposites has been carried out by means of microscopic techniques, such as scanning and transmission electron microscopy (SEM & TEM). The morphology was related to thermo-mechanical properties such as Young's modulus, heat distortion temperature (HDT) and notched Izod impact strength at room temperature. Thermogravimetric analysis (TGA) has been done in order to know the residue left by clay in the nanocomposites.

RESULTS AND DISCUSSION

The results have shown that sepiolite has a lot of influence, not only in the morphology, but also in the mechanical properties.

In that sense, the blends with 3 wt% of sepiolite has reached a best balanced properties than its homologous with MMT and even higher mechanical properties than blends with higher MMT content as could be compared with our previous work.[3]

Nevertheless, the blends with 5 wt% of sepiolite have not reached best balanced properties than its homologous with 5 wt% of MMT, indicating that the relationship EPDMgMA:MMT is not valid for fibrous clays as sepiolite.

In reference to the surface functionalization of sepiolite, the blends reinforced with 3 wt% have not shown differences in the mechanical properties. However, the blends with 5 wt% of sepiolite modified with silanes have reached better properties than those reinforced with sepiolite modified with ammonium salts. That indicates that the Si-OH groups of sepiolite, interact with the amide groups of the matrix and this improves the stiffness of the blends with a slight loss in toughness.

Abstract

This contribution reports on the dispersion by simple meltblending of tinyamounts of carbon nanotubes (CNT) in nitrile butadienerubbers (NBR). Acrylonitrile (ACN) units of NBR are known to generate free radicalsuponheating and/or shearing. This studyhighlightselementsevidencingapossibility for NBR polymerchains to react by a free-radical mechanism and to graft onto CNT surface all along the process of mechanicalblending of NBR withCNTs. More precisely and since the formation of the free-radicalstakesplace on the ACN units, the influence of the ACN relative content in NBR on the grafted CNT amount has beenstudied. It comes out that the polymer-grafting rate onto the CNT surface increaseswith the ACNcontent in NBR. Interestingly, the nanotubes proved more finelydispersed in NBR containinghigherrelative ACN content as evidenced by morphological observations as well as electricalmeasurements.

Introduction

Various NBR samplescharacterized by increasing content in ACN have been chosen for the production of conductingelastomernanocompositesfilledwithmultiwallCNTssurfacegraftedby NBR chains. Firstly, wewillhighlightthat the thermooxidativeand/or thermo-mechanicaldegradation of the polymertaking place during the meltblendingprocess leads to the covalentgrafting of elastomerchains onto the nanotube surface.

Wewill show that the content in surface-graftedCNTsincreaseswiththe ACN relative content spreadalong the NBR chains. Finally,transmissionelectronmiscroscopy (TEM) and electricalmeasurementswillbeapproached for highlighting the effect of the ACNcontent on the extent of dissociation of the native nanotube bundlesand the quality of the nanofillers distribution and dispersionthroughout the NBR matrix.

Processing conditions

NBR/CNT composites werepreparedusing a two-step process.
The components (i.e. NBR, CNTs and vulcanization agents, if any)were mixed simultaneously in a Brabenderinternalmixer.
Exceptwhenindicated, all the compounds werepreparedat 50°C for 10 min at 60 rpm and werethenvulcanizedat 190°C under50 bars for 15 min.

Results and Discussion

During the meltblending of NBR withCNTs, the graftingreactionof somepolymerchains onto the nanotubes surface has beenevidenced. This grafting more likelyresultsfrom the formation offree-radicalsalong the polymerchains as generated by thermooxidationand/or thermo-mechanicaldegradationmechanisms.
Interestingly the vulcanization, i.e., a free-radical reaction, involvesthe CNTsreducing the number-averagemolar mass between thecrosslinkingnodesathigher nanotubes content. Sinceitiswellacceptedthatboth thermo-oxidative and thermo-mechanicaldegradationsof NBR chainstake place on ACN units[1–3], it has alsobeendecided to study the effect of ACN relative content of NBR on thepolymer-grafting rate in NBR/CNT blends.
Reducing the ACN relative content in NBR also leads to a decrease of the amount of surface-graftedCNTs, shiftingfrom 1.4% to 0.2%, respectively, for rubberscontaining 44 and18 wt.% ACN units. The more the NBR elastomercontainsACN groups, the more the CNTs in the NBR/CNT blends aresurface-grafted. Such an observation mightbeexplained by the relativelyhigheramount of free-radicalsthusgenerated on the ACNgroups and the affinitybetween the acrylonitrile functions andthe nanotubes.

Conclusion

It wasshownthatduring the blendingprocess, the polymerchains are graftedonto the CNT surface via a free-radical mechanism. Indeed, NBRgenerates free-radicalsfromits ACN unitsuponheating and/orshearing. As a result of the highinherentaffinitybetween the CNTsand ACN units, and due to the formation of ACN-based free-radicalsleading to NBR-grafting on CNTs, increasing the ACN relativecontent along NBR chains triggers higherpolymer-grafting on thenanotube surface.

Introduction

The heterogeneous nature of aqueous heterophase polymerizations is the base for an easy route to unique block copolymers, for the development of new and more effective polymerization strategies. [1-5] The aim of this project is to produce inorganic - polymeric nanocomposites in a one-step procedure and to carry out studies regarding the synthesis and the properties of block copolymers and double hydrophilic block copolymer particles which are easily and only accessible by a special aqueous heterophase polymerization technique. Water-soluble hydrolytic precursor polymers with hydroxymethyl end groups such as poly(ethylene glycols) m-PEG 5 (methoxy terminated PEG a molecular weight of 5000g/mol) and various hydrophobic monomers such as VTMEOS (vinyl trimethoxysilane), VTEOS(vinyl triethoxysilane), VTISOPOS(vinyl triisopropoxysilane), VTISOPREnOS (vinyl triisopropenoxysilane), NIPAM (N-isopropyl acrylamide) were used to synthesize silica containing triblock copolymer particles by radical polymerization with ceric ion redox initiation mechanism in water.

Materials and Methods

Chemicals. The monomers were either carefully distilled or at least two times re-crystallized prior to use. Methoxy-terminated PEG with a molecular weight of 5000 g/mol (mPEG 5000, Aldrich), vinyl trimethoxy silane(VTMeOS,Aldrich),Vinyltriethoxysilane (VTeOS, ABCR), Vinyl triisopropoxysilane(VTISOPOS, ABCR) and Vinyl tri phenoxysilane(VPhEOS,ABCR), were used as received. Cerium ammonium nitrate from (Fluka) was used as ceric ion source. All block copolymers were synthesized in a CPA200 reaction calorimeter (ChemiSens AB, Lund, Sweden). Before any analysis the final latexes were purified by ultrafiltration through a YM-100 membrane (regenerated cellulose) with a cut-off of 100 kDa until the conductivity of the eluate reached a constant value. Then, the block copolymers were isolated by freeze drying (Beta 1-16, Christ, Germany). FT-IR spectra were recorded with a Varian 1000 Scimitar in ATR mode (Pike Miracle ATR cell). Transmission and scanning electron microscopy (TEM, SEM) was performed with a Zeiss EM 912 Omega microscope operating at 100 kV and a Leo Gemini 1550 according to standard procedures, respectively.

Results and Discussion

The silica containing triblock copolymer particles (peg-pnipam-pvteos, peg-pnipam-pvtmeos, peg-pnipam-pvtisopos,peg-pnipam-pvtisoprenos) were characterized regarding morphology by TEM and SEM. FT-IR spectroscopy was used to characterize the chemical composition. The results revealed a strong influence of the nature of the siloxane. After ultrafiltration and freeze drying the solid triblock copolymers are easily redispersable in water. The SEM image (Fig.1a) clearly shows regions which suggest the presence of silica at the particles. The solid triblock copolymers were, in a further reaction step, calcined at 550 °C for 7 hours. If the solid triblock copolymers are treated with a high temperature flame (~2000 °C) the residual organic parts burn away and the remaining SiO_2 melts and forms quartz pearls (Fig.1b). After calcination the silica is porous as proven by SEM images (Fig.1c). The structure of the triblock copolymer is proven by FT-IR spectroscopy (Fig 1d). The vibration spectrum of the triblock copolymer unambiguously shows, besides the characteristic bands of the PNIPAM and the PEG blocks, the existence of SiO_2 units already in the triblock copolymer.

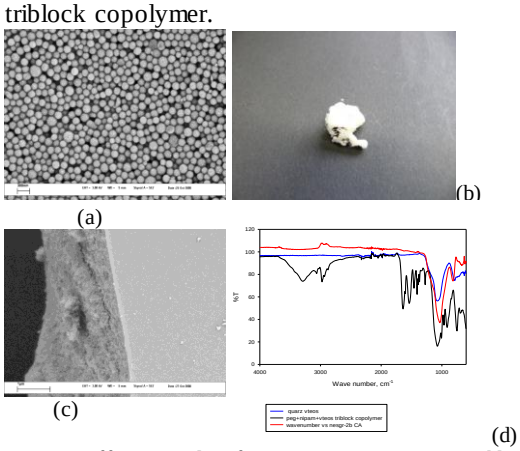

Fig. 1. Different results of PEG-PNIPAM-PVTEOS triblock copolymer a) SEM images, (b) quartz pearls after burning the solid polymer in a high temperature flame, (c) SEM images of the calcinated block copolymer, (d) FT IR spectra

Conclusions

The established strategy for the synthesis of block copolymer particles via aqueous heterophase polymerization is versatile and could be successfully applied to produce novel silica-containing block copolymer particles in an effective one step procedure.

Introduction: It is well known the concern of scientists in producing devices for conversion and clean power generation. Among the devices studied stand out the organic light emitting diodes (OLEDs), the polymer light emitting diodes (PLEDs) and light emitting devices based in luminophors components. The efficiency of these devices has increased in recent years; however, more studies should be conducted to enlarge it. This paper presents the construction and characterization of components of an electroluminescent device consisting of: Monolayers of composites of various thicknesses (4 µm-20 nm) containing poly (3-thiophene methyl acetate) PT3MA doped with ferric chloride ($FeCl_3$), the polymer poly (vinylidene fluoride) and the luminophor $ZnSiO_4$: Mn (zinc silicate doped with manganese), which were dissolved in dimethylformamide (DMFA) and deposited by spinner or drop casting techniques on Indium Titanium Oxide (ITO) and silicon wafers. The film formed was then taken to evaporation of metals and in its opposite face deposited aluminum to form external contacts. The samples were characterized with the techniques of atomic force microscopy (AFM), focused ion beam (FIB) scanning electron microscopy, ellipsometry, perfilometry and I-V characteristic curve.

Materials and Methods

Figure 1: Device fabrication process

The steps for assembling and preparing the device (Figure 1) are: 1) partial removal of the ITO by corrosion process using Zn powder and HCl 1:1 [1], 2) clean of substrate with solvents (acetone, water and isopropyl alcohol using ultrasound) [1], 3) deposition of the composite by drop casting or spinner, 4) evaporation of the solvent in the vacuum oven, 5) deposition of aluminum by sputtering with the aid of mask

Results and discussion: The average thickness determined by Perfilometry and FIB to the composite deposited on the substrate by drop casting was 4 µm. In the tests evidence of depositions by spinner, nanocomposites of the material can be obtained and their values of thicknesses determined by ellipsometry. The solutions spin coated at 1000 rpm and 2000 rpm formed membranes with thicknesses near 20 nm. The SEM images showed an excellent distribution of luminophors in the films thicker, however low their distribution in the nanocomposites deposited by spinner resulting in an increase of the agglomeration of luminophors particles in the extremities of the ITO surface.

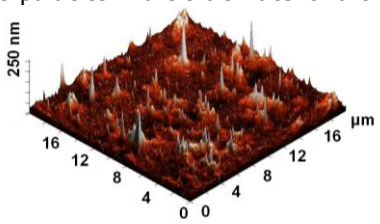

Figure 2: AFM images of nanocomposite

AFM images were performed to determine quantitatively the average roughness of the composites deposited on the substrates. Figure 2 shows the surface topography of the composite deposited on ITO substrate by spinner at 2000 rpm with a value of average roughness of 11 nm. Composites with values of 450 nm and 14 nm of roughness were obtained respectively by drop casting and spinner at 1000 rpm. The I-V characteristic curve of composite PT3MA / PVDF / ZnSiO4: Mn with 2µm of thickness and 0,3 cm² of area is presented in Figure 3. The measurements were performed for a sample polarized with direct current (DC) voltage using a slope of 93 mV/dec.

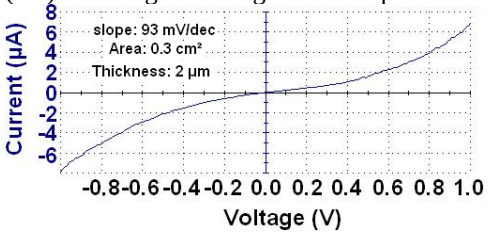

Figure 3: I-V characteristic curve voltage x current

Analyzing the curve is possible to observe that the device presents a behavior characteristic of a semiconductor diode. However for voltages greater than 3 volts a new behavior is observed, because the curves show the formation of hysteresis (graph not reported in this paper). These results are similar to those reported for blends of PVDF-PT3MA [2].

Conclusion: The films obtained this work presented low roughness, excellent distribution of luminophors, especially the thicker films. The electrical characteristic voltage versus current (VxI) showed a diode behavior and not resistive for the device.

Formation and Size Tuning of Colloidal Microcapsules via Host-Guest Molecular Recognition at the Liquid-Liquid Interface

K. Merve Türksoy, Fırat Özdemir, Amitav Sanyal

Bogazici University, Department of Chemistry, Bebek, 34342, Istanbul, Turkey

email: amitav.sanyal@boun.edu.tr

Microcapsules are classes of functional materials that have recently aroused great interest. They can be utilized as containers as an alternative to micelles and vesicles for applications such as drug delivery devices. A strategy based on the host-guest complexation ability of cyclodextrins, the formation of stimuli-responsive colloidal microcapsules due to crosslinking via specific non-covalent 'host-guest' chemistry was examined. Unlike covalently cross-linked microcapsules, the reversible nature of these bridging interactions can be used to manipulate the size of these capsules via introduction of competing amphiphilic guest molecules. Partial disruption of interfacial cross-linking allows microcapsules to coalesce with each other to form larger capsules.

Introduction

Caprolactone derived materials are good candidates for tissue engineering. Although previous works demonstrate that methacrylate-endcapped caprolactone (CLMA) and 2-hydroxyethyl acrylate (HEA) copolymer networks present good response when cultured with chondrocytes [1], they lack of sufficient mechanical properties for hard tissue engineering applications like bone. The hybridation of the organic matrix with silica (SiO_2) by the polymerization of the organic phase during the simultaneous in situ sol-gel polymerization of a silica precursor has been presented as and strategy for mechanical reinforcement and bioactivity improvement [2]. The aim of the present work is the synthesis, characterization and evaluation of the cellular response of new CLMA-co-HEA/SiO_2 hybrids.

Materials and Methods

The hybrids were obtained through the co-polymerization reaction of CLMA and HEA in monomers ratio 60/40% (w/w) and the simultaneous acid-catalyzed sol-gel polymerization of TEOS as described elsewhere [2]. 1 mm thickness sheets were obtained with different proportions of SiO_2 (up to 30 wt.%). Effective silica network formation was confirmed by infrared spectroscopy (FTIR). Thermogravimetry (TGA) allowed determining the real quantity of SiO_2 in the hybrids. The glass transition temperature of the samples was assessed by differential scanning calorimetry (DSC). Dynamic mechanical measurements (DMA) allowed measuring the storage modulus as a function of temperature. The ability of the samples to form a layer of hydroxyapatite (HAp) on their surface was tested *in vitro* by soaking them in a simulated body fluid (SBF) [3]. MC3T3-E1 pre-osteoblastic cells were cultured *in vitro* on the materials to evaluate their osteogenic potential.

Results and Discussion

The weights of the inorganic residual at 650ºC of the TGA curves agree well with the nominal ones. FTIR spectra show the characteristic peaks of the silica network: at 1060–1100 and 800 cm^{-1} (attributed to the Si-O-Si asymmetric and symmetric stretching vibration, respectively) and at 950 cm^{-1} (characteristic of the Si-OH stretching vibration). Their intensities increase proportionally to the silica content, mainly at silica contents above 15%. This abrupt increase is correlated with the percolation of the silica network. The copolymer is amorphous and random showing a single glass transition at -23ºC. It monotonously shifts to higher temperatures with the increase of the silica content, up to 9.48ºC for the 30% SiO_2 sample. The rubbery modulus does not vary significantly up to 15% SiO_2 content when it markedly increases due to the formation of a continuous inorganic network. Scanning electron microscopy (SEM) images of the samples after 7 days of immersion in SBF show few hydroxyapatite nuclei grown on their surface. After 14 and 21 days the copolymer and the hybrid with a 15% SiO_2 are completely covered by a layer of HAp (formed by the typical needle-shape crystals) with aggregates of a second and third layer (Figure 1 left). On the contrary, although the sample with a 30% SiO_2 is bioactive it presents a HAp layer with some imperfections. Electron dispersive X-ray spectroscopy shows that the coatings are mainly composed of calcium and phosphorous, with Ca/P atomic ratio close to the stoichiometric apatite, 1.67. The MTS proliferation assay shows an increment in the number of cells at 7 days of culture, being the number of cells independent of the silica content. Confocal laser scanning microscopy images of the immuno-histochemistries (Figure 1 right) show cells producing osteocalcin and collagen type I, typical markers of osteoblastic differentiated cells.

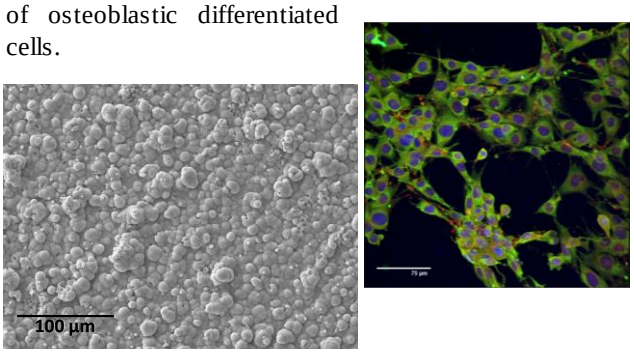

Figure 1. Left: SEM image of the hydroxyapatite layer grown on the 15% SiO_2 hybrid, 14 days immersed in SBF; right: double immunofluorescence image showing staining of osteocalcin (green) and collagen type I (red) of pre-osteoblastic cells cultured on the 15% SiO_2 hybrid at 14 days. Cell nucleus is stained with Dapi (blue). Bar equal to 75 µm.

Conclusions

The new silica hybrids have improved mechanical properties in comparison to pure copolymers, are bioactive and induce the osteoblastic differentiation as good candidates for bone tisuue engineering.

Introduction

The mechanisms of radiative processes taking place in spin coated thin films of the electroluminescent polymer MDMO-PPV, were identified through photoluminescence (PL) spectra.

Materials and methods

Thin films of poly[2-methoxy-5-(3′,7′-dimethyloctyloxy)-1,4-phenylene vinylene] (MDMO-PPV) [1], were deposited by spin coating and its optoelectronic properties were explored by a combination of transmittance, photoluminescence and conductivity measurements as a function of temperature (13K-410K) [2].

Results and discussion

A temperature dependent blue shift of the Q band was observed (See figs. 1 and 2).

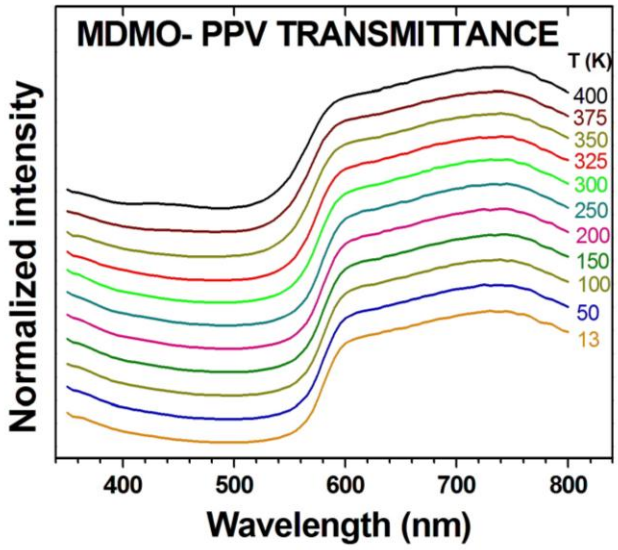

Figure 1. Transmittance of a MDMO-PPV film in the temperature range 13K-410K.

This behavior was investigated by combining optical and electrical measurements in a wide range of temperatures (13K to 410K). Both, transmittance and PL spectra show an unusual shift of the optical bandgap towards shorter wavelengths as the temperature increases. Further analysis of the temperature dependency in optical spectra and electrical conductivity data, suggests segmentation and self-ordering of the polymer chains.

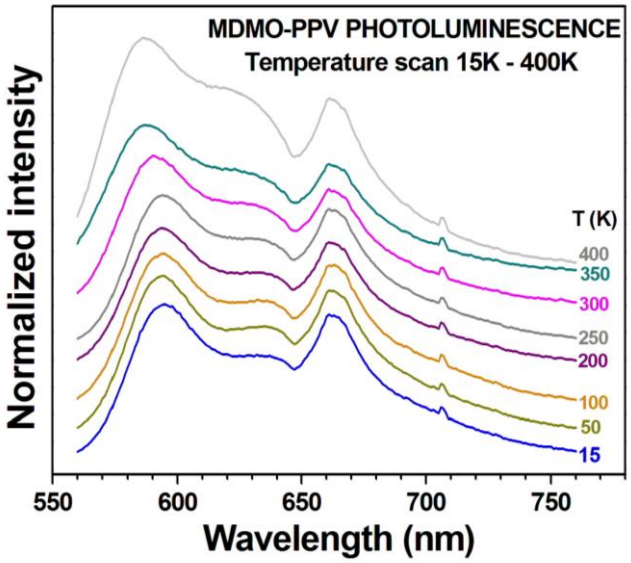

Figure 2. Temperature dependent Photoluminescence measurements on MDMO-PPV films, in approximately 50K intervals.

Conclusions

The results allow deducing a phenomenological model for the observed structural changes in the organic film. Thus, the heating process results in an improvement of the molecular order and therefore, according to the model, an enhancement of the electroluminescence is expected.

The Thermodynamics of Formation and Structure Peculiarities of Nanostructured Polyurethane/Poly(2-Hydroxyethyl Methacrylate) Interpenetrating Polymer Networks

L.V. Karabanova[a]* *Yu.P.Gomza* [a], *S.D.Nesin* [a]

email: abrosim@mail.kar.net

Interpenetrating polymer networks (IPNs) based on polyurethane (PU) and poly(2-hydroxyethyl methacrylate) (PHEMA) were synthesized by sequential method. The thermodynamic miscibility and structure peculiarities by SAXS have been investigated. A study of the thermodynamics of the process of a multicomponent polymer system formation was carried on. It was shown that the values of free energy of mixing of the polymer's components Δgx (Gibbs free energy) are positive for all compositions under investigation. It means that polymeric components of the system are thermodynamically incompatible. The synthesized IPNs have a structure of incomplete phase separation. A study of the particular structure of interpenetrating polymer networks by methods of small angle and wide-angle scattering was done. It was shown (Fig.1) that SAXS curve of initial PU shows intensity maximum that evidences nanophase separated structure of such a component. The SAXS curve of PHEMA is completely structureless and has low level of intensity that evidences homogeneity of morphology.

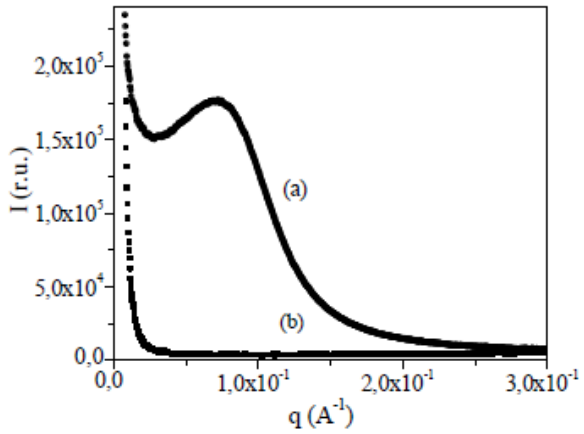

Fig.1. Scattering intensity I(q) . q2 versus scattering vector q, for Polyurethane network (a) and for PHEMA (b).

The curves of all the IPNs show two set of interference maxima. They are located at the wave vector values corresponding characteristic lengths in the ranges 6 – 9 nm and 26 – 28 nm, respectively (Fig.2).

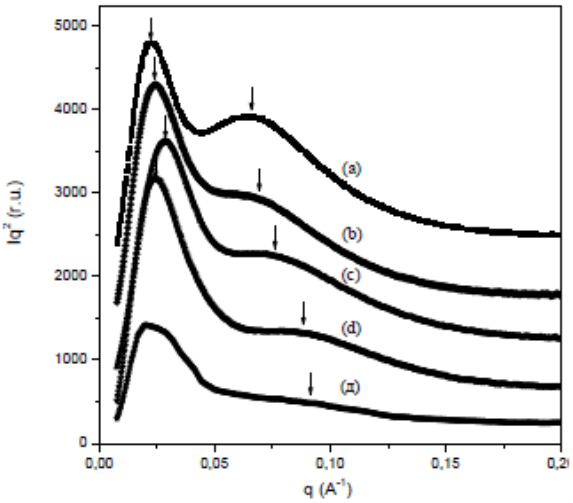

Fig.2. Scattering intensity I(q) . q2 versus scattering vector *q* curves of PU/PHEMA semi-IPN's for different PHEMA contents:16.2 (a), 21.4 (b), 31.9 (c), 40.4 (d); 57.7% (e).

The first set maxima reflect a presence of PU nanophase structure and the second ones are attributed to the frozen nanophase separated structure of IPNs formed by nanodomains which are rich by one of the components. The first type maximum in the IPNs curves reflect an existence of spinodal decomposition type anophaseseparated structure induced by chemical reaction. The second interference maxima are connected to the PU nanophase separated structure and evidence the presence of the PU-rich domain. The presence of two hierarchical levels of heterogeneity in the IPNs was established and the features of each of them was analyzed. The first level of heterogeneity is recorded in the early stages of spinodal decomposition, the fluctuations of concentration with size of 30 - 40 Å were found. The second level of heterogeneity corresponds to later stages of microphase separation and is characterized by highlighting almost pure polyurethane and PHEMA domains, which include crosspassing chains of polyurethane.

acuellarb@unal.edu.co

Polyurethane urea (*PUU*) elastomers are formed by joining blocks of two chemically dissimilar segments along the polymer backbone. These polymers have the general structure $(A\text{-}B)_n$, where *B* is the soft segment. The hard segment (*A*) is formed by extending a diisocyanate with a low molecular diol or diamine. Organically modified clays play an important role in the formation of the structure and morphology of polymer/clay nanocomposites, and thus significantly influences material properties [1-3]. Therefore, the choice of modifiers used to treat clay is crucial to prepare polymer/clay nanocomposites with enhanced properties [4]. Thermoplastic polyurethane urea (*PUU*)/Clay nanocomposites were prepared via solution processing using ether type *PUU* and a modified organoclay. The *PUU* was prepared from isomer mixture of methylene diisocyanate (*MDI*), polyether polyol (*PTMG*) and ethylenediamine (*EDA*) as chain extender. The hard segment concentration of the final copolymer was 36 wt % (by reaction stoichiometry), assuming all *MDI* and *EDA* contribute to the hard segments. Two differently modified organoclays (denoted as 93, 10) and pristine montmorillonite (*MT*) were intercalated and exfoliated in the *PUU* matrix using an intercalation technique for solution and subsequently characterized by X-ray diffraction (*XRD*), atomic force microscopy (*AFM*) and *DSC*.

The figure 1 shows *PUU360*, *PUU365_10* and *PTMG*, where nanocomposite containing final concentration of 5 w/w%. The pure *PUU* (*PUU360*) exhibits an amorphous halo near 2θ = 20°, consistent with the result of Dai et al. [5] and is found at the same location for the composite. This is implying that *PUU* is intercalated into layered silicates, exfoliated and dispersed in *PUU* matrix amorphous.

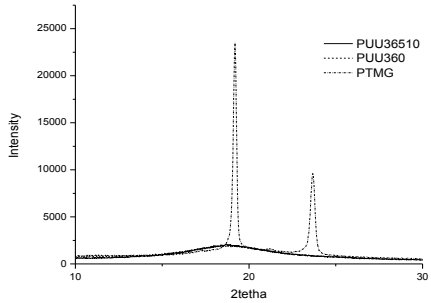

Figure 1. *XRD* patterns of *PUU*: 0.0 w/w % clay (PUU360); 5.0 w/w % clay (PUU365-10) and PTMG.

Finally, morphological changes induced by the addition of clays were analyzed using *DSC* and *AFM*. The *DSC* melting curves of copolymer pristine and nanocomposite show the thermal behavior of *PUU* at a scanning rate of 10°C/min, the curves had an exothermic peak (cold crystallization, at about -20°C) and an endothermic peak (melting of crystallization, at about 20°C), while there was crystallization peak on the cooling. After adding nucleating agents organically modified clays, the exothermic peak decrease on the heating curve. It can be concluded that in the course of heating less crystal was formed [6].

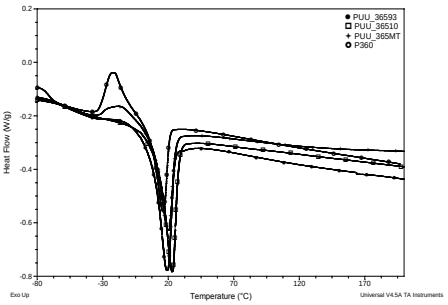

Figure 2. *DSC* melting curves of pure *PUU* and nanocomposite with clay modifiers 10, 93 and *MT*.

Figure 3 shows the hard domains light and soft dark by noncontact *AFM*. Pure *PUU* of left is amorphous with aggregation of hard domains (*PUU360*), while nanocomposite of the right has a slight crystallization. The other modified presented different morphologies without crystallization.

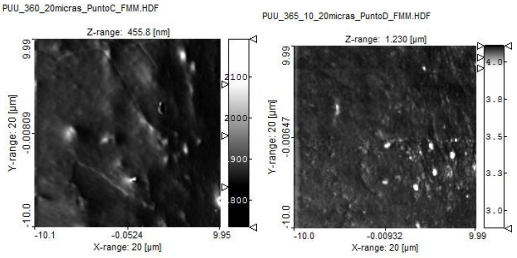

Figure 3. Ambient temperature tapping *AFM* force image of *PUU360* and *PUU365-10*.

In conclusion, the cold crystallization presents in pure polyurethane is reduced by the effect of clay modifiers addition. Furthermore, the modifier affects the morphology obtained by crystallization soft domains or segregation of the hard domains.

anatoli.serghei@univ-lyon1.fr

The present contribution aims to review the applications of Broadband Dielectric Spectroscopy in polymer nanoscience. The broad frequency and temperature range of this technique allows one investigations on a variety of physical phenomena taking place on different time- and length-scales: density fluctuations[1] (and thus phase transitions), polymer dynamics (molecular fluctuations, glass transition, chain dynamics, capillary flow[2-3]), charge transport phenomena in the bulk and at interfaces[4]. Its high accuracy in measuring low signals enables one measurements on extremely small amounts of matter, down to the level of attograms (1 attogram=10^{-18} gram). The present contribution will exemplify the strengths of Broadband Dielectric Spectroscopy in measuring polymer systems having one, two or three dimensions on the nanometric length scales (ultra-thin layers, monolayers and sublayers, polymer nanorods, nanowires and nanotubes, single polymer chains). A special emphasis will be placed on polymer nanofluidics[2-3], in particular, on investigations of capillary flow of polymers into cylindrical nanopores (Fig. 1).

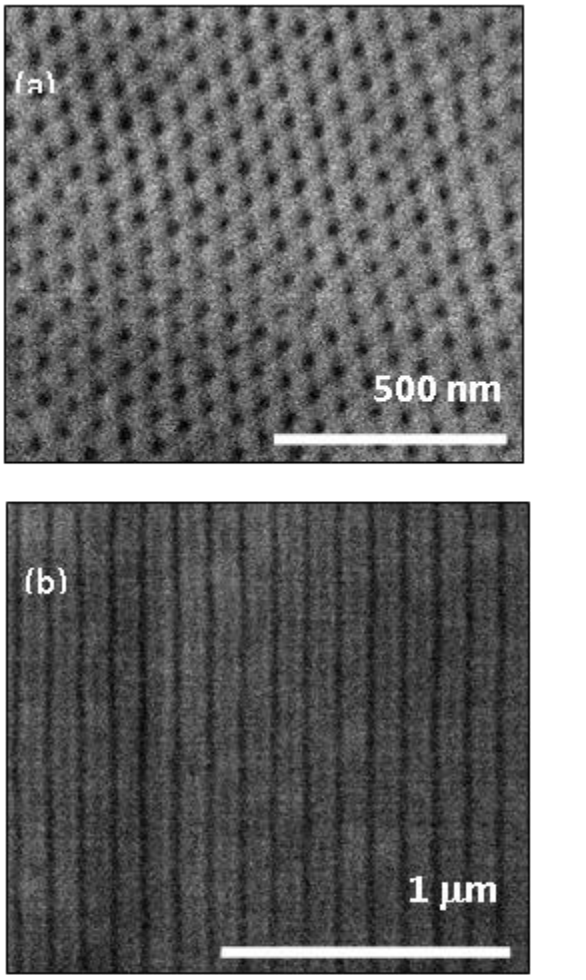

Fig. 1: SEM images of ordered nano-porous media: (a) top view (b) cross-section view; (c) measurement cell for experiments in the field of nanofluidics. Thin electrodes of gold are deposited onto both sides of the porous membrane and connected to the measurement device. The capillary flow of polymers into nanometric channels is continuously monitored in time by measuring the dielectric response of the sample cell[2-3].

During the last decade a lot of attention in polymer science was focused on polymer nanocomposites formation that offers a combination of properties generally notavailable in polymers. Recently much interest h as been given to the use of carbon nanotubes (CNTs) in polymer composite materials to improve their mechanical and electrical properties. CNT-filled plastics are used already in several commercial applications. The electronic packaging industry, for example, uses CNTs-filled plastics to protect sensitive electronic parts such as integrated circuits and hard disc drives from antistatic shock during fabrication and handling. The automobile industry uses CNTs filled nanocomposites to prevent electrostatic discharge in fuel lines and pumps. CNTs-filled polymers are very promising material for antistatic shielding in airplane wings and fuselages. However, such materials require also the complex of properties such as resistance to low temperatures, semiconductivity behavior and good mechanical properties [1].

Polycyanurate Networks (PCN) originating from Cyanate Ester Resins are perspective high-performance materials for use in industrial applications especially for space and aircraft building. They are the most romising group of high-temperature thermosetting polymers [2,3].

In this work we have studied the PCN composites containing from 0.02 to 1.2 wt. % of multiwall-CNTs (MWCNTs) prepared using sonication technique followed by thermal curing. The structure of MWCNTs was investigated using Raman spectroscopy and Transmission Electron Microscopy. The glass transition temperatures (determined by differential scanning calorimetry) is higher than 265 °C for all the nanocomposites and do not change significantly with variation of the MWCNTs content. The dependence of the electrical conductivity on the MWCNTs content was analyzed using percolation theory [4] yielding the percolation threshold *pc* = 0.0038 (0.38 wt. %). The temperature dependence of conductivity was investigated in very broad temperature range. The results were discussed in terms of different models of electrical conductivity in heterogeneous materials [5] and it was found, that the Fluctuation Induced Tunneling model [6] is the most appropriate. The samples above *pc* show very weak temperature dependence of the conductivity what is related to high connectivity of the MWCNTs network.

Such nanocomposites can find potential applications as antistatic materials of automobile parts and in electronics; their good performance at low temperatures makes also possible using such materials in aircraft and space constructions.

Templating Functional Nanoporous Materials with Macromolecular Architectures of Controlled Degradability

Rim Majdoub, Daniel Grande

"Complex Polymer Systems" Laboratory, Institut de Chimie et des Matériaux Paris -Est, 2 rue Henri Dunant, 94320 Thiais, France

E-mail : grande@icmpe.cnrs.fr

It is a great challenge to produce nanoporous polymeric membranes with a simultaneous control of porosity and functionality (surface chemistry),[1,2] while maintaining mechanical properties and a chemical stability. There is a need to obtain such functional porous systems by simple and highly reproducible approaches, being cost-effective and compatible with the production of materials at an industrial scale.[3,4]

The main thrust of this communication is to address two original routes to (meso)porous frameworks with a simultaneous control over the porosity and functionality. The first approach relies on the synthesis of well -defined polystyrene-*block*-poly(D,L-lactide) (PS-*b*-PLA) diblock copolymers with a functional group (*e.g.* carboxylic or sulfonic acid groups) at the junction point between the two blocks. By the proper design of initiating systems and copolymer composition, as well as a good control over the polymerization processes, copolymers with a preferentially cylindrical morphology (PLA cylinders in a PS matrix) could be obtained.[5-7] By taking advantage of the well-known hydrolytic degradability of aliphatic polyesters, the PLA block was subsequently removed by basic hydrolysis, leaving behind a porous PS membrane with functional groups located along the walls of the channels. The second synthetic strategy entails the preparation of acidfunctionalized PS/PLA-based (semi-)Interpenetrating Polymer Networks (IPNs), where the styrenic subnetwork served as the future membrane material while the polyester partner could be selectively removed under mild conditions in a subsequent step.[8,9]

This communication will examine the scope and limitations of both complementary routes to meso- or macro-porous polymeric materials with defined porosity and functionality. It essentially focuses on the investigation of the correlations between the nanoscale solid-state organization of the precursors and the morphology of the resulting porous frameworks, as examined by different physico-chemical techniques, *e.g.* Differential Scanning Calorimetry (DSC), Scanning Electron Microscopy (SEM) and Small -Angle X-ray Scattering (2-D SAXS). The newly prepared (nano)porous materials were also analyzed by nitrogen sorption porosimetry. Obtained functional porous materials are of potential interest for heterogeneous supported catalysis, and selective transport applications.

Preparation and Characterization of EVA Nanocomposites Obtained from Montmorillonite and Methylene-blue

M.I. Beltrán, A. Marcilla, V. Marchante, V. Benavente and I. Pelaez

Chemical Engineering Department, Alicante University, Spain

e-mail:maribel.beltran@ua.es

Introduction: Polymer/nanoclay nanocomposites are innovative materials that show interesting mechanical, chemical, and physical properties (1). Nanopigment are a new type of pigments that present some of the organic colorant properties and better light and environmental stability than conventional pigments and dyes (2). Moreover, they are prepared from nanoclays and they are expected to improve the mechanical properties of the materials that include them. To our knowledge, there are no commercial applications of nanopigments with polymers and they have only been used with polyethylene at a lab scale (3). Nanocomposites are usually prepared via melt mixing at high shear stress conditions in order to achieve the adequate dispersion of the nanoclay in the polymer matrix since exfoliation is essential to benefit from the excellent nanoscale properties that nanoclays confer (4).

In this work nanocomposites based on EVA containing different quantities of montmorillonite nanoclay and nanopigment (montmorillonite/methylene blue) were prepared by melt mixing. The caharacterization of the samples was performed by different techniques.

Materials and Methods: EVA (18%VA) from trithene was employed, the monmorillonite (MO) was the EXM 757 grade (gently supplied by Süd Chemie) with a cation exchange capacity (CEC) of 95mg/100g and the methylene blue (MB) (C.I. Basic Blue 9). Nanopigments (NP) were sinthesized at a lab scale with the method described elsewhere (3).

The formulations included EVA plus 0.1 to 5 phr (part per hundred of resin) of unmodified montmorillonite (0.1MO, 1MO and 5MO), 1phr of nanopigment synthesized with different quantities of MB, from 5 to 100% of the total CEC of the MO (NP5, NP20 and NP100) and 1 phr of unmodified montmorillonite plus the same quantity of MB introduced in the nanopigments (MO0.02MB, MO0.07MB and MO0.28MB). An EVA reference was also processed under the same conditions than the other samples. Ingredients were mixed in a Banbury GUIX-2P batch mixer at 90ºC and 8 min and in a Brabender Plasticorder PL2000 under the same temperature and time conditions. Obtained samples were compression molded at 130ºC and 100 bar for 10 min to obtain 1 mm thickness sheets.

The properties of the nanocomposites were analyzed trough differential scanning calorimetry (Pyris 6 DSC), thermogravimetric analysis (TGA Netzch TG 209), oscillatory rheometry (Bohlin CS-50), mechanical behavior (Instrom 4411) and transmission electron microscopy (TEM-Jeol JEM-2010). The micro- and nano-dispersions were analyzed through XRD (Seifert JSO-DEBYEFLEX 2002). To assess the colorimetric behavior of the samples, their spectral reflectances over black and white substrate have been measured (spectrophotometer Konica Minolta CM-2600d).

Results and Discussion: The rheological behavior and thermal properties of the samples prepared with and without the additives did not show important modifications due to the low concentrations employed. A remarkable increase in the Young's Moduli of the samples including the nanopigments have been obtained (up to 20% at 1phr), specialty in those cases where intercalation and/or partial exfoliation was attained, as shown in Figure 1 (those samples including NP and specially those processed at the higher shear rates). Respect to the color performance, much higher levels of transparency and coloring power was observed for the samples containing the nanopigments than for the corresponding references with the same proportion of the pigment.

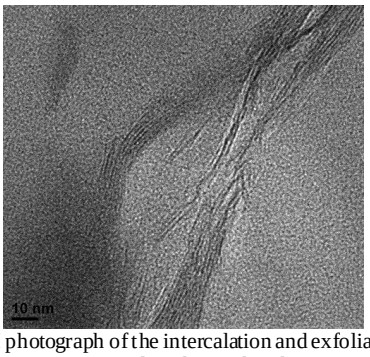

Figure 1. SEM photograph of the intercalation and exfoliation attained by NP20 processed in the Brabender mixer.

Conclusions: Intercalation and/or partial exfoliation were found to occur for the formulations based on the nanopigments and specially for those processed under the higher shear rates. No intercalation took place with samples obtained with the unmodified montmorillonite. The mechanical properties were clearly improved when intercaled and or exfoliated structures appeared, and a higher transparency and coloring power was observed for the samples containing the nanopigment than for the corresponding references.

The nanopigments appear as a promising alternative to conventional pigments and dyes in applications with polymers.

Nanostructures in Polymer Surfaces Controlled by Mechanical Orientation

C. Fuentes, J. P. Fernández-Blázquez, A. del Campo

Max-Planck-Institut für Polymerforschung. Ackermannweg 10, 55128 Mainz, Germany

fuentes@mpip-mainz.mpg.de

We have recently shown that plasma-based roughening can be exploited as a low-cost method for producing useful nanopatterns.[1] Here we present the correlation between the mechanical pretreatment of the polymer film and the resulting plasma-etched surface topography in semycristalline polymers. PET, PE, PEO or PP samples with known thermal history are stretched under different experimental conditions (T, rate) have been prepared, analyzed and treated with oxygen plasma. The resulting topography was examined by SEM and AFM. Our results provide insight into the pattern formation mechanism and into the possibility of defining the pattern geometry and dimensions by the thermal and mechanical properties of the polymer sample.

E. Lozano

Departamento de Química Macromolecular, Instituto de Ciencia y Tecnología de Polímeros (CSIC)
lozano@ictp.csic.es

Introduction and objectives

Free radical polymerization of acryl-furanic compounds (Figure 1), Furfuryl acrylate (FA) and methacrylate (FM) leads to cross-linked polymeric networks, which can be employed to make biomaterials [1]. Moreover, the copolymerization of these compounds with hydrophilic comonomers such as vinylpyrrolidone and 2-hydroxyethyl methacrylate produces cross-linked hydrogels, which have shown to be useful as coating agents in bioactive compounds controlled delivery system [2]. In the case of these intricate polymerizing systems in which insoluble gels are obtained, the values of the parameters characterizing network structure (e.g cross-link density) are not easily obtained experimentally. However, they can be readily be theoretically estimated, for instance, by means of mathematical models using kinetic schemes [3-5] In this way, the aim of this work is focused in the estimation of average cross-link density ($\bar{\rho}$) of the networks formed in the bulk thermopolymerization of FM through two mathematical models (Tobita's model [3] and cross-linked model [3-5]). In turn, by means of values of $\bar{\rho}$ given for both models, the influence of polymerization temperature on the network formation is studied.

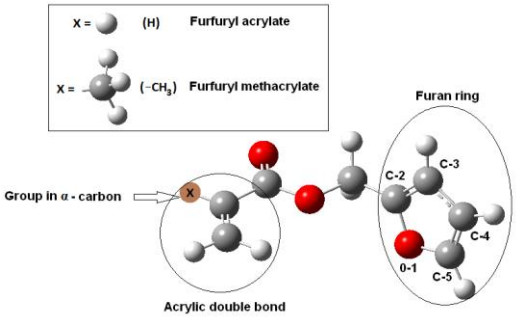

Figure 1: Molecular estructure of furfuryl acrylate (FA) and methacrylate (FM)

Simulation

For simulation of the experiments with cross-linked model, a numerical multi-step integration subroutine **ODE15S** [6] of non-linear ordinary differential equations system was used. The validity of values of kinetics constants involved in cross-linking process was corroborated by means of frontier orbital theory using Density Functional Theory [7]

Results and Discussion

In order to compute the values of $\bar{\rho}$ for both models, the values of kinetic constants involved in network cross-linking were obtained by means of Arrhenius's equations [5]. It was also possible to obtain the values of pseudo-kinetic rate constants by means of the Tobita's model. Also, the values of $\bar{\rho}$ in polymeric network at a given monomer conversion were calculated using the radical and pendant group concentrations into primary chains as estimated by cross-linked model (Fig. 2).

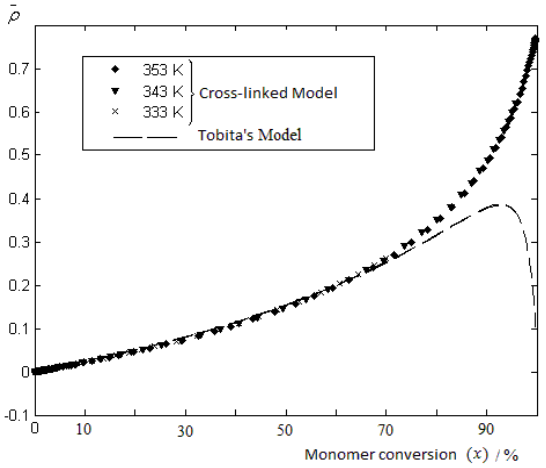

Figure 2: Evolution of average cross-link density of the network ($\bar{\rho}$) with monomer conversion at different temperatures.

As shown in Fig. 2, the results computed for both models are computationally equivalent until 70% of monomer conversion. This equivalence has also been proved for the photopolymerization of FM at low conversions and when low polymerization temperatures are employed [3]. The practical importance of this result is that, known the values of the pseudo-kinetics constants, is possible to simply predict the values of $\bar{\rho}$ by the Tobita's model, without solving complicated non-linear ordinary differential equations. On the other hand, polymerization temperature do not influence upon the values of average cross-link density in networks during all polymerization.

msanchez@inescop.es

Introduction

Nanoencapsulation presents a new option for the shoe industry as its application can transform traditionally used materials or products into smart ones capable of interacting with feet. For instance, they can improve quality of life by incorporating products for foot care such as properly dosed essential oils or other products. The nanoencapsulation of active substances to be incorporated in different footwear components in order to obtain an "active shoe" presents an opening up of a new way of innovation.
The *in situ* polymerization allows the formation of micro and nanocapsules containing a water-immiscible dispersed phase, with improved mechanical properties and thermal stability. The properties of the membrane depend not only on its chemical structure but also on all the synthesis conditions. In the case of melamine-formaldehyde nanocapsules, the polycondensation of the amino resin occurs in the continuous phase, and the phase separation is linked to the pH and the melamine-formaldehyde resin molar ratio.
In this study a series of melamine-formaldehyde (MF) nanocapsules containing essential oils with different polymer to oil ratio was prepared to be applied to footwear materials (lining, insoles, etc…) by an *in situ* polymerization (O/W) method. Their physicochemical properties have been characterized by different experimental techniques.

Materials and Methods

Synthesis of melamine-formaldehyde nanocapsules containing essential oil. First of all, a melamine-formaldehyde (MF) resin to be used as nanocapsules shell was prepared from the monomers, melamine and formaldehyde. After that, an O/W emulsion was prepared. The oil phase was composed of the active substance, and the aqueous phase was constituted of distilled water and sodium dodecyl sulfate (SDS) as surfactant. Next the above prepared prepolymer is added and the pH adjusted, which causes the coagulation of the polymer around the oil droplets. Subsequently, hardening of the polymeric membrane was attained by raising the temperature. Finally, it was allowed to cool down to room temperature and the pH was adjusted to basic.

Characterization of nanocapsules. Physicochemical properties of the synthesized nanocapsules containing the oil have been characterized by different experimental techniques. The average size distribution of the nanocapsules was determined using a particle size meter Coulter LS 230. The thermal decomposition behavior was studied by thermogravimetic analysis (TGA). Finally, the nanocapsules morphology was analyzed by scanning electron microscopy (SEM).

Results

Nanocapsules containing an essential oil showed a narrow particle size distribution in number with a medium particle size around 100 nm. The higher resin ratio the higher the nanocapsule size.
The thermogravimetric analysis (TGA), showed the thermal decomposition behavior of the microcapsules. Three main decomposition zones can be observed. The first one (around 150ºC) corresponding to the oil volatilization or decomposition. The second and third ones correspond to the resin decomposition. The first resin decomposition process is around 240ºC and the second between 300-450ºC. As the resin/oil ratio increases in the nanocapsule the oil decomposition temperature moves towards higher temperatures, possibly due to the wall shell growth, according to the previous particle size measurements. The area of the resin decomposition peaks changes as the resin/oil ratio increases may be due to the oil interaction with the resin.
Finally, the morphology of the nanocapsules containing essential oil was studied by Scanning Electronic Microscopy (SEM). There are several interesting changes in the nanocapsules morphology as the resin/oil ratio increases. The nanocapsules formation is observed only for resin/oil ratio over four, thus ensuring the encapsulation of the oil.

Conclusions

Regarding the nanocapsules synthesis containing oils, the relationship between the resin mass that forms the shell and the active substance contained in the core largely determines the efficiency of the nanoencapsulation process and the morphology of the nanocapsules and the particle size distribution thereof. Themogravimetry provides valuable information regarding the structure of the nanocapsules.

Stable dispersions of chemically functionalized carbon nanofibers in waterborne polyurethanes

Elena Orgilés-Calpena, Francisca Arán-Aís, Ana M. Torró-Palau, César Orgilés-Barceló

INESCOP. Innovation and Technology Centre.
Industrial Zone Campo Alto. 03600 Elda, Alicante (Spain).

eorgiles@inescop.es

Introduction

Carbon nanofibers (CNFs) are considered as ideal reinforcing fibers for polymer matrices in many technological applications due to their unique structure and properties: high aspect ratio, high Young's modulus, excellent mechanical strength and good thermal conductivity. They are excellent nanofillers in polyurethane matrices originating a new polymeric material, exhibiting the same chemical properties as organic polymers, whereas the rheological and thermal properties may be greatly improved. However, the incorporation of carbon nanofibers to waterborne polyurethanes implies a great difficulty because of their tendency to form aggregates, which sometimes prevents an efficient dispersion [1]. In this sense, it is necessary to insert functional groups on the surface of the nanofibers, either to induce a repulsive force between the particles or to improve their interaction with the polymer in aqueous phase, thus obtaining a stable dispersion and the subsequently sedimentation [2,3]. Therefore, to improve the dispersion of nanofibers in the waterborne polymer, they must undergo a pre-oxidation, thus increasing the number of surface functional groups with oxygen, such as C=O, COOH, OH, NH_2, etc.

Materials and Methods

From the primal polyurethane dispersion (WBPU), four adhesives were prepared with a different amount of carbon nanofibers (0.10, 0.25, 0.50 and 1 wt%). Previously, a chemical treatment based on acids was carried out and the nanofibers oxidation was produced in order to improve the compatibility between the polymer matrix and the nanofiller. Finally, stable mixtures of carbon naofibers in the polyurethane dispersion were achieved.

Results and Discussion

Although the addition of the carbon nanofibers does not affect the segmented WBPU structure monitored by DSC, the kinetics of crystallization of the soft segments is decelerated [4], indicating the formation of a reinforced structure, being more noticeable as the content of the carbon nanofiber increases. Regarding the rheological properties, the addition of the carbon nanofibers produces a noticeable increase in both elastic and viscous moduli of the WBPU, indicating again the existence of nanofiber-polyurethane interactions.

This increase is more pronounced as the content of the nanofiber increases [5], due to the existence of a great number of CNFs-polyurethane interactions.

Furthermore, DMA results confirm the existence of polyurethane–CNFs interactions and a more enhanced structure, in agreement with DSC and plate–plate rheometry results.

Conclusions

The obtained results indicate that chemical functionalization method enables the dispersion of the carbon nanofibers in the polyurethane matrix, contributing to the stability of the adhesive. The addition of the carbon nanofibers to the polyurethane dispersions influences in its rheological and viscoelastic properties, producing an increase in the moduli (storage and elastic), which indicates the existence of a more enhanced structure after the addition of these nanofibers. Additionally, an increase of crystallization time is observed, indicating also the formation of a more reinforced structure that difficult the interactions between polyurethane chains during the crystallization process.

Conformation and aggregation behavior of polymer-coated gold nanoparticles studied by dynamic light scattering experiments and Monte Carlo computer simulation

Ramón Pamies, José Ginés Hernández Cifre, and José García de la Torre

Departamento de Química Física, Facultad de Química, Universidad de Murcia, Spain

jgt@um.es

Introduction:

Gold nanoparticles (AuNPs) are known to be biocompatible and non-toxic materials and the modification of their surface has opened a wide range of uses in biomedicine such as cancer therapy or drug delivery. In biological or high-ionic-strength media, the stabilization of the colloidal nanoparticles is required since the screening of the electrostatic repulsion may result in aggregation. Physisorption of macromolecules is one of the strategies used to coat the surface of the AuNPs and thus flocculation is avoided. It has been proved that, generally, oppositely charged polyelectrolytes have a stronger tendency to form a core-shell complex with AuNPs than neutral polymers. In this work, we have performed Dynamic Light Scattering (DLS) experiments and Monte Carlo (MC) computer simulations to evaluate the behavior of hybrid nanoparticles with a gold core and a polymeric corona made with a positively charged polusaccharide, hydroxyethylcellulose (HEC).

Materials and Methods:

The charged HEC samples with 7 mol % (HEC(+)7) and 60 mol % (HEC(+)60) charges were prepared directly from HEC as it is described in [1]. The preparation of the hybrid nanoparticles is done just by mixing HEC(+) solutions with AuNPs solution.

The DLS experiments were conducted with the aid of an ALV/CGS-8F multidetector compact goniometer system, with eight off-fiber optical detection units, from ALV-GmbH, Langen, Germany. The beam from a Uniphase cylindrical 22 mW He−Ne laser, operating at a wavelength of 632.8 nm with vertically polarized light.

MC simulations were performed with the program MONTEHYDRO [2], which is freely available at http://leonardo.inf.um.es/macromol/ and implements the rigid-body treatment to calculate hydrodynamic properties. With this approach, the polymeric chains are treated as having instantaneous rigid conformations to calculate their overall hydrodynamic properties. Thus, a set of conformations of the model chain is generated randomly following certain statistical rules (i.e., a MC procedure), and then the conformational properties of each conformation are evaluated using the procedures applicable to rigid particles and the final results are taken just as sample averages. Therefore, a simple and convenient way to build the polymeric chain is the usage of beads as elements. Springs with a suitable potential energy have been employed to connect these beads, , in the so-called bead-and-spring model.

Results and Discussion:

Two different driving forces for adsorption have been evaluated: the electrostatic interaction between the positive charges on the polymers and the negatively charged gold surfaces and the affinity of the polymers for gold due to hydrophobic interactions. The comparison between the data obtained from curved and planar surfaces suggests a strong correlation between surface curvature and adlayer conformation in the formation of the hybrid polymer−gold nanoparticles. The influence of particle size on the amount of adsorbed polymer has been evaluated for the different polymers. The impact of the ionic strength on polymer adsorption has been explored, and the adsorbed polymer layer has been found to protect the gold nanoparticles from aggregation when salt is added to the solution. The addition of salt to a mixture of gold particles and a charged polymer can induce a thicker adsorbed layer at low salinity, and desorption was found at high levels of salt addition.

Regarding the simulations, in a previous work we used the bead-and-spring model to simulate the behavior of star polymers in equilibrium and under different kinds of flow. Based on this, we have designed the core-shell structures as star-shaped chains containing a big core and several arms consisting on linear chains which elements have a much smaller size than the central bead. Thus, two different kinds of elements can be found in the model: a big sphere which represents the hard core and several small beads forming the arms which simulate the polymeric shell. Therefore, these linear chains mimic the behavior of the polymers coating the metallic nanoparticle.

Conclusions.

Positively charged hydroxyethylcellulose derivatives have been found to be useful for the formation of hybrid polymeric−inorganic nanoparticles when solutions of these polymers are mixed with citrate-coated gold nanoparticles. The thickness of the adsorbed layer for these systems depends on the nature and concentration of the polymer and on the ionic strength of the solution. MC simulations of a bead-and-spring star shaped structure were found to mimic the behavior of core-shell nanoparticles in solution.

Chain Dimensions, Entanglement Features and Linear Rheology of Short Chain Branched Polyethylene Models: Simulations and Experiments

J.F. Vega, J. Ramos, J. Martínez-Salazar

Departamento de Física Macromolecular, Instituto de Estructura de la Materia, CSIC, Serrano 113 bis, 28006 Madrid, Spain

e-mail: jfvega@iem.cfmac.csic.es

A combined study including computer simulations, dilute solution experiments, and rheological properties is presented for molecular models of ethylene/1-hexene copolymers with different short chain branching content obtained from single-site catalyst polymerization.

For the computer simulations, a series of linear and branched C_{1000} polymer chains were equilibrated using advanced Monte Carlo moves,[1] and Molecular Dynamics trajectories were then calculated.[2] From these simulations the melt entanglement nanoscale features as the molecular weight between entanglements, M_e, and the entanglement equilibration relaxation time, τ_e, were directly obtained. The values of M_e and τ_e obtained from the simulations, together with the molecular weight distribution obtained from dilute solution experiments have been used within the reptation framework to explain the experimental melt linear viscoelastic properties (storage and loss moduli) of a set of model ethylene/1-hexene copolymers.[3,4]

The results can be summarized as follows: **(i)** the chain dimensions obtained from both the simulations and the experiments account for a molecular size contraction and a dilated tube (or increased M_e values) as the amount of short chain branches increases;[5] **(ii)** a slowing down in chain dynamics is obtained as the amount of short chain branches increases, characterized by increased τ_e values and a decrease of the Rouse segmental rate;[6] and **(iii)** the curves derived of the dynamic shear modulus using the simulated values of M_e and τ_e and the reptation theory nicely coincide with the experimental ones (see Figure 1 for the linear case).

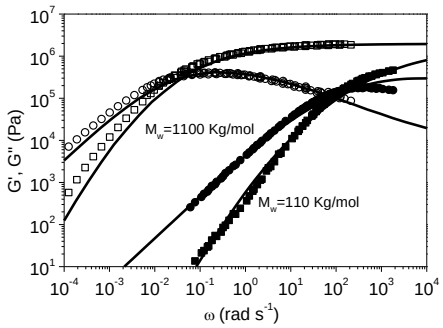

Figure 1. Comparison of calculated (lines) and experimental (symbols) dynamic moduli for two linear polyethylene samples of different molecular weight at 160 ºC. The simulated values of M_e and τ_e, together with the molecular weight distribution have been used to compute the dynamic moduli.

Motivation

Gel particles are promising delivery vectors that are formed by local phase separation of oppositely charged species. They can be used to carry drugs and other molecules of biological interest. Viral infection and synthetic vectors are today the most used tools for gene delivery.

The species used for gel particle formation are usually a polyelectrolyte droplet that is complexed by an oppositely charged surfactant. The success of the preparation of such particles by a mixture of a polyelectrolyte and a surfactant is attributed to the fast complexation rate of the droplet compared to the dissolution rate of the polymer droplet.

The motivation of this study is to build stable gel particles by using two (or more) oppositely charged polyelectrolytes. JR400, a cationic cellulose based polymer, is here combined with polyacrylates of different molecular weights.

Materials

Polyelectrolytes used are polyacrylic acid 450KDa (PAA 450), polyacrylic acid 2KDa (PAA 2) and JR400, a cellulose derivative polycation with 500KDa. A nonionic polymer, Polyethylene oxide, with 1000KDa was also tested.

Methods

Particles were prepared by dropwise addition method, where drops composed of 2-7wt% of aqueous solution of JR400 were added to 2mL of oppositely charged polymer solutions.

The particles were kept in the polyelectrolyte solution until they reached maximum swelling. This takes 30 minutes for PAA 2 solutions, 4 hours for PAA 450 and 1 hour for PAA 2/PAA 450 mixed solution.

Rheological measurements were carried out in a Stress Tech Rheometer with automatic gap in a bob and cup measurement system.

Achievements

Polyelectrolyte-based particles can be formed at sufficiently high polymer concentrations. Temperature plays an important effect on particle formation but the major contribution comes from the balance between droplet dissolution rate and complexation rate. In agreement to this, the particles are more stable by using two polyelectrolytes with different molecular weights as complexing agents.

Transparent Flexible Electrodes using Carbon Nanotubes

Jordi Figueras, Jordi Pérez-Puigdemont, Oriol López, Angel Fabregas, Aida Abiad-Monge, Nuria Ferrer-Anglada

Applied Physics Department, Universitat Politècnica de Catalunya, Barcelona, Spain

nuria@fa.upc.edu

Abstract: Thin films of conductive, transparent and flexible structured single walled carbon nanotubes (SWCNTs) network can be used for electronic devices, sensors and solar cells [1]. We prepared a thin SWCNT network on transparent and flexible substrate (PC) with different SWCNT densities using a simple spray method [2]. We measured the electric impedance at different frequencies Z(f) by two different techniques: 1) two probes contact method, in the frequency range from 40 Hz to 110 MHz, and 2) a Corbino (coaxial) geometry, in the range from 10MHz to 20GHz [3]. We measured the optical absorption and electrical conductivity in order to optimize the conditions for obtaining optimum performance, films with both high electrical conductivity and transparency. **Figure 1** shows the transparency (%Transmittance at 550nm) versus the resistance per square, R□. We observe a square resistance from 8,5 to 2 kOhm for samples showing 85% to 65% optical transmittance respectively.

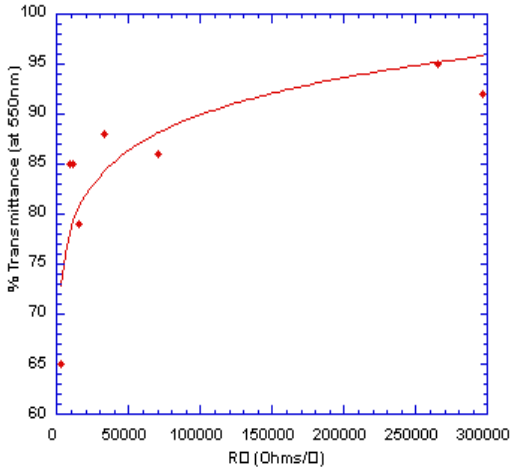

Figure 1. Optical transmittance (at 550 nm) versus sheet resistance R□ of SWCNTs network with different carbon nanotubes densities

Moreover for some applications we need flexibility and not transparency. By the same method we obtained random network films of single-wall carbon nanotubes (SWCNTs) on a flexible silicone substrate by spraying an aqueous SDS carbon nantotubes suspension. At high SWCNT density, the samples are quite conductive and flexible, the square resistance is as low as 200Ω, and it can be bended and stretched. We stretched uniaxialy the samples at different elongations up to 20 percent the original length and we measure the electrical conductivity. The **electrical resistance** increases slightly with the stretching, recovering the initial value for small elongations, up to 10%. We realised **Raman spectroscopy** on the same stretched and non stretched samples, **Figures 2, 3**. We could observe a shift on the

RBM mode, the G line is practically not changed, indicative that we are not introducing defects when stretching [4], the tubes are elongated and maybe deformed on the silicone substrate but not damaged or broken. Polarized Raman spectroscopy could be indicative of a partial alignment of single-wall carbon nanotubes on the elongated samples.

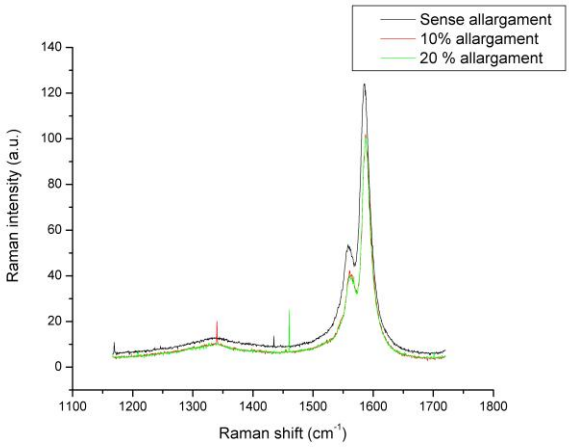

Figure 2. The Raman G line spectra from unstretched and stretched samples is nearly not changed. Laser excitation is 514,5nm, non polarized.

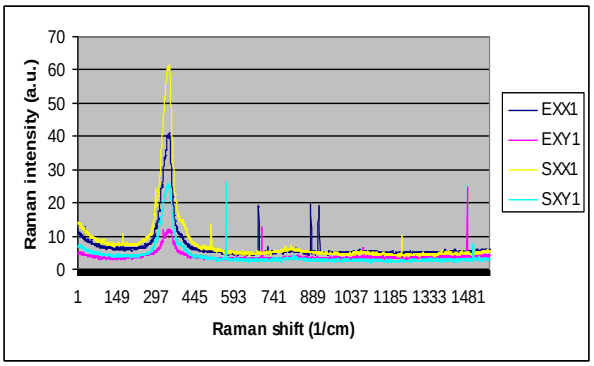

Figure 3. Polarized Raman RBM (radial breathing mode) spectra on the unstretched SXX1, SXY1 and stretched EXX1, EXY1 samples.

Mesoporous CuO as New Catalyst for Advanced Energetic Composites of Polyurethane Matrix

José Luis de la Fuente

Instituto Nacional de Técnica Aeroespacial "Esteban Terradas", INTA.
Ctra. de Ajalvir, Km 4. 28850 Torrejón de Ardoz. Madrid. Spain.

e-mail: fuentegj@inta.es

In the past few years the development of organicinorganic hybrids and nanocomposites has attracted much interest because of the superior engineering properties compared to neat polymers [1]. The polymer composite materials have been regarded as a new generation of high performance materials, combining the advantages of inorganic moiety and those of the organic polymer matrix. As a clear example, transition metal oxides (TMOs) based materials are of great interest in many areas of modern science and technology, and in particular in (photo)catalysis, sensors, optics, separation, and smart coatings [2]. In addition, nanoporous materials are now widely applied in many technological fields due to their defined pore structure and size distribution. In most of applications, the pore structure, especially the pore size, size distribution and pore volume have become the crucial factors determining the applicability of these materials. Recently there has been an intense interest in preparing mesoporous TMOs. Several mesoporous TMOs have been prepared with large specific surface area due to their possible uses in the areas mentioned previously, being mesoporous copper oxides of particular interest. Thus for example, CuO has been studied as a unique and attractive monoxide material, due to its both fundamental investigations and practical applications. CuO is a well-known component of catalysts, and is widely employed commercially for the direct decomposition of N2O to N2, CO oxidation, and the complete combustion of hydrocarbons. However, an
application much less known is as combustion catalyst in highly energetic materials of polymeric matrix, such as composite solid propellants.

Composite propellants are highly particle-filled elastomers, which are made by embedding a finely divided solid oxidizing agent, generally ammonium perchlorate (AP) in a plastic, resinous, or elastomeric matrix. The matrix material usually provides the fuel for the combustion reaction, although solid reducing agents are frequently included in the compositions, such as aluminium. Composite solid propellants based on hydroxyl-terminated polybutadiene (HTPB) have become the workhorse propellants in the present-day aerospace solid propulsion technology world-wide. The polyurethane network obtained by curing HTPB with a suitable diisocyanate provides a matrix for inorganic oxidizer and metallic fuel which are dispersed in the propellant grain. Others ingredients are plasticizers, bonding agents, stabilizers and catalysts. The main objective of this study is to broaden the knowledge of the use of mesoporous fillers as combustion catalysts. Thus, the effect of mesoporous copper (II) oxide particles on the burning rate and on the thermal and combustion properties of composite solid propellants based on HTPB has been deeply studied. To do that, mesoporous CuO particles were incorporated in AP/Aluminium/HTPB-based composite propellants by using the slurry cast technique.

Mesoporous CuO particles with high surface area are expected to possess better catalytic activity than those of micro- and nano-meter sized with low surface area. This is due to the catalytic reactions taking place on the surface of catalysts, so the reaction rates are greatly related to the surface area of the catalyst. Therefore, it is worthwhile to use mesoporous CuO with a relatively large surface area in this application. The total surface areas of the different CuO samples selected in the present study were evaluated using the Brunauer-Emmett-Teller (BET) method, and the found values are collected in **Table 1**. The calculated BET surface area for the mesoporous CuO, denominated as CuO-3, was 32 m2/g, being logically much higher than the others CuO samples; fifteen and five times over the BET surface areas of CuO-1 (micrometric particles) and CuO-2 (nanometric particles), respectively. Besides, the adsorption pore-diameter distribution plot exhibited a broad maximum around 3 nm for the CuO-3 sample. The morphology and particle size of the raw powders were also determined by scanning and transmission electron microscopy and laser diffraction, respectively; and the crystallographic properties were analyzed by Xray diffraction. The thermal and combustion characteristics of these highly energetic composite materials with differently CuO powders, in terms of steady burning rates, showed how better is the performance of mesoporous CuO compared to non-porous and traditional CuO propellants. The thermal characterization of these advanced composites was also carried out, by differential scanning calorimetry and thermogravimetry analysis, demonstrating that the incorporation of mesoporous CuO particles in the formulations improves their combustion behaviours, shifting the temperature decomposition peak toward lower temperature, and decreasing the activation energy.

Table 1. Physical characteristics of the CuO used in the preparation of energetic composites based on HTPB.

CuO sample	Particle size (nm)	BET (m^2/g)
CuO-1	11250	2.1
CuO-2	42	5.9
CuO-3	44300	32

Evaluation of the Phase Inversion in HIPS/Silver Nanoparticles Nanocomposites through UV-Vis spectrophotometry

Graciela Morales and Florentino Soriano

Centro de Investigación en Química Aplicada

gmorales@ciqa.mx

Introduction

UV-Vis spectrophotometry and transmission electron microscopy (TEM) are the most important techniques to characterize metallic nanoparticles as they present free conduction electrons which in the presence of an electromagnetic field (i.e. UV-Vis) oscillate collectively at a specific wavelength[1]. This optical phenomenon, known as surface resonance Plasmon (SRP), depends on the size, concentration, geometry[2], distance between nanoparticles and the refraction index (*n*) of the surrounded media where some changes in the substrate color can take place[3].

On the other hand, during the polymerization of styrene in the presence of a rubber to obtain high impact polystyrene, (HIPS) several events take place: i) initially the reaction medium consists of a homogeneous solution of rubber dissolved in styrene (St), ii) phase separation and as the PS increases, iii) a co-continuous phase is formed followed by iv) the phase inversion (PI) phenomenon where the morphology of the rubber phase is established[4]. The generation of PS and graft copolymer (PS-*g*-PB) provokes these changes and modifies the *n* values that reaches a maximum in the co-continue stage due to the periodical arrangement in the system's morphology.

This work deals with the evaluation of the PI phenomenon in HIPS/silver nanoparticles (AgNP´s) nanocomposites through the evolution of SRP as a function of conversion by UV-Vis spectrophotometry and TEM.

Materials and Methods

For the synthesis of HIPS/AgNP´s nanocomposites: St monomer, benzoyl peroxide (Aldrich Co.), Styrene-Butadiene block copolymer (Dynasol Elastómeros), and spherical silver nanoparticles (4-30 nm) (Servicios Industriales Peñoles) were added in a steel reactor with anchor-turbine stirrer at 40 rpm and 90 °C. Conversion was evaluated gravimetrically. The SRP was carried out using a Shimadzu UV-2401 (λ=200-700nm) spectrophotometer. PI phenomenon was corroborated by TITAN transmission electron microscope.

Results and Discussion

Phase inversion can be estimated from the values of SRP wavelength (λ) as a function of X (Fig. 1) where a sudden decrease in the λ, after reaching a maximum value, indicates that phase inversion (PI) occurs. This behavior can be interpreted as follows: the first stage of the curve relates to a reaction mixture presenting a rubber rich continuous phase with an slightly increase in the amount of graft copolymer, b) λ reaches a maximum and then decreases; during this period a co-continuous phase is present and the increase of the λ can be attributed to the increase in the *n*. At the end of this period the phase inversion occurs and the λ values decrease due to a decrease in the *n* values. The increase in λ at X>0.33can be attributed to the increase of PS volume and to new grafting reactions that take place at the occlusions into the rubber particles. Then, the reaction mixture presents a rich PS continuous phase and *n* and λvalues increase. The changes in color during the different reaction steps, as a function of X are shown in Fig.1, where color shifts from strong blue to strong red.

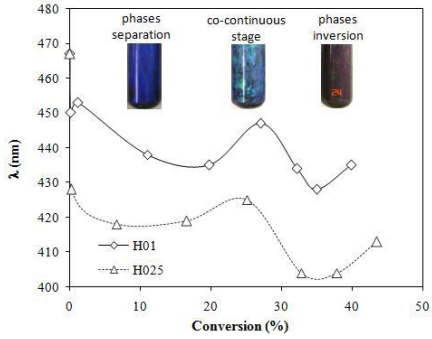

Figure 1. Evolution of λ as a function of X for HIPS with 0.1 (H01) and 0.025 (H025) wt-% of AgNP´s.

TEM micrographs corresponding to X=0.1, 0.28 and 0.32 are shown in Fig. 2 where the PI interval was corroborated. At X=0.1(rubber rich region) micelles and extended structures were observed (phase separation), followed by co-continuous stage (X=0.28) in the form of lamellas characteristic of the rubber copolymer used [6]. At X=0.32 the PI phenomenon was reached.

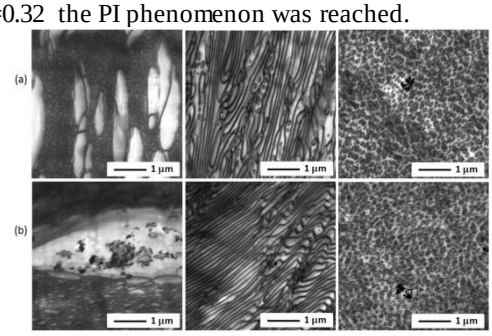

Figure 2. TEM micrographs for a) H025 and b)H01, both at X=0.1, 0.28 and 0.32.

Conclusions

The evaluation of PI through of UV-Vis spectrophotometry was successful as it is closed to that evaluated by TEM.

Biopolymers / Clays Nano-Biocomposites: Impact of Clay Organo-Modification on the Morphology and Properties of these Hybrid Materials

E. Pollet, L. Avérous

Université de Strasbourg, France

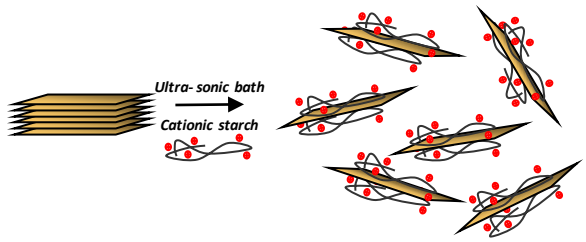
eric.pollet@unistra.fr

Introduction: Nano-biocomposites are a combination of biodegradable polymer matrices and nanosized fillers, such as nanoclays. Interestingly, relatively small amounts (less than 5 wt%) of these nanoclays are required to obtain the best properties. To achieve such improvement, the filler has to be homogeneously dispersed into the matrix and for that nanoclays are often organo-modified. Thus, numerous parameters such as the type of clay, clay modifier, plasticizer, process… may influence the morphology and thus the materials final properties [1-2].

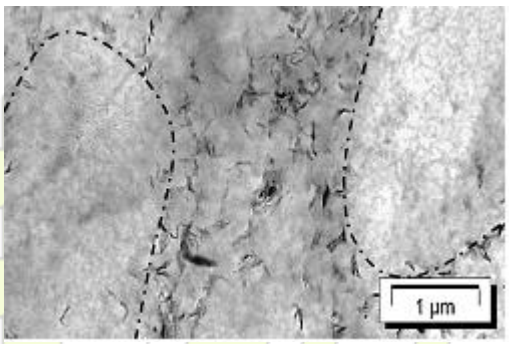
This study focus on the "formulation-processing-morphology-properties" relationships of nano-biocomposites based on plasticized starch and polyhydroxyalkanoates (PHB & PHBV) matrices filled with different nanoclays (montmorillonite, sepiolite).

Results and discussion:

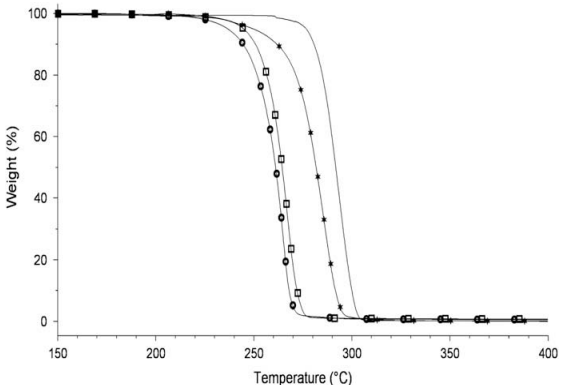
First, the impact of the clay/matrix affinity is highlighted through the difference in clay dispersion quality achieved in plasticized starch with different nanoclays. Indeed, our results show the great benefits of montmorillonite organo-modification performed with cationic starch, resulting in nano-biocomposites with exfoliated morphology and thus greatly improved properties[3].



Besides, the morphologies obtained with montmorillonite and sepiolite clays evidence a possible negative impact of glycerol as starch plasticizer that may induce phase separation phenomena, heterogeneous clay dispersion [4-5] and thus poor barrier properties [6].



In addition, the influence of clay organo-modification on polyhydroxyalkanoates based nano-biocomposites is detailed in terms of thermal stability of the obtained materials. The results highlight the dramatic influence of some ammonium salts, used as clay organo-modifiers, on the PHB and PHBV thermal stability.



Indeed, our results evidenced that the ammonium salts degradation products catalyze the thermal degradation of polyhydroxyalkanoates [7]. As a consequence, clay exfoliation is difficult to reach and thus the obtained nanocomposites do not present significantly improved properties [8].

Conclusions:

The various biopolymer/clay systems presented here give a broad overview of the "products-process-morphology" relationships for these nano-biocomposites. The great impact of clay organo-modification and plasticizer addition on the mechanical, thermal and barrier properties of such hybrid materials is more particularly evidenced.

Abstract: This study describes the development of poly(lactide) (PLA) microspheres by an emulsion method for braquitherapy. The effects of both PLA and PDLA polymers on holmium encapsulation efficacy were evaluated. Microspheres containing holmium were prepared and characterized by thermal analysis, X-Ray diffraction, Scanning Electron Microscopy, FTIR spectroscopy, and zeta potential measurements. The experimental data showed that both polymers formed microspheres, however the PLLA1 of small viscosity inherent formed more microspheres with size distribution smaller when comparable with PLLA2 and PDLA.

Introduction

Three different types of material substrates have been investigated, i.e., biodegradable polymer-based, glass-based, and resin-based microspheres. Nowadays there is a project concerning the labeling of these 3 materials with ^{166}Ho being developed at IPEN-CNEN/SP and coordinated by the Radiopharmacy Directory. The nuclide ^{166}Ho($t_{1/2}$=26.8h) is a beta particle emitter (E_{max}=1.84 MeV), with suitable properties for radiotherapy and it can be produced with the relatively low neutron flux from theBrazilian Nuclear Reactor IEA-R1m. As an initial experience we used resin-based microspheres, a cation exchange resin labeled with ^{166}Ho, which showed the essential characteristics for liver cancer therapy. Preliminary results concerning the preparation of glass-based microspheres labeled with ^{165}Ho showed that 5% of Ho_2O_3 was incorporated in an aluminosilicate glass, through the process of spheronization by flame, which produced spherical microspheres with 20-40 µm particle size. The preparation of biodegradable material, polymer-based microspheres, is in its initial stage and the objective is to prepare and label different polymer-based microspheres with ^{165}Ho. These combined efforts have been done to offer a radiotherapeutic product for the Brazilian nuclear medicine community at reasonable cost and also to offer a viable possibility of treatment for patients affected by liver malignances [1]. In the present study, we report the effects on the PDLA e PLLA polymers after the Ho encapsulation efficacy and the characterization of the materials by different techniques: SEM, Thermal analyses, EDX, zeta potential, porosity and infrared spectroscopy (IR) [2].

Experimental

The PLLA1 (M_w 101,700), PLLA2 (M_w 152,000), PDLA polymers, and polyvinyl alcohol (PVA, MW = 31 KDa, hydrolyzation degree = 88%) were provided by Sigma Aldrich. Holmium acetylacetonatetrihydrate (HoAcAc) was prepared as described previously [2].

The microspheres with HoAcAc were prepared by solvent evaporation as described previously (Fig.1) [2]. The HoAcAc and the polymer were dissolved in chloroform. The resulting homogeneous solution was added to an aqueous solution of PVA. The mixture was stirred at500rpm, and the formed microspheres were filtered through sieves.

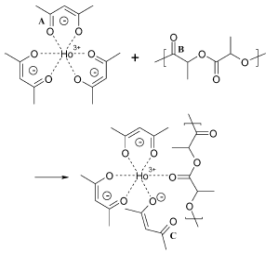

Fig. 1.Reaction of the formation of holmium microspheres.

Results and discussions

Microspheres were prepared by solvent evaporation and sieved to retain particles in a suitable size range.

Fig. 2 shows the SEM micrographs of microspheres without holmium in different polymers. As it can be seen, they are spherical with a relatively small index of polydispersity according to the zeta potential results.

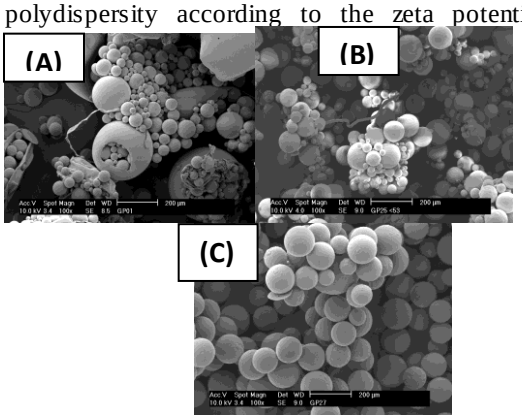

Fig. 2.SEM of PDLA (A) PLLA1 (B) and PLLA2 (C) microsphere without holmium.

The results showed that there was significant difference between the FTIR spectra of the microsphere-Ho when compared to the spectra of individual components.

Thermal analysis curves showed that both PLLA samples have the characteristic melting points of the crystalline polymers, indicating that the crystallinity was maintained. EDX analysis showed the concentration of Ho in the material.

Conclusion

This study showed that microspheres were formed with and without holmium, and that the microspheres containing holmium present promising results for braquitherapy application.

hazel@biomat.uh.cu

Introduction

Cryogels are polymeric macroporous materials obtained by cryotropic gelation of monomers or polymer precursors in moderately frozen state (liquid microphase). The gel formation occurs in liquid microphase, where the concentration of monomer and other dissolved substances is higher. Crystals frozen solvent act as porogen during gel formation giving rise after defrost system to a three-dimensional maze interconnected macropores allowing diffusion without impairments of solutes of practically any size throughout the volume of the gel [1].

Poly(*N*-isopropylacrylamide) crosslinked is a typical temperature-sensitive gel, which exhibits a volume phase transition at about 34°C. Below this temperature, p-NIPA gels are swollen, hydrated, and hydrophilic, temperatures above the gels shrink.

Sensitivity temperature p-NIPA gels have attracted much attention for their usefulness in drug delivery systems sensitive to temperature, separation techniques in biotechnology, agricultural processing and as sensors. These applications require a quick response of the hydrogel against external stimuli. To increase the response speed of the gels p-NIPA, various techniques have been proposed [2]. In the case of "smart materials" such as p-NIPA, the speed of response to temperature change increases significantly when prepared as macroporous gels compared to gels obtained by in bulk polymerization [3].

Synthesis of the p-NIPA cryogels

Poly(*N*-isopropylacrylamide) (p-NIPA) cryogels were synthesized by free radical polymerization of NIPA under freezing conditions. Polymerization reaction was carried out by dissolving the monomer NIPA in water. N,N'-methylenebisacrylamide (NNMBAM) was added to the solution and N_2 gas was bubbled for 15 min. For the initiation of the reaction *N*,*N*,*N'*,*N'*-tetrametiletilendiamina (TEMED) was added and the solution was placed in an ice bath for 5 min. Ammonium persulfate (APS) was added to the reaction mixture and stirring was maintained for 1 min. 2 mL aliquots of the reaction mixture was poured into plastic tubes.

The tubes containing the reaction mixture were placed in to cryostat for 1 hour at - 20 °C and after 16 hours at - 12 °C. The cryogels obtained were freeze-dried.

The preformed cryogels were loaded with previously obtained and characterized chitosan/bemiparin nanoparticles in suspension at 0%, 5% and 15%.

The lyophilized samples were cut into disks and weighed before and after loading with nanoparticles.

Swelling study of p-NIPA cryogels

Swelling kinetics was performed in PBS buffer (pH= 7.4) at 15 °C and 37 °C. Three replicates of each sample (0%, 5%, 10%) were made.

Results and Discussion

Cryogels showed thermoresponsive swelling behavior at 15 ºC, below the lower critical solution temperature (LCST) of p-NIPA and de-swelling at 37 ºC, above its LCST.

Similar behavior was obtained for cryogels charged at 5% and 15% with nanoparticles.

Cryogels of p-NIPA have a highly porous structure. As shown in Figure 1.

Nanoparticles loading of cryogels is evidence by SEM and ATR analysis.

ATR spectrum of cryogels loaded with nanoparticles showed a band corresponding to stretching vibration of S=O bond of bemiparin at 1235 cm^{-1}.

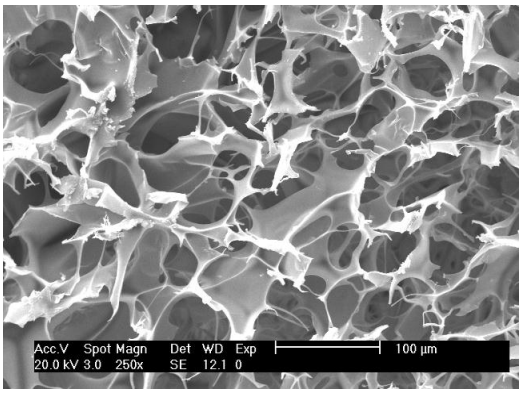

Figure 1 SEM photography of p-NIPA cryogel

Conclusions

The p-NIPA cryogels were successfully synthesized. They have a highly porous morphology and were able to incorporate chitosan/bemiparin nanoparticles. Swelling kinetics of cryogels of p-NIPA was studied at two temperatures (above and below the LCST), obtaining an expected behavior for this type of system temperature dependent.

Biologically Inspired Polymer Scaffold Development for Artificial Skin

Mohana Marimuthu[1], Jeongho An[2], and Sanghyo Kim[1]

[1]College of Bionanotechnology, Kyungwon University, Seongnam-si, Gyeonggi-do, 461-701, SOUTH KOREA, [2]Department of Polymer Science & Engineering, SungKyunKwan University, Suwon, Gyeonggi-do, 440-146, SOUTH KOREA

samkim@kyungwon.ac.kr

By utilizing polymeric materials integrated microfluidic technology, we have developed a novel porous microfiber (MF) scaffold embedded with Poly(D,L-lactic-*co*-glycolic acid)-Glucosamine (PLGA-GlcN) microparticles (MPs) to minimize post implant inflammatory effect spontaneously and to produce controlled protein release simultaneously. Previously, ketoprofen as non-steroidal anti-inflammatory drug (NSAID) delivery system was studied based on the electrospunpolycaprolactone based fiber scaffold. A microfluidic apparatus has been developed by Lee *et al.* that creates a continuous process for the production of protein loaded MF by employing the "on the fly" phase inversion processes. Present method differs from that of Lee group in bringing the microfluidic technology for porous fiberfabrication by altered dual mechanisms: precipitation by evaporation and immersion precipitation, and in the development of new anti-inflammatory drug based on naturally occurring GlcN, an amino monosaccharide evinced as natural COX-2 inhibitor , and their encapsulation into MF scaffold in order to prevent the adverse effects caused by NSAIDs.

Chemical grafting of the PLGA-g-GlcN was prepared with EDC system. Briefly, the GlcN solution was mixed to the PLGA/DMAP and EDC solution at room temperature. After 3 h, the mixed solution was poured into excess of acetone to produce precipitates, and were dissolved in PBS and dialyzed for two days to remove the ungraftedGlcN. Later, the sample lyophilized to dryness and stored. PLGA GlcNMPs were made using W/O/W double emulsion technique. Amphiphilictriblock copolymer, poly (p-dioxanone-co- caprolactone)-block-poly (ethylene oxide)-block-poly(p-dioxanone-co-caprolactone)(PPDO-co-PCL-b-PEG-b-PPDO -co-PCL) MF loaded with MPs with/without fibronectin werefabricated using a modified microfluidic device reported previously by our group. Microfluidic system differs from the established method in such a way that, inner diameter of the core inlet micropipette (200µm and 50 µm diameter at outer and at pulled end, respectively) was twice larger than outlet micropipette (100 µm at both ends). The core solution (10% PPDO-co- PCL -b-PEG- b-PPDO- co -PCL copolymer in CH2Cl2) and sheath solution (DI water with or without PLGA-GlcN MPs) were injected through the micropipette inlet and 12-guage needle inlet using infusion pumps and their flow rate were controlled at 10 µl/min and 100ml/hr respectively. The extruded porous fibers were collected in precleanedpetridish (Figure 1).

The morphology of all 3 samples obtained from FE-SEM images. Cell viability of all scaffolds were evaluated using cell proliferation reagent WST-1 kit (Figure 2). Cytocompatability for MPs containing MF are reasonably higher than that of MPs and MF alone. This may be due to synergistic activity of higher surface roughness for both MF and MPs. These results support and confirm that the MPs loaded microfibers could be potentially used as a candidate for drug delivery and tissue regeneration applications with minimized post-implant inflammatory response due to PLGA-GlcN.

Introduction: In this study, we propose a sensor architecture for the preparation of tyrosinase-based biosensors using the non-manual electrochemically controlled integration of tyrosinase within Os-complex functionalized electrodeposition paints. An Os complex functionalized cathodic electrodeposition polymer was used to entrap tyrosinase in a simple, controlled and reproducible way on a platinum electrode surface. A modified bi-layer architecture of the sensor was designed to reduce ascorbic acid interferences by entrapping ascorbate oxidase within a second outer polymer layer. Polymer thickness, enzyme-polymer volume ratio, applied potential, and sensor stability were optimized aiming on the design of sensitive and selective biosensors for catechol and phenol determination.

Materials and Methods: Tyrosinase (EC 1.14.18.1, lyophilized power, _1000 unitsmg_1 solid, from mushroom), ascorbate oxidase (AscOx, EC 1.10.3.3, lyophilized power, 1000–3000 unitsmg_1 protein, from Cucurbita sp.) were obtained from Sigma (Deisenhofen, Germany). Constant potential amperometry, differential pulse voltammetry (DPV) and cyclic voltammetry (CV) were performed using an Autolab PGSTAT12 potentiostat (Eco Chemie, Utrecht, The Netherlands) controlled by the GPES 4.7 software (Metrohm, Filderstadt, Germany) in a three-electrode configuration with a Ag=AgCl (3M KCl) reference electrode, a Pt-wire counter electrode and a Pt disk (1mm) working electrode.

The cathodic electrodeposition polymer (EDP) was synthesized following a strategy reported previously [1, 2]. In a miniaturized electrochemical cell the cathodic paint was precipitated on the electrode surface using a potentiostatic pulse sequence of -1200mV for 0.8 s and 0mV for 5 s. The pulse sequence was continuously applied up to 80 times.

Results and Discussions: An amperometric biosensor for the detection of phenolic compounds was developed based on the immobilization of tyrosinase within an Os-complex functionalized electrodeposition polymer. Integration of tyrosinase within the redox polymer assures efficient catechol recycling between the enzyme and the polymer bound redox sites. The non-manual immobilization procedure improves the reproducibility of fabrication process, greatly reduces the desorption of the enzyme from the immobilization layer, and, most importantly prevents fast inactivation of the enzyme by its substrate due to fast redox cycling.

A two-layer sensor architecture was developed involving ascorbic acid oxidase entrapped within an electrodeposition polymer in a second layer on top of the redox polymer=tyrosinase layer. Using this sensor architecture it was possible to eliminate the current interference arising from direct ascorbate oxidation up to a concentration of 630 mM ascorbic acid. The effects of the polymer thickness, the enzyme= polymer ratio, and the applied potential were evaluated with respect to optimal sensor properties. The sensitivity of the optimized sensors for catechol was 6.1 nA mM_1 with a detection limit of 10 nM, and for phenol 0.15 nA mM_1 with a detection limit of 100 nM [3].

Conclusion: The electrochemically induced deposition of an Osmium-complex modified electrodeposition polymer under simultaneous entrapment of tyrosinase is a straight forward way for the non-manual fabrication of catechol and phenol sensors. The developed sensor architecture can be optimized by adjusting the volume ratio of the enzyme and polymer stock solutions. Moreover, the polymer film thickness can be modulated by changing the number of potential deposition pulses.
The sensor architecture can be further extended to additional layers by a sequence of pH-induced polymer precipitation steps. The successful formation of an anti-interference layer containing ascorbate oxidase could be demonstrated. Fast substrate recycling within the polymer layer does not only lead to high sensitivity but obviously contributes to the preservation of the tyrosinase activity and hence to an improved longterm stability. Future work will be directed to the determination of phenolic compounds in real samples.

Introduction: Currently there is a high interest in the study of synthetic biodegradable polymers for use as biocompatible scaffolds in different areas of tissue engineering and regenerative medicine. Poly(epsilon-caprolactone) (PCL) and poly(diisopropilfumarato) (PDIPF) have proven to be good substrates for adhesion, growth and differentiation of two osteoblastic cell lines, mouse calvaria derived MC3T3E1 and rat osteosarcoma UMR106, suggesting that these polymers can be useful in bone tissue regeneration. A blend material with better mechanical properties, intermediate degradation rate between the two homopolymers and demostrated biocompatibility was prepared and compatibilized by high intensity ultrasound starting from PCL and PDIPF(1). The aim of this study was to characterize and to evaluate the activity of MC3T3E1 cells compared to porous and non porous matrices of PCL/PFIP compatibilized.

Materials and Methods: The compatibilized sample was obtained according to previously described method (1). Non-porous films were obtained by casting of 4%w/v solutions on Petri dishes (5.5 cm diameter). Solvent was evaporate at ambient conditions in a fume hood and finally dried under vacuum until constant weight. Porous films were obtaining by electrospraying (flow rate = 1.5 ml / h, applied voltage = 0.7 kV / cm) and collected on glass slides (2.6 cm x 1.8 cm). The morphology of both kind of films was evaluated by scanning electron microscopy (SEM) and optical microscopy (OM). The hydrophobicity of films was determined by contact angle measurement. Adhesion and proliferation test: MC3T3E1 cells cultured on the films for 1 or 24 h, washed with PBS, fixed with methanol and stained with Giemsa. The number of cells was evaluated by counting the cells in 10 fields/films using an inverted microscope. Alkaline phosphatase activity (ALP), a markers of osteoblastic phenotype associated with bone-forming capacity was evaluated as previously reported (2). The control experiments were performed on plastic petri dishes for cell culture. The results are expressed as mean ± SEM obtained from experiments. Differences between groups were evaluated by a linear model with Tukey post-hoc using GraphPad in Stat version 3.00. A p value <0.05 was considered significant for all statistical analysis.

Results and Discussion: SEM images (Fig. 1 A,B) shows the morphology of the membranes obtained by electrospraying consist of a highly porous structure with interconnected pores, formed by polymer droplets of a size 6.7 µm ± 0.1 µm. In contrast, the films obtained by casting display a smooth surface, only few pores can be observed.

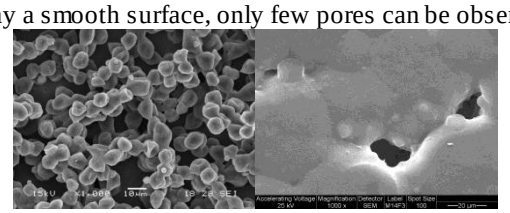

Figure 1: SEM micrographs of PCL/PDIPF matrices obtained by electrospraying (left), and solvent casting (right).

Biocompatibility studies showed that both adhesion and cell proliferation as well as ALP increased significantly in cells cultured on the porous matrix with respect to non-porous scaffold ones (Fig.2).

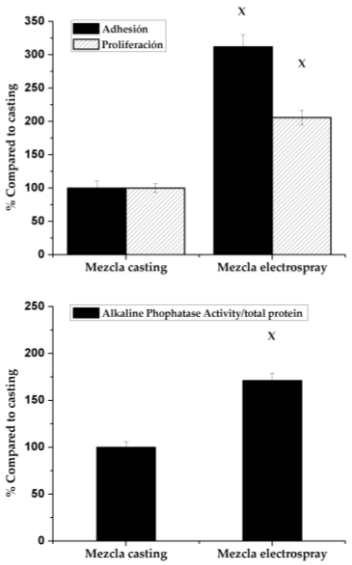

Figure 2: Cell adhesion and proliferation (upper graph) and Alkaline phosphatase specific activity (lower graph).

Conclusions: Matrices obtained by deposition of droplets by the method of electrospraying allow us to obtain polymeric matrices with structures of interest in the field of bone tissue engineering.

Reducing Fibrillation Tendency of Polyvinyl Alcohol Fiber by Incorporating Cellulose Nanowhiskers

Ahmed Jalal Uddin, Jun Araki, YasuoGotoh

Introduction: Polyvinyl alcohol (PVA) has a broadrange of industrial and technical applications, especiallyin fiber-reinforced concrete. High strength PVA fiberreinforces the strength, toughness and crack resistanceof concrete due to its high strength, high modulus andgood adhesion to the matrix but it suffers in poorbending and compressive strength [1]. Moreover, highlyoriented PVA fiber fibrillates when subjected toabrasion or agitation due to its high orientation and lackof lateral cohesion between fibrils.

With a view to reducing the fibrillation behaviour offibres, several methods have been attempted in order toenhance the lateral interactions of molecular chains viacross-linkers [2], but they have not been shown toreduce the fibrillation tendency of fibres to the desiredlevels. In the present work, we explored a newtechnique to reduce the fibrillation properties of PVAfibres by inserting cellulose nanowhiskers (CWs) in theinter-fibrillar regions in a highly oriented form. Due toabundant surface hydroxyl groups, highly oriented CWscan be considered to create strong hydrogen bondingwith the surrounded PVA microfibrils and reinforceagainst fibrillation. Since CWs exhibit very highmechanical properties along their longitudinal axis,highly oriented CWs interlinked with PVA fibrils areexpected to contribute greatly to enhance themechanical properties of PVA fibres.

Materials and Methods: The CWs suspension wasobtained by hydrolysis of cotton powder by 65%sulfuric acid at 70°C for 10 min under vigorous stirringfollowed by washing with distilled water using acombination of centrifugation and dialysis. The stablecolloidal suspension of prepared CW (5 wt%) wasincorporated into the spinning dope of PVA (DP:ca.1500) aqueous solution various whisker contents (5-30wt% against the solid PVA). The spinning dopeswere extruded into cold methanol to form gel fibers. Asspunfibers were then undergone hot-drawing to their maximum possible draw ratio.

Results and Discussion: Fig.1 shows the SEM images of the fibers after pulverization test through a laboratory blender at 14,500 rpm for 30 sec. The images reveal that the introduction of a small amount of CWs drastically enhances the fibrillation resistance of PVA fibers. This reason may be attributed to the reinforcing of interfibrillar phase by whisker network. The fibrillationresistance of fibers results in a remarkable improvementin knot-pull strength as shown in Figure 2.

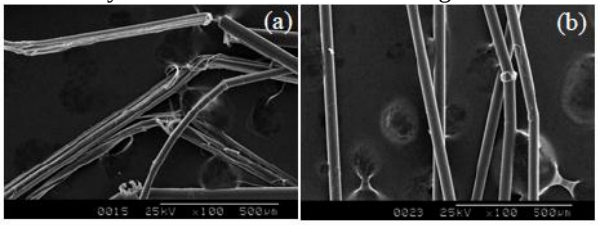

Fig 1. SEM images of fibers after fibrillation test. (a) Neat PVA, and (b) PVA-CW 5%.

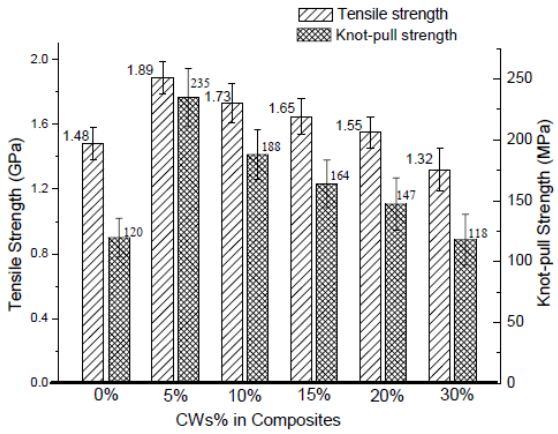

Fig 2. Tensile and knot-pull strength of neat PVA and PVA-CW composite fibers.

We consequently examined the knot configuration ofPVA-CW fibres to study their response againstcompressive and shear stresses. In the knot or loopstate, the fibre configuration turns out to be highly bent.The fibre undergoes severe axial stress in the outer layerand high compressive stress at its buckled inner layer[3]. As seen in Fig. 3, it is clear that the fibrillated PVA fibre cannot withstand such a high stress differenceimposed between the outer and inner layers, andconsequently the fibre shows a dilapidated appearance.Conversely, in case of PVA-CW fibres, possibleinteraction of the CWs with the PVA fibrils causesgeneral chain slippage and homogeneous shearing offibrils. Therefore, the PVA-CW fibres nearly retainedtheir original structures in the bent state.

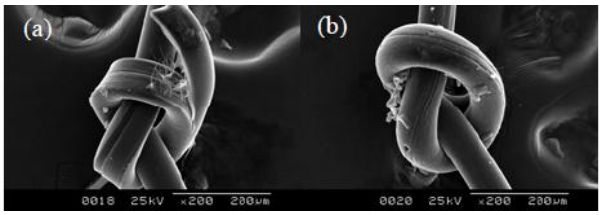

Fig. 3. The structure of knotted (a) neat PVA and (b) PVA-CW 5% fibers.

Introduction. The synthesis of optically active artificial biomimic materials has been of great interest to modern polymer science in the past years.[1-5] This is due to the fact that their resemblance to naturally occurring optically active polymers makes them good candidates as chiral and molecular recognition systems, enantiomeric separation materials, specific catalysts and vehicles for drug delivery.[1,2,6] The synthesis of such materials required polymerisation conditions employing specialised catalysts or monomers.[7] Up to date a number of optically active methacrylic monomers has been reported containing functional moieties such as amino acids, urea and cholesteryl groups in order to induce optical activity.[8-11] The synthesis of optically active methacrylic monomers, characterised by structural simplicity has not been reported so far. Herein we report for the first time the synthesis of a new, simple and optically active methacrylic monomer using conventional methods. The respective homopolymers and water-soluble diblock copolymers are also synthesised and characterised. Micellisation of diblock copolymers possessing an optically active block segment may lead to nanoparticles with size and shape that can be tuned to match biological constructs.

Results and Discussion.*Synthesis of a new optically active monomer.* The new optically active monomer, (*S*)-(-)-2-methyl-1-butyl methacrylate [(S)-(-)-MBuMA] was synthesised*via* a typical methodology reported in literature.[12] The corresponding optically active alcohol was allowed to react with methacryloyl chloride in THF in the presence of triethyl amine at. The monomer structure was confirmed by ^{1}H NMR analysis spectroscopy.

Synthesis of homopolymers. (*S*)-(-)-MBuMAhomopolymers were synthesised using conventional RAFT polymerisation in benzene in the presence of AIBN. Two chain transfer agents were used for the synthesis of these polymers, namely cumyldithiobenzoate (CTA1) and 2-cyano-2-propylbenzodithioate (CTA2). All polymers appeared as pink solids soluble in most common organic solvents in which typically *n*-butyl methacrylate dissolves. Even though it has been reported in literature that there is no difference in the reactivity of the above mentioned CTAs [12] we observed that polymers using CTA1 gave much lower yields (30%) than those synthesised using CTA2 (65%). All polymers were characterised using Gel Permeation Chromatography (GPC) with an Refractive Index (RI) detector calibrated with PMMA standards and ^{1}H NMR spectroscopy. All polymers gave unimodal molecular weight distributions with polydispersity indices (PDI) ranging from 1.12-1.27. The specific optical rotation values of the homopolymers determined by polarimetry were found to be independent on the molecular weights of the polymers. This is in agreement with results reported in literature.[8,10]

*Synthesis of block copolymers.*Amphiphilic block copolymers were generated by chain growth of the poly[(*S*)-(-)-(MacroCTA1) via the addition of the hydrophilic and ionisable 2-(dimethyl amino)ethyl methacrylate (DMAEMA). The polymerisation degrees (DP) of DMAEMA were 104, 230 and 475 respectively whereas the DP of (S)-(-)-MBuMA was in all cases 55. The resulting block copolymers were characterised by a unimodal molecular weight distribution indicating that complete extension has occurred providing further evidence for the "living" nature of the polymerisation under these conditions.[8,12]

Micellisation of (S)-(-)-MBuMA-b-DMAEMA. The (*S*)-(-)-MBuMA-*b*-DMAEMA amphiphilic block copolymers were dissolved in a selective for the DMAEMA block solvent (water) to form micelles. It should be noted at this point that the optically active block segment [(*S*)-(-)-MBuMA] of the diblock copolymers constructed the micelle's core whilst the hydrophilic segment (DMAEMA) formed the shell of the micelle. The morphological characteristics of the micelles were determined using dynamic light scattering (DLS) and atomic force microscopy (AFM).

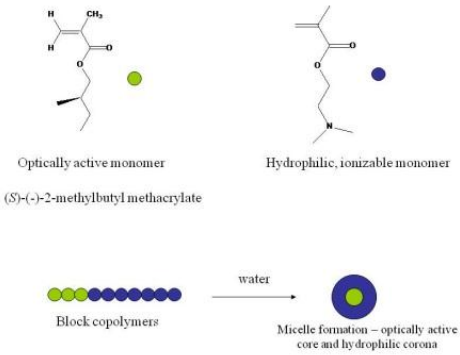

Fig. 1: Chemical structures of the monomers used for the synthesis of optically active block copolymers and their micellisation in aqueous media.

Introduction. Polyaniline (PAni) is one of the most intensively studied electronically conducting polymers because of its potential commercial applications in microelectronics, electrochromic displays devices, etc. PAni can be synthesized either by chemical or electrochemical oxidation of aniline monomer in acidic aqueous medium. Enzymatic polymerization of aniline has been proposed as environmentally and friendly alternative using Horseradish Peroxidase (HRP) and Soy Bean Peroxidase (SBP)[1,2]. In any case, like all other enzymes, there are some disadvantages that have to be considered for practical applications; among others is the instable nature of these biomacromolecules. The immobilization of enzymes in natural inorganic hosts has merge as interesting approach, due to its promising potential in improving enzyme thermal or pH stability, at the same time work as nanoreactors[3]. Halloysite is a naturally occurring aluminosilicate nanotube, chemically similar to kaolin. The size of halloysite particles vary between 1-15 micrometers and have an inner diameter of 10-150 nm.

Few papers on the use of the inner lumen of halloysite particles as nanoconfined reactors have been published. Herein, we employ halloysite tubules as hollow enzymatic nanoreactors for the polyaniline synthesis.

Materials and Methods. Soy Bean Peroxidase (SBP) was purchased from Organic Technoligies (Coshocton, OH, USA). Aniline, N-methyl-2 pyrrolidinone (NMP), (2,2-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt) (ABTS) and ptoluenesulfonic acid monohydrate (TSA) were purchased from Sigma–Aldrich. Halloysite nanotubes (HNTs) were from NaturalNano, (Rochester, NY, USA). Deionized water (DW) was used in all experiments.

SBP was immobilized in the HNTs suspension (HNTs/SBP) by dissolving 40 mg of SBP in 100 mL of DW (pH 3.0, using PTSA). Then 200 mg of HNTswas added to this solution.HNTs/SBP, was lyophilized and stored for further studies. The peroxidise activity in the HNTs/SBP was measured by spectrophotometry, using ABTS as substrate (λ_{max}= 405 nm, 36.8 mM^{-1} cm^{-1} extinction coefficient). Polyaniline synthesis was carried out using the HNTs/SBP. HNTs/SBP (240 mg) and aniline (400 µL) were added to 100 mL of DW. The pH (2.0) was adjusted with 800 mg of PTSA. The reaction was initiated by adding H_2O_2 and after that washed with methanol, centrifuged and freeze-dried.

Results and discussion. The peroxidise activity in the HNTs/SBP was measured by spectrophotometry, using ABTS as substrate (λ_{max}= 405 nm, 36.8 mM^{-1} cm^{-1} extinction coefficient) and show that the SBP was successfullyimmobilized inside the lumen of the HNTs. The HNTs/SBP at pH 2.0 was catalytically more active than the free SBP.

The spectrum of the HNT/SBP/PAni in acid media shows the characteristic two polaron bands (400nm and 775nm) of the electrically conductive form of polyaniline. Figure 1 shows the XRD patterns of the halloysite before and after aniline polymerization. Because not appreciable differences were found between the difractograms of HNTs/SBP and (HNTs/SBP/PAni (Fig. 1A. and Fig. 1B, respectively), both shows a diffraction pattern typical for halloysite. Therefore, the HNTs nanotubes were eliminated with HF. The new XRD pattern at (100) and (111) are signals corresponding to 21° and 26.2°, characteristic of a pseudorombic cell, associated with the structure of the emeraldine salt for the PAni (Fig. 1C).

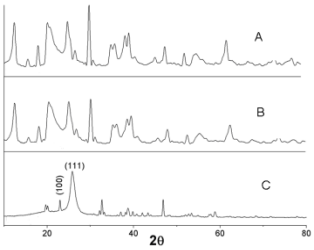

Fig. 1. Powder X-ray diffraction patterns of a). HNTs/SBP, b). HNTs/SBP/PAni and c). HNTs/SBP/PAni after HNTs were eliminated with HF.

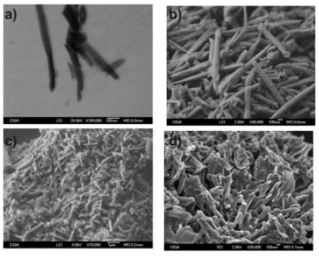
Morphologies by STEM analysis of HNTs/SBP and HNTs/SBP/PAnidid not show major differences with the original HNTs sample (Fig b,c and a respectively). However, after removing the HNTs with HF is evident the complete filling of the inner halloysite space with the synthesized polyaniline in the form of nanowires (Fig. 2d). The electrical conductivity using the four point of this material was 1 Scm^{-1}.

Fig. 2. STEM images of: original HNTs (a), HNTs/SBP (b), HNTs/SBP/PAni and HNTs/SBP/PAni after HNTs were eliminated with HF.



Conclusions.HNTs were successfully used as SBP support in a physical immobilization process. Using this supported SBP was possible to obtain electrically conductive PAni.

Introduction: Biopolymers have received increased attention as excipientsin pharmaceutical formulations as they are derived from natural sources [4]. Silver has a long history of use in human healthcare and medicine [11]. A number of healthcare products such as wound dressing materials, body wall repairs, augmentation devices, tissue scaffolds, and antimicrobial filters now contain silver [16]. In this study, alginate-nanosilver-anthocyanin hybrid sponges (ANAHS) were prepared by in-situ synthesis of silver nanoparticles in an aqueous alginate solution. Antimicrobial activity and pro-inflammatory cytokine inhibition of ANAHS were investigated.

Materials and Methods: A solution of 1.0 wt/v% alginate and anthocyanin was prepared by dissolving alginate and anthocyanin in a 100ml of distilled water. Silver nitrate (2ml, 5.0 wt/v% in water) was dropped in 100ml of the alginate and anthocyanin solution. After 1 hour, freshly prepared sodium borohydride solution (2ml, 1.0 wt/v% in water) was slowly added under magnetic stirring. A rapid color change to dark brown indicated the formation of silver nanoparticles. The mixture was stirred for 3 hours at room temperature in order to lead entire reduction. And then, the solution was dialyzed for 2 days to eliminate the salts which were formed while alginate and silver nitrate were synthesized. The alginate-nanosilver-anthocyanin solutions were freeze-dried. Finally, the ANAHS were prepared by cross-linking of the freeze-dried matrices, washing, and freeze-drying.

The ANAHS were characterized by transmission electron microscopy (TEM), X-ray diffraction (XRD), and ultraviolet-visible (UV) spectroscopy. Cytotoxicity of the ANAHS were checked by 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxy phenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) assay. Pro-inflammatory cytokines 9 (IL-1β, IL-6, and TNF-α) were measured by cell culture of RAW 264.7 cells and enzyme-linked immunosorbent assay (ELISA).

Results and Discussion: The size of nanoparticles in the TEM images of the alginate solution are about 5-20 nm. Figure 1 is TEM images of the ANAHS. Nano-sized silver crystals were spread in the sponge.

We confirmed the presence of silver in the ANAHS by XRD as shown.

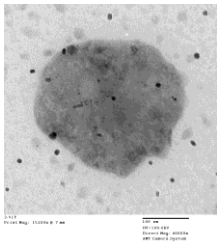

Figure 1. TEM images of silver nanoparticles in the ANAHS.

The ANAHS revealed the 97-99% reduction of number of colonies of staphylococcus auseus and klebsiellapneumonia.

From results in Figure 3, we confirmed that the ANAHS inhibited the production of IL-1β, IL-6, and TNF-α

Conclusively, the ANAHS had a good microbial activity and anti-inflammatory property. They are considered a candidate for the application as wound dressing material.

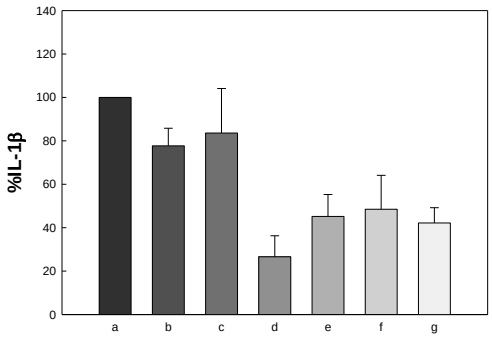

Figure 2. Relative amount of IL-6 produced by RAW264.7 cells cultured with the sponges of (a) alginate, (b) alginate-anthocyanin (0.05%), (c) alginate-anthocyanin (0.1%), (d) alginate-nanosilver (0.1%), (e) alginate-nanosilver (0.1%)-anthocyanin (0.05%), (f) alginate-nanosilver (0.05%)-anthocyanin (0.1%), and (g) alginate-nanosilver (0.1%)-anthocyanin (0.1%).

Degradation of polyethylene by a thermophilc bacterium

*YeunSugJeong and*Mal Nam Kim

Department of Biology, Sangmyung University, Seoul, Korea

mnkim@smu.ac.kr

Introduction

Polyethylene is one of the most consuming plastics due to its durability and excellent mechanical properties. It is being widely used for many single use applications. However due to the recently grown up environmental pressure, eventual fate of plastics after use became more and more important.

It has been admitted that the molecular weight of polyethylene should be lower than 500, otherwise it should be at least formulated with transition metal pro-oxidants and then oxidized to low molecular weight so as to be biodegraded. A lot of researches have been carried out to examine biodegradation of polyethylene containing pro-oxidants and to explore microorganisms degrading polyethylene having deliberately been oxidized [1-3].

Few studies have been devoted to exploring biodegradation of PE free from pro-oxidants. The molecular structure of PE formulated with pro-oxidants should be different from that of neat PE after the pretreatment, and thereby this should lead to different biodegradation behavior.

In this study, a thermophilc bacterium able to degrade LMWPEs was isolated from compost. LMWPEs were prepared by thermal degradation of HDPE and LDPE under strict nitrogen atmosphere. Biodegradation of LMWPEs whose average molecular weights were well above 500 was examined by using the isolated strain.

Results and Discussion

A microorganism isolated from the compost made from aminal fodder formed clear zone with about 4mm of diamenter at 58℃. The isolated strain was a rod shaped Gram negative bacterium. Analysis of 16S rDNA coding gene sequence resulted in the phylogenetic tree as shown in Fig. 1.

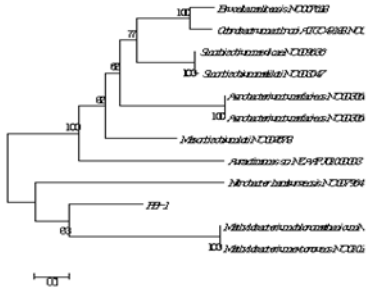

Fig 1: Phylogenic tree of the isolate

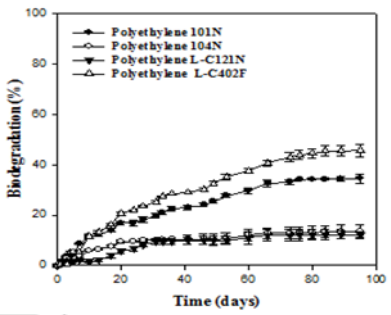

Fig. 2: Biodegradation rate of polyethylenes

Based on the results of the 16S rDNA analysis, the present strain was identified as *Methylobacteriumchloromethanicum.*

Mineralization of polyethylenes with different molecular weights was examined at 58℃, as shown in Fig. 2.It can be seen that the bacterium acclimated with the low molecular weight PE1 was active not only for the degradation of PE1 but also for the other higher molecular weight LMWPEs, PE2, PE3 and PE4. However the biodegradability decreased with increase in the molecular weight of the LMWPEs.

Contrary to the expectation that the biodegradation should reduce the molecular weight of PE1, the weight-average-molecular weight (Mw) of PE1 increased from 1,700 to 2,400 during the biodegradation. This should be attributed to the preferential assimilation of the low molecular weight fraction of PE1 by the microorganism.

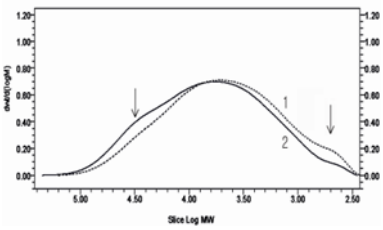

Fig. 3: GPC profile of PE4 before and after the biodegradaion

Fig. 3 shows the GPC chromatogram of PE4, having the highest molecular weight among the LMWPEs tested. The biodegradation also raised both Mn and Mw of PE4. However the shoulder peak at $10^{2.6}$ appearing in the chromatogram of PE4 before biodegradation vanished and the new shoulder peak at $10^{4.5}$ showed up after the biodegradation. As a result, the polydispersity of PE4 remained almost unchanged in spite of the differences in Mn and Mw.

Stimuli-responsive Hydrogels for Recognition of Ions and Biomolecules

Tobias Hennecke[1], *Nadia Adrus*[1,2], *Dana M. Balster*[1], *Mathias Ulbricht*[1]

e-mail: tobias.hennecke@uni-due.de

Smart molecularly imprinted polymer (MIP) hydrogels can combine both responsivity to external stimuli and recognition properties towards guests such as biomolecules including proteins or antibodies.[1] The key motivation is to mimic biological functions and natural feedback systems.
In our work we synthesized and investigated poly(acrylamide) (PAAm) and poly(*N*-isopropyl-acrylamide) (PNIPAAm)-based MIP and non-imprinted (NIP) hydrogels for protein recognition via photo initiated free radical crosslinking copolymerization (15 min irradiation, intensity ~ 30 mW/cm^2, $\lambda > 300$ nm). We used lysozyme as template protein. Two different template-selective monomers were used; i.e. 2-acrylamido-2-methylpropane sulfonic acid (AMPS) and methacrylic acid (MAA), along with *N*,*N'*-methylene-bisacrylamide (MBAAm) as crosslinker and Irgacure 2959® as photoinitiator. After polymerization, all hydrogels were washed with NaCl solution. The washing solutions were analyzed with TOC in order to quantify monomer conversion and to monitor the removal of template protein.
Based on previous experiments,[2] it was necessary to wash P(AAm-co-AMPS)-based hydrogels with at least 1.0 M NaCl in order to remove the template protein. After that, swelling experiments were done at room temperature (RT) for up to 24 h. However, under this extreme condition, the hydrogels were partially collapsed and this contributed to a lower binding capacity (Table 1).

Table 1: P(AAm-co-AMPS)-based hydrogels

	Conversion [%]	Swelling ratio (-)	Binding capacity* [mg/g]
NIP	84	5.0	30.4
MIP	80	4.8	24.4

**(100 mg dried gel in 100 ml 0.5 g/l lysozyme, RT, 24 h)*

Table 2: P(NIPAAm-co-MAA)-based hydrogels

	Conversion [%]	Swelling ratio (-)	Binding capacity# [mg/g]
NIP	97	13.4	111
MIP	92	12.9	441

#(10 mg dried gel in 10 ml 0.5 g/l lysozyme, RT, 24 h)

Therefore, P(NIPAAm-co-MAA)-based hydrogels were washed in both 1.0 M (results not shown) and 0.3 M NaCl (Table 2). In this case, the washing conditions with lower salt concentration were already sufficient. The hydrogels had high swelling degree and very high binding capacity. Note that in this case, the gel dimension was 10 times smaller. This may have influenced the measured binding capacities and must be reconfirmed.

The sorption experiments with the P(AAm-co-AMPS)-based hydrogels showed a higher binding capacity for the NIP than the MIP (Table 1). This was related to the comonomer AMPS leading to an ion exchanger gel, which causes specific binding for the imprinted gel and also non-specific binding for both the imprinted and the non-imprinted gel. Judged by the much higher capacities for MIP than NIP, the effect of non-specific binding was reduced with MAA (Table 2). More important, for P(NIPAAm-co-MAA) the protein binding selectivity (lysozyme over cytochrome C) was much higher for MIP than for NIP. Nevertheless, the template removal has emerged as the major problem; a complete protein removal could not be obtained during the washing step, even through solvent and washing condition variations. Hence, hydrogels with entrapped lysozyme were obtained. This seemed to contribute to a densification of the polymer network, causing a reduced swelling ratio at increasing fraction of entrapped protein (Tables 1 and 2).
In ongoing studies these preparations are optimized and adapted in order to fill macropores with such MIP hydrogels to obtain a size- and protein-selective membrane.
Another approach is the preparation of ion-sensitive stimuli-responsive hydrogels for the detection and quantification of potassium concentrations in the human blood. These hydrogels are PNIPAAm-based and containing crown ether units. This leads to a pronounced change in the swelling degree, depending on the concentration of specific ions. This will enable the detection of these ion's concentration via swelling pressure measurement in a sensor system.
Our first results showed that the ion sensitivity depends on the content of benzo-18-crown-6 units in the hydrogel, a higher content caused a higher sensitivity. Furthermore a significant change in the swelling ratio depending on the ion concentration was observed; the effect decreased in the order $Ba^+ > K^+ > Na^+$. In the ongoing work these hydrogels have to be optimized with focus on the potassium selectivity and sensitivity.

Introduction

To protect the protein drugs from the harsh environment in the stomach before they can be absorbed in the intestine, pH-sensitive polysaccharides like chitosan and alginate have attracted increasing attention due to their favorable properties including biocompatibility, biodegradability, pH sensitivity, and mucoadhesive property. In this study, a novel pH-sensitive hydrogel system composed of chitosan and alginate was developed for delivering of nano-pearl powder.

Experimental

Alginic acid (3 wt%) was dissolved in distilled water and stirred continuously with a homogenizer (Polytron; Kinematica, AG, Switzerland) at 26,000 rpm for the desired amount of time. During homogenization, nano-pearl powder was added to the solution in order to prepare hollow hydrogel beads for the drug-release experiments. Calcium chloride (0.25 M) was dissolved in distilled water and N, O-carboxymethyl chitosan was added to the solution during homogenization to prepare $CaCl_2$ solution. The alginic acid/ nano-pearl powder solution was then dropped using a hypodermic syringe into $CaCl_2$/ N, O-carboxymethyl chitosan solution to obtain the hydrogel beads. The in vitro release profiles of hydrogel beads were studied in simulated gastric and intestine mediums, respectively. IEC-6 cells were seeded and cultured on the hydrogel beads to examine the biocompatibility of the carrier. In the in vivo studies, the nano-pearl powder levels (percentage oral dose) in blood with time after the oral administration of hollow hydrogel beads loaded with nano-pearl powder was compared with the levels after the oral administration of an aqueous nano-pearl powder solution in mice.

Results and discussion

As shown in Fig. 1, the hollow hydrogel beads incorporated nano-pearl powder exhibited low release profile and no erosion in SGF (pH 1.2). Such behavior is contributed to hydrogen bonding between –COOH from alginate and –OH from chitosan, leading to dense structure of hydrogel beads. The amount of nano-pearl powder released from hollow hydrogel beads was lower than 28 % at acidic environment. As the beads transferred to SIF (pH 7.4), their release was faster than in SGF. Since the –COOH groups from alginate were deprotonated to -COO^- when the buffer pH was high than its pKa (3.3~3.5), leading to loose structure of hydrogel beads. Under basic environment, the amount of nano-pearl powder released from hollow hydrogel beads was increased up to 36~84 %.

Fig. 2 shows the result of the IEC-6 cells culturing in the well, containing different kinds of hydrogel beads after 1, 3, 5, 7 days culture. The result shows the viable cells number increased slowly from 1 to 5 day, because the samples were acidic. The viable cells number increased obviously at day 7. We confirmed that the hollow hydrogel beads made from alginate-chitosan should not be cytotoxic.

Fig. 3 shows the means release rate of nano-pearl powder after oral administration of nano-pearl powder solution and loaded nano-pearl powder beads. At 6 hr, the release rate of nano-pearl powder solution was already reached maximum (81.7 %) and the release was terminated at 12 hr. However, the release rate of loaded nano-pearl powder beads was sustained for the next 6 hr (67.1 %) in comparison with solution. The in vivo release studies confirmed that hollow hydrogel beads have the controlled and sustained release ability.

Conclusions

The results suggest the pH-sensitive alginate-chitosan hydrogel system can be used as a promising vehicle for oral delivery of health nutrients.

Reinforced Composites Based on Biodegradable Polymer Matrix and Microcrystalline Cellulose

Fernanda A. dos Santos[1]*, *Maria Inês B. Tavares*[2], *Roberto P.C. Neto*[3]

Instituto de Macromoléculas Professora Eloísa Mano (IMA)
Universidade Federal do Rio de Janeiro (UFRJ)

[1*]fabbate@ima.ufrj.br; [2]mibt@ima.ufrj.br; [3]robertoneto@ima.ufrj.br

Introduction: Polylactic acid (PLA) is a biodegradable material that has a great potential to replace petroleum-based plastics [1]. The reinforcement of PLA using biomaterials like cellulose has been studied with the goal of obtaining fully bio-based composites [2].

Cellulose has been used largely like reinforcement in polymers matrix. The goal of the present study was to produce PLA based composites using microcrystalline cellulose (MCC) and characterize the obtained materials by NMR, DRX and SEM.

Experimental:

Materials: PLLA 2002D (NatureWorks LLC product), MCC PH 102 (Viapharma), Chloroform (Merck)

Methods: MCC suspensions containing an adequate amount of reinforcement were mixed in PLA solutions and run in a Blender for 24 h. The formulations were then casted in Petri dishes and left to evaporate in room temperature for one day. One formulation containing just PLA and three others with PLA and 3%, 5% and 7% wt MCC were obtained.

Results and Discussion:

The XRD spectra for MCC, PLLA neat (film and pellet) and PLLA/MCC system with 5 wt % MCC are presented in Figure 1.

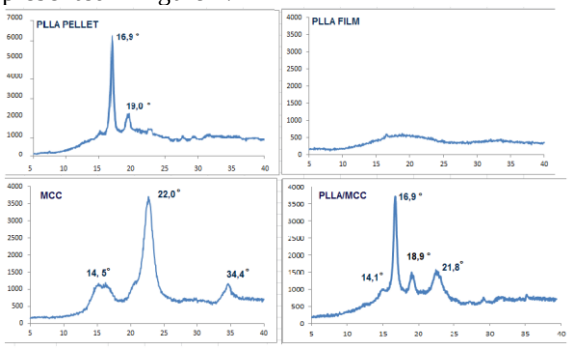

Figure 1: X-ray spectra for PLLA, MCC and PLLA/MCC

The X-ray diffraction patterns of neat PLA shows that the PLA FILM exhibits no peaks showing an amorphous nature. However, the result of x-ray experiment for PLLA in a pellet form shows that the material appears semi-crystalline. In the result of x-ray for the system PLLA/MCC appears diffraction peaks related to cellulose and PLLA.

Figure 2 shows the SEM micrograph of PLA/MCC system. It is possible to see from figure 2 that the MCC dispersion on the polymeric matrix is reasonable, presenting some aggregates.

Proton spin-lattice relaxation times (T_1H) obtained to the PLLA was 650 ms and 184ms for MCC. For the systems PLA/MCC with 3, 5 and 7% wt, T_1H was 592, 580 and 538 µs respectively. Analyzing PLLA resin, one value for the relaxation parameter was found. It was attributed to mobile region, which is constituted by amorphous phase. This result indicates that there was an increase in the molecular mobility of the polymeric chains with MCC addition.

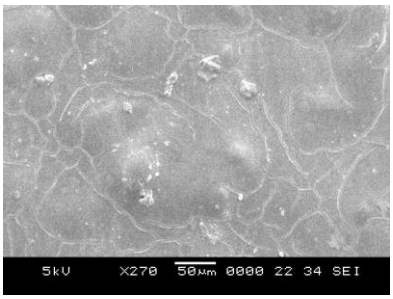

Figure 2: SEM image of PLLA/MCC film with 5% wt MCC

Figure 3 shows the domain curves for PLLA, MCC and for each system PLLA/ MCC obtained. Composites showed no change in the baseline width for the neat polymer and there was also no denotative displacement of the domains, indicating that addition of MCC did not affect the structural organization of the polymer and also that there was good dispersion of the load in the matrix.

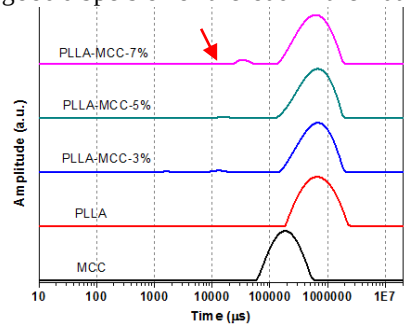

Figure 3: Domains Curves for MCC, PLLA and composites

However, in the PLLA with 7% wt of cellulose appeared a second domain (red arrow), which indicates that from this cellulose content begins to occur filler dispersion impairment in the matrix.

Conclusions: The X-ray diffraction (XRD) studies on the materials showed that cellulose can act as nucleating agent on the crystallization of PLLA. The morphology study on composites showed that the MCC were reasonable well dispersed in the PLA matrix due to the MCC particle self-aggregation. T_1H value decrease with MCC addiction, indicating increase in molecular mobility of PLLA chains. MCC decreased the stiffness of the PLA polymer chains, reducing the relaxation times of the pure polymer, ie, increasing its molecular mobility, indicating that weak intermolecular interactions were formed between MCC and PLLA. Despite the tendency of self-aggregation of cellulose, the results show that it is possible to obtain a good dispersion of MCC until 7 wt%, without adding any coupling agent or having to undergo any type of cellulose treatment.

Combined Effect of Temperature and Humidity on the Biodegradation Behaviour of Polylactic Acid (PLA) and its Nanocomposites

Kontou E., P. Georgiopoulos, M. Niaounakis

Department of Applied Mathematical and Physical Sciences, Section of Mechanics, National Technical University of Athens 5 Heroes of Polytechnion, GR-15773, Athens, Greece

ekontou@central.ntua.gr

Polylactic Acid (PLA) is biodegradable polymer with an expanding range of potential applications. However, its poor thermal and mechanical resistance, limited barrier properties and relatively higher production costs hinder the penetration of PLA across a wide range of industrial sectors. The addition of a small amount -up to 4 wt.%- of nanosized fillers leads to the enhancement of the thermomechanical and barrier properties of pristine PLA [1]. So far, the biodegradability of PLA and PLA/nanocomposites has been tested in terms of storage under atmospheric conditions [1,2], while a large number of works has been performed on the hydrolytic degradation behavior of PLA films in neutral media [3]. Little work has been done on the variation of the thermal and tensile properties (Young's modulus and yield stress) of PLA and its nanocomposites with ageing. Moreover, the role of the nanofillers in the degradation procedure of PLA is an open issue. The aim of the present work is to study the effect of specific environmental conditions, namely exposure to 80% relative humidity at 40 °C for a period of up to six months, on the thermomechanical properties of PLA and PLA/nanocomposites.

Two different types of nanofillers and their mixtures were introduced in pristine PLA: Silica (Si) particles with an average size of 16 nm and Montmorillonite clay (MMT) both surface modified. Based on PLA and the two nanofiller-types, three series of PLA nanocomposites were prepared by melt mixing, namely PLA/Si and PLA/MMT nanocomposites with a filler content of 2, 3 and 5 wt.% of silica (Si) and montmorillonite clay (MMT), respectively; as well as PLA nanocomposites with a filler content of 4 wt.% based on MMT/Si ratio of 60/40 and 40/60. Experimental techniques including Scanning Electron Microscopy (SEM), Differential Scanning Calorimetry (DSC), Dynamic Mechanical Analysis (DMA), and tensile measurements were employed to analyze both the degree of thermomechanical enhancement of PLA due to nanofillers and their influence on the biodegradability of PLA and PLA/nanocomposites.

Both nanofiller types acted as nucleating agents, leading to an increment of crystallinity content, varying from 50 to 57% for the PLA/Si and from 32 to 50% for the PLA/MMT nanocomposites. On the other hand, the mixture of the two nanofillers showed no effect on the crystallinity content. Regarding Young's modulus, the higher degree of enhancement was observed at 2 wt.% and 3 wt.% of silica and MMT, respectively. The PLA/Si nanocomposite with a filler content of 3 wt.% silica gave the highest yield stress. The concurrent addition of both nanofillers caused the yield stress to decrease and the Young's modulus to increase compared to pristine PLA matrix. After exposure to the ageing conditions, a distribution of holes in the PLA/Si and cracks in the PLA/MMT intercalated nanocomposites was detected by SEM, related directly to the selective hydrolytic degradation of PLA matrix and removal of the chains in the amorphous regions. Crystallinity content was initially decreased with ageing time, and hereafter increased, effect which was interpreted by the molecular weight reduction. This was further supported by the lowering of the cold crystallization temperature. The same trend was observed in Young's modulus and yield stress, while the strain at break was decreased dramatically. MMT appears to have a higher impact on yield stress in comparison with silica. On the other hand, silica has a greater effect in Young's modulus and strain at break, compared to MMT. On the basis of the experimental results, it can be concluded that both nanofillers accelerate the degradation process of PLA. In addition, the degradation mechanism of PLA is greatly affected by the quality of nanofillers dispersion, due to the creation of aggregates.

Introduction

Cationic polymers, such as the poly-methacrylamide of [*N*-(2-aminoethyl pyrrolidine)] (EPA) (**Fig. 1**) are not only interesting due to their pH sensitivity and their application in controlled release, but also for their ability to complex with another systems, of anionic nature, such as drugs or nucleic acids. Cationic polymers are being evaluated as alternative vectors to viruses in Gene Therapy, due to some advantages like the absence of immunogenicity or patogenicity risk, or their lack of limitation in the length of the nucleic acid that is going to be delivered. Nevertheless, the transfection levels observed are significantly lower than using viral vectors *(a)*. The low transfection efficiency could be, in part, due to some excess of positive charge, aspect that could be improved by copolymerization with some neutral and hydro soluble monomers, such as dimethylacrylamide (DMA) or the methacrylamide of N-(2-hydroxypropyl) (HPMA), that are biocompatible, nontoxic, and non immunogenic. In our previous works, some of these copolymers were evaluated, and the results showed that the biocompatibility and transfection efficiency of these non viral vectors was significantly improved with respect to the EPA homopolymer.

In the present work the systems were prepared using another biocompatible and more complex monomer, a permethylated monomer derived from β-Cyclodextrin (βCD), a cyclic oligosacharide, that was copolymerized with EPA and the resulting copolymers were evaluated as non viral vectors (**Fig 1**).

Materials and methods

The EPA monomer was synthesized as previously described *(b)*, and the βCD monomer was prepared by the Química Bio-orgánica Group (IQOG-CSIC).

The EPA-CD copolymers were prepared by free radical polymerization using two different molar ratios of βCD, 5% and 10% molar. These polymeric systems were characterised by ^{1}H-NMR. The molecular weights were determined by GPC and the sensitivity to pH was measured by an acid-base titration. Polymers complexation ability with plasmidic DNA, at different N/P ratios (w/w) was studied by Gel Retardation Electrophoresis. Alamar Blue assay and an haemolysis assay were carried out in order to check their toxicity and biocompatibility. The particle size of the polyplexes and their superficial charge were measured, in order to check if they were suitable for the internalization into the cells. Finally transfection experiments were carried out using 3T3 cells in serum free media and luciferase as reporter gene. The transfection levels were determined by measuring the luciferase activity after 48 hours of incubation, using Polyethylenimine (PEI) (25000 kDa, hyperbranched) as positive control.

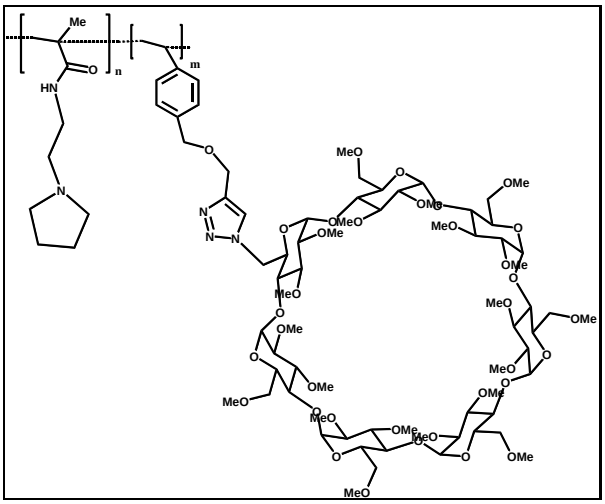

Fig 1. Chemical structure of the EPA-CD copolymers.

Results and Discussion

The ^{1}H-NMR spectra of the prepared copolymers confirmed the chemical structure and high purity grade.

The Gel Retardation Electrophoresis shows that all copolymers were able to complex with the plasmidic DNA at different N/P ratios (w/w), obtaining polyplexes with a proper size for internalization into the cells (200 nm), that are also stable in solution (Z-potential around 30 mV). The Alamar Blue results indicate that these systems are biocompatible. Finally, the transfection levels obtained after 48 hours in serum free media are significantly higher than the levels reported with the PEI, and also significantly higher than the results in our previous study with the copolymers of EPA with HPMA or DMA.

Conclusions

New cationic systems EPA-βCD were prepared and characterized. These copolymers exhibited low levels of toxicity and better transfection efficiency than the systems previously studied, and the obtained by the positive control PEI.

Biomimetic Block Copolymer Membranes for Functionalized Surfaces

S. Toughraï, E. Rakhmatullina, V. Malinova, N. Bruns, W. Meier

Department of Chemistry, University of Basel, Klingelbergstrasse 80, CH-4056 Basel, Switzerland.

Smahan.toughrai@unibas.ch

Introduction: The functionalization of surfaces using biomimetic block copolymer membranes aims at developing smart surfaces for biotechnological applications such as biosensing. Instead of lipid membranes, amphiphilic block copolymer membranes were chosen as mimics of biological membranes due to properties such as tunable thickness, chemical and mechanical stability, lower permeability, fluidity, mobility, etc. Upon insertion of membrane proteins, these systems could allow for the preparation of mechanically and chemically robust and air-stable biosensor devices.

Materials & Methods: Surface-initiated atom transfer radical polymerization (ATRP) provides good control of brush thickness by controlling polymer molecular weight and by initiating polymerization of a second monomer from the free end of the first chain. Poly(2-hydroxyethyl methacrylate)-*block*-poly(n-butyl methacrylate)-*block*-poly(2-hydroxyethyl methacrylate), PHEMA-*b*-PBMA-*b*-PHEMA block copolymers were synthesized with the first PHEMA block anchored to a self-assembled monolayer of initiators on a gold surface, while the other PHEMA block was exposed to the outer surface. To achieve this, a self-assembled monolayer of ($BrC\text{-}(CH_3)_2COO(CH_2)_{11}S)_2$) initiator was formed by disulphide − gold covalent bonding. This initiator was synthesized as previously reported[1]. HEMA monomer was then polymerized by ATRP. The first PHEMA block initiated the polymerization of BMA. Subsequently, the PBMA block initiated HEMA polymerization, thus resulting in a triblock copolymer membrane anchored to the gold substrate. Gold surfaces were prepared according to Naumann et al.[2]. Block copolymer brushes of differing block lengths were prepared and characterized, both on the gold surfaces and – after detaching from the solid support – in solution.

Results and Discussion[3]: The grafted triblock copolymer brushes exhibit an amphiphilic structure where hydrophilic (PHEMA) and hydrophobic (PBMA) blocks of the polymer chain that have the potential to respond variably to solvent treatment. To test the solvent response behaviour of the triblock copolymer, block-selective solvent as well as an effective, common solvent for the entire triblock system were used for swelling experiments. Ethanol was chosen as a solvent for the triblock copolymer chains, whereas hexane and water selectively swell PBMA and PHEMA blocks, respectively. The PHEMA blocks swell considerably in water, whereas the hydrophobic PBMA block minimizes its contact with aqueous surroundings. However, the phase segregation was shown to be reversible because re-immersion of the sample into one of three tested solvents resulted in reproducible morphologies. Figure 1(a) shows the 3D topography image of the wet copolymer chains on the gold surface. After drying, the sample acquired nanodomain surface topography [Fig. 1(b)].
Upon swelling in water, the brush-like structure of the macromolecules assumes a stretched conformation of the PHEMA chains. Drying most probably causes a collapse of the polymer brushes and thus formation of nanodomains. The reversibility of the phase segregation proves the covalent attachment of the block copolymer layer and shows the potential use of these block copolymer membranes as responsive surfaces.

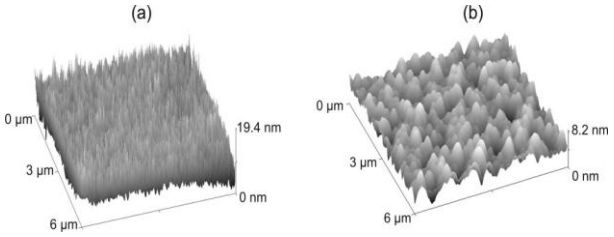

Fig. 1: Contact mode AFM analysis of the amphiphilic triblock copolymer membrane in water (a) and after sample drying (b).

Conclusion: ATRP was successfully applied to the grafting of ABA-triblock copolymer membranes from gold supports. The length of each individual block was controlled by varying the polymerization time. The amphiphilic character of the triblock copolymer brushes provided a responsive surface that showed a solvent-dependent arrangement of the block copolymer chains, which was also reflected in the morphologies of the dried films. Polymer brushes such as these, exhibiting a hydrophilic-hydrophobic-hydrophilic sequence, could be regarded as the first example of solid supported, biomimetic block copolymer membranes prepared by a "grafting-from" approach.

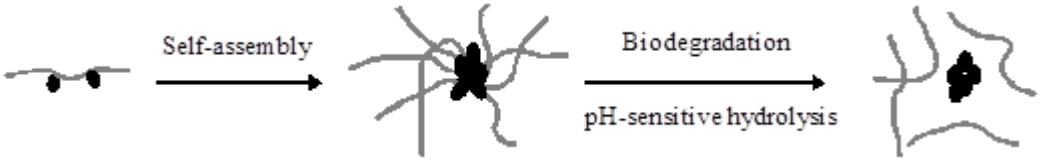
Biodegradable Micellar Polymer Drug Carriers Based on *N*-(2-Hydroxypropyl)methacrylamide Copolymers

Petr Chytil, Tomáš Etrych, Karel Ulbrich

Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, v.v.i.
Heyrovský Sq. 2, 162 06, Prague 6, Czech Republic

e-mail: chytil@imc.cas.cz



Introduction

N-(2-Hydroxypropyl) methacrylamide (HPMA) copolymers are used as polymer precursors in the synthesis of water-soluble polymer-drug conjugates. The conjugates containing anticancer drug, e.g. doxorubicin or dexamethasone, bound through a pH-sensitive hydrazone bond exhibited a significant therapeutic effect in the treatment of mouse lymphomas[1]. While the hydrazone bond is relatively stable at neutral pH (modeling blood pH), drug is released under mild acid conditions imitating intracellular environment (endosomes in tumour cells).

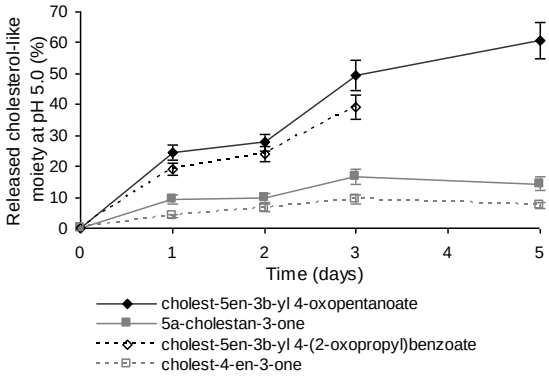
Introduction of hydrophobic cholesterol moieties into the HPMA copolymer structure resulted in an amphiphilic copolymer self-assembling into micelles in aqueous solutions[2]. The conjugate of such high-molecular-weight drug carrier with doxorubicin showed enhanced tumour accumulation and significant anti-tumour activity (with up to 100 % of long-term survivors) in the treatment of EL-4 lymphoma due to the EPR (enhanced permeability and retention) effect.

Here, we present the synthesis and physico-chemical properties of biodegradable micellar polymer drug carriers. While the former micellar system was nondegradable, the new one is designed as hydrolytically degradable. Micelles are formed by self-assembly of amphiphilic HPMA copolymer bearing hydrophobic cholesterol-derived moieties, bound by pH-sensitive hydrazone bond. Degradation of the linkages in mildly acidic environment of tumour cells followed by disassembling of the supramolecular structure might facilitate renal removal of polymers forming micelles from the body.

Result and Discussion

A set of amphiphilic polymer drug carriers was prepared by conjugation of linear water-soluble HPMA copolymer bearing free hydrazide groups (5.7 mol%) with hydrophobic cholesterol-like moieties, i.e. 5*a*-cholestan-3-one, cholest-4-en-3-one, cholest-5en-3*β*-yl 4-(2-oxopropyl)benzoate and cholest-5en-3*β*-yl 4-oxopentanoate. Formation of hydrazone bond did not significantly influence molecular weight of the copolymers, which was aprox. $2.5 \cdot 10^4$. However, introduction of hydrophobic substituents (1 – 3 mol%) resulted in self-assembly of the copolymers in aqueous solutions and formation of micelles. Hydrodynamic radii (R_H) and apparent molecular weights (M_{app}) of the micelles were growing with increasing content of hydrophobic moieties. These findings are in agreement with results of our previous study using cholesterol-bearing HPMA copolymers with cholesterol bound by ester bond almost stable in body fluids[2]. Presence of doxorubicine attached to the carrier by hydrazone bond influenced neither R_H nor M_{app}.

The amount of cholesterol-derived moieties released from the micelles incubated in phosphate buffers of pH 5.0 or 7.4 at 37°C was determined by HPLC or GC after their extraction into chloroform. 5*a*-Cholestan-3-one and cholest-5en-3*β*-yl 4-oxopentanoate were released at pH 5.0 with the highest rate while cholest-4-en-3-one or cholest-5en-3*β*-yl 4-(2-oxopropyl) benzoate were released more slowly as a result of stabilization of hydrazone bond situated in vicinity of aliphatic or aromatic double bonds. The rates of release of all cholesterol derivatives at pH 7.4 were significantly slower.



The direct observation of hydrolysis was performed by DLS. During hydrolysis R_H increased with time from ~13 nm up to 30 – 60 nm while their distribution became narrower. Probably, in this static settings of experiment the released cholesterol-like moieties did not escape from micelles, rearranged their hydrophobic core forming new and larger micelles.

Conclusion

HPMA copolymer-cholesterol micelles are promising polymer drug carrier with high potential for solid-tumour-targeting and polymer elimination after fulfilling its carrier role.

PEG and Tartaric Acid: crosslinking agents and spacers for targeting delivery of chitosan nanogels

Leyre Pérez, Maite Artetxe and L. Carlos Cesteros

New Materials and Supramolecular Group. Department of Physical Chemistry, Faculty of Science and Technology, University of the Basque Country 48940 Leioa, Vizcaya, Spain

leyre.perez@ehu.es

Introduction: Chitosan is a renewable polysaccharide widely used in pharmaceutical and medical areas because of its favorable biological properties[1]. A limiting factor in the application of chitosan is its low solubility in aqueous media at neutral conditions. Due to the presence of reactive amino groups, chitosan can be modified easily to achieve the desired moieties, create crosslinked structures or get improved properties. The toxicity of the most used chitosan covalent crosslinker, glutaraldehyde, has supposed a need of developing non-toxic and biocompatible crosslinking agents for chitosan. Only a few studies[2] have proposed this dual-purpose chemical modification of chitosan with a biocompatible hydrophylic crosslinkers in order to generate biocompatible chitosan networks and, simultaneously, impart water-solubility properties to the gel.

Besides, chitosan was found to be an attractive targeting nanodevice for drug and gene delivery because of its high positive charge density and relatively low cytotoxicity[3]. In this regard, it has been roughly accepted that the introduction of a spacer molecule among the nanodevice and the targeting agent enhances the cellular association of nanocarrier.

According to the previous information, the aim of this work was to synthesize chitosan nanogels by modification with biocompatible dicarboxylic acids which play a triple role: first as biocompatible crosslinking agent, second improving hydrophilicity of the nanogels and third playing as spacer molecule for posterior targeting reaction.

Materials and Methods: The chitosan and crosslinker agent microemulsions were separately prepared mixing their aqueous solution with cyclohexane, n-hexanol and by adding Triton X-100 until the mixed emulsion became transparent. The W/O microemulsion of crosslinker was previously activated with *N*-(3-Dimethylaminopropyl)-*N´*-ethylcarbodiimide hydrochloride (EDC) and *N*-hydroxysuccinimide (NHS). The crosslinking reaction took place after the addition of the crosslinker microemulsion into the chitosan microemulsion during 24 hours at room temperature. The nanoparticles were isolated and washed by dispersion in ethanol and posterior centrifugation. Finally, the obtained nanogels were dispersed in acetic acid solution, ultrafiltred and dried.

Results and Discussion: Chitosan was crosslinked with two dicarboxylic acids with different chain length, such as, tartaric acid and Poly(ethylene glycol) bis(carboxymethyl)ether $PEG(COOH)_2$, by inverse microemulsion with different chitosan/crosslinking ratios in order to obtain simultaneously crosslinked and activated nanogels as Figure 1 shows.

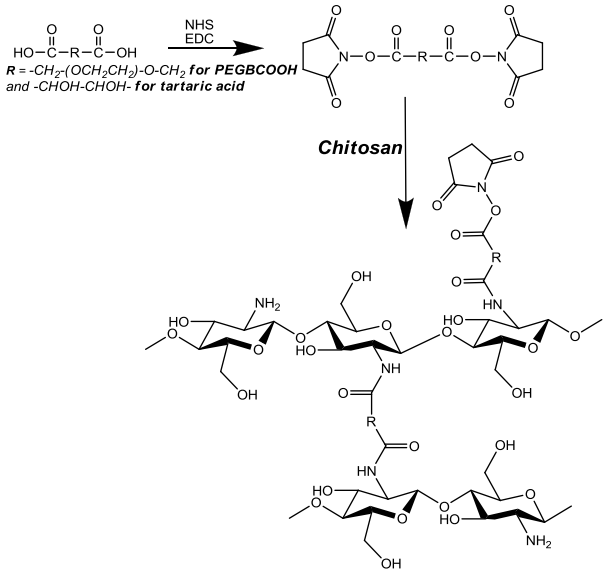

Figure 1. Chitosan modification reaction

The structure of modified chitosan was clearly confirmed by IR and ^1H NMR spectroscopy. The qualitative study of the evolution of the crosslinking reaction was performed by IR spectroscopy. The amide C=O stretching at 1655 cm^{-1} and amide N-H stretching at 1560 cm^{-1} was increasing in the spectra of chitosan while crosslinking proportion increased. In the case of tartaric acid, the closed nature of the network was confirmed by the presence of the band at 1730. cm^{-1} in IR spectra at long time of reaction corresponding to the ester bond of NHS-pendant groups unable to react. The crosslinking reactions could be quantitative evaluated by the decreased of the peak located at 3.2 ppm in the ^1H NMR spectra assigned to the proton of H-2 protons of glucosamine moieties. In all the cases maleic acid was used as internal standards (D_2O, δ = 6.0 ppm).

TEM images of chitosan nanogels indicated that the particles are spherical and have a mean particle size closed to 50 nm.

The pH dependence of the water dispersability of synthesized nanogels was studied by turbidimetry and, in most cases, improved properties were obtained respect to chitosan as crosslinker ratio increases.

Conclusions: Chitosan nanoparticles have been obtained by partial modification with $PEG(COOH)_2$, and tartaric acid resulting in activated systems for potential applications in targeting therapy.

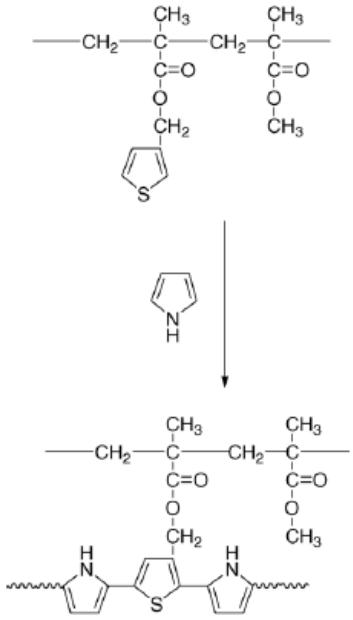
Introduction: Biosensors containing enzymes have been widely applied in chemistry and biology due to their high sensitivity and potential selectivity, in addition to low cost and possibility of miniaturization or automation. In this study, immobilization of glucose oxidase was done via entrapment within three different polypyrrole/poly(methyl methacrylate (PMMA)-co-thienyl methacrylate (PMTM)) matrices (Scheme 1). The types of PMMA-co-PMTM random copolymers were coded as MT1, MT2, and MT3. Although they have the same segments, they have different copolymer
compositions (Table 1). These random copolymers were synthesized and characterized previously [1]. Optimu conditions for immobilized glucose oxidase, such as pH, temperature, and kinetic parameters (Km and Vmax) were investigated. The operational stability studies of these enzyme electrodes were done. The amount of glucose in two orange juices of Turkey were determined using these enzyme electrodes.



Scheme 1: Synthesis of conducting polymer of PMMA-co-PMTM/PPy.

Table 1
Random copolymers

Code	Mn	Copolymer composition (mol%)	
		PMTM	PMMA
MT1	1.1×10^5	17	83
MT2	1.1×10^5	25	75
MT3	1.2×10^5	45	55

Materials and Methods: Glucose oxidase, (37,700 U/g) Type II-S, (GOD, EC:1.1.3.4), peroxidase, Type II, (POD, EC: 1.11.1.7), *o*dianisidine, and sodium dodecyl sulfate (SDS) were purchased from Sigma. Pyrrole (Merck) was distilled before use and stored at 4 °C. Sulfuric acid and hydrogen peroxide were supplied by Merck. Potentioscan Wenking POS-73 potentiostat and Shimadzu UV-160 model spectrophotometer were used.

Immobilization process was achieved by electropolymerization of pyrrole on bare or any one of MT1-, MT2-, MT3-coated platinum electrodes (1 cm2). Polymerization reactions were carried out by applying 1.0V for 20 min at 25 ◦C. In order to determine maximum velocity of the reaction (V_{max}) and the Michaelis–Menten constant (K_m) for each electrode, activity assay was applied for different concentrations of glucose. The reaction temperature was changed between 10 and 80 ◦C while glucose concentration was kept constant at 10Km for every case. For pH optimization at 25 ◦C, the pH of the reaction was altered between pH 4 and 11 while glucose concentration was kept constant at 10 Km. The activities were determined as previously described [2].

Results and Discussion: This study shows that GOD can be successfully immobilized in PPy, MT1/PPy, MT2/PPy, and MT3/PPy matrices. As regards to temperature, pH and operational stability MT1/PPy/, MT2/PPy, and MT3/PPy enzyme electrodes yield very good results. Only other hand, PPy electrode reveals the best Km and Vmax values among enzyme electrodes. Immobilization of glucose oxidase enzyme in conducting polymer electrodes was studied as an alternative method.

Conclusion: The enzyme electrodes can be used with a considerable activity for determination of glucose. Their wide working ranges observed for temperature and pH and biosensing advantages over conventional methods such as their simplicity, rapidity and low cost make them very useful. For the determination of glucose amount in fruit juices and results show that this significant development can successfully replace the classical methods.

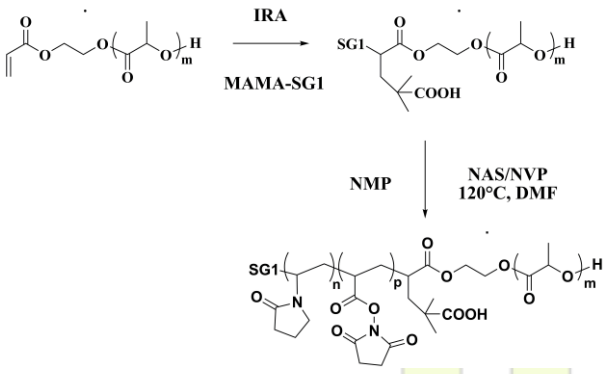
Introduction

Polylactide (PLA) nanoparticles are attractive candidates for drug delivery systems because of their biocompatibility and biodegradability properties.[1,2] Their potential could be further increased through the coupling of appropriate receptor ligands at the particle surface. However, such coupling can hardly be performed due to the lack of functional groups on PLA. In this context, we focused on the synthesis of poly(D,L-lactide)-*b*-poly(*N*-acryloxysuccinimide-*co*-*N*-vinylpyrrolidone) (PLA-*b*-P(NAS-*co*-NVP)) and their use as surface modifier in the PLA particle preparation process, for further coupling of amino-bearing biomolecules of interest through the *N*-succinimidyl ester moieties of the NAS units

Results and Discussion

For this purpose, nitroxide mediated polymerization (NMP) of NAS and NVP was performed from a SG1 functionalized poly(D,L-lactide) (PLA-SG1) macro-alkoxyamine as initiator, in the presence of free SG1 nitroxide (*N*-(2-methylpropyl)-*N*-(1-diethylphosphono-2,2-dimethylpropyl)-*O*-(2-carboxylprop-2 yl)hydroxylamine), in DMF at 120°C. The PLA-SG1 macro-alkoxyamine was previously obtained by 1,2-intermolecular radical addition (IRA) of the MAMA-SG1 alkoxyamine (BlocBuilder MA) onto acrylate end-capped PLA previously prepared by ring opening polymerization (ROP) (scheme 1).[3]



Scheme1. Strategy of synthesis of PLA-b-P(NAS-co-NVP), using PLA-SG1 macro-alkoxyamine as initiator for NAS/NVP NMP.

The reactivity ratios of NAS and NVP were determined to be r_{NAS}=0.17 and r_{NVP}=0,02, when copolymerization was conducted from PLA-SG1 macroinitiator, indicating a strong alternating tendency for the P(NAS-*co*-NVP) block, and were very similar to those obtained for a P(NAS-*co*-NVP) initiated from a molecular alkoxyamine as initiator (MAMA-SG1). The PLA-*b*-P(NAS-*co*-NVP) block copolymer was characterized by GPC in DMF and ^{1}H NMR.

This copolymer was then further used as a surface modifier for the PLA diafiltration and nanoprecipitation processes to achieve biodegradable nanoparticles in the range of 450 nm and 150 nm, respectively, without aggregates, as shown in figure 1. The presence of the *N*-succinimidyl ester moieties at the particle surface was evidenced by ethanolamine derivatization and zeta potential measurements.

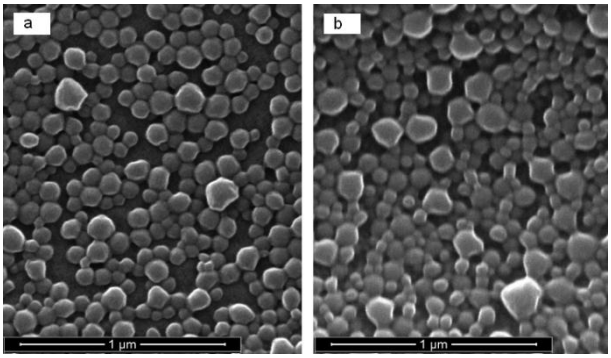


Figure 1. SEM images of functionalized (a) and naked (b) nanoparticles PLA particles obtained by nanoprecipitation

Conclusions

These particles with highly functional surface properties represent a generic system of high interest in drug delivery applications for coupling of amino-bearing ligands.

Preparation of Pluronic Micelles for Ophthalmic Delivery Using Ethyl Acetate as a Dispersion Agent

Hong-Ru Lin, Pei-Csang Chang, Huei-Jen Kao[1]

Department of Chemical and Materials Engineering, Southern Taiwan University, Tainan 710, Taiwan
[1]Department of Pharmacy, Chia-Nan University of Pharmacy and Science, Tainan 717, Taiwan

E-mail: hrlin@mail.stut.edu.tw

Introduction

Pluronic is a class of block copolymers, consisting of poly(oxyethylene) (PEO) and poly(oxypropylene) (PPO) units. Once blocks of PEO and PPO are combined, one can expect amphiphilic characteristics and aggregation phenomena at higher temperatures. In this study, ethyl acetate used as a dispersion agent was added to the pluronic solution to prevent gel formation. One the other hand, the surface of the pluronic micelles was modified by poly (ethylenglycol) methyl ether (MPEG) to improve their surface hydrophilicity. The improvement in hydrophilicity is expected to improve the encapsulation efficiency of loading hydrophilic drug.

Experimental

Two drops of span 80 were added to pluronic solution with fast agitation, and then ethyl acetate solution with MPEG was slowly added and was stirred completely until completely dispersed. Finally, the completely mixed solution was freeze-dried to obtain micelle particles. The particle size and its distribution of the micelles were investigated. The morphology of the micelles was observed by transmission electron microscopy (TEM). Turbidity test of the micelle solution was investigated.

Results and discussion

When the Pluronic concentration and the characteristic temperature are above a critical point, this block copolymer forms micelles. These micelles will aggregate to form gel by the chain entanglement between the micelles. In order to prevent gel formation, ethyl acetate used as a dispersion agent was added to the pluronic solution. The hydrophobic chains in both ends of ethyl acetate may interfere with the chain entanglement between micelles, thus preventing the gel formation. Figure 1 shows the photographs of pluronic solution at critical micelle concentration (28 wt %). The solution formed gel without the addition of ethyl acetate (Fig. 1 (A)), however, no gel formation was found when the ethyl acetate was incorporated (Fig. 1 (B)).

Figure 2 shows the typical morphology of micelles observed by TEM. The micelle with a spherical shape (Fig. 2 (A)) has a core-shell like structure with hydrophobic segments in the core (light region in the photograph) and hydrophilic segments in the shell (dark region in the photograph). The particles of micelles were well distributed as shown in Fig. 2 (B). The average size of pluronic micelles is about 200 to 350 nm. In this study, the surface of the pluronic micelles was modified by MPEG to improve their surface hydrophilicity. The improvement in hydrophilicity is expected to improve the encapsulation efficiency of loading hydrophilic drug. The size of pluronic micelles was increased (300 to 500 nm) after surface modification by MPEG.

Different amount (0.05 and 0.1 g) of micelles was soaked in the PBS and was observed by UV-Visible to investigate their turbidity (Fig. 3). The result indicates both amounts of micelles had constant turbidity during 5 h investigation. This suggests the micelles prepared in this study were very stable in the PBS environment. In the case of 0.05 g of micelles, the penetration was higher than 90% even after 5 h investigation; the blurred vision can be avoided after topical administration of the micelles suspension.

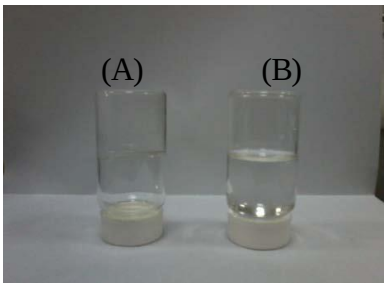

Fig. 1 The photographs of pluronic solution at critical micelle concentration (28 wt%). The solution formed gel without the addition of ethyl acetate (Fig. 1 (A)), however, no gel formation was found when the ethyl acetate was incorporated (Fig. 1 (B)).

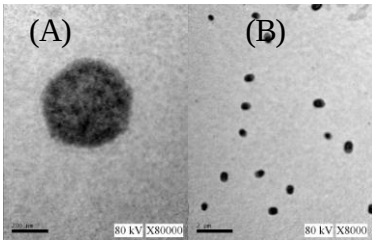

Fig. 2 The morphology (A) and distribution (B) of micelles observed by TEM.

Effect of the crosslinker in Molecularly Imprinted Polymers

I. Iturralde, M. Paulis, J. R. Leiza

POLYMAT-Grupo de Ingeniería Química. Fac. Química SS, EHU/UPV

ibon.iturralde@ehu.es

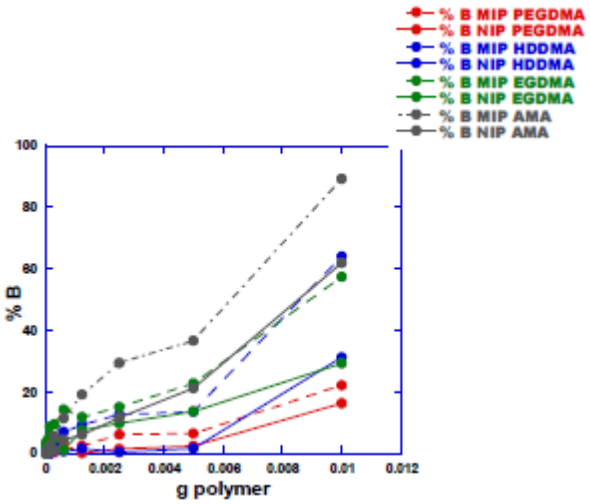
Introduction: Molecularly Imprinted Polymers (MIP) are synthetic materials with high molecular recognition capacity that mimic the functions of enzymes and biological antibodies. Molecularly Imprinted Polymers present higher robustness to temperature, pH, solvents or impurities of the reaction and molecular recognition media than the enzymes and biological antibodies.

The art of molecularly imprinted polymer synthesis involves the self-assembly between a functional monomer and a template molecule in presence of a crosslinking monomer and a solvent that acts as porogen. Typically, molecularly imprinted polymers synthesis is carried out by bulk polymerization in which MAA is used as functional monomer and EGDMA as crosslinking agent.

The following work involves the synthesis of molecularly imprinted polymers of Propranolol with different crosslinking agents bearing different chain lengths. The influence of the different swelling capacities produced by each crosslinker on rebinding capacity and specificity of the MIP was also studied.

Materials and Methods: Methacrylic Acid (MAA) (0.02 mmol), used as functional monomer, was purchased by Sigma Aldrich. The crosslinking agents (1 mmol) Ethylene Glycol Dimethacrylate (EGDMA), 1, 6 Hexanodiol Dimethacrylate (HDDMA), 200-Poly Ethylene Glycol Dimethacrylate (PEGDMA) and Allyl Methacrylate (AMA) were obtained from Sigma Aldrich. The R, S-Propranolol Hydrochloride was used as template (Sigma Aldrich). The R, S-Propranolol was hydrophobized by an aqueous solution of NaOH and extracted in presence of Chloroform. The initiator used was 2, 2′-Azobisisobutyronitrile (0.025 mmol) supplied, by Wako. Toluene was employed as porogen. The polymerization took place in vials at 70ºC. In order to establish the amount of template specifically adsorbed, the same recipes without template were polymerized in order to obtain the non-imprinted polymers (NIP). The resulting monoliths were grounded and cleaned in AcOH NH_4/MeOH/AcOH/H_2O solution, followed with several cleanings with MeOH/AcOH (90/10 volume ratio) in order to extract the R, S-Propraonolol. L-[4-3H]- Propranolol, purchased by Perkin Elmer, was used for rebinding experiments according to the procedure developed by Andersson [1]. The experiments were carried out in a Packard liquid sparkle detector, Tricarb 2000 CA model. The swelling experiments were performed using the methodology proposed by Lu et al.[2] and Tan et al.[3]. Surface BET analysis was carried out to determine the structural characteristics of the MIPs and NIPs (ASAP 2020 apparatus).

Results and discussion: MIPs having different chain length crosslinker were used in rebinding trials. MIPs synthesized with AMA rebound the highest amount of L-[4-3H] – Propranolol, while PEGDMA MIPs presented the lowest rebinding capacity. Regarding to the specificity, the difference between the template rebound in MIP and NIP, surprisingly AMA samples showed the highest value. HDDMA and EGDMA samples presented quite similar high specificity and PEGDMA MIP had poor selectivity for L-[4-3H] – Propranolol.



Swelling and specificity results were compared in order to establish a relationship between structure and template affinity. The highest swelling was related to the less specific MIP, the one synthesized with PEDGMA. The lowest swelling was obtained for the MIP with AMA. Quite similar values were observed for MIPs synthesized with EGDMA and HDDMA.

Conclusions: MIPs having different branch length crosslinkers were synthesized. Surprisingly, the highest imprinting capacity and specificity was observed for MIPs synthesized with AMA and HDDMA. MIPs with EGDMA, widely used in the literature, showed a slightly lower specificity. PEGDMA did not present any specificity for Propranolol. High swelling ratios were related with to imprinting capacity.

Chitosan based microspheres with good swelling characteristics

Małgotzata Maciejewska, *JoannaOsypiuk-Tomasik*

Faculty of Chemistry, Maria Curie-Skłodowska University, Gliniana 33, 20-614 Lublin, Poland

e-mail: mmacieje@umcs.pl

Introduction

Polymer microspheres are broadly defined as spherical polymer particles in the size range of about 20 nm to 2,000µm. They can be derived from numerous inorganic and organic monomers as well as naturally occurring polymers e.g. chitosan. Chitosan, [poly-β(1-4)-2-amino-2-deoxy-D-glucose], is a polymer derived from chitin in the process of deacetylation. Commercially available preparations have degrees of deacetylation ranging from 50 to 90%. Chitosan is inexpensive, biodegradable, and biocompatible. The main applications concerns agriculture and water treatment, food and cosmetic industries and biopharmaceutical uses[1]. Because of the stable, crystalline structure, chitosan is normally insoluble in aqueous solutions above pH 7. However, in dilute acids, the free amino groups are protonated and the molecule becomes fully soluble below ~pH 5. The lack of solubility in higher pH creates great numbers of limitation in many kind of applications. An addition of suitable amount of hydrosoluble polymer can improve the hydrophilicity of the system. Due to its nontoxicity, biocompatibility and good complexing properties 1-vinyl-2-pyrrolidone can be a good choice. In this work we present the preparation of crosslinked microspheres based on chitosan and 1-vinyl-2-pyrrolidone(VP).

Materials and Methods

Preparation of crosslinked chitosan microspheres

0.8g of chitosan was dispersed in 30ml of 3% acetic acid. The mixture was stirred for 5 h and then sonificated for 15 min. The crosslinker (ethylene glycol dimetacrylate) and the mixture of 1-vinyl-2-pyrrolidone with the initiator (2,2'-azobisisobutyronitryle) were directly added the solution. Different ratios of crosslinker/chitosan and VP/chitosan were used to modulate the crosslinking extent and hydrophilicity of the final product.

The above solution was strirred for 7 h and then poured into a syringe equipped with a micro-pipette tip and dropped into 50mL solution containing 70% of ethanol and 30% of aqueous amomonia solution at 35w/w %.

The droplets give rise to microspheres suspended in the coagulant. They were left under low stirring for 6 h in 65ºC to complete the reaction of crosslinking.

The obtained microspheres were filtred out, washed with deionised water to neutral pH and dried under vacuum. In this way we obtained regular beads with diameter ranging between 300 – 500 µm. The SEM micrograph of the disscused microspheres is presented in Fig. 1.

Swelling

In order to determine the swelling behaviour a suitable number of microspheres was placed into a stainless steel basket containing various buffer solution at 25ºC. The swellability coefficient (B) was expressed as:

$$B = \frac{W_s - W_d}{W_d} \times 100\%$$

where:

W_s-weight of the swollen polymer

W_g- weight of the dry polymer

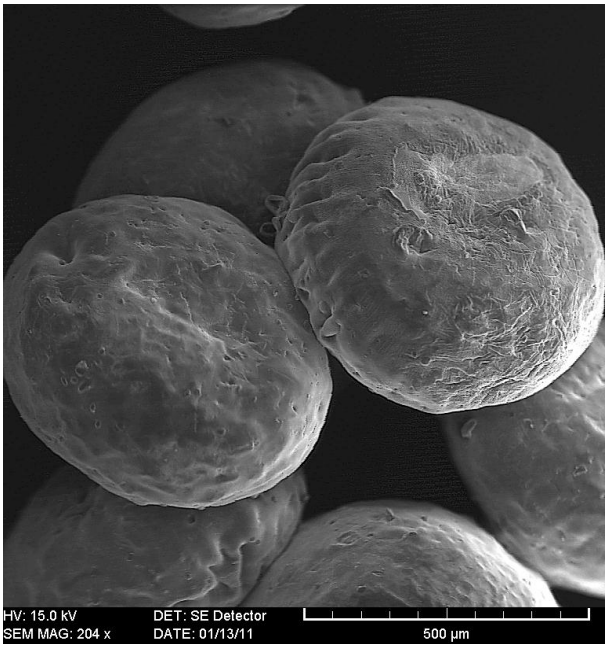

Fig1. SEM micrograph of the obtained microspheres.

Results and Discussion

In contrast to neat chitosan gels, which swell only in acid solution, the chitosan-vinylpyrrolidone microspheres posses the capability of reversible swelling in water at room temperature at pH 7. The swellability coefficient determined in water is strongly dependent on the crosslinking extent and amount of VP incorporated into chitosan matrix. The value of B changes from 0 to 200 and it takes 240min to reach equilibrium swelling, whilethe time necessary to reach the half of the equilibrium is about 60min. Also the pH of the solution influences the value of swellability coefficient. The high value of B in acid environment dropped dramatically after increasing the value of pH above 5.5. The sensitive behaviour ofchitosanmicrospheres is connected with the ioniztation of $-NH_2$ groups.

Purification and Characterization of Adhesive Proteins for Footwear

N. Cuesta, M.J. Escoto, C. Orgilés

INESCOP. Footwear Research Institute. 253. 03600 Elda (Alicante)

ncuesta@inescop.es

Introduction

Nowadays, several legislative, economic and environmental awareness factors make necessary the introduction of new industrial production systems that without losing competitiveness were increasingly more and more environmentally friendly.

In response to this need, INESCOP is working on a research line focused on the application of protein adhesives with microbial origin, as the base polymer for the formulation of industrial adhesives.

One of the advantages of using these polymers, compared to other with a non-renewable synthetic origin, lies on the reduction of the risk of environmental pollution which favors the elimination of their waste without harming the environment. Moreover, its composition makes these proteins to be soluble in aqueous medium, avoiding the use of organic solvents in the formulation of adhesives.

Materials and Methods

The study has been focused on a protein from *Bacillus subtilis*, Gram-positive, non-pathogenic and biofilm-forming bacteria, capable of producing high amounts of proteins. According to a sequence alignment analysis (BLAST), this protein has a high percentage of homology with sequences of proteins with known adhesive function.

The involvement of selected protein in biofilm formation mechanisms has been assessed by carrying out bioadhesion assays.

The gene that encodes for the protein was subcloned into a commercial expression vector, pQE60, adding in the carboxyl tail a 6 histidines tag which has been used to purify the target protein throughout a column with a nickel resin bed.

Once the protein had been purified, several tests were conducted to characterize the possible adhesive properties of the protein for its possible use as an adhesive in the shoe industry.

Results

After over-expressing the protein of interest, an increase in the amount of biofilm was determined and a greater affinity for the test surface was observed. In addition, the target protein was purified obtaining remarkable concentration. Finally, the wettability and adhesive ability have been analyzed, showing surprising results that could be improved incorporating leveling and moisturizer additives.

Conclusions

The overexpression of the target protein promotes the biofilm adhesion.

It has been established a protocol for protein purification at laboratory scale.

The purified protein has a good wettability for different substrates representative of materials used in the manufacture of footwear.

The target protein shows remarkable adhesion on the surface. However, the adhesive suffers from a low cohesive strength, which should be improved for its application.

Flocculation by Cationic Amphiphilic Polyelectrolytes: Relating Efficiency with Polymer Characteristics and Concentration

Luminita Ghimici, *Marieta Nichifor*

"Petru Poni" Institute of Macromolecular Chemistry, Aleea Grigore Ghica Voda, 41A Iasi, Romania

e-mail: lghimici@icmpp.ro

Introduction

Ionic polymers are widely used to improve the flocculation process efficiency which is of considerable importance in the wastewater treatment. Theoretical and experimental data revealed that the flocculation activity of a polyelectrolyte is strongly sensitive to the polymer characteristics and environment.[1] Although a considerable range of flocculants is now available, new types have to be introduced either to reduce the cost or to provide special functional groups to match the surfaces on which they are required to adsorb. In this context, the current work centers on the flocculation properties of some amphiphilic polyelectrolytes based on dextran carrying pendent quaternary ammonium groups randomly distributed along the polymer backbone (Fig. 1). These polycations varied in hydrophobicity (by variation of the length of the alkyl substituent at the quaternary nitrogen, alkyl= ethyl, butyl, octyl, dodecyl), molar mass (M=40, 200, 400 kg mol^{-1}) and charge density (X= 0.42 and 0.96) and are therefore useful in probing the competitive effect between electrostatic and hydrophobic interactions on the flocculation efficiency.

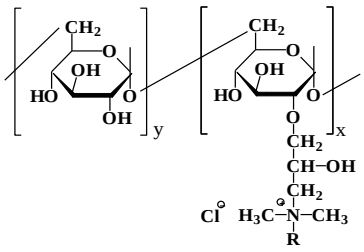

Fig. 1: DM-RX
R= Et (ethyl); Bu (butyl); Oct (octyl); Dod (dodecyl)

Materials and Methods

Cationic polysaccharides with pendent quaternary ammonium groups were synthesized by chemical modification of dextran samples.[2] Each sample was purified by repeated precipitation and dialysis, and finally recovered as a white powder by liofilization. The chemical structure was proved by ^{1}H-NMR, elemental analysis (nitrogen content) and potentiometric titration with 0.02N $AgNO_3$ aqueous solution (chloride ion content). Clay dispersions with concentration of 1g L^{-1} were prepared in distilled water, sonicated for 30 min, followed by vigorous stirring during 15 min.

Turbidity measurements were carried out using a HACH 2100 AN turbidimeter. The zeta potential of clay suspensions in the presence and absence of polycation was measured with a Zetasizer Nano-ZS, ZEN-3500 model (Malvern Instruments). Measurement of particle dimensions was done using laser diffraction technology with a Mastersizer 2000 system (Malvern Instruments, Malvern, England).

Results and Discussion

Influence of polymer dose and hydrophobicity.

Examination of the residual turbidity-polycation dose plots for D40-R30 (Fig. 2) demonstrated a downwards trend of the residual turbidity with increasing polycation dose until a minimum was reached, followed by an increase with a further increase in polycation dose.

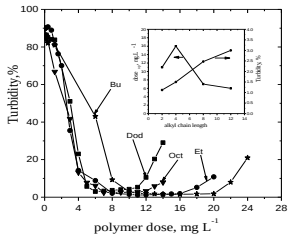

Fig. 2: Residual turbidity dependence on the polymer dose; settling time =15 min.

The alkyl chain length greatly influenced the polymer dose where the maximum clarity degree was reached (Fig. 2, inset) as well as the width of the flocculation window since these parameters increased when the ethyl group was replaced by a butyl group and decreased for longer R. The different behavior of D40-R30 could have resulted from the various conformations of their macromolecular chains in solution: extended for R=ethyl and butyl and more compact coils for R=octyl and dodecyl. The magnitude of the zeta potential increased significantly as the polycation dose increased for all amphiphilic polysaccharides. The negative value of ζ at the optimum polycation dose and floc size measurements point to contributions from both patch and bridging mechanisms for the flocculation process

Influence of the charge density molar mass

The maximum clarity degree was shifted to a lower polymer dose when the charge density increased.

Influence of the molar mass

The dextran derivative with higher molar mass flocculated better, but no dramatic effect was observed in the range of molar mass investigated.

Conclusions

Flocculation of clay dispersion by some amphiphilic polyelectrolytes based on dextran is strongly influenced by the polymer hydrophobicity and charge density, but less by molar mass. The combined information supplied by turbidity, zeta potential and laser diffraction measurements were consistent with destabilization of clay suspension by the combined mechanisms of electrostatic patch and bridging.

[3]Clermont Université, UBP, Laboratoire de Photochimie Macromoleculaire, F-63000 Clermont-Ferrand

mkoutny@ft.utb.cz

Introduction: Presently, polymer scientists are looking for the possible replacement of conventional polyolefins by biodegradable alternatives [1,2]. The perspective materials are represented by synthetic copolyesters with content of aromatic and aliphatic components [3,4]. Changing the component ratio one is able to balance processing properties of the copolyester and its biodegradability [5,6,7]. Several these materials were already commercialized and they are available on the market [8]. Another candidate appears to be polylactide, which is a synthetic polymer but the corresponding monomer can be obtained from renewable resources. In general, these materials especially well comply with composting technologies of waste treatment but, as we show here, biodegradation of such materials can be greatly affected by the form of the sample specimen.

Material and methods: The polymers used throughout the study were:
P1, aromatic aliphatic copolyester containing units of terephtalic acid, adipic acid and 1,4-butane-diol (producer 1).
P2, aromatic aliphatic copolyester containing units of terephtalic acid, adipic acid and 1,4-butane-diol (producer 2).
P3, polylactide (3251D, Natureworks).
Polymer processing. Raw polymer in the form of pellets was processed to obtain different forms of the polymer with different specific surfaces.
Films. Films were prepared by compression molding at 140°C. According to the inserted steel frame films of 100 μm and 300 μm were prepared.
Powder. Chloroform solution of polymer (50 mg/ml) was poured into four volumes of ethanol and the mixture was vigorously stirred. Obtained precipitate was filtered out and dried on air.
Thin coating on inert surface. Calculated volume (4 ml) of the chloroform solution of polymer (50 mg/ml) was applied on the surface of pre-weighed porous inert material (perlite, 7 g) and stirred. Then the solvent was stripped out with air leaving the polymer coating on the surface of perlite.
Biodegradation experiment. Three components were weighed into 500 ml biometric flasks: polymer samples (200 mg), mature compost or any of tested soils (5 g of dry weight) and perlite 7 g. Biometric flasks were equipped with septa on stoppers. Sample flasks were incubated at 58°C. Head space gas was sampled at appropriate intervals through the septum with a gastight syringe and then injected manually into a GC instrument (Agilent 7890).

Results and discussion: Investigated copolyester was designed to be a biodegradable material with potential applications in agriculture. Preliminary experiments showed (data not presented) that biodegradation of relatively thick compression (100 μm) molded polymer films appeared to be relatively slow. We decided to test whether this phenomenon was caused by low specific surface of the films. To answer the question we prepared two other forms of the polymer with higher specific surfaces, solvent precipitated powder of the polymer and deposition of the polymer on high specific surface inert material (perlite).
Copolyesters (P1 and P2) of both producers showed quite similar properties. Samples in forms of thin and thicker films behaved almost equally and end up with about 20-40% carbon mineralization after 90 days of incubation. However for the two forms of samples with higher specific surfaces the results are clearly more optimistic with results from 45% to more than 80% at the end of the observation period. The copolymers proved its good biodegradability under composting conditions. However, our experiments clearly showed that specific surface of polymer specimens affects greatly the rate of biodegradation. Experiments with polylactide (P3) are still on the way. The results will be added to the final poster presentation together with a general conclusion.
This contribution was created with support of Operational Program Research and Development for Innovations co-funded by the European Regional Development Fund (ERDF) and national budget of Czech Republic, within the framework of project Centre of Polymer Systems (reg. number: CZ.1.05/2.1.00/03.0111).

Synthesis and Characterization of Organic-Inorganic Hybrid Biomaterials Based on 2-Hydroxyethylmethacrylate/Triethoxyvinylsilane Composites

Łukasz John, Marta Bałtrukiewicz, and Piotr Sobota

University of Wrocław, Faculty of Chemistry, 14 F. Joliot-Curie, 50-383 Wrocław, Poland

e-mail: john@eto.wchuwr.pl

Introduction. Research and developments in the area of organic-inorganic hybrid materials based on silica bioceramics and polymeric biocomposites increased rapidly over the past decade.[1] Demands in bone tissue engineering have promoted various synthetic materials that interact with biological systems (cells, tissues, organs, body fluids, growth factors, peptides, hormones, etc.). Since the beginning of the 21st century, a very special interest is related to so-called second- and third-generation biomaterials which are allowed to induce tissue repair and regeneration through the bionic approach.[2]
Poly(2-hydroxyethylmethacrylate) (pHEMA) constitu-tes a biocompatible polymer widely used in bio-medicine.[3] There are also known some examples of pHEMA-based biocomposites that demonstrates the attractive in vitro activity in biological fluids.[4] Here we report our previous studies on organic-inorganic hybrid biomaterials based on 2-hydroxyethylmethacrylate/ triethoxyvinylsilane (HEMA/TEVS) systems – pure and doped by Ca^{2+} and PO_4^{3-} ions. The present topic is devoted to the design of biohybrids that can bond to living bone via hydroxyapatite (HAp)-layer formation and appropriate architecture which allows bone tissue penetration. Surface structure of the samples were examined by powder X-ray diffraction, Fourier-transformed infrared and physisorption analysis.

Materials and Methods. *Chemical reagents:* HEMA (2-hydroxyethylmethacrylate), TEVS (tri-ethoxyvinylsilane), calcium dichloride, and triethyl phosphate were used as starting materials without further purification.
Experimental: Mixture of HEMA/TEVS with various molar ratio was dissolved in EtOH. The mixture was polymerized by heat treatement at 70°C with tert-butyl hydroperoxide as initiator. In case of Ca^{2+} and PO_4^{3-}-doped materials, obtained polymer solution was mixed with calcium dichloride and triethyl phosphate. Then, solution was cast in PP mold and dried in the range of RT to 70°C. Homogenous and transparent gels were obtained for all synthesized materials.
In vitro assays: A small amount (~ 60 mg) of a hybrid material was immersed at 37°C for 0.5h, 1h, 6h, 12h, 1d, 2d, 3d, 4d, and 7 days in ca. 10 ml of a standard Dulbecco's modified Eagle medium (DMEM, Biochrom AG, Germany). After interaction, the samples were removed from the fluid and air-dried.
Measurements: powder XRD, FT-IR, ICP-AES, TEM-EDS, DSC, physisorption analysis.

Results and Short Discussion. In the body environment, the hydrophylic nature of HEMA-based organic and inorganic composites enables them to interact well with cells and have been used for variety of applications such as drug delivery. From this perspective we have synthesized a series of promising hybrids with the general compositions: HEMA-TEVS, HEMA-TEVS-Ca and HEMA-TEVS-Ca-P (where: HEMA/TEVS = x/(1-x), x = 0.1, 0.5, and 0.9; Ca = Ca^{2+}, and P = PO_4^{3-}). TEVS has alkoxysilane groups that may provide silanol moieties ≡Si-OH after hydrolysis, whereas HEMA may provide hydrophilic polymer matrix in the materials.

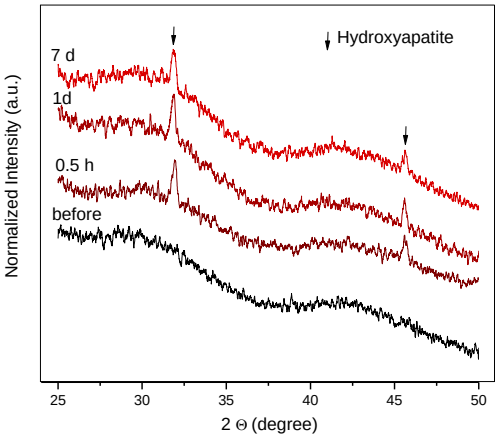

Figure 1. X-ray diffraction patterns of the sample of 0.9HEMA-0.1TEVS-Ca(15 mol%), before and after soaking in DMEM solution for various periods.

In vitro studies conducted in the Dulbecco's modified Eagle medium (DMEM) have shown that formation of a bone-like apatite layer occurs on material surface after exposure to the biological fluid. All of the samples were immersed for 0.5h – 7 days at 37°C. The formation of the HAp surface is induced both by dissolution of calcium ions, and by silanol groups in the hydrated silica gel formed on the surface. Surprisingly, in the case of 0.9HEMA-0.1TEVS-Ca, nanocrystalline HAp-layer formation is observed after 30 minutes of exposure in DMEM (Figure 1).

Conclusions. The organic-inorganic hybrids derived from HEMA-TEVS-based composites doped by Ca^{2+} and PO_4^{3-} ions have a potential as a bioactive material for bone repairing and replacing agents.

Controlled delivery of gentamicin antibiotic from bioactive electrospun polylactide-based ultrathin fibers

Sergio Torres-Giner, Antonio Martinez-Abad, Maria J. Ocio and Jose M. Lagaron

Novel Materials and Nanotechnology Group, IATA, CSIC, Avda. Agustín Escardino 7, 46980, Burjassot, Spain

e-mail: lagaron@iata.csic.es

Abstract Body: Post-surgical infection is an emerging problem, which frequently develops after surgical procedures. This kind of infections may even require secondary surgical intervention, which is not only time-consuming and costly, but also increases the potential for further infections, scar tissue formation, and even later rejections. Prevention of infections can thus decrease the overall hospital costs and the severity of complications, and can also ease the technical complexity and/or need for subsequent surgery. Wound healing currently not only aims to restore the milieu required for tissue regeneration but also to protect the wound from environmental threats and penetration of bacteria. Novel bioresorbable wound dressings successfully avoid clinical changing since they do not need to be removed from the wound surface once they have fulfilled their role [1,2].

The purpose of the present study was to investigate the use of PLA and collagen electrospun blends to develop antibiotic-loaded fibrilar structures which, in addition to biocompatibility, display adjustable release characteristics in functional dressings for wound healing applications. For this purpose, gentamicin was chosen as the incorporated drug since this is a well-known antibiotic that can inhibit or kill bacteria of most typical post-surgical infections. Therefore, electrospun ultrathin fibers containing gentamicin of PLA, PLA-collagen blend, and co-axial PLA-collagen-PLA fibers were produced. It was investigated how the choice of polymer chemistry and antibiotic distribution within the fibers influenced the morphology and release properties of the biomedical fibers. Preliminary antibacterial effectiveness against Staphylococcus epidermis, Pseudomonas aeruginosa and Escherichia coli were also tested to establish the appropriateness of these electrospun fibers to be applied for decreasing frequency and severity of post-surgery infections.

From the results, it was found out that incorporation of gentamicin antibiotic in ultrathin fibers of PLA, uniaxial PLA-collagen and coaxial PLA-collagen-PLA was successfully performed by electrospinning. The study recognized that the drug location within the electrospun morphology largely determined the delivery characteristics. This also showed that release rates were extremely correlated with the hydrophilicity of the polymer fibers. Resultant fibers not only displayed high antibacterial performance but also cell biocompatibility.

The present results provide a basis for further design to generate ultrathin electrospun antibiotic-loaded fibers in order to achieve highly sustainable, controllable, and effective antibiotic-releasing kinetics.

Stress-Strain Analysis Of Poly (Lactic-Co-Glycolic) Acid / Poly (Isoprene) Blend For Use As Implants

Douglas Ramos Marques[1], Luis Alberto dos Santos[1]

1- Biomaterials Laboratory, Engineering School , Federal University of Rio Grande do Sul, Porto Alegre - Brasil.

E-mail: dougmarques@ibest.com.br

The development of a raw material to an implantable medical device that approach the ideal behavior requires a plausible combination of mechanical properties and tissue response. With this sight, the polymeric blend of Poly(Lactic-Co-Glycolic) Acid (PLGA) and natural latex rubber – or Polyisoprene (IR) – was idealized, uniting the good biocompatibility and absorption capacity by the organism of the PLGA with the specific mechanical characteristics promoted by IR. To determine the mechanical behavior of blend in the compositions 100% PLGA, 50%PLGA+50%IR, 60%PLGA+40%IR, 75%PLGA+25%IR, tensile test was performed with the compositions. The test aims generate the stress vs strain curves for the different compositions, to determinate the influence of IR amount in the mechanical properties of blend, specially observing variations in materials tenacity. To perform the test, the polymeric blend was obtained by the polymers' solubilization (PLGA and IR) in organic solvent, following 24 hours drying in 30°C stove for volatilize solvent. Three samples for each composition were made by injection molding (model Haake Minijet II, Thermo Scientific, Netherlands). These samples were submitted to tensile test (model Autograph AG-X 50KN, Shimadzu, Japan) in proceedings based on standard ISO 527-1. As results, we can observe that the IR presence in the blend modifies significantly its mechanical properties, and the tenacity can be raised approximately 90% in compositions with bigger IR proportion, as well as increase in total tensile at break in the samples with increasing in the rubber's proportion.

Comparative Study of the Polymer – Lipase Complexes

D.O. Soloveva, S.Yu. Zaitsev, E.V. Tulskaya

Moscow State Academy of Veterinary Medicine and Biotechnology;

e-mail: d.solovieva@mail.ru

Introduction:

One of the modern methods of polymer and biological chemistry, nanotechnology and biotechnology is the method of enzyme immobilization on polymeric carriers.

Such systems as polymer - enzyme have several advantages that making them more convenient for the effective applications:

Increasing the stability of the enzyme in time to various denaturing agent;

It became possible to reuse the enzyme;

More simple and rapid separation of the reaction medium [1,2].

The purpose of this study was to prepare complexes of PE-240 and lipase from various sources possessing high catalytic activity.

Materials and Methods:

We used the following reagents: lipase from porcine pancreas, triacylglycerols, Na-polystyrenesulfonate (PSS), polydiallildimethylammonium chloride (PAMA), copolymer based on polypropylene oxide (PE-240). The lipase activity was measured using the method of potentiometric titration on an automatic titrator of the "Radiometer" Company (Copenhagen). It was measured by the rate of hydrolysis of the substrate. The main advantages of this method are high accuracy, high sensitivity and the ability to carry out the titration in the more dilute solutions than it allows visual indicator methods.

Results and Discussions:

It was found that the lipase activity in the PSS presence was higher than the control at 17 and 15 % at a ratio of 1:10 and 1:100 (lipase:PSS). It can be explained by increasing of the microheterogeneity system due to the interaction of lipase with polyelectrolytes (fig. 1). At a ratio 1:1 the lipase activity was decreased to 77% due to the insufficient number of PSS for the formation of microheterogeneous systems.

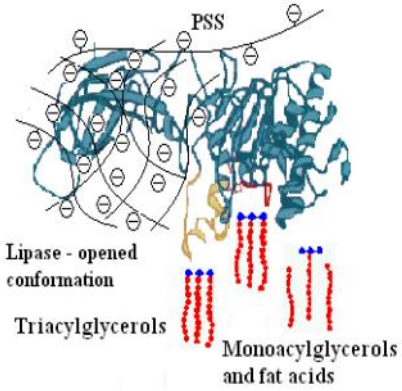

Figure 1. - Model of lipase:PSS 1:1 complexes with "low activity".

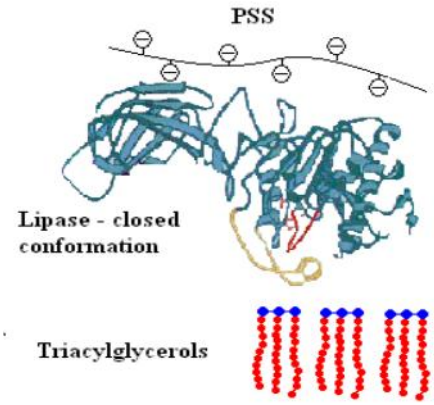

Figure 2. - Models of lipase:PSS 1:10 complexes with "high activity".

In the presence of PAMA the lipase activity was decreased to 94% at a ratio 1:10 (lipase:PAMA). It can be explained by that the lipase is negatively charged at neutral pH during complex formation is located inside the globule of a positively charged polymer and becomes less accessible to substrate.

In the presence of PE-240 the lipase activity was decreased to 88% at a ratio 1:5 (lipase:PE-240) and was higher than the control at 12% at a ratio 5:1.

Conclusions:

Thus, the lipase activity depends on polyelectrolyte parameters (molecular mass, charge, chain flexibility etc.) and ratio of polyelectrolyte to enzyme. The best systems are the following: lipase:PSS 1:10 and 1:100, lipase:PE-240 5:1 and 1:1, which are promising for application in bioengineering and biotechnology.

Acknowledgments:

The authors are grateful to Yu.G. Shtyrlin from Kazan (Volga Region) Federal University for PE-240 preparation and Russian Foundation for Basic Research for financial support.

Magnetic Nanoparticles Coated with a Molecularly Imprinted Polymer Synthesized by RAFT Polymerization

Carlo Gonzato, Pamela Pasetto and Karsten Haupt

Compiègne University of Technology

karsten.haupt@utc.fr

Molecularly imprinted polymers (MIPs) are tailor-made biomimetic receptors that are obtained by polymerization of interacting and cross-linking monomers in the presence of molecular templates. They contain binding sites for target molecules with affinities and specificities on a par with those of natural receptors such as antibodies, hormone receptors, or enzymes. One of their main application areas is as artificial antibodies in pseudo-immunoassays and in chemical sensors[1].

Superparamagnetic nanoparticles are attracting increasing interest in bioanalysis because they can easily be separated from a matrix by using a magnetic field without retaining residual magnetism[2]. If the magnetic nanoparticles are functionalized with a MIP layer, the specific recognition properties of the polymer can be combined with a magnetic response.

The aim of this research work is therefore to synthesize magnetic hybrid nanoparticles composed of iron oxide cores and a molecularly imprinted polymer shell.

Examples of magnetic MIPs are already known in the literature[2;3]. The originality of our approach consists in the controlled synthesis of these materials, starting the polymerization from the iron oxide surface using a controlled/"living" radical polymerization technique instead of the conventional free radical polymerization.

The use of the Reversible Addition-Fragmentation chain Transfer (RAFT) technique allows to build a more regular polymer network and to preserve living chain ends, giving access to hierarchical structures, core-shell materials and composites.

The first step of the synthesis of the hybrid nanoparticles was the grafting of a RAFT agent onto the iron oxide nanoparticles, and the second to fine-tune the polymerization process parameters. An ultrasonic bath was used to stir our system during synthesis, and a number of solvents were tested for the synthesis of the imprinted layer, based on their different ability to stabilize the dispersion of RAFT-modified Fe_3O_4. In that way we obtained nanocomposites with different sizes and morphologies.

The thus obtained materials were characterized using FTIR, thermogravimetric analysis, energy dispersive X-rays spectroscopy (EDS) and superconducting quantum interference device magnetometer (SQUID) measurements, as well as transmission electron microscopy. For example, nanocomposite particles synthesized in heptyl cyanide had diameters of 50nm, with MIP layers of 7nm thickness. The absence of hysteresis curves confirmed that the superparamagnetic properties were preserved in the nanocomposites. Moreover, radioligand binding experiments were performed to evaluate the binding ability of the nanocomposites. Selective binding of the radiolabeled target molecule, here the beta-antagonist propranolol, was demonstrated. While molecularly imprinted particles showed a considerable binding of the target, the non-imprinted control particles (chemically identical but synthesized in the absence of template) showed virtually no binding.

Finally the presence of "living" fragments on their surface has was demonstrated to further functionalize them by polymerizing an additional monomer, ethyleneglycol methacrylate phosphate . This showed the versatility of our approach for fine-tuning the surface properties.

matteo.gigli@unibo.it

Introduction.

In recent years, biodegradable polymers have gained much attention as green materials and biomaterials. Aliphatic polyesters, due to their favorable features of biodegradability and biocompatibility, are one of the most important classes of synthetic biodegradable polymers: polycaprolactone, poly(hydroxybutyrate), poly(L-lactide), poly(butylene succinate) (PBS), etc. are nowadays available commercially [1]. Among all, PBS is used in a wide range of applications, such as packaging film, bags, flushable hygienic products and garden mulch [2], but shows a quire slow rate of degradation [1]. As is well known enzymatic biodegradation of a polymer is controlled by several factors: the most important one is the nature of the polymer itself, i.e. its chemical structure; hydrophilicity and consequently water uptake increases degradation rate; moreover, the degree of crystallinity is a crucial factor, since enzymes preferably attack the amorphous domains of a polymer. Conditions like temperature, pH and concentration of enzyme also play a important role [1]. In our study, the effect of chemical modification as well as of molecular architecture on PBS biodegradation rate has been investigated. In addition, different enzymes and different operating conditions have been explored.

Materials and methods.

Copolymers of PBS containing diethylene succinate sequences with different molecular architecture have been prepared in our laboratories via reactive blending in the presence of Ti-based catalyst (PBSPDGS). In particular, a block copolymer with long sequences and the random one have been considered. For comparison the parent homopolymer PBS has been also synthesized by the usual two-stage melt polycondensation. Four different commercially available lipases were tested from *Candida rugosa*, *Candida cylindracea*, *Aspergillus niveus* and hog pancreas and a serine protease (alpha-chymotrypsin from bovine pancreas) (50U/ml in 0.1M phosphate buffer pH 7.4, 30°C, 100 rpm). To evaluate the biodegradability of the polymers under investigation, two kind of tests were carried out: i) turbidimetric film assay, which has high sensitivity to very small extents of degradation and ii) weight loss measurements. ATRIR analysis and DSC measurements have been performed to correlate degradation rate with crystallinity degree. Lastly, NMR analysis was performed to follow changes in composition of the copolymers under investigation.

Results and Discussion.

The molecular and thermal characterization data of the polymers under investigation are reported in Table 1.

Table 1: Molecular and thermal characterization data.

Polymers	M_n	*BS* (mol %) (^{1}H-NMR)	L_{BS}	*b*	T_g (°C)	T_m (°C)	ΔH_m (J/g)
PBS	38300	100	-	-	-36	114	82
PDGS	28200	0	-	-	-21	-	-
PBSPDGS*block*	28200	52.5	22.7	0.12	-30	112	44
PBSPDGS*random*	27000	49.9	1.85	1.03	-32	51	29

Preliminary results based on turbidimetric film assay, indicate that the most active enzyme is the lipase from *Candida cylindracea*, and that the best operative conditions are: [E]=50 U/ml (at higher [E] biodegradation is too fast for correct monitoring), T= 30°C (close to ambient temperature; high degradation rate) and pH =7.0 (highest degradation rate). Copolymers degrade to a much higher extent than PBS (see Figure 1). Moreover, random copolymer degrades faster than the block one, probably due to its lower degree of crystallinity (see Figure 1).

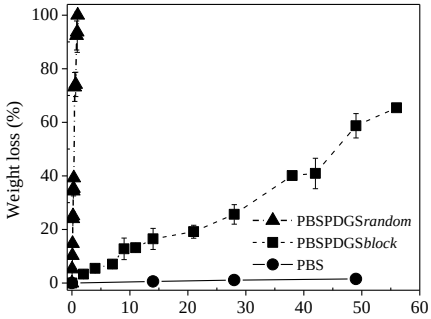

Figure 1. Weight loss (%) as a function of incubation time

ATRIR and DSC analyses confirm that the amorphous phase is the region attacked first by enzyme. Lastly, in the case of PBSPDGS*block* an evident decrease of DGS content is observed by means of NMR analysis with the proceeding of degradation, indicating that enzyme hydrolysis involves preferentially ester groups of DGS sequences, probably because of their higher hydrophilicity.

Conclusions.

Relevant results have been obtained from the present research. They can be summarized as follow:

1. Copolymerization is an efficacious way to increase PBS biodegradability.
2. Biodegradation rate can be modulated changing the molecular architecture, which affects the crystallinity degree.

Synthesis and characterization of hydrogels based on copolymers 2-hydroxyethyl methacrylate –*co*- zwitterionic carboxybetaine (meth)acrylamide for tissue engineering

Nina Yu. Kostina, Cesar Rodriguez-Emmenegger, Jiri Michalek, Eduard Brynda

Institute of Macromolecular Chemistry AS CR, Heyrovskeho Sq. 2, Prague 6, 162 06, Czech Republic

E-mail: kostina@imc.cas.cz

Introduction

The main goal of tissue engineering is to regenerate a function or part of a damaged tissue. For this purpose, scaffolds based on advanced materials with controlled properties are required.[1] Hydrogels are excellent scaffolds owing to their mechanical properties, high water content, and structural similarity to macromolecular-based components of the body. The attachment of bioactive molecules interacting specifically with cells as well as a protection against changing these interactions by non-specific fouling in cell cultivation media or physiological environment are essential for a successful cell growth on a material surface. Highly wettable zwitterionic polymer brushes have been shown to suppress protein fouling[2] and provide functional groups for covalent immobilization of bioactive molecules. So far, no attempts to use them as hydrogel components has been made. Herein the preparation of hydrogels based on copolymer of 2-hydroxyethyl methacrylate (HEMA) and zwitterionic carboxybetaine acrylamide (CBAA) or newly synthesized carboxybetaine methacrylamida (CBMAA) is presented.

Materials and Methods

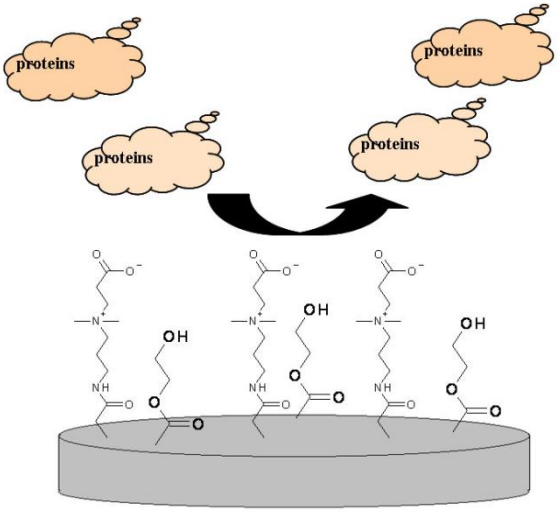
Hydrogel films from copolymer of HEMA and CBAA (poly(HEMA–*co*-CBAA)) or HEMA and CBMAA (poly(HEMA–*co*-CBMAA)) with different molar ratios of the monomer units were prepared by radical polymerization between glass and Teflon plates initiated with UV-light irradiation for 30 min at room temperature.

Chemical composition, morphology and mechanical properties were studied by FTIR, transmission electron microscopy, and measuring compressive and tensile moduli. Wettability and swelling degree were studied by sessile bubble contact angle measurement and gravimetry. The data were correlated with the non-specific protein adsorption studied by FTIR. Model systems based on polymer brushes were also synthesized using surface initiated atom transfer radical polymerization. Non-specific protein adsorption on the brushes was determined using surface plasmon resonance and compared with that on hydrogels.

Results and Discussion

Chemical composition of the hydrogels was confirmed by FTIR. All the hydrogels containing zwitterionic betaines showed a much higher hydration and wettability than that from HEMA homopolymer. Hydrogels with low molar content of betaines showed good mechanical properties while high betain content considerably impaired the mechanical properties. Importantly, even low content of carboxybetaines provided excellent antifouling properties while keeping good mechanical properties.

The increase in wettability of co-polymeric hydrogels of poly(HEMA–*co*-CBAA) and poly(HEMA-*co*-CBMAA) seemed to correlate with the decrease in the fouling.



Conclusions

Poly(HEMA–*co*-CBAA) and poly(HEMA-*co*-CBMAA) hydrogels with different molar content of zwitterionic monomer units were synthesized and characterized. Good anti-fouling properties associated with a high wettability and electroneutrality of the zwitterionic betaines and the presence of carboxylic groups capable of easy functionalization make these hydrogels a promising platform for tissue engineering.

Introduction

Cataracts treatment usually involves the extraction of the opaque crystalline lens and its replacement by an implanted intraocular lens (IOL) [1,2]. A serious problem associated to this procedure is the appearance of a post-surgery infection called endophthalmitis which is mainly caused by *Staphylococcus epidermidis*, *Staphylococcus aureus* and *Pseudomonas aeruginosa* [3,4]. To overcome these issues, acrylate-based IOLs having the ability to load and to release norfloxacin in a controlled way and at efficient therapeutic levels were synthesized. Different acrylate-based copolymers were prepared. Norfloxacin was loaded from aqueous drug solutions as well using a supercritical CO_2 ($scCO_2$) impregnation/loading method [5]. Prepared samples were characterized by different methods. Loading capacities and drug release profiles were obtained, compared and discussed in terms of copolymer composition and of the employed drug-loading method.

Materials and methods

Hydrogels synthesis - 2-hydroxyethyl methacrylate (HEMA) and 2-butoxyethyl methacrylate (BEM) mixtures (100:0, 80:20, 60:40, 40:60, 20:80, 0:100) were prepared and ethyleneglycol dimethacrylate (EGDMA) was added as cross-linker. Methacrylic acid and 2,2´-azo-bis(isobutyronitrile) (AIBN) were added to different aliquots of comonomer mixtures. After polymerization (at 50ºC/12 h and at 70ºC/24 h), obtained hydrogels were boiled in water, cut into 10 mm diameter discs and dried at 70ºC/12h.

Hydrogels characterization - Glass transition temperatures (T_g, ºC) were determined by DSC (TA Instruments, Q100, UK). Water sorption capacities (S, %) were obtained by gravimetry. Water contact angles and surface free energy were determined by an OCA 20 contact angle apparatus (Dataphysics Instruments GmbG, Germany). Hydrogels IR spectra were obtained in a FTIR-ATR (Jasco, model 4000, Japan) after being dried at 40ºC until constant weight. Optical transparency of hydrated hydrogels was evaluated spectrophotometrically at 600 nm.

Norfloxacin loading experiments – Norfloxacin loading with $scCO_2$ was carried out at 40 ºC and at two pressures: 150 and 300 bar. Processing time was 14 h and depressurization rate was 1 bar min^{-1}. Loading from norfloxacin aqueous solutions (0.0096 g/L) was carried out by discs immersion and soaking. Drug-loaded amounts were determined spectrophotometrically for both drug-loading methods.

Norfloxacin release experiments – Norfloxacin-loaded discs were immersed in artificial lachrymal fluid at 37ºC, under orbital stirring and release solution absorbance (at 273 nm) was measured continuously for 8h. Other measurements were performed after 48h.

Results and discussion

As expected, DSC results showed that T_g decreased as the BEM composition increased. Same trend was observed for water sorption capacities while water contact angles showed the opposite behavior (table 1).

Table 1. IOLs polymer physical characterization

Hydrogel	Tg (ºC)	S (%)	Contact angle, H_20 (º)
100:0	111.9	54.4	50.6
80:20	84.2	28.5	72.8
60:40	64.5	12.1	75.2
40:60	41.1	5.6	75.8
20:80	17.2	2.9	77.5
0:100	-14.7	0.6	81.1

Total norfloxacin released amounts from those hydrogel discs processed with $scCO_2$ were almost twice the released amounts that were obtained by the immersion loading method. Although release rates were faster for samples containing higher HEMA compositions, all norfloxacin release experiments presented controlled release profiles. An example is presented in Figure 1.

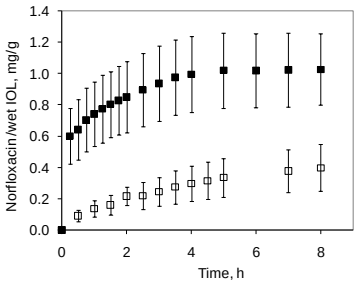

Figure 1. Norfloxacin release profiles from loaded hydrogels (100:0): ■ SSI □ immersion

Conclusions

Cross-linked HEMA:BEM-based hydrogels were synthesized, characterized and loaded with norfloxacin by soaking in aqueous drug solutions and by a $scCO_2$ loading method. Total norfloxacin released amounts from discs impregnated using $scCO_2$ were almost twice those released from hydrogels loaded by the soaking method. For most prepared and processed hydrogels, obtained thermomechanical, water-sorption, wettability and optical properties seemed to be adequate for their potential application as IOL materials.

Synthesis of biodegradable polymer and evaluation of its elastic properties available for stent coating layer

Min Ji Kim, Jeongho An, Dong June Chung

Department of Polymer Science & Engineering, Sungkyunkwan University

Tel:+82-31-290-7302, Fax: +82-31-292-8790, e-mail: djchung@skku.edu

Introduction

The implantation of a stent in coronary artery is widely practiced for the treatment of patients with coronary artery disease. Several kinds of commercialized bare metal stents have been used for clinic, but it has some risk such as inflammation, late thrombosis or restenosis due to the low biocompatibility and toxicity. To reduce the problems, surface treated stent were developed. These are typically made by coating a metallic stent with a biodegradable polymer. In this work, we examined the electrospray coating poly(glycerol-co-sebacate)(PGS) on metal surface. PGS was synthesized by condensation polymerization and it has biocompatibility, biodegrability and suitable mechanical strength. After coating on the stent, we checked the durability, surface morphology and thickness of coated polymer.

Experiments

The PGS prepolymer was synthesized by polycondensation of equimolar glycerol(Aldrich) and sebacic acid(Aldrich). Both elements were mixed together in a three-necked flask at 130℃ under argon for 3 h. The reaction was continued for 36 h at 40 mtorr and 130℃. The bare metal stents used in this study were nitinol stents. The stent was placed in a electrospray machine, polymer solution of each concentration in acetone was sprayed on the stent. For the process of cross linking, coated stents were placed in vacuum oven at 120℃ in a day. The surface morphologies and thickness of coated stents were observed by SEM.

Result

At first, we checked that PGS polymers have biocompatibility, biodegrability and suitable mechanical strength. And the surface morphologies of coated stent were smoother than bare stents. We can control the surface and thickness by changing the solution parameters and conditions of electro spraying. The thickness of polymer film which used high concentration(10wt%) was thicker than one which used low concentration(1wt%). It is expected that drug-eluting stent(DES) coated with drug and PGS polymers can be applied practically for clinical applications.

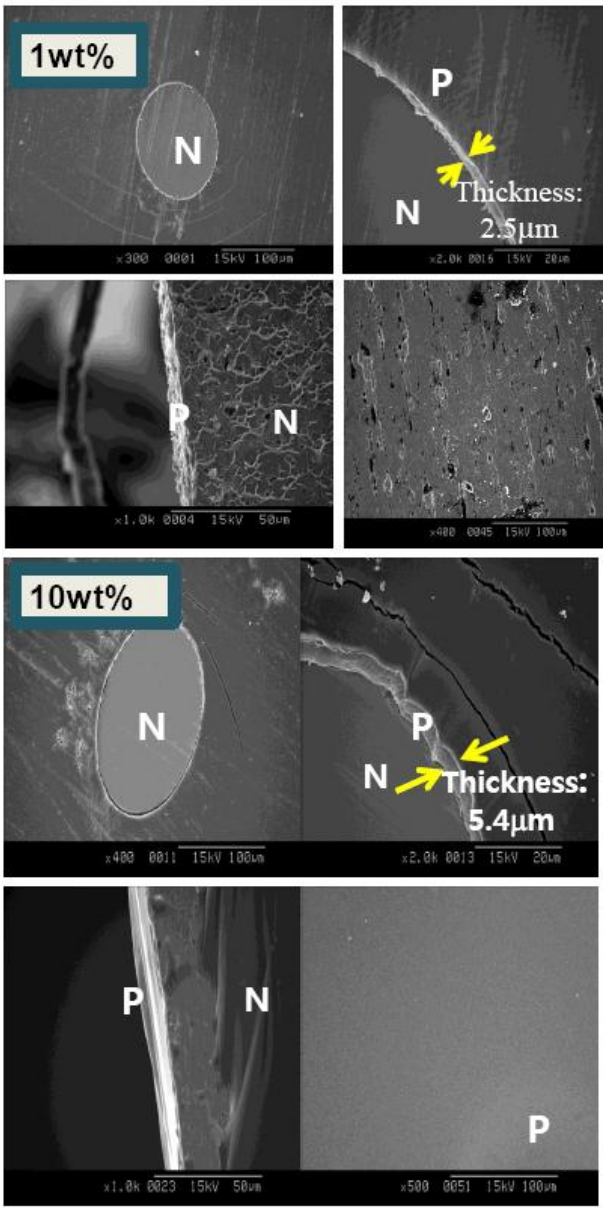

Fig 1.) SEM observation of PGS coating with EtOH solutions (a) 1wt% (b) 10wt% (polymer concentration) on nitinol stent at 15cm of working distance, 0.6mL/h of flow rate(N; nitinol stent, P; PGS polymer).

Bio-FET using biotinylated F8T2

Electronics and Telecommunications Research Institute, Daejeon, 305-700 Korea

Recently, there has been much interest in OTFT new biological, chemical, and environmental applications. One example of such device is a biologically sensitive field-effect-transistor (BioFET) to detect specific protein. We present the effects of electrochemical and chemoresistive changes on the electrical performance of organic thin-film transistors (OTFTs). 0.8 wt % of biotinylated F8T2(poly(9.9-dioctylfuorene-co-bithiophene)) in p-xylene were spin coated for a channel layer of OTFTs, and it has functional group with biotin hydrazide.binding of avidin (from egg white)to the biotin moieties caused drastic changes to photoluminescence of the polymer in solution, and to the electrochemistry and conductivity of the polymer in thin films. We have demonstrated a bio-organic-FET, or BioFET, in which the current was modulated over three orders of magnitude from the 2-terminal resistor(I-V) measured.

Correlation of physical and surface properties of polyurethane films with their chemical structure

Cansu Citak, Ahmet Sirkecioglu, F. Seniha Guner

Istanbul Technical University, Department of Chemical Engineering, Maslak 34469 Istanbul, Turkey

e-mail: guners@itu.edu.tr

Polymeric materials are widely used in biomedical applications due to their desired properties. Among these, polyurethanes are one of the most important classes of polymers due to their segmented (hard and soft) polymeric character.

The aim of the study is to correlate some physical and surface properties of the polyurethane (PU) films with their chemical structure. The study is performed in two steps; (a) synthesis of the films and determination of their chemical structure and some physical properties, (b) treatment of the film surfaces by plasma and determination of their performance in view of protein adsorption.

In the preparation of the films castor oil (CO) and polyethylene glycol (PEG) are used as polyol sources, and hexamethylene diisocyanate (HDI) is used as diisocyanate component. The films are prepared in various CO/PEG weight ratios (50/50, 60/40, 70/30, 90/10 and 100/0) without using any solvent and catalyst. The samples are characterized by Fourier transform infrared (FTIR) spectroscopy, differential scanning calorimeter (DSC), thermal gravimetric analysis (TGA) and dynamic mechanical analysis (DMA). Crosslink density and molecular weight between crosslinks are determined by Flory-Rehner method. Swelling behavior of the films is investigated in phosphate buffer solution (PBS) medium. Gel content is determined by Soxhlet extraction. Densities of the films are also determined.

For surface modification the films prepared with the CO/PEG weight ratio of 50/50, 70/30 and 100/0, are priorly exposed to radio frequency low-pressure argon plasma treatment at working power of 50 W for 2 min, and then acrylic acid (AA) plasma treatment is applied at 50 W for 5 min. The effect of plasma polymerization on protein adsorption is determined by using bovine serum albumin (BSA) and bovine serum fibrinogen (BSF). The adsorption experiments are performed by the batch process. Protein is analyzed by UV spectrophotometer at 280 nm and the specific adsorption rate constant is calculated for each polymer surface. The water contact angle and surface free energy are measured by a goniometer. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) are used for inspecting surface topology. The existence of the polyacrylic acid layer on PU surface is observed by x-ray photo spectrometer (XPS) analysis.

The glass transition temperature (T_g), loss tangent (tan δ), crosslink density and gel content of the films increase with increasing CO/PEG ratio. On the other hand, the molecular weight between crosslinks, swelling ratio, density and transparency of the films decrease with increasing CO/PEG ratio.

As shown in Figure 1, the water contact angles are determined to be c.a. 91, 68 and 61° for the films prepared with the CO/PEG ratio of 100/0, 70/30and 50/50, respectively. After plasma polymerization, the water contact angles for all films are c.a. 43°. Before plasma treatment, protein adsorption increases with decreasing CO/PEG ratio (Figures 2 and 3). After plasma polymerization the content of protein adsorbed decreases for each films. XPS results are given in Table 1 for the PU film before and after plasma treatment and after protein adsorption.

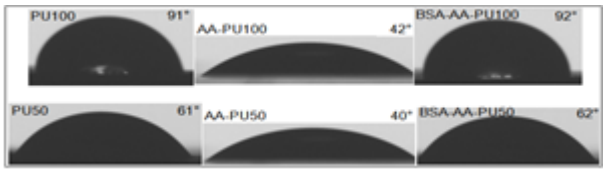

Figure 1: Water contact angle of the PU films

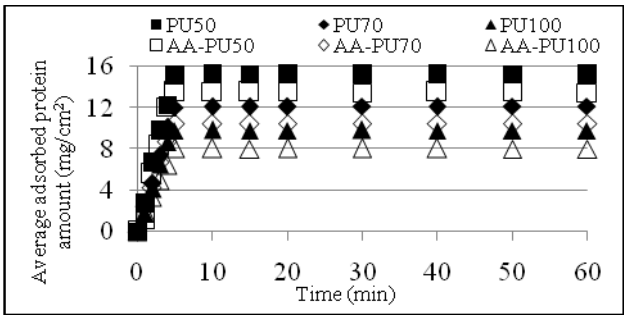

Figure 2: BSA adsorption for the PU films

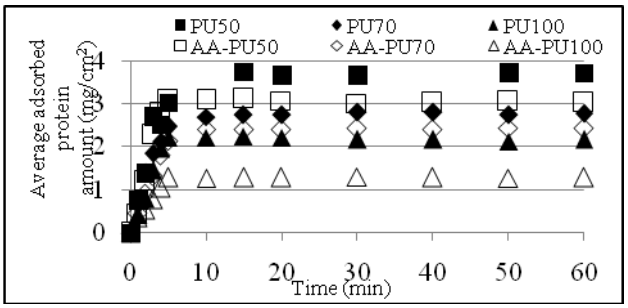

Figure 3: BSF adsorption for the PU films

Table 1: Surface composition of the PU films obtained by XPS analysis

Sample	C	O	N	O/C	N/C
PU	74.6	22.2	3.2	0.298	0.04

Johanna.saunier@u-psud.fr

Introduction: For polymeric medical devices, the surface plays an important role for the biocompatibility. The invasive devices have to be sterile and are thus subjected to a sterilization treatment that can change the surface properties by modifying the chemistry and the topography of the surface [1]. Moreover, the treated surface may evolve with time [2]. In this work, polyurethane catheters were treated with a cold nitrogen plasma dedicated to the decontamination of medical devices and the post treatment aging of the catheter surface was studied for several storage conditions (temperature, humidity…). As commercial polymers contain additives that can bloom onto the surface [3, 4], a specific care was taken to characterize the behavior of these low molecular weight compounds during the post-treatment aging.

Material and methods: Pellethane 2363 80AE ® (Dow Chemical), a poly (ether urethane), was the major constituent of the catheters that contained also two additives, a lubricant (ethylene bis stearamide) and an antioxidant (Irganox 1076®). Plasma [5] was obtained using a pulsed corona discharge (voltage: 10 kV, frequency : 10 kHz, mean power : 15 W) on a pure nitrogen gas at atmospheric pressure. Samples were subjected to treatment during 40 minutes. To characterize the surface, contact angle measurements were carried out with different liquids (diiodomethane, ethylene glycol, water and formamide), and X ray photoelectron spectroscopy (Thermo Electron VG Escalab 220iXL) was performed. Additives and polymers were moreover characterized by differential scanning calorimetry (Q1000 TA instrument), thermostimulated current analysis (Setaram TSC) and powder X-ray diffraction (PANalytical X-ray).

Results and discussion: Evolution toward a hydrophobic surface state was observed for the stored treated material. The kinetic depended on temperature and relative humidity: a faster evolution was observed for higher temperatures and higher relative humidity. At 25°C a fast evolution of the surface energy and polarity was observed during the first two days following treatment, but then the evolution was slow. At 45 °C, the evolution was complete after 24 hour storage, with a surface energy of the catheter surface that was in the same range than that of the non treated samples. A study of the phase transitions and relaxations of the polymer and of the additives, associated to contact angle measurements on the different constituents (polymer, antioxidant and lubricant) showed that the additive phase transitions might governed the post treatment aging process on the catheter surface and explained in this particular case the difference in aging at 25°C and 45°C.

Conclusion: To understand the evolution of a surface after a cold plasma treatment, conditions of storage must be controlled. Moreover, the polymer relaxations and phase transitions and the surface chemistry have to be characterized: if additives bloom onto the surface, they can influence in an important way the kinetic of the post treatment surface aging, depending on their transitions and relaxation temperatures, and on their polymorphic form.

A Comparative Kinetic Study of the Controlled Drug Release Ability of the Hydrogels Synthesized from Diepoxy-Terminated Poly(Ethylene Glycol)s and Aliphatic Polyamines

Bogdan Cursaru, Mircea Teodorescu, Cristian Boscornea, Paul O. Stanescu, Stefania Stoleriu

Polytechnic University of Bucharest, Faculty of Applied Chemistry and Material Science, 149 Calea Victoriei, 010072, Bucharest, Romania ,
e-mail: bogdancursaru@yahoo.com

Introduction

The present work describes a comparative kinetic study of the controlled release of diclofenac sodium (DCF-Na) and 5-fluorouracil (5-FU) from PEG-based hydrogels with various structures and properties, synthesized from diepoxy-terminated poly(ethylene glycol)s of different molecular weights (600, 1000, 2000 and 4000 Da, $DEPEG_X$) and aliphatic polyamines of different chain length and functionality: ethylenediamine (EDA), 1,8-octanediamine (ODA), 1,12-dodecanediamine (DADD), diethylenetriamine (DETA) and triethylenetetramine (TETA).[1,2] DCF-Na and 5-FU were used as model drugs, as we expected them to interact in a different manner with the PEG chains.

Materials and methods

The $DEPEG_X$-polyamine hydrogels (epoxy groups/H_{amine} = 1/1) were synthesized as previously described.[1,2] The hydrogels were loaded by swelling into the drug solution of known concentration, followed by drying at room temperature to constant weight. The drug release experiments were carried out at 37°C in PBS (pH = 7.4).

Results and discussion

The drug release experiments showed a much slower discharge of DCF-Na as compared to 5-FU (Fig. 1), which was ascribed to a stronger interaction of DCF-Na with the PEG chains.

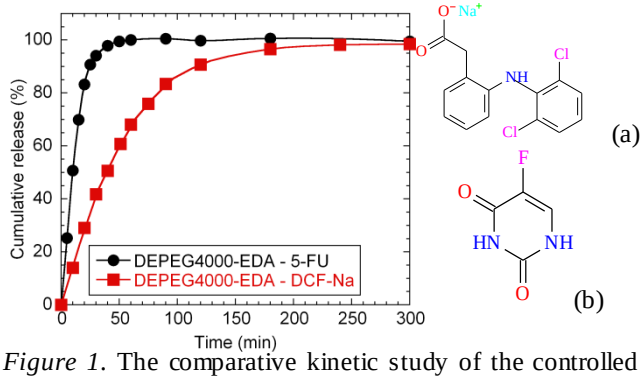

Figure 1. The comparative kinetic study of the controlled release of DCF-Na (a) and 5-FU (b) from the $DEPEG_{4000}$ – EDA hydrogels.

This supposition was supported by SEM analysis, which revealed smaller and deep inside located crystals on the surface of the DCF-Na loaded xerogels as compared with the 5-FU xerogels (Fig. 2).

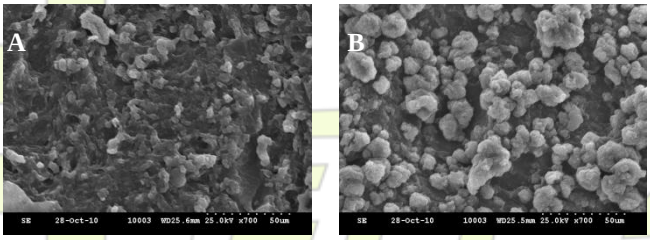

Figure 2. SEM micrographs of $DEPEG_{4000}$ xerogels loaded with DCF-Na (A) and 5-FU (B).

The mechanism of drug diffusion was also investigated according to the Ritger-Peppas equation, and it was anomalous (non - Fickian) in all cases, as indicated by the values of the diffusion exponent n ranging between 0,81 and 0,97.

The influence of the network structure (molecular weight of the PEG chains and amine functionality and chain length – Figure 3) upon the release rate of the drug was also investigated in the case of DCF-Na.

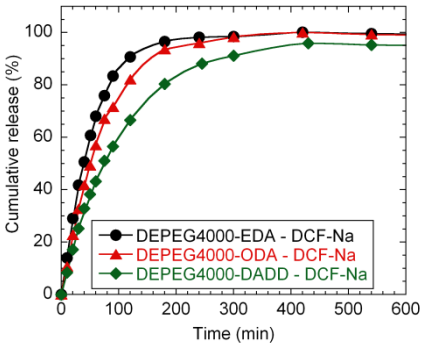

Figure 3. The influence of the amine chain length upon the controlled release of DCF-Na.

Conclusions

The hydrogels loaded with DCF-Na displayed a lower release rate as compared to 5-FU due to the presence of the sodium cation, which presumably promotes the formation of some structures similar to the crown ethers complexes, leading to a stronger interaction with the network. Both hydrogels with the shortest PEG chain and the longest amine hydrocarbon chain showed the smallest release rate of DCF-Na.

Computer Simulation of Lysine Based Peptide Dendrimers

I.Neelov, S.Falkovich, A.Darinsky, H.Tenhu

Institute of Macromolecular Compounds, RAS, St.Petersburg, Russia
University of Helsinki, Helsinki, Finland

i.neelov@mail.ru

Introduction: Dendrimers are star-like molecules, with regular spherically symmetric branching in each arm (dendron). Dendrimers are widely used in industry and biomedical applications. Many dendrimers (PAMAM, PEI, carbosilane and others) have spherically symmetric branched backbone with two (or three) spacers of the same chemical structure (and thus the same number of chemical bonds (for example, seven bonds for PAMAM)) originating from each branching point. At the same time there are some dendrimers with non symmetrical branching of backbone. For example for poly-L-Lysine dendrimer there are two spacers with different chemical structure and different lengths (three and seven bonds) originating from each branching point. The lysine dendrimers are less toxic than widely used PAMAM and PEI dendrimers and thus are very promising for different biomedical applications. Our goal is to investigate the structure of such asymmetric dendrimers and their conjugates with short peptides.

Materials and Methods: In present work we performed simulation of lysine based dendrimers Method of molecular dynamic simulation with full atomic details (Amber99 forcefield) was used for this goal. One lysine dendrimer of generations g=3, 4 and 5 (or 3.5 generation conjugate with KFFE peptides) were placed in periodic box with 7000-8000 explicit water molecules (TIP3P model). The same number of negative counterions Cl- were added to system for compensation of dendrimer charge. All calculations were performed at temperature T=300K. The length of each molecular dynamics trajectory was equal to 100ns. Computational package OpenMM [1] for computer simulation of molecular systems with full atomic details on graphical processor units (GPU) was used.

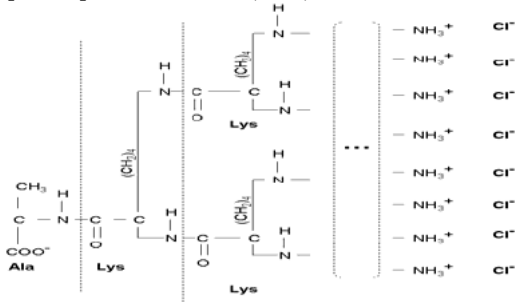

Fig.1 Schematic representation of lysine dendrimer

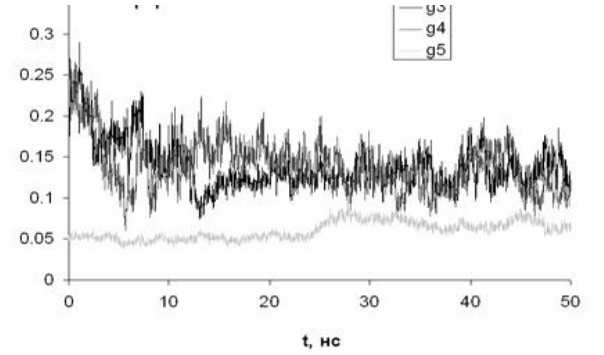
Results and Discussion: Main global characteristics of dendrimers are their gyration radius, asymmetry and distribution of density (for all atoms and for terminal groups) around the centre mass of molecule.. We calculated these characteristics for all lysine dendrimers and conjugate of dendrimer with KFFE tetrapeptides Time dependence of gyration radius of dendrimer was used to distinguish the relaxation and equilibrium parts of trajectory. 20ns was usually enough for full relaxation of system while the rest 80 ns were used for calculation of average values and distribution functions. We obtained that lysine dendrimer of generation g=3 after relaxation has rather asymmetric shape while dendrimers



of generation g=4 and 5 are more spherical.
Fig.2 Tine dependence of asphericity of lysine dendrimers of generation g=3, 4 and 5

Dendrimers of g=4 and 5 have rather extended tails of radial density distribution while distribution of terminal groups has significant plateau-like region. Chemical attachment of KFFE peptides in hybrid structure doesn't influence the general dendrimer structure but slightly increase distance of terminal group from centre.

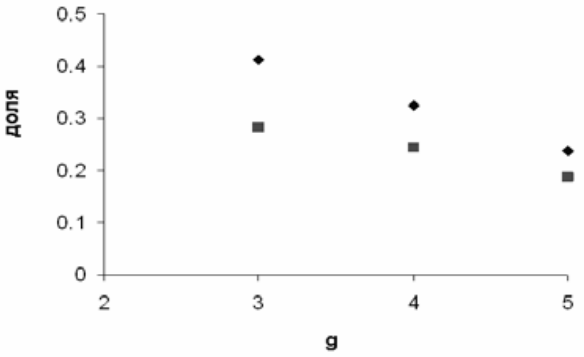


Fig. 3 Dependence of part of terminal groups of dendrimer not connected with counterions (diamonds) and part of counterions not connected to terminal groups of dendrimer (squares)

Conclusions

Lysine dendrimers of small generation has rather asymmetric shape which become more spherical for dendrimers of larger generations. Counterions play important (generation dependent role) in structuring the dendrimers. Short KFFE peptides attached to terminal groups of dendrimer doesn't influence its internal structure.

Introduction

The hyaluronan (HA) or hyaluronic acid sodium salt is a naturally occurring biopolymer, composed of a repeating disaccharide that consists of alternating units of N-acetyl-β-D-glucosamine and β-D-glucuronic acid. It's widely distributed in the human body composing the extracellular matrix of biological tissues. The biocompatibility and biodegradability of HA have made of it a material commonly used in treatment of osteoarthritis, drug delivery, ophthalmic surgery and tissue engineering (1-5). Despite these benefits, its fast water dissolution and a short residence times in biological tissues make necessary some structural modifications in order to overcome this drawbacks. The crosslinking process is the key to ensure better mechanical integrity in aqueous environments. Crosslinking heterogeneous methods have been reported (6) where reactions are carried out on solid HA, cast in the form of films or membranes, using glutaraldehyde (GTA) as crosslinker agent.

Polymer crosslinking processes not only improve the strength of materials, also make it more rigid and fragile. In this work we propose the use of triacetin (TA) during the formulation to mitigate this unwanted effect, leading to more ductile materials.

Materials and Methods

HA/GTA and HA/GTA + TA solutions were prepared using bidistilled water as solvent. The amount of each reactive was adjusted to achieve (1:2) and (1:4) HA/GTA molar ratios. The plasticizer, TA, was used in order to attain a 20% of the solid weight in the casted films.

Crosslinking reactions have been accomplished under acidic conditions, pH adjusted with 0.01M HCl. HA molecular weight was 1.56 x 10^6, and solution concentration was 1 wt %. After 24-h reaction time stirring at room temperature, the gels were casted at room temperature under extractive hood. Different size Petri dishes were used to obtain variety on film thicknesses.

Contact angle (CA) was tested on a Kruss, EasyDrop Standard, DSA 15 goniometer. Mucoadhesive studies were performed using mucin as simulated biological substrate. Stress-strain tests were obtained in an Instron 3369 tester in traction mode at 2 mm/min at room conditions.

Results and Discussion

The table 1 summarizes the amount of each reactant and some of the most important results obtained in this work.

The contact angle measurements clearly show the increment of this parameter with the use of more GTA as crosslinker agent in the reaction process. CA is also incremented with the incorporation of TA to the mixture.

Table 1: Contact angle and mucoadhesive strength.

HA/GTA*	TA%	C. Angle	Mucoadh. (kgf/cm^2)
1:0	0	-	153,241
1:2	0	43.025	198,781
1:4	0	47.075	226,744
1:2	20	56.419	220,431

*molar ratio

A marked increment is also evidenced in the mucoadhesive strength needed to unstick the films from the mucin layer, both for using GTA and TA in the formulation. This is attributed to the increment in the chain mobility favored by the presence of the plasticizer.

In the stress strain studies the crosslinked films exhibit fragile behavior. The specimens break before the reaching the yield point. The incorporation of TA to the formulations changes the stress-strain performance from fragile to ductile. All the plasticized samples attained the yield point and had a plastic deformation.

Conclusions

The use of GTA as crosslinker agent for HA films significantly improves the integrity of HA films in aqueous environments incrementing the bioadhesiveness of HA to mucin and reducing the wettability of the material.

Incorporation of TA as plasticizer to the formulation not only enhances the strength and the bioadhesiveness of the material, but also made it more ductile and less rigid.

Thermoset biodegradable elastomers with tunable mechanical properties and degradations.

A. Harrane, H. Nouailhas, A. Leroy, B. Nottelet and J.Coudane

IBMM, Artificial Biopolymers Group, UMR-CNRS 5247, UM1-UM2, 15 Av. C. Flahault, 34093 Montpellier, France

Benjamin.Nottelet@univ-montp1.fr

Introduction: Biodegradable elastomers have recently attracted growing attention. Indeed, for the regeneration of soft tissues such as blood vessels their ability to provide a structural support with similar mechanical properties to those of native tissues in dynamic environment makes them of a particular interest.[1] Among them, thermoset elastomers have the ability to degrade by combination of bulk and surface erosion which guarantee a constant shape during degradation as well as a linear drug release profile.[2] We describe here the preparation of degradable elastomers based on short photo-cross-linkable PLA-PEG-PLA triblocks with chosen amphiphilic balance to provide intermediate degradation times and linear degradation profiles. In addition, we would like to illustrate the possibility to obtain various mechanical behaviours from the same initial tribloc depending on the presence and the nature of the cross-linker. Finally degradation and biocompatibility are discussed.

Materials and Methods: PLA_9-PEG_{45}-PLA_9 was synthesized according to a methodology developed in our group.[3] Methacrylation was carried out in dry CH_2Cl_2 with methacryloylchloride and triethylamine. Irgacure® 184, 2,4,6-triallyloxy-1,3,5-triazine (TAC), and pentaerythritol triallyl ether (PETAE) were used in conjunction with a PentaFUSION UV system for UV-cross-linking. Mechanical properties were evaluated on an "Instron 4444". Degradation was followed in PBS at 37°C. Biocompatibility was evaluated with MTT tests.

Results and Discussion: PLA_9-PEG_{45}-PLA_9 was obtained with a 90% yield. ^{1}H NMR analyses confirmed a ratio EO/LA of 2.5 and a polymerization degree of PLA blocks of 9 in agreement with the expected theoretical values. Methacrylation reaction was conducted for 72 h at room temperature under nitrogen (yield 88%). Each elastomer was then prepared by UV-curing of mixtures containing i) the tribloc copolymer (TC) ii) Irgacure® 184 (I) or no photo-initiator and iii) TAC or PETAE (0 to 100% with respect to alkene groups) or no cross-linker. After soaking of the resulting elastomers in CH_2Cl_2, the cross-linking efficiency was calculated and ranged from 80 to 90% without significant influence of the composition on the grafting efficiency.

Figure 1. Picture of elastomer $TC_{I\text{-}PETAE100}$

Thermal properties of the ed. The glass transition temperature (Tg) increased with the cross-linking. For TC Tg is -38.2°C but increased to -11.7 °C for the elastomer cross-linked with TAC ($TC_{I\text{-}TAC100}$) and -13.4 °C for the one cross-linked with PETAE ($TC_{I\text{-}PETAE100}$). In accordance with known elastomers behaviours, Tgs increased with the cross-linking ratio. Elastomers were found to be soft and amorphous **(Figure 1)**. TAC and PETAE have very different structures, the first one being much more rigid and hydrophobic than the second one. **Figure 2** demonstrates the influence of the cross-linker nature on the elastomers mechanical properties, $TC_{I\text{-}TAC100}$ being the stiffest one (E = 4.45 MPa) whereas $TC_{I\text{-}PETAE100}$ is the most deformable one (ε_{break} = 60 %). As expected when considering the hydrophilicity of TAC *vs.* PETAE, this difference was even more pronounced in the hydrated state (not shown here).

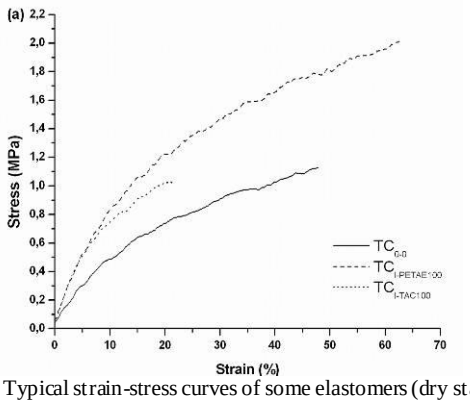

Figure 2. Typical strain-stress curves of some elastomers (dry state)

All elastomers degraded linearly and at the same rate up to 30 days, with for all samples a weight loss of 30%. Beyond, while degradation continued, degradation rates changed as a result of the elastomers structures. The higher the hydrophilicity, the faster and more complete the degradation was **(Figure 3)**. MTT tests were done on the various elastomers and demonstrated that all compositions led to biocompatible materials.

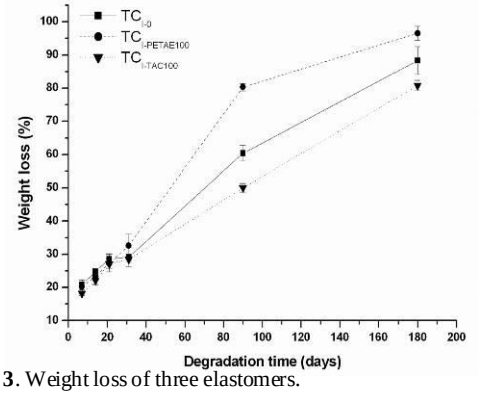

Figure 3. Weight loss of three elastomers.

Conclusion: Design of soft degradable elastomers having defined mechanical properties and degradability can be achieved by the careful choice of the amphiphilic character of pre-polymers and the nature of the cross-linkers.

Introduction:

In the industrial production of citric acid from sugar cane using *Aspergillus niger*, big amounts of the fungi's mycelia is obtained as a byproduct. Most of the mycelia is sold, at a very low price, as food supplement for cattle.

The chitin contained in the mycelia can be transformed into chitosan by enzymatic or chemical processes. Chitosan is a biodegradable and biocompatible polymer with many applications.

Commercial chitosan is also obtained from crustaceans. Cross-linking of chitosan affords three-dimensional networks known as hydrogels. Hydrogels are polymers that exhibit the ability to absorb a considerable amount of water without dissolving. This behavior is usually achieved by a low degree of cross-linking.

Different types of hydrogels sensitive to temperature, pH, ionic force, and other stimuli have been synthesized. A particular characteristic of chitosan hydrogels is their sensibility to pH changes. This behavior could allow their use in intelligent systems for substances release. In this work chitosan was extracted from *Aspergillus niger* in order to produce hydrogels using dialdehydes and dicarboxylic acids as cross-linking agents. Kinetic studies of drug release were carried out.

Method and Materials:

Chitosan was extracted by basic hydrolysis at 110ºC, followed by washings with water and ethanol. The filtrate was dissolved with HCl and then precipitated with 30% NaOH. The extracted chitosan was characterized by FTIR (Shimadzu FTIR-8400 spectrophotometer) and ^{1}H NMR in a 400 MHz Bruker instrument. Chitosan molecular weight was measured with a capillary reverse flow viscometer, applying the Mark-Houwink-Sakurada equation.

Chitosan deacetylation degree was calculated by elemental analysis and potentiometry. Hydrogels were prepared using dialdehydes as cross-linking agents at 30 ºC. Alternatively, dicarboxylic acids were used as cross-linking agents. The synthesis was carried out at room temperature, using a carbodiimide (EDC) and N-hidroxysuccinimide. The hydrogels were characterized by thermal (DSC y TGA), spectroscopic (FTIR) and mechanical tests (DMA). Some swelling and controlled drug release studies were performed.

Results and discussion:

Chitosan extraction was favored using hydrochloric acid and concentrated solutions of sodium hydroxide, reaching a yield of 6,0%. The FTIR spectrum of chitosan revealed the strong absorption band at 3300 cm^{-1} attributed to the O-H and N-H groups, and at 1650 cm^{-1} the stretching vibrations of C=O group. The ^{1}H-NMR spectrum of chitosan revealed a signal at 2.02 ppm corresponding to the mehyl groups of N-acetylglucosamine; signals between 3 and 4 ppm were assigned to carbons C2-C6 from glucosamine and N-acetylglucosamine subunits, 4.7 ppm signals from C1 from N-acetylglucosamine, and at 4.8 ppm the signal of C1 from glucosamine. Deacetylation degree was 76.33% and the molecular weight was 1.15 x 10^5 Da. This results show that a good percentage of chitin was converted into chitosan. The experimental data suggest that the swelling process follows a second-order kinetics. The swelling rate constant and the equilibrium water content of hydrogels were dependent on the cross-linking degree and pH in the swelling medium. The hydrogels transitions and their decomposition were determined by differential scanning calorimetry, DSC, and termogravimetric analysis, TGA. Drug release kinetics was followed by UV/Vis. Some differences in the release speed related with the percentage of cross-linking and the dicarboxilic acid type used in each case were observed.

Conclusions:

The use of concentrated basic solutions increases the percentage of chitosan isolated from *Aspergillus niger*. Variations in cross-linking agent type (dialdehyde or diacid) and the percentage itself, modified hydrogels properties. The hydrophilic character from hydroxyl and amino groups also modifies the swelling behavior of hydrogles and the controlled drug release at different pHs.

Introduction:

Diabetic foot ulceration is the prime reason for limb amputation in the USA. As a result, considerable efforts are being implemented to both understand the etiology of foot ulcers, and predict patients who are at elevated risk.Our team is using a novel polymer that has been patented (US 7127950 B2) for measuring and understanding mechanical stresses at the foot-ground interface. The so-called "Surface Stress Sensitive Film" (S3F), holds special promise for not only quantifying plantar surface skin stresses but also for evaluating biomedical implant interfaces in general.

Material and Methods:

S3F is a polymer film-based optical measurement system that provides a force map over the entire contact surface. It records the vertical pressure gradients and lateral (shear) forces being produced by a foot, tire, air, water, or other force generating activities. Examples of shoe contact measurements are shown in Figure 1.

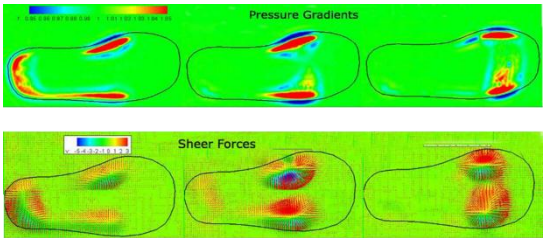

Figure 1. Pressure gradients and shear force maps produced by a child's shoe, at three walking motion time points, on the S3F Measurement System.

The response of the film to a tangential force is depicted in Figure 2. The response of the film may be visualized by considering a series of markers on the surface on the film. The markers will be displaced as the film shears, where the displacement is a function of the film thickness and shear modulus. The response of S3F to a normal force is depicted in Figure 3.

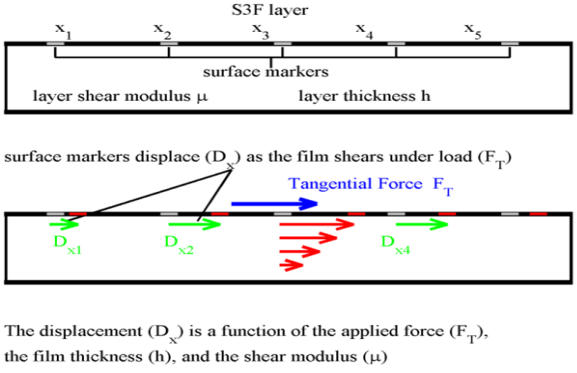

Figure 2. Response of the S3F to a tangential load.

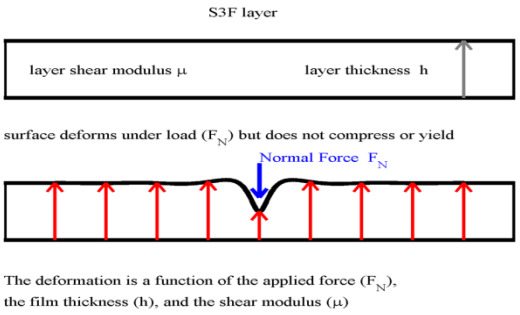

Figure 3. Response of the S3F polymer to a normal load applied to the top surface.

The *Foot Pressure and Shear Mapping System* integrates (i) the S3F polymer film for contact force analysis and (ii) a force plate system (Bertec Corporation) for human gait analysis and biomechanics research. Shear distributions can be extracted from a pair of unloaded and loaded images taken by a single hi-resolution CCD camera. The force plate provides combined measures of the six forces and moments (Fx, Fy, Fz, Mx, My, Mz) which are used for global force comparisons. For this study, data were collected on 12 subjects walking at a self-selected speed.

Results and Discussion

Currently the system is being clinically tested and statistical analysis of a preliminary study was conducted to determine the level of repeatability associated with this system. As illustrated in Figure 4. Interclass Correlation Coefficients where calculated, as a function of trails, for the peak normal (pressure) and shear displacement in each region of the foot. The results of the ICC analysis showed excellent repeatability between trails for each foot region.

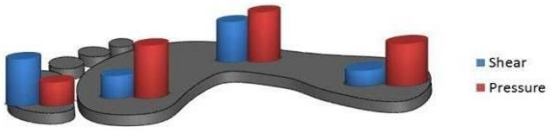

Figure 4. ICC values as a function of trials.For peak pressure the ICC's in the four regions where 0.966 (Heel), 0.844 (Midfoot), 0.892 (Forefoot) and 0.944 (Hallux). The ICC's for peak shear in the four regions where 0.924 (Heel), 0.709 (Midfoot), 0.839 (Forefoot) and 0.948 (Hallux).

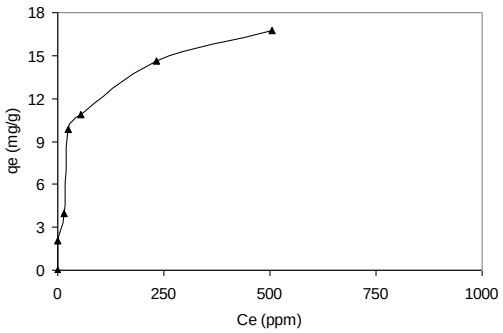
fsewailm@kacst.edu.sa

Abstract

Biomass materials, which may be considered natural polymers, such as nut shells, rice hulls, and sugar canes remaining are known to have good adsorption affinity towards heavy metal ions. In the current research we are reporting initial results of the adsorption isotherms of lead and cooper on two types of date pits grown largely in the arabian peninsula region. Figure 1 below showed that one of the two types of date pits has a good adsorption capacity for lead ions even at lower concentrations. We believe that date pits surface characteristics, e.g. functional groups and pore size, had able lead ions to attach to the surfaces in an efficient manner.



Fig(1): Equilibrium isotherm of lead ions adsorption on sucaray date pits

Amphiphilic Segmented Elastomeric Polyurethane Bio-Based on PLLA: Synthesis and Characterization

Introduction

Poly(L-lactide) (PLLA) is a very important synthetic material widely used in tissue engineering due to its biodegradability, biocompatibility and excellent shaping and molding properties [1]. However, interaction between the polymers, as PLLA, and cells can not be adequate, leading to in vivo foreign body reactions, such as inflammation, infections, local tissue necrosis etc [2]. Moreover, due to lack of functional groups, they cannot be modified easily with biologically active moieties.

Recently, many investigations have attempted to improve the hydrophilicity of polyester. Copolymers based on poly(ethylene glycol) is often introduced because of its hydrophilicity, nontoxcity, biocompatibility and nonimmunogenicity. Segmented Polyurethanes (SPUs) are very important strategic macromolecules and suitable for biomedical applications such as sutures, artificial tissues, implants and drug delivery because of their excellent physical properties, biocompatibility and biodegradability. SPU is generally synthesized by incorporating soft segments susceptible to hydrolysis, such PLLA, into PU [3]. Poli(lactic acid) is synthesized via two different polymerization mechanisms, direct polycondensation of lactic acid and ring-opening polymerization (ROP) of the cyclic dimer, lactide [4]. In either case, the lactoyl units may possess a single stereo-configuration, usually L, leading to semicrystalline poly(L-lactic acid), or they may be the racemic mixture, leading to amorphous poly(D,L-lactic acid) (PDLLA). ROP provides more precisely targeted and potentially higher molecular weight [5]. Therefore the PLLA diol was synthesized by ROP from L-lactide using stannous di-octoate as initiator and ethylene glycol as co-initiator. In this study, amphiphilic segmented polyurethanes based on hydrophobic poly(L-lactide) diol – PLLA-diol (Mn ~ 2,500 g mol^{-1}) and hydrophilic multiblock copolymers poly(propylene glycol)-*block*-poly(ethylene glycol)–*block*–poly(propylene glycol) - PPO-PEO-PPO (Mn ~ 2,700 g mol^{-1}) were synthesized. The SPUs were characterized by proton nuclear magnetic resonance spectrometry (^{1}H-NMR), attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR), gel permeation chromatography (GPC), differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA) and X-ray diffraction (XRD).

Material and Methods

Equimolar ratio of diols and toluene diisocyanate (TDI) was used for the polyurethanes synthesis and stannous octanoate was used as catalyst (0.05 wt% relation to diol). The reaction was carried out in chloroform under reflux and under nitrogen atmosphere. TDI was added slowly to the reaction at 0.1 mL h^{-1} rate, for 3.5 hours. The resulting polyurethane was precipitated in ethyl ether, filtered and vacuum oven-dried for air renewal at 35 ° C for 12 h. Finally, the SPUs were dried in the vacuum oven (35 ° C) for 6 h. The global composition of the synthesized SPUs was: 100; 70; 50; 30 and 0 wt% of PLLA-diol, named PU-PLLA100; PU-PLLA70; PU-PLLA50; PU-PLLA30 and PU-PLLA0, respectively. Molar mass of these polyurethanes varies from 20,000 g mol^{-1} for PU-PLLA0 to 70,000 g mol^{-1} for PU-PLLA100.

Results and Discussion

^{1}H NMR as well as ATR-FTIR spectra show evidences of the SPUs formation. X-ray difractograms and second DSC heat scans of the segmented polyurethanes revealed that the crystallization of both PPO-PEO-PPO and PLLA segments was mutually restricted. The SPUs present only one glass transition which is dependent on the composition. The glass transition temperatures (Tg) occur at values between the Tg of PU-PLLA100 and PU-PLLA0, suggesting miscibility of the blocks awarded by randomly-distributed blocks. Storage modulus at higher temperatures than Tg of SPU increases as the amount of PLLA blocks increases, while the peak in the Loss modulus curves corresponding to glass transition is broader for PU-PLA100 due to the presence of different microambients: amorphous and crystalline phases and interface. Water swelling tests show that the equilibrium water content (EW%) of PU-PLLA100 is 5,5% and increases as the amount of the hydrophilic block contents increases up to 164% for PU-PLLA0. The EW% values for the other SPU are intermediate, indicating the amphiphilic character of the segmented PUs.

Conclusions

The amphiphilic elastomeric segmented polyurethanes bio-based on PLLA diol and PPO-PEO-PPO diol were synthesized. SPUs compositions influence the physical-chemistry properties and the swelling tests show an increase in mass gain with the increase of hydrophilic multiblock copolymers percentage, it was one of the factors that determined the level of cytocompatibility of samples.

Introduction: Polyhydroxyalkanoates (PHAs) are bio-polyesters produced by a wide variety of bacteria as intracellular carbon and energy storage materials. The most commonly bio-synthesized PHAs are short-chain-length (SCL) copolymers containing 3-5 carbon atoms such as poly(3-hydroxybutyrate) (PHB)) and poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (P(HB-*co*-HV)) [1]. The versatility of these microbial polyesters in terms of physical properties and therefore of commercial and biomedical applications, is increased when more carbon atoms are presented in their molecular structure [2]. Thus, medium-chain-length (MCL) PHA copolymers containing 6-14 carbon atoms represent a great commercial alternative for more specific biopolyesters with a range of additional favorable material properties [3].
This work studies the production and characterization of short-chain-length and medium-chain-length (MCL, 6-14 carbon atoms) PHAs produced by bacterial bioconver-sions of *Cupriavidus necator* via bioprocessing strategies using crude glycerol and rapeseed residues generated from industrial biodiesel production. Chemical structures and physical properties of produced PHA copolymers were analyzed by using Fourier Transform Spectroscopy (FTIR), ^{1}H- and ^{13}C-Nuclear Magnetic Resonance (^{1}H- and ^{13}C-NMR), Differential Scanning Calorimetry (DSC), and Termogravimetric analysis (TGA).

Results and Discussion: Biopolymers extraction was carried out by dispersion with sodium hypochlorite and chloroform [4]. A standard PHB sample was also included during the analysis in order to compare the properties of obtained copolymers. ^{1}H- and ^{13}C-NMR results shown that SCL copolymer correspond to P(HB-*co*-HV), while the other sample can be identified as a medium-chain-length PHA copolymer.
Thermal properties of PHB and PHA copolymers are presented in Table 1. It should be stressed that marked differences between melting point (T_m), and degree of cristallinity (X_c) confirms the incorporation of higher carbon atom monomers into original PHB structure.

Table 1. Thermal properties of PHB, SCL- and MCL-PHA copolymers

Sample	T_m (ºC)	ΔH_m (J/g)	X_c (%)
PHB	170.6	91.83	61.5
SCL-PHA	155.0	72.61	48.6
MCL-PHA	140.9	44.11	29.5

TGA profiles for the three studied biopolyesters are shown in Fig. 1. TGA results indicate that MCL-PHA has a lower degradation temperature than PHB and P(HB-*co*-HV) due to the incorporation of higher carbon atom monomers.

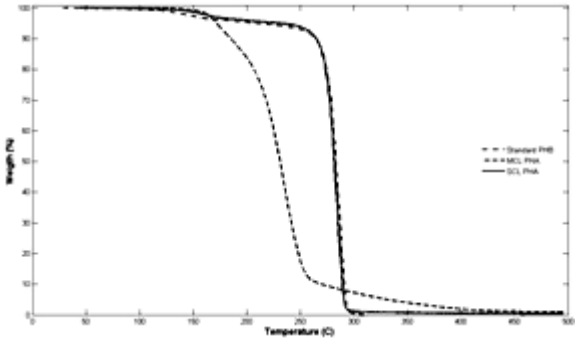

Figure 1. Thermogravimetric analysis (TGA) for standard PHB, SCL- and MCL-PHA copolymers.

FTIR and ^{1}H- and ^{13}C-NMR (data not shown) also indicate that MCL-PHA copolymer has at least three different monomeric units such as 3-hydroxybutyrate, 3-hydroxyvalerate, and other higher carbon atom monomer which is being identified by comparing its experimental ^{1}H- and ^{13}C-NMR spectra with theoretical predicted one.

Conclusions: Complex media generated from by-products of the biodiesel manufacture used as carbon source by bacterial bioconversions of *Cupriavidus necator* give different SCL- and MCL-PHA copolymers. The main goal of this work is the biosynthesis and characterization of PHA copolymers with a bigger spectrum of commercial applications obtained from agroindustrial residues of biodiesel manufacture.

Introduction

Caffeic acid (CA) is a well-known and important phenolic antioxidant present in many plants and beverages, including coffee, apple juice and white wine. It is usually found in the presence of many other related compounds so its isolation and preconcentration from such complex matrices, although of genuine of interest, can be complicated. However, this isolation and preconcentration aim can potentially be realised by using molecularly imprinted polymers (MIPs) to bind the target molecule (CA) in a selective manner even although CA is present in a complex matrix. In this context, MIPs are biomimetic materials which function as antibody binding mimics. In the present work, we present the first example of a caffeic acid molecularly imprinted polymer which has been synthesised in the form of well-defined polymer microspheres.

Materials and Methods

The polymers were prepared by precipitation polymerisation in a fashion similar to the procedure described by Wang et al.[1] For the preparation of MIP, CA (0.66 mmol), 4-vinylpyridine (2.65 mmol), divinylbenzene-80 (13.23 mmol) and α,α'-azobisisobutyronitrile (0.58 mmol) were dissolved in a mixture of acetonitrile and toluene (100 ml, 75/25 v/v) in a 250 ml, polypropylene bottle. The mixture was degassed with oxygene-free nitrogen for 10 minutes while cooling on an ice bath, sealed under nitrogen atmosphere and left to polymerise on a low-profiler roller housed inside a temperature-controlable incubator. Reaction temperature was raised from 25ºC to 60ºC for 2 h and then kept at 60ºC for a further 24 h.

Results and Discussion

The morphological characterisation of the polymer was carried out by means of scanning electron microscopy (Fig. 1) (narrow size distribution: ~ 5 and 1.5 µm for MIP and NIP [non-imprinted polymer], respectively) and nitrogen sorption porosimetry: specific surface area of 340 and 350 $m^2\ g^{-1}$ for MIP and NIP and average pore volume of 0.17 and 0.19 $cm^3\ g^{-1}$, for MIP and NIP, respectively.

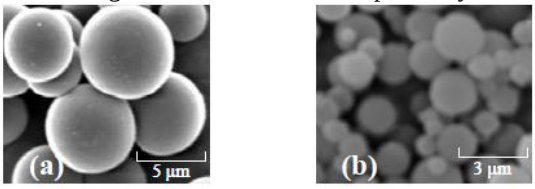

Fig. 1. Scanning electron micrographs of MIP (a) and NIP (b).

The polymers were evaluated by batch rebinding analysis and the derived Freundlich isotherm (number of binding sites (N_K) = 0.6 and 0.3 mmol/g for the MIP and NIP, respectively, and apparent average adsorption constant (K_N) = 10.0 and 1.6 L/mmol for MIP and NIP, respectively). The molecular recognition character of the MIP was evaluated by packing it into a stainless steel LC column (50 mm x 4.6 mm i.d.) and exploiting the MIP as an LC stationary phase. These experiments corroborated the imprinting phenomenon and selective recognition of CA by the imprinted material since very good selectivity was achieved when CA was perfectly isolated in a matrix with eight structurally related compounds. The performance of the imprinted microspheres was proven superior to conventionally prepared bulk and solution polymers when the imprinted column was used directly with juice samples without any clean-up step allowing an efficient removal and recovery of CA from such complex samples.

The CA recoveries obtained were quantitative in all cases and higher than 81 %. It is worthwhile to mention that reproducible responses were noted for both NIP and MIP materials for the template over a 12-month-time-period.

Conclusions

In this work, the technique of molecular imprinting by precipitation polimerisation has been successfully used to produce the first CA MIP in the form of well-defined microspheres. The binding properties of the MIP and the NIP were evaluated by batch rebinding studies and using the derived adsorption isotherms. From the fitting parameters we calculated the affinity distributions for MIP and NIP demonstrating the imprinting phenomenon and strong adsorption ability of the MIP towards CA. Finally, when the imprinted LC column was used for the selective recognition of CA over eight related compounds, a very good selectivity was obtained and it allowed an efficient removal of CA from apple juice samples.

lemeins@enscbp.fr

Introduction: Liposomes or lipid vesicles are known for a long time. They are largely used in cosmetics and pharmaceutics applications but suffer from a lack of stability. Polymer vesicles also called polymersomes are quite recent supramolecular structures discovered in the nineties. These promising structures exhibit tremendous properties but their high stability might be a drawback in applications where a transient carrier is required (for instance in drug delivery). Therefore, we propose to elaborate a new type of vesicles, namely hybrid vesicles assembled from both phospholipids and polymers which will bring novelty in terms of vesicular membrane properties (permeation, elasticity, stability…) and membrane nano-structuration (creation of domains in analogy to lipid rafts in cell's membrane) which plays a significant role for future therapeutic applications.

To the best of our knowledge only three papers have been published so far in this field.[1-3] Up to now, only membranes in which block copolymers and lipids are homogeneously distributed have been obtained. The creation of "spot like" lipid rich domain have been achieved only in one particular case, using an external driving force to perturb the initial equilibrium homogeneous state of the vesicles. We show in this study that spontaneous membrane structuration can occur provided an appropriate choice of copolymers and lipids.

Materials and methods: We have used models copolymers well described in the literature for their ability to form polymersomes. One provided by Dow Corning is a grafted copolymer with Poly (dimethylsiloxane) backbone and poly (ethyleneoxide) as pendant chains (PDMS-*g*-PEO). Its average molar mass is in the range of 3000 g/mol and a 5 nm membrane core thickness has been reported, close to the value reported for liposomes. Another available block copolymer is poly(butadiene)-b-poly(ethyleneoxide) (PBut-b-PEO) with a number-average molar mass of 3800 g/mol and a 9.0 ± 1 nm membrane core thickness. As phospholipids we used the synthetic ones POPC and DPPC from Avanti Polar Lipids. A fluorescent lipid was used as a marker to reveal lipid phases in the membrane. Giant vesicles were prepared by electroformation.

Results and discussion: All the vesicles observable by optical phase contrast microscopy (Fig 1-a) were also observable using epi-fluorescence microscopy (Fig 1-b) whatever the molar content of phospholipid (10-80%) attesting to the presence of block copolymer and phospholipids in all vesicles. Interestingly, in one particular case (PBut-*b*-PEO/DPPC (90/10)) vesicles are obtained but no fluorescence could be detected. In all other combinations of lipid and polymer, the fluorescence signal was clearly visible at 10% molar ratio of lipid.

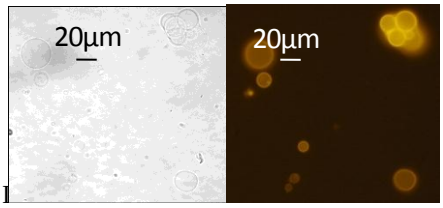

Figure 1 Vesicle formed from PDMS-g-PEO/POPC (90/10).Phase contrast. b) Fluorescence mode

This particular situation may be ascribed to a self quenching effect resulting from a compaction of DPPC phase induce by block copolymer in analogy to what has been reported for DPPC/cholesterol vesicles[4,5]. This has to be confirmed by further experiments.

Preliminary Cryo-TEM experiments have been performed on hybrid vesicles with PDMS-*g*-PEO choosen for its hydrophobic thickness (5nm) commensurate with lipid bilayer thickness (~4nm). Hybrid vesicle (PDMS-*g*-PEO/POPC 75/25) were reduced to a size close to 100nm by extrusion process and compared to pure PDMS-*g*-PEO vesicles. In both cases the vesicular structures are clearly seen. The enveloppe appears as thick line of electron scattering matter for PDMS-g-PEO polymersomes, while for the hybrid vesicles, areas with two lines (inset of figure 3) characteristic of lipid bilayer structures coexist with areas with one single line (in contact with the carbon film). This attest the presence of lipid bilayer domains in the vesicles.

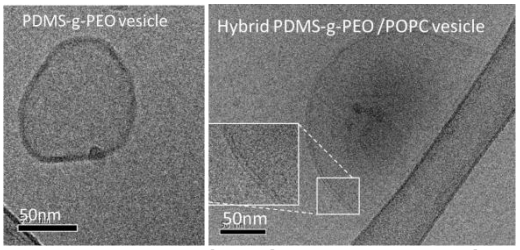

Figure 2: Cryo-TEM images obtained on PDMS-g-PEO polymersomes (left) and hybrid vesicles (right).

Conclusions On the basis of these results it is clear that we can obtain hybrid vesicles at micro and nanoscale and that depending on the nature and molar mass of the block copolymer as well as the nature of phospholipids, complex membrane structuration can be realized. Further experiments will be devoted to a full characterization of the membrane structure (Confocal Microscopy, FRAP…) their resulting properties (permeability, elasticity…) and evaluation of the ability of these hybrid vesicles to encapsulate and release anticancer drugs (Doxorubicin)

Chitosan is a partially acetylated glucosamine biopolymer which exists in the cell wall of some fungi such as the Mucorales strains (1). It mainly results from deacetylation of chitin, a major component of arthropod and crustacean shells such as lobsters, shrimps, crabs and cuttlefishes. Chitosan is an excellent biosorbent presenting abundance, non-toxicity, hydrophilicity, biocompatibility, biodegradability, anti-bacterial property, inexpensiveness and effective sorbtive ability for all classes of dyes, except for basic. Coagulation and flocculation have their place among the conventional processes that are frequently cited for treating dye-containing effluents(2).

In this study; a coagulation/flocculation process was employed for the treatment of model reactive (Remazol Brillant Blue R-RBBR) and acid (Napthol Blue Black-NBB) dye solutions. A semi-natural biopolymer flocculant synthesized from chitosan and polyacrylic acid in organic media with microvawe irradiation. The flocculants (Chitosan and Chitosan-PAA) were tested for synthetic wastewater containing dyes (NBB, RBBR). For the synthetic RBBR dye solution, color removal carried out about 80 % with flocculant (chitosan-PAA).

Keywords: flocculant, chitosan, dye

mithatcelebi@yalova.edu.tr

Treatment of synthetic dyes in wastewater is a matter of great concern. Extensive research has been directed towards developing processes in which enzymes are employed to remove dyes from polluted water (1). A large amount of chemically different synthetic dyes are used for various industrial purposes and significant proportions of it appear in the form of wastewater and are spilled into the environment. Synthetic dyes which are normally employed in textile and dyeing industries. Biodecolorization of dyeing wastewaters by microbial enzymes is a promising, eco-friendly and cost competitive alternative (2). Free radicals mediators have been used to enhance the oxidation activity of peroxidase (1).

In the present study the ability of Lignin peroxsidase (LiP) on decolorization of Naphtol Blue Black (NBB) and Remazol Brillant Blue R (RBBR) has been investigated. Various concentrations of HOBT (1,5-20 mM) were prepared from a stock solution of 450 mM HOBT in DMSO. At different incubation times optimum HOBT and enzyme (LiP) concentration was determined at pH 5.0 (50 mM asetate buffer) in lab. temperature. The synthetic solutions of textile dyes were prepared in distilled water to examine their decolorization by LiP. The efficiency of color removal was expressed as the percentage ratio of the decolorized dye concentration to that of initial one. Dye decolorization rates (%) of NBB and RBBR increase at the presence of mediator HOBT. At optimum enzyme and HOBT concentration dye decolorization carried out almost (%) 95 for two weeks.

*antonioluismedina@ugr.es

Introductions: In the last years, there has been an increasing interest in the design and fabrication of super-paramagnetic polymeric nanoparticles (SPHNPs). Many efforts have also been done in order to multifunctionalise these SP-HNPs. The immobilization of biomolecules1 is a feasible way to introduce different functionalities on the SP-HNP surface, and, in addition, the immobilization of biomolecules could provide an increase of their performances. The covalent coupling of biomolecules on the surface of SP-HNPs allows the design of multifunctional nanoparticles which have important properties: (1) very high magnetic susceptibility to an external magnetic field; (2) the capacity of co-immobilize other compounds (drug, dyes, etc…) in the core of these nanoparticles; (3) the properties of the attached biomolecule on the shell: e.g. enzymatic activity or antibodies specificity.

Materials and methods

A novel monomer A was synthesized:

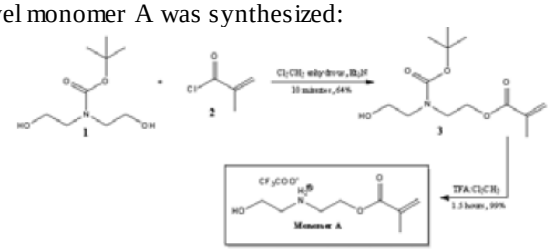

Fig.1. synthesis of a novel polymerisable monomer

The monomer A was used for synthesis amine functionalized SP-HNPs by two step miniemulsion polymerization, then SP-HNPs were functionalized with bis-vinyl sulfone (SP-HNPs-VS).

The vinyl group of the SP-HNPs-VS was used to covalent attach of different (bio)molecules by a Micheltype reaction. The (bio)molecules used were: (1) aminodamsyl (AMD), (2) avidin, (3) Invertase, (4) peroxidase. The fluorescent of avidin-biotin system was measured using a 1.5 mm optical fiber, coupled into magnetic collector. The catalytic activities of invertase and peroxidase on SP-HNPs-VS were also measure. **Result and discussions:** We describe herein a new strategy to immobilize biomolecules on superparamagnetic crosslinked nanoparticles based on the reactivity of vinyl sulfone groups with naturally occurring functional groups present in biomolecules (amine and thiol). A new monomer containing a polymerizable methacryloyl group and a secondary amine group was synthesized and characterized (see Fig.1.). It was used to prepare super-paramagnetic hybrid nanoparticles (SP-HNPs) by two-step miniemulsion polymerization using ethyleneglicol dimethacrylate (EDMA) as cross-linker (see Fig.2.). By this way, were achieved SP-HNPs with amino secondary groups in its surface. Then, these nanoparticles (SP-HNPs) were modified by a Michael addition reaction between bis-vinyl sulfone and the secondary amine groups localized on the nanoparticles surface, and thus was introduced the vinyl sulfone function on the SP-HNPs (SP-HNPs-VS).

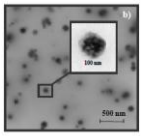

Fig.2. HRTEM picture of SP-HNPs.

In order to demonstrate that the interactions between (SP-HNPs-VS) and biomolecules is covalent and, that the catalytic activity of biomolecules is maintained after immobilization aminodamsyl and three different enzymes were used. Amino-functionalized SP-HPNs were used as negative control and were treated exactly in the same conditions that the vinyl sulfone modified nanoparticles. The Fig.3. shows the high catalytic activity of Invertase and peroxidase after its immobilization on SP-HNPs-VS. The catalytic activity for the controls (SP-HNPs) was practically cero.

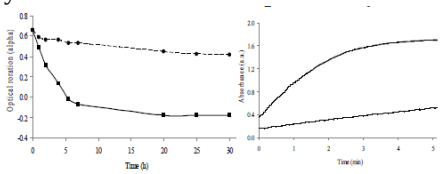

Fig.3. Catalytic activity of SP-HNPs-VS (□; solid line) and SP-HNPs (---; dashed line) incubated with a) invertase and b) peroxidase.

Conclusions: We have synthesized and characterized a novel monomer to develop a new and attractive route in the design of bio-active super-paramagnetic nanoparticles. The developed SP-HNPs show a relatively narrow size distribution and have very high magnetic susceptibility to an external magnetic field; they are completely collected in less than 1 min under magnetic field. In addition, we demonstrate that the SPHNPs functionalized with DVS react with biomolecules

in mild conditions by means of a Michael-type reaction. The only prerequisite is the presence of amine and/or thiol groups which are naturally present in most of the biomolecules. In this work we have demonstrated the high efficiency of the covalent coupling between SPHNPs- VS and biomolecules, which maintains their catalytic activity after their immobilization.

Introduction

Since aromatic polyesters are quite resistant to hydrolytic degradation under physiological conditions, the insertion of aliphatic ester units by copolymerization opens the possibility to obtain materials combining the excellent thermal and mechanical properties and biodegrability of both aromatic and aliphatic polyesters respectively.[1] Taking this fact into account, a series of new random copolyesters derived from poly(hexamethylene terephthalate) and containing 1,4-dioxan-2-one units *(PHT_xDO_y)* (Figure 1) were obtained by ring opening polymerization and their thermal properties were studied.[2] In this work we would like to report on their thermal degradation under inert atmosphere which has been evaluated by combining thermogravimetry, NMR and viscosimetry analysis.

Figure 1. Chemical structure PHT_xDO_y copolyesters.

Materials and Methods

PHT_xDO_y were obtained by ring opening polymerization of cyclic hexamethylene terephthalate oligomers and 1,4-dixoxan-2-one.[2] NMR spectra were recorded on a Bruker AMX-300 in $CDCl_3$. TGA analysis was carried out under nitrogen atmosphere within a temperature range from 30 to 600 ºC. Viscosimety measurements were performed in dichloroacetic acid using an Ubbelhode viscosimeter.

Results and Discussion

The dynamical thermogravimeric analysis of these copolyesters showed a two step degradation process, with maximum degradation rates at 300 and 420 ºC, similar to that reported in a recent work on block terpolyesters containing ethylene-*co*-hexamethylene terephthalate and 1,4-dioxan-2-one.[3]

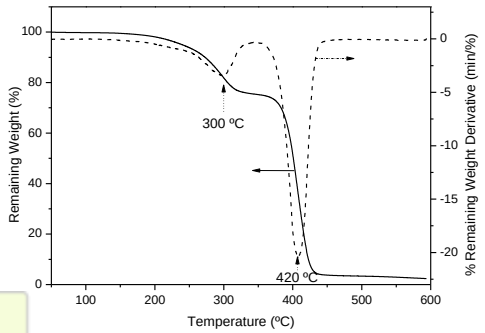

Figure 2. TGA traces of $PHT_{57}DO_{43}$ copolyester.

In order to elucidate the mechanism of degradation, isothermal studies were performed on PHT_xDO_y at 180, 220, 300 and 350 ºC, studying the residues and volatile products by NMR and viscosimetry. It was observed that the copolyesters isothermally treated at 180 and 200ºC lost different amounts of 1,4-dioxan-2-one units and the molecular weight of the residual copolyester increased two or three times when samples were treated for one or two hours respectively. Samples heated at 300 ºC showed that 1,4-dioxan-2-one units were lost in 10 minutes. The spectrum of the residue was essentially poly(hexamethylene terephthalate) (PHT) whereas the volatile was pure 1,4-dioxan-2-one (Figure 3).

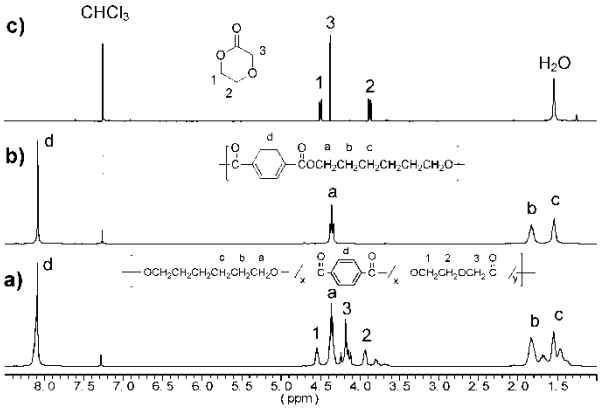

Figure 3. ^{1}H NMR spectra of (a) $PHT_{57}DO_{43}$, (b) residue and (c) volatile left from sample treated at 300 ºC for 10 min.

When the PHT_xDO_y copolyesters were treated at 350 ºC, it was observed in the ^{1}H-NMR spectra of both residue and volatiles, the presence of vinyl end groups, indicating that a β-elimination process takes place, similarly to that observed in PET and PBT, with generation of carboxylic and vinyl end groups.

Conclusions

The mechanism proposed for the thermal degradation of PHT_xDO_y copolyesters at 200-300 ºC happens with elimination of dioxanone due to an intramolecular cyclation process accompanied by esterification of end carboxylic and hydroxyl groups and subsequent formation of high molecular weight PHT. At higher temperatures a β-elimination process takes place which implies chain scission and generation of vinyl and carboxylic end groups accompanied by volatilization when low molecular weights fragments are reached.

Financial support given by MICINN with grant MAT-2009-14053-CO2-01 is acknowledged. Our thanks to the Venezuelan government (FONACIT) for the Master Thesis grant awarded to G.G.

Microwave Assisted Conjugation of BSA & Chitosan

Zafer Omer Ozdemir

Yildiz Technical University,
Faculty of Chemical & Metallurgical Eng.Bioengineering Dept.

ozdemirz@yildiz.edu.tr

Chitin is the second most important natural polymer in the world[1]. Chitosan is deacetylation product of chitin. Chitosan has a unique properties because of holding NH_2 group in chemical structure. There is no other polysaccahryde which contains NH_2 functional group. Chitosan is linear, hydrophilic, positively charged and has mucoadhesive property. It is an excellent biopolymer for preparation of microparticles and nanoparticles owing to its excellent biocompatibility and biodegradability[2].

BSA is the carrier protein. Its role is very functional for organism. Also BSA is very beneficial protein for conjugation reactions[3].

In this research Chitosan BSA conjugation reaction was investigated. Conjugation reactions were done with activators (HBTU, EDC) in organic (DMF) and aqueus media.

Investigation of Cellulase-Dextran Conjugates

Lutfi Karagoz, Zafer Omer Ozdemir

Yildiz Technical University,
Faculty of Chemical & Metallurgical Eng.Bioengineering Dept.

ozdemirz@yildiz.edu.tr

Cellulose is the major polysacharide in plants and is most abundant biological material on earth. In addition to this great amounts of wastes include cellulose, because of this reason cellulose-degrading enzymes become very important. Cellulose–degrading enzymes, which exhibit three types of activities are called as cellulases[1]. (1) Endonuclease hydrolyse internal bonds in cellulose molycule. (2) Cellobiohyrolase hydrolyse terminal bonds and (3) β-glucodisase hydrolyse cellobiose and little olisaccarides to D-glucose.

In this study, cellulase from *Aspergillus niger*[2] was examined. Dextran is oxidated to its aldehyde derivative[3] by using $NaIO_4$. The amount of aldehyde groups at dextran molecule was determined FT-IR.

Acknowledgments

Thermal Degradation of Polyuronic Acids and their Ionic Complexes

Ainhoa Tolentino, Abdelilah Alla, Antxon Martínez de Ilarduya and Sebastián Muñoz-Guerra

Departament d'Enginyeria Química, Universitat Politècnica de Catalunya, ETSEIB, Diagonal 647, 08028 Barcelona

abdel.alla@upc.edu

Introduction

Comb-like polymers consisting of a stiff backbone with long flexible side chains are able to form supramolecular assemblies of interest to prepare materials for novel practical applications.[1] Our research is currently addressed to comb-like systems based on ionic complexes of biotechnological polyacids and alkyltrimethyl-ammonium surfactants bearing long alkyl groups. In this work we report on the thermal degradation under inert atmosphere of the polyuronic acids and their alkylammonium ionic complexes.

Materials and Methods

Alginic acid sodium salt (Na·*co*PGuMnA), polygalacturonic acid (PGaA) and the octadecyl trimethylammonium bromide (18ATMA·Br) were purchased from Sigma-Aldrich. 20 and 22ATMA·Br were obtained using the procedure described in the literature.[2] ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX-300 spectrometer at 25.0 °C operating at 300.1 and 75.5 MHz, respectively. TGA analysis was carried out under inert atmosphere within a temperature range of 30 to 800 ºC.

Results and Discussion

The ionic complexes were obtained following the method used by Pérez-Camero *et al*.[3]

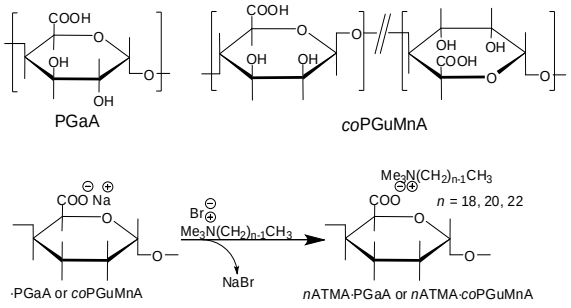

Figure 1. Polyuronic acids and their ionic complexes.

Thermal stability of the polyuronic acids and their ionic complexes was investigated through thermogravimetric analysis; the results of the non isothermic TGA analysis of these polymers are compared in Table 1.

The TGA traces revealed that these polymers are highly hygroscopic with an initial loss of water near to 90 °C. The polyuronic acids present one-step degradation process that starts at about 230 °C with a maximum degradation rate around 250 °C. On the contrary, the ionic complexes showed a three-step degradation process. ^{1}H-NMR analysis of the volatiles arising from isothermal degradation treatment at different temperatures reveals, in the case of the polyuronic acids, the occurrence of formic and acetic acids, and furfural at amounts increasing with the time of treatment.

Table 1. Thermal parameters of Na·*co*PGuMnA and PGaA and their ionic complexes.

Compound	T_o[a] (ºC)	T_d[b] (ºC)	W[c] (%)
PGaA	232	95/252	90/16
18ATMA·PGaA	211	100/229/270/381	93/65/17/0
20ATMA·PGaA	212	100/227/281/398	97/66/18/0
22ATMA·PGaA	207	99/219/301/411	97/71/22/0
Na·*co*PGuMnA	227	100/237	90/23
18ATMA· *co*PGuMnA	204	84/210-217/266/381	88/58/13/0
20ATMA· *co*PGuMnA	206	94/211-220/289/392	88/58/16/0
22ATMA· *co*PGuMnA	202	82/209/301/400	89/65/20/0

[a] Onset decomposition temperature.
[b] Maximum rate decomposition temperature.
[c] Remaining weight at the end of each step.

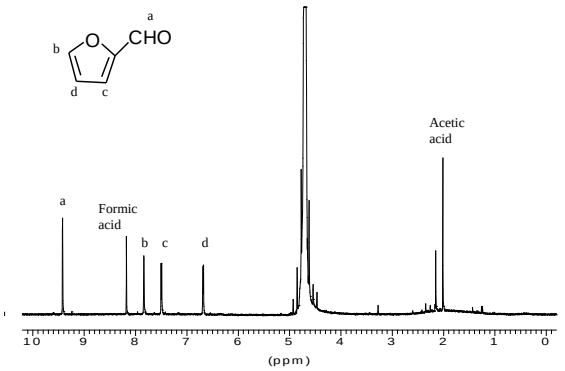

Figure 2. ^{1}H-NMR in D_2O of volatile compounds obtained from PGaA after heating at 250 ºC for 15 min in a nitrogen atmosphere.

The ionic complexes degraded through a much more complicated process implying several parallel and successive decomposition reactions. The ^{1}H-NMR spectra revealed in the volatiles the presence of methanol, *N*,*N*-dimethylalkylamine and trimethylamine. These results suggest that dissociation of the ionic complex occurred at the first stage of decomposition followed by a simultaneous degradation of the alkylammonium surfactant and the polyuronic acid.

Introduction

Electrospinning is an enabling fabrication technique for creating micro/nanofibrous tissue-scaffolds having extracellular matrix-like environment with tailored properties for tissue engineering and drug delivery applications [1]. The scaffolds intended for use in cardiac and vascular tissue regeneration have to undergo repeated cyclic flexing with respect to blood flow with little or no hysteresis. Segmented poly(ester urethane urea)s are elastomeric polymers with good biocompatibility, soft-tissue mechanical properties and controlled degradation characteristics. The preparation and characterization of an aliphatic segmented poly(ester urethane urea) (PHH) was recently reported [2,3]. Polydioxanone (PDO) is a semicrystalline, flexible and biodegradable polymer whose mechanical strength is capable of withstanding pulsatile blood flow and that possesses shape memory, preventing kink formation in vascular structures. In this study, electrospun fibrous of PHH/PDO blends were obtained and its properties were compared with the corresponding scaffolds prepared with the single components. The meshes were characterized for their biomechanical properties, in both dry and hydrated conditions, and structural and morphological properties for soft-tissue engineering applications.

Materials and methods

The novel PHH was synthesized from polycaprolactone, hexamethylene diisocyanate and an aliphatic diurea-diol chain extender according to previously reported procedures [2,3]. Electrospun scaffolds were obtained by electrospinning technique using PHH (25 % w/v), PDO (15 % w/v), and PHH/PDO blend (1/1) (15 % w/v) in 1,1,1,3,3,3-hexafluoro-2-propanol. The setup consisted of a syringe pump (2 mL/h), a power supply (25 kV), and a rotating mandrel (400 rpm). The scaffolds were characterized by scanning electron microscopy, atomic force microscopy (AFM) in contact mode, and differential scanning calorimetry (DSC). The porosity was calculated from the apparent density measurements. PBS uptake was determined to evaluate the hydrophilicity. Uniaxial tensile properties of dry and hydrated tubular specimens were tested using a Bose Electroforce LM1 machine.

Results and Discussion

The scaffolds show randomly oriented bead-free fiber meshes with relatively narrow distribution of fiber diameters (PHH/PDO: 758.9 ± 169.4 nm). The fiber diameters of PHH and PHH/PDO are comparable to the typical diameters of collagen fibers found in natural arteries (50 nm to 500 nm). AFM was performed on the individual fibers, obtaining the highest roughness for PDO fibers (788.8 nm), followed by PHH/PDO (257.3 nm) and PHH (154.1 nm). This could be attributed to a high crystallinity of PDO fibers, leading to a high surface waveness. The increase in surface area favors the cell attachment and proliferation. DSC tests displayed that PHH, PDO and also PHH/PDO blend have semicrystalline morphology. Very high porosities with interconnected pore network and very high surface area-to-volume ratio are characteristics for electrospun meshes. The porosity values showed that the PDO samples were the most porous (79.2 %), followed by the PHH/PDO (71.7 %) and the PHH scaffold (66.4 %). Interestingly, the PBS uptake ability of the PHH/PDO (852.5 %) scaffold was higher than that of the one component scaffolds (PHH: 197.1 % and PDO: 503.3 %). This could be due to a favorable combination of high interconnected porosity and decreased crystallinity. The addition of PHH to PDO conduced to mechanical properties values intermediates between those of the two pure scaffolds. The ultimate tensile strength value was 2.0 ± 0.47 MPa while the Young's modulus was 3.9 ± 1.05 MPa, both measured in hydrated conditions, resulting lower than the dry-sample values. As for the elongation at break, the blend had approximately the same value as the PDO under hydrated conditions (150.2 ± 44.4 %). The mechanical properties of electrospun PHH and PHH/PDO scaffolds are comparable to those of elastomeric polymeric materials reported for cardiac tissue engineering in the literature [4]. Studies on the protein adsorption, platelet adhesion and thrombus formation showed excellent blood compatibility of the PHH for potential blood contacting applications [2,3]. Degradation behavior and cell-scaffold interactions should be undertaken to warrant its potential use in this soft-tissue engineering.

Conclusions

Electrospun PHH/PDO scaffolds showed high porosity and tensile properties comparable to that of cardiac or vascular tissues, demonstrating the feasibility to prepare cardiac patch that mimic the nanoscale structure and mechanical properties of native tissues.

Introduction

Polymeric nanoparticles (NPs) have been widely studied as particulate carriers in the pharmaceutical and medical fields as drug delivery systems [1]. Nanoparticles have the capacity to deliver ocular drugs to specific target sites and therein, provide solutions in the therapy of many eye diseases [2]. Recently, we have synthesized copolymers based on 2-hydroxyethyl methacrylate (HEMA) and a methacrylic derivative of a three star poloxamer (Bayfit® 10WF15) (Bayfit-MA) which had thermosentive behavior in an interval temperature close to that of cornea [3], suggesting that the proposed systems can have application as carriers in ocular drug delivery, e.g. for topical ophthalmic administration. Here, we report the preparation and characterization of NPs of these copolymers and the biocompatibility studies of the particulate systems by in vitro and in vivo experiments.

Experimental

HEMA-co-Bayfit-MA copolymers with HEMA:Bayfit-MA ratios of 99:1, 95:5 and 90:10 (w/w) were used for NPs preparation, named as NP1, NP5 and NP10, respectively. NPs were obtained by dialysis of 50 ml of DMSO copolymeric solutions in distilled water (2 mg/ml). Aqueous dispersions were concentrated to 10 ml by rotary evaporation. Particle size distributions were determined by light scattering (Coulter Electronics). *In vitro* tolerance was assessed by the MTT assay in presence or not of trehalose (T) using immortalized human corneal-limbal epithelial cells (HCLE), normal human conjunctival cells (IOBA-NCH) and macrophages from Swiss male mice. In order to simulate chronic therapies, in which the formulations are in contact with the ocular surface for short and long periods of time, times of contact were 15 minutes (short term exposure) and 1 and 4 hours (long term exposures).

In vivo tolerance was studied with New Zealand rabbits. Each rabbit received 10 µl of one of the formulations in the right eye every 30 min for 6 h. The left eye was used as a control.

Results and Discussion

NPs dispersions in water were obtained by the dialysis method. The aqueous dispersions were concentrated up to values of 1.58±0.1, 2.20±0.7 and 1.88±0.5 mg/ml, for copolymers containing 1, 5 and 10% Bayfit-MA. Size distributions of the NP1 samples after concentration were bimodal, with average diameter of 0.24±0.06 µm and 1.91±0.17 µm respectively. For NP5 and NP10 samples size distributions showed a main peak, which gave average particle diameters of 0.14±0.01 and 0.15±0.02 µm respectively, and a slight tendency to present a small fraction of aggregates. In all cases these concentrated aqueous dispersions were used for tolerance assays.

In vitro tolerance of the NP formulations was carried out by means of cellular viability measurements. For topical ophthalmic administration, the osmolarity of the solutions must be adjusted and firstly *in vitro* tolerance studies in macrophages were carried out with four trehalose (T) concentrations. Results revealed that a trehalose concentration of 72 mg/ml, corresponding to a hypotonic solution, produced the less cytotoxicity in all cases and it was chosen to test NPs in further cell culture experiments. In general, cellular viability of HCLE cells in presence of or not of trehalose was around 100% and results are shown in Figure 1. Values of cellular viability in normal human conjuntival (IOBA-NCH) cells ranged between 85 and 97% after 15 min and 1 h of exposure, but at longer times (4 h) IOBA-NCH cells viability decreased to values around 80% for NP tested in absence of trehalose and around 70% for assays containing trehalose, independently of NP composition.

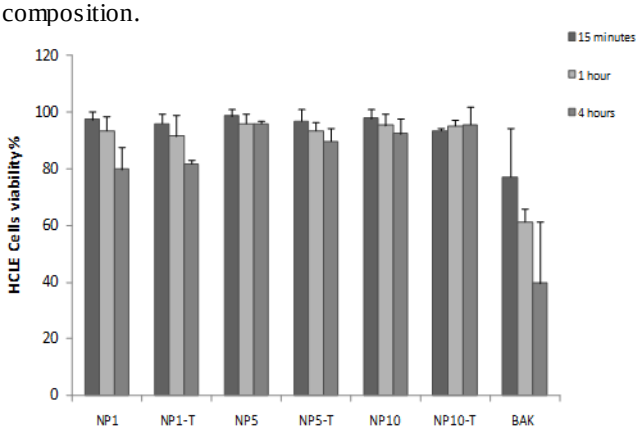

Figure 1. HCLE cells viability in percentage (coefficient of variation, c.v.) for different NPs formulations.

Macrophages viability was higher than 80% after 15 min and 1 h for all samples but it decreased to values between 34 and 67% after 4 h depending on NP composition. The best result at this time was obtained for the NP10-T sample. *In vivo* tolerance assays revealed no significant differences between control and treated eyes for each formulation and all rabbits showed no signs of discomfort during the 24 h assay.

e-mail: kaminski@chemia.uj.edu.pl

Introduction:

Biopolymers and their cationic derivatives are increasingly important in pharmacological sciences. One of the possible applications is related to their impact on blood coagulation. Protamine sulfate is an example of cationic biopolymer which have found clinical applications. It is important to find out the factors governing the interactions between the cationic biopolymers and blood components, erythrocytes in particular. Cationic polymers interact strongly with the phospholipid bilayer of the erythrocytes due to its negative charge which may result in erythrocyte aggregation, which is an undesired and potentially dangerous effect.

Materials and Methods

In our studies we have studied the cationic derivatives of dextran, HPC, and chitosan with different degree of modification. Determination of the cationic polymers concentration which results in the erythrocyte aggregation was carried out using optical microscope. Full blood samples were inspected after addition of excess of polymer solution.

Results and Discussion

We are reporting results showing that the aggregation induced by the cationic polymers depends strongly on the structure of the biopolymer, positive charge density of the of the polymeric chain and the zeta potential of the macromolecules. The greater value of the zeta potential the lower was the concentration of the polymer necessary to start aggregation.

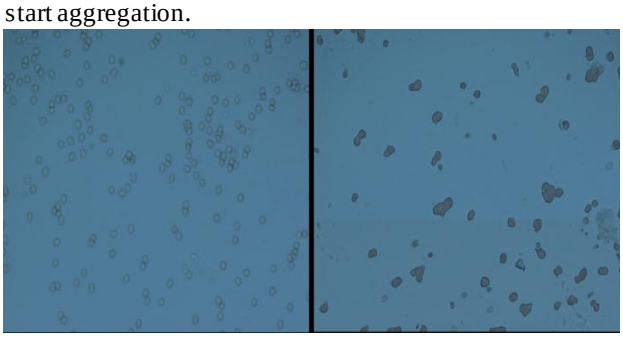

Figure 1. Human erythrocytes under the influence of protamine sulfate (PS). Left Picture: 2,52 ug PS in 1 ul human blond,; right picture: 2,88 ug PS in 1 ul human blood

Conclusions

It was found that for some cationic biopolymers the aggregation of erythrocytes occurs at similar concentration as for clinically-applied protamine. That means that they may be potentially used intravenously for heparin reversal during emergency medicinal procedures.

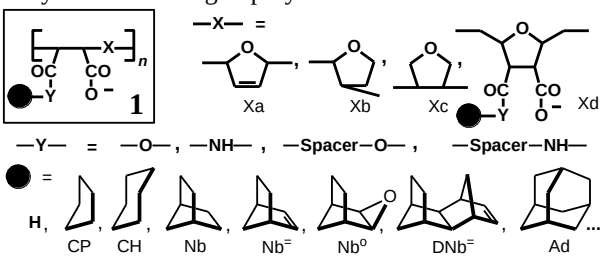
Introduction

Early the alternating copolymers of structure series **1**:



containing the controlled combinations of variable alicyclic and anionic side groups have been designed, synthesized and evaluated as anti-viral agents. On the experimental models *in vitro* of cells infected by the human immunodeficiency virus type 1 (**HIV-1**), among the polymers **1**, the potent inhibitors of the viral entry, most probably fusion step (fig.1), were discovered [1].

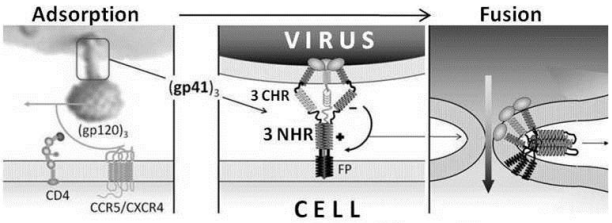


Fig. 1. HIV-1 entry:
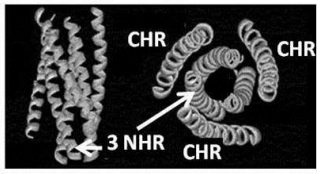
Adsorption removes the $[gp120]_3$. The [FP of $gp41]_3$ anchors into cell membrane, and the $[CHR]_3$ hairpin-like rearranges to $[NHR]_3$ forming the six-helices bundle and inducing the virus - cell membranes fusion



The six-helices bundle of heptade repeat regions (NHR and CHR) of three macromolecules of HIV envelope protein gp41 (fig.1) is starting switch for the fusion, and the $[NHR]_3$ pre hairpin core prevention against contacts with CHR is key mode for the fusion (entry) blockage. Predicting a selective tropism (via electrostatic-co-hydrophobic manner) of **1** to the $[NHR]_3$ tri-helices core we undertook a computational modelling *in silico* of the synthetic (**1**) – viral ($[NHR]_3$) polymers inter-actions as the most expected mechanism of the HIV-1 entry inhibition experimentally observed *in vitro*.

Objects and Methods

Taken from the open PDB 3D structures of the $[NHR]_3$ were used as target. The fragmentary models **M1.i** step-by-step approximated to the real structures of the investigated polymers **1** (fig.2) were applied for docking

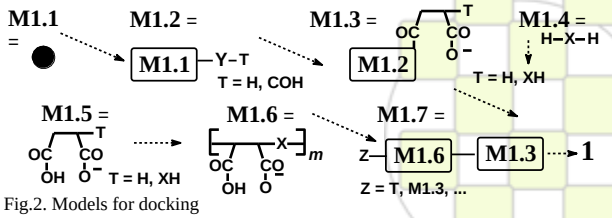


Fig.2. Models for docking

Results and Discussion

The target constructed by three equal NHR regions α-helices is a nano-object (~2x7nm) of trimer-adequate symmetry. Locations of H-bond-active, ionized, and hydrophobic/-philic points/sites were mapped.

The M1.1, lipophil spheroid ● models docked to the target surface by wide distribution in accordance with the hydrophobic sites location. But next generation **models M1.2** (with polar atoms of –Y–) corrected this distribution toward concentration within the ~ nine hydrophobic cavities of target, predominantly to 3 main cavities (**MC**) around target at the inter-helices triplet of hydrophobic amino-acid clusters $(Leu565,568, Val570, Thr571)_3$. **Models M1.4-5**, single fragments of polymer **1** backbone, also were widely distributed on the target surface, but at H-bonds enriched positions, exhibiting similar accumulation nearly the MC, but due to co-clustered triplet of (ionized Lys+574 and H-bond active $Gln567,575,577)_3$. **M1.6**, the anion-oligomer fragments (free of ●) actively docked for lengthwise directions (A, fig.3) along the α-helices (from C-terminal to MC and N-terminal cavities between the parallel helices).

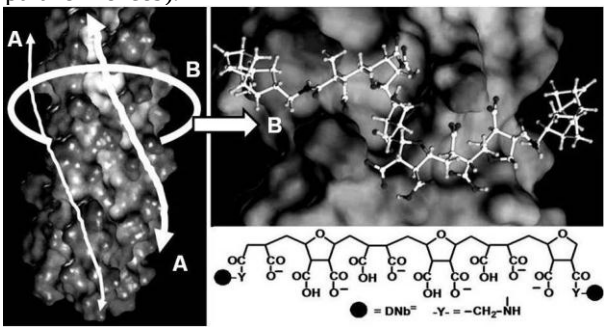

Fig.3. *The $[NHR]_3$ 3D state wit axial (A) and belting (B) directions for docking, and an example of the belting capable minimal fragment*

Unlike M1.6 the **M1.7**, models "equipped" by the ● -sensors become more mobile for complex adaptation to the target configuration. At the optimal chain flexibility and distance between the ● -sensors the **M1.7** models possessed capacity to effective docking by both axial, and "belting" (B, fig.3) mode, predominantly around the mentioned MC triplet. The calculated *in silico* hierarchy of the ● effectiveness (CP,CH << Nb, $Nb^{=}$, Nb^{O} < $DNb^{=}$ ~ Ad) correlated with the anti-HIV efficiency *in vivo* (especially by Chem-Score usage). The X, Y, m, n parameters-efficiency relationship was estimated too.

Conclusion

In contrast with the known small-molecular (mono-point/site) or peptide related (axial) blockers of NHR the newly studied polymers **1** possess the unique adaptability to combined axial-co-belting (from pocket to pocket) multi-blockage for the HIV entry prevention.

Novel bioactive resin adhesives inhibit dentin MMPs mediated collagen degradation.

Osorio R,Yamauti M, Sauro S, Watson TF, Quintana M, Toledano M.

Aim of the study: Bonding to dentin requires an etching step and subsequent resin infiltration. Effective inhibitors of matrix metalloproteinases (MMPs) may be included in resin-dentin bonded interfaces to protect the seed crystallite-sparse collagen fibrils of the scaffold, from degradation. Bioactive parcticles, able to release minerals, may also be included in order to facilitate dentin remineralization. MMPs mediated collagen degradation in the different bonded interfaces has to be determined.

Methods: An in vitro assay with dentin beams was performed. Dentin beams were obtained and immersed in: 1) 10% phosphoric acid (PA); 2) 0.5 M EDTA and 3) no demineralized. Dentin beams were resin impregnated with four prototypes of bioadhesives containing a light curing resin (HEMA and BisGMA mixture) and bioactive microparticles (tricalcium phosphate and tricalcium silicate). In some resin mixtures 1% of $ZnCl_2$ or 20% of ZnO particles were added. Four dentin beams were tested for each condition. Dentin beam specimens were incubated in 500 µl of media artificial saliva at 37°C for 24 h, 1 and 3 wk. Supernatants were analyzed for the release of collagen degradation product (C-terminal telopeptide of type I collagen -ICTP-) using a radioimmunoassay. Values were analyzed by ANOVA and SNK multiple comparison ($P<0.05$).

Results: Mean ICTP values and multiple comparisons results are in the table. Identical numbers in each row indicate no significant difference. In each column values with identical letters indicate no difference.

Conclusions: Addition of 20% of zinc oxide particles alone or combined with 1% $ZnCl_2$ provide a stable dentin MMPs inhibition at the resin/dentin hybrid layers created with the tested resin mixtures, regardless of the previous dentin treatment. MMPs degradation of collagen is strongly reduced in all tested resin infiltrated dentin beams.

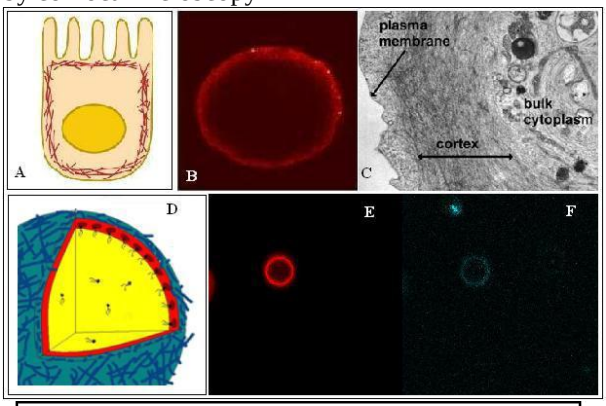
Actin Networks at Interfaces: Microrheology of Reconstituted Cell Cortex

Dmitry Ershov1; vander Gucht, Jasper1

Wageningen University Lab of Physical Chemistry and Colloid science1

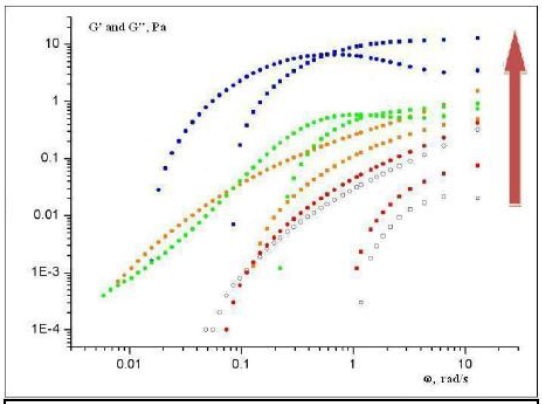
dmitry.ershov@wur.nl

Although there have been quite a number of promising attempts to investigate mechanical and structural properties of cells' actin cortex in vivo, the factors that determine the properties of the cortical actin network are not well understood. A first step towards reaching such understanding is the development of an in-vitro reconstituted actin cortex. In our attempt to develop an actin system that would be analogous to the cell cortex and closely mimicking its structure, we attach actin filaments to lipids lining the surface of an oil droplet using biotin-streptavidin bonds; we show that in this way we can form a very thin actin network that could be visualized and studied by confocal microscopy

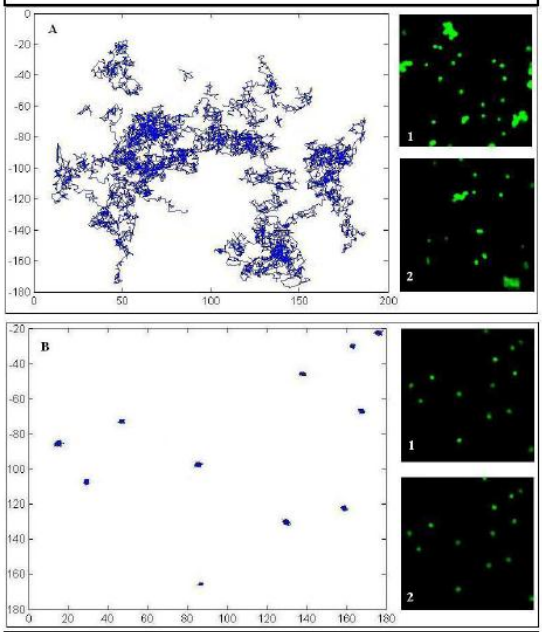


Animal cells' cortex sketch (A, cortical actin filaments are shown in red) and images obtained from different types of microscopy (B, C) and a sketch of our system (D, streptavidin is shown in red and actin filaments in blue) and confocal microscope images (E –streptavidin signal, F – filaments signal).

To measure the visco-elastic properties of this reconstituted actin cortex, we use microrheology based on multi-particle tracking, which allows extracting storage and loss moduli from the mean square displacement of the traced particles moving in the cortex. Our approach allows incorporating different actin-binding proteins or even motor proteins into this "2D-network" with an opportunity to quantitatively characterize their effect on the mechanical properties of the actin cortex. We show that adding cross-linkers to this network increases its elasticity similarly to "3D" cases, and addition of myosin in the presence of ATP causes a quick and sharp stiffening of the cortex.



Storage (G', squares) and loss (G'', circles) moduli of the reconstituted cortex. Different colors for different cross-linker concentrations. Arrow indicates the direction in which the cross-linker concentration (streptavidin) incorporated into network increases. Blank datapoints characterize an interface with no actin network on it.



Mean square displacement of tracked particles before (A) and after (B) stiffening caused by motor proteins upon addition of ATP. Insets show the position of particles in the beginning (1) and in the end (2) of observation.

We believe that our approach opens a variety of possibilities to study visco-elastic properties of the cell cortex in vitro even in the non-linear regime, allowing incorporating any protein of interest into the system.

Surface Nanostructuring and Biofunctionalization through PAMAM Chemical Immobilization

A. Lungu, D.M. Dragusin, E. Rusen, A. Mocanu, E. Vasile, I.C. Stancu, H. Iovu

University Politehnica of Bucharest, Romania

adriana_lungu2006@yahoo.com

Introduction:

Bio-inspired materials and increased bioactivity of the biomaterials represent two top challenges in hard tissue engineering (HTE). Providing macro- and micro-organized scaffolds with surface nano-features remains very important when aiming HTE [1-2]. This work refers to the engineering of polymer-based surface-nanostructured smart biomaterials with cluster-like architecture and functionality. Polyamidoamine (PAMAM) dendrimers were selected as surface modifiers, their multifunctional reactive shell providing increased efficiency for the delivery of various bioactive species [3-4].

In the first part the surface chemical nano-texturing with PAMAM molecules is described. The second part of this study presents the set up of a new strategy for the chemical loading of the dendrimer-modified scaffolds with bioactive species. The technique is highly thiol-specific and it leads to multibiofunctional materials. The influence of the dendrimer generation is also emphasized.

Materials and Methods:

Generations 2 and 4 of amino-ended PAMAM were chemically immobilized on solid polymer substrates, consisting in poly(hydroxyethyl methacrylate) (PHEMA) – based compact scaffolds and microparticles, coated with (2,3-epoxypropyl)-methacrylate (GMA). The coupling occurred through the direct reaction between epoxy groups of the substrate and amines from the reactive shell of PAMAM molecules. The chemical immobilization was studied through FT-IR, XPS, UV-VIS. Moreover, the morphology of the obtained materials was investigated through SEM and AFM. Roughness analysis was also performed in order to quantitatively prove the nano-texturing of the surfaces. The resulted materials were biofunctionalized through specific bioconjugation leading to thiol-reactive conjugates. Glutathione (GSH) was then used as a model peptide for the highly selective immobilization of thiol-ended species.

Results and Discussion:

The chemical modification of the substrate with dendrimer macromolecules was successful. The PAMAM immobilization led to surface nano-texturing of the studied materials. Both roughness and chemical functionality increased with the dendrimers generation. Nano-structures with the size between 50 and 70 nm were visible and homogeneously spread onto the PAMAM-grafted materials (Figure 1).

Dendrimers formed multifunctional clusters on which GSH was efficiently linked. GSH successful coupling was firstly qualitatively evidenced through FT-IR. The coupling efficiency has been also proved through UV-VIS detection of the Py-2-thione formed during the coupling reaction.

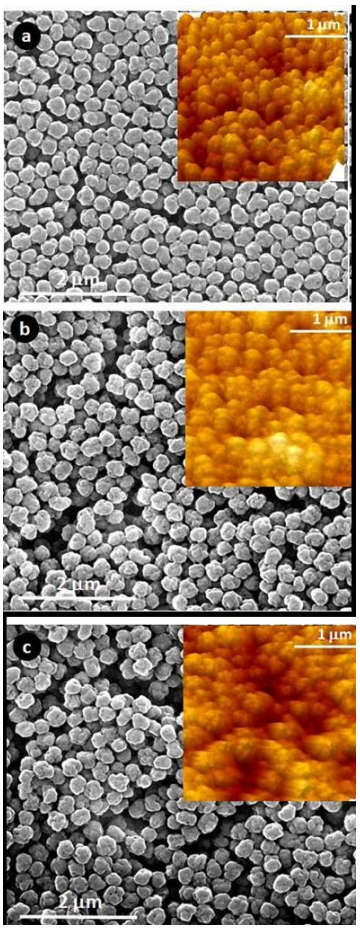


Figure 1. Surface morphology through SEM and AFM for polymer microparticles modified with PAMAM:
a) control sample without PAMAM,
b) particles modified with PAMAM-2 and
c) particles modified with PAMAM-4.

Conclusions:

Multifunctional nanorough surfaces were created. The selective reactivity with respect to thiol-ended species was demonstrated. The dendrimer-modified structures are promising candidates for biofunctionalization and further loading into biomaterials for HTE.

Transport properties in plasticized biodegradable polymers.

A. Chaos, E. Agirrezabal, A. Gonzalez, A. Etxeberria.*

Polymer Science and Technology Departament and Institute for Polymer Materials (POLYMAT). UPV/EHU. P.O. Box 1072. 20080 Donostia-San Sebastián (Spain).

1. Introduction:

The similar structure of the general biodegradable polymers, usually esters in the main chain, makes it share the same disadvantages, like its hydrofilicity, its thermal instability and difficulties in their processability due to its rigidity and brittleness[1341]. A large number of substances have been blended with this kind of polymers in order to increase its flexibility.

The compatibility of the two or more components, affects physical properties such as T_g, T_m, crystallinity and morphology. Consequently, other properties of the macroscopic material are also modified.

In the present work the modification of transport properties of PHB has been studied by the addition of a low molecular weight additive, tributyl citrate.

In the same way, a large amount of research was devoted to the plasticization of PLA[2]. PEG was found to be an effective plasticizer, but phase separation and its migration to the surface over time results in an unstable blend[3]. Blends of PLA and PEG chains of different molecular weights (630, 1500 and 4600) are being studied. Films were prepared by solution-casting from chloroform on glass plates. In both systems, the study has been focused on the permeability of the blends to carbon dioxide, oxygen and water vapour.

2. Results and discussion.

2.1. PHB-Tributyl citrate blends.

The decrease of T_m and crystallinity is related to the effect of the plasticizer in PHB´s neat with increasing molecular mobility.

Content (%wt)	T_m (°C)	% Degree of crystallinity	% Degree of crystallinity PHB
PHB 100	170	70.1	70.1
TbC 2.5	170	67.0	68.7
TbC 5	168	64.5	67.9
TbC 10	169	66.4	73.8
TbC 20	168	60.6	75.6

Table 1. Thermal data obtained by DSC measurements for films of neat and plasticized PHB.

As was observed in Table 1, the melting peaks were slightly shifted to lower temperature from the neat PHB.

The permeability of the blends is directly related with the values of crystallinity. As it can be seen, the plasticization increased all the values for the different compositions, especially the 5 % in weight of TbC.

A larger reduction of the PHB crystallization has been observed for the 5% TbC composition. This effect is reflected on a higher permeability for all the penetrans, see Figure 1.

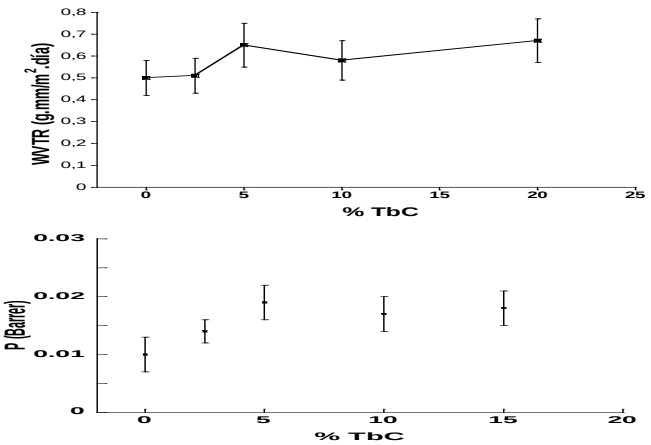

Figure 1: Permeability for water vapour and O_2 of PHB/TbC blends.

2.2. PLA-PEG blends.

This system consists of two semi-miscible crystalline phases dispersed in an amorphous matrix[4]. In our samples, even at low concentration of PEG, both components crystallize.

In table 2, permeability of PLA/PEG samples are summarized. In the case of oxygen, surprisingly, an increase in the barrier property has been found. The opposite behaviour is observed in the water vapour case, as it can be expected when plasticizers are present, where the barrier property suffers a progressive decrease.

Content (% wt) Mw= 4600	MOCON Permeability O_2 (Barrer)	WVTR (g mm/ m^2 dia)
PLA	0.24 ± 0.00	4.3 ± 0.3
PEG 5%	0.22 ± 0.00	6.2 ± 0.3
PEG 7.5%	0.22 ± 0.02	7.2 ± 1.8
PEG 10%	0.19 ± 0.01	10.3 ± 1.3
PEG 15%	0.16 ± 0.01	19.9 ± 3.3

Table 2. Permeability values for blends of PLA/PEG 4600.

Development of PVA-based Polyurethane Microparticles for Enzyme Immobilization

S. Budriene, A. Straksys, T. Romaskevic

Department of Polymer Chemistry, Vilnius University, Naugarduko 24, LT-03225, Vilnius, Lithuania

saulute.budriene@chf.vu.lt

Introduction. There are some basic ways for synthesis of polyurethane (PU) particles. One of the most popular methods is the one-step polyaddition polymerization of in organic medium [1]. Another way of synthesis of PU particles is one step or two step procedure in aqueous medium [2]. Only few reports were found where PVA was used instead of polyols in synthesis of PU [3]. Crosslinked PVA found promising application in the preparation of biomedical materials as films [4] and magnetic-field-sensitive gels [5]. Maltogenase, an exo-acting enzyme, which hydrolyzed 1,4-α-glucosidic linkages in starch, is used for production of high maltose syrups.

In the present work the preparation of PU microparticles derived from PVA and blend of 1,6-hexamethylene diisocyanate (HMDI) and 2,4-toluene diisocyanate (TDI) in dimethyl sulfoxide (DMSO) solution was studied. PU microparticles were used for immobilization of maltogenase by covalent binding.

Materials and Methods. PVA-based PU microparticles were synthesized by one-step method according to our previous works [6-8]. Content of isocyanate and hydroxyl groups and nitrogen in PU was determined by chemical methods. Molar composition of PU was evaluated from quantity of functional groups. The morphology and size of the microparticles was investigated by using the optical microscopy measurements. The structure of PU was characterized using FT-IR analysis.

Results and discussion. PU microparticles were synthesized from PVA and blend of diisocyanates HMDI and TDI when initial molar ratio of PVA and diisocyanates was from 1:0.5 to 1:1 and initial molar ratio of HMDI and TDI in the blend was: 1) 0.25:0.25; 2) 0.35:0.35; 3) 0.50:0.50; 4) 0.40:0.60; 5) 0.75:0.25; 6) 1.00:0.00). Influence of ratio of components, their reactivity, reaction temperature and time on structure of PU microparticles was investigated. Increasing of molar amount of diisocyanates in initial molar ratio of PVA and (HMDI:TDI) and molar amount of HMDI in the blend of diisocyanates resulted in increasing yield of PU and quantity of isocyanate groups. Increasing reaction temperature resulted in increasing yield of PU and decreasing quantity of NCO groups. The highest yield of PU microparticles and quantity of NCO groups was in the case when molar ratio of PVA:(HMDI:TDI) was 1:(0.75:0.25). The isocyanate groups of 2.4-TDI have different reactivities with the 4-position approximately four times the reactivity of the 2-position and at least two orders higher than isocyanate group in HMDI. Structure of PU has been proven by FT-IR spectra. FT-IR spectra of PU microparticles, shows ν N-H at 3394 cm^{-1}, amide I (ν C=O) at 1625 cm^{-1}, amide II (δ N-H, ν C=N) at 1569 cm^{-1}, amide III (ν C=N, δ N-H) at 1251 cm^{-1} and ν C-O-C at 1020 cm^{-1} absorption bands. Obtained PU microparticles consist of macromolecules with three types of monomeric units: non-reacted hydroxyethylene monomeric unit (type I), monomeric unit with one urethane group after reaction of hydroxyethylene monomeric unit with one isocyanate group from either of diisocyanates (HMDI or TDI) (type II) and monomeric unit with two urethane groups after crosslinking reaction of two hydroxyethylene monomeric units with two isocyanate groups from either of diisocyanates (type III). The increasing amount of diisocyanates in initial reaction mixture resulted in decreasing quantity of monomeric units of type I and increasing quantity of monomeric units of type II and III. Increasing of quantity of HMDI in HMDI-TDI blends resulted in increasing units of type II and decreasing units of type III in PU. PU microparticles are tended to agglomeration, however single PU particles are in the narrow size distribution (10-30 μm).

MG was immobilized onto PU microparticles. Efficiency of immobilization (EI) of MG depends on content of NCO groups in PU and it was increased with increasing quantity of diisocyanates in initial mixture of synthesis of carrier. Prolongation of reaction time and increasing of temperature of synthesis of PU was resulted in decreasing of EI of MG. The highest EI of MG was 111 %. Immobilized MG is stable in time and after 28 days more than 95 % of initial activity of MG was remained.

Conclusions. The increasing amount of diisocyanates in initial reaction mixture as well as increasing quantity of HMDI in HMDI-TDI blends resulted in increasing of isocyanate groups and crosslinks in PU. PU microparticles have relatively narrow size distribution in the range from 10 μm to 30 μm. High efficiency of MG immobilization onto PU microparticles and storage stability of immobilized preparations was obtained. MG immobilized onto PU microparticles could be used in biotechnological industry.

Preparation of Polyurethane-Gold and Polyurethane-Silver Nanoparticles Conjugates for Immobilization of Enzyme

T. Romaskevic[a], *S. Budriene*[a], *A. Ramanaviciene*[b], *N. Ryskevic*[b]

[a]Department of Polymer Chemistry, [b]Center of Nanotechnology and Material Science,
Vilnius University, Naugarduko 24, 03225 Vilnius, Lithuania

tatjana.romaskevic@chf.vu.lt

Introduction. Gold and silver nanoparticles have been used for various technological solutions within past three decades. The silver nanoparticles (Ag-NPs) have aptly investigated for their antibacterial property. The gold nanopartilces (Au-NPs) demonstrate not susceptible photobleaching, they are not cytotoxic and show excellent biocompatibility to biomolecules [1]. Au-NPs and Ag-NPs are excellent candidates for bioconjugation with proteins because amine groups and cysteine residues in the proteins are known to bind strongly with gold and silver colloids. Although the Au-NPs bioconjugates with proteins showed excellent catalytic activity, a major drawback was that their reusability was extremely poor [2]. It was primarily due to the difficulty in separating the bioconjugate material from the reaction medium. In this report, functionalized Au-NPs and Ag-NPs embedded on the surface of porous poly(vinyl alcohol)-based polyurethane (PU) microparticles were prepared and investigated. Obtained conjugates were applied as carriers for immobilization of starch hydrolyzing enzyme – maltogenase.

Materials and methods. PU microparticles in the range of 20-60 □m were obtained from poly(vinyl alcohol) and hexamethylene diisocyanate according to our previous works [3, 4]. The Au-NPs and Ag-NPs were synthesized by reduction of tetrachloroauric acid and silver nitrate with sodium citrate, respectively [5, 6]. It was estimated from AFM measurements that shape of height histograms of formed nanoparticles are near monodispersed. Distribution in diameter is narrow, within the range of 12-16 nm for Au-NPs and 20-40 nm for Ag-NPs. The PU was modified with Au-NPs and Ag-NPs by two different methods: (I) adsorption onto polymer surface of Au-NPs and Ag NPs from prepared colloidal solutions and (II) formation of Au-NPs or Ag-NPs from tetrachloroauric acid solution or silver nitrate via reduction with sodium citrate, respectively.

Results and discussions. Modification of PU by Au-NPs or Ag-NPs could be very attractive because of extremely high surface-to-volume ratio of conjugates. Binding of colloidal Au-NPs or Ag-NPs to the PU through nitrogen atoms in polyurethane backbone obviates the need for additional surface modification of PU. It was estimated, that higher amount of Au-NPs was remained in conjugates in the case when adsorption method of Au-NPs and Ag-NPs onto PU surface was applied. Total saturation of Au-NPs onto PU surface was obtained when Au-NPs and PU weight ratio was 1:500 and 1:800 for PU/Au-NPs samples, obtained by adsorption and formation of nanoparticles onto PU surface, respectively. In the case with PU/Ag-NPs conjugates total saturation of Ag NPs onto PU surface was obtained when Ag NPs and PU weight ratio was 1:950 and 1:2300, for I and II modification methods, respectively.

It was determined from TEM and SEM measurements that Au-NPs and Ag-NPs in the range of size 12-17 and 18-42 nm are well dispersed on PU.

Structures of PU-nanoparticles conjugates were proven by FT-IR spectra. It was estimated, that Au-NPs and Ag-NPs were attached to PU surface due to interaction between nitrogen atom of the –NH– of PU and Au-NP. FT-IR results were confirmed absorption of Au-NPs onto PU surface resulted in hydrogen bond formation. Comparable results were achieved in study of PU with Ag-NPs.

Fluorescence spectra of PU, PU/Au-NPs and PU/Ag-NPs conjugates were obtained under 266 nm YAG:Nd^{3+} laser excitation. The fluorescence spectrum of PU contained one broad band peaked at 2,73 eV (corresponds to 454 nm). It was supposed, that fluorescence of PU could be caused by formation of higher aggregates with intramolecular and intermolecular hydrogen bonds between urethane groups. Fluorescence of PU/Au-NPs conjugates shows fluorescence quenching, which is caused by change of nonradiative rate. In the case with PU/Ag-NPs conjugates, fluorescence enhancing with slight peak shift to 2.78 eV (447 nm) was determined.

Using PU/Au-NPs or PU/Ag-NPs conjugates for immobilization enzyme was bound through amine groups to the Au-NP or Ag-NP in the carrier. High catalytic activity (about 89 %) of immobilized biocatalyst was observed when PU/Au-NPs conjugates were used. No maltogenase activity was found in the solution after immobilization; however activity of immobilized enzyme on carrier was reduced. During immobilized enzyme stability assay was found that part of enzyme was leached to the solution after 40 days of storage, though almost all activity of enzyme (about 98%) on the carrier was remained. It is supposed, that part of enzyme was immobilized into PU/Au-NPs conjugate structure and could not be reached by substrate. Efficiency of maltogenase immobilization onto PU/Ag-NPs conjugates reached over 100 %. Immobilized maltogenase remained 61 % of initial catalytic activity after 35 days.

Conclusion. It is predicted that PU/Au-NPs as well as PU/Ag-NPs conjugates have immense potential for the immobilization of enzymes and it could be suitable for biotechnological applications.

Introduction

Nowadays, the concept of self-assembled nano structures plays an important role in the cancer treatment. Nanoparticles (NPs) are used as tumor-specific drug delivery to provide an enhanced therapeutic efficacy and the reduction of adverse side effects. Nanoparticles can passively accumulate [1] in tumours as a result of the enhanced permeability and retention effect. Due to their small size, they can be efficiently internalized by tumor cells and subsequently released the loading active drug [2]. In the present work, self-assembled nanoparticles have been prepared with polymeric drugs obtained previously [3] by radical copolymerization of a hydrophilic monomer, vinyl pyrrolidone (VP), with a glycomonomer, oleyl -2-acetamide -2-deoxy -α-D-glucopiranoside methacrylate (OAGMA) which has demonstrated antimitotic activity against glioma cells. Biological assays were designed in order to investigate the activity of the NPs in cell cultures using human glioblastoma (A-172) and human fibroblasts cell lines and the qualitative evaluation of NPs invagination.

Materials and Methods

Nanoparticles of a OAGMA:VP copolymer [2] of composition 80:20 (mol-%) (NP) were obtained by nanoprecipitation of a dioxane solution in distilled water, in concentrations between 1 and 0.02 mg/ml. Particle size distribution and zeta potential of nanoparticles were determined by dynamic light scattering (DLS) and morphology analyzed by transmission electron microscopy (TEM). Surface chemical structure was analyzed by X-ray photoelectron spectroscopy (XPS).

Cytotoxicity of nanoparticles was assessed by MTT assay. NP dispersions were obtained in water at concentrations in the range 1 to 0.1 mg/ml. Afterwards, 100 µl of each dispersion was mixed with 100 µl of DMEM and the resulting 200 µl dispersions were used for cytotoxicity assays. Assays based on fluorescence were performed for internalization studies. Coumarin-6 loaded NPs were obtained by applying the same procedure except that 0.01 wt% coumarin 6 was added to the dioxane copolymeric solution.

Results and Discussion

Self-assembled nano structures based on the statistical copolymer OAGMA:VP 80:20 (mol-%) were obtained in a dilute aqueous medium mainly due to the amphiphilic "blocky sequences" microstructure. Size of these self-assembled aggregates was analyzed by dynamic light scattering getting an unimodal distribution and narrow P.D.I. values as it is shown in Figure 1A for a NPs suspension of 1 mg/ml. It is worth noting that the nanoaggregates showed a drop in their size when the concentration of NPs suspension decreased. The apparent hydrodynamic diameter (D_h) of the copolymeric nanoaggregates oscillated between 106.8±0.5 and 208.9± 1.9 nm. The zeta potential (ξ) value of -20 mV revealed the presence of negative charge on the NPs surface. The ξ absolute value of these nanoparticles is considered to be enough to ensure their stability. TEM characterization of nanoparticles showed a spherical morphology and confirmed the NPs size obtained by DLS. The surface chemical structure analyzed by XPS revealed that the experimental percents of C1s, O1s and N1s were in close agreement with the stoichiometry percents. On the other hand, the C1s high resolution spectrum (Figure 1B) was deconvoluted into three peaks attributed to hydrocarbon species (BE = 285.0 eV), C-C=O, C-OH/OR and C-N species (BE = 286.24 eV) and N-C=O, O-C=O and O-C-O functional groups (B.E. = 288.12 eV).

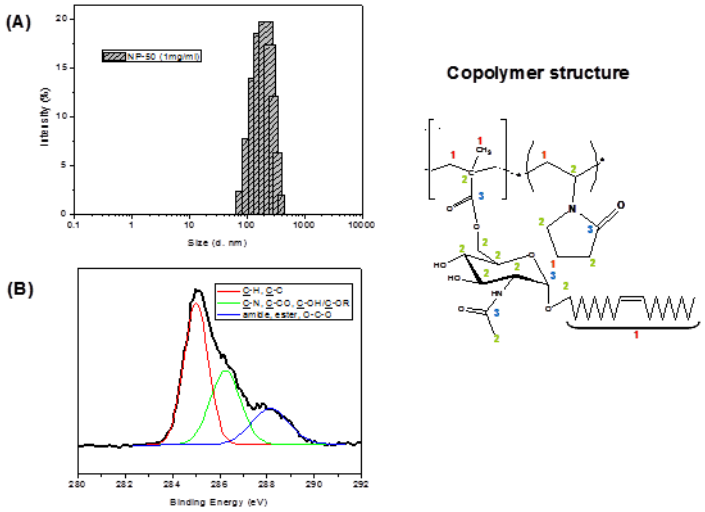

Figure 1. (A) Particles size distribution by DLS and (B) High resolution C 1s XPS spectrum of NPs obtained form a suspension of 1 mg/ml.

Biological activity of nanoparticles at different suspension concentrations was evaluated in human glioblastoma cells and human fibroblasts. At any NP concentration, an inhibition of glioblastoma cells around 45% was observed. However, cell viability of fibroblasts remained between 80 and 100 %.

Endocytosis of nanoparticles by the tumour cells was evaluated with coumarin 6 loaded nanoparticles. The fluorescence images of A-172 cells after incubation with the water:DMEM 50:50 dispersion showed the presence of coumarin 6 loaded nanoparticles mainly inside the cells or attached to the cellular membrane.

Introduction

The preparative techniques to build up multilayer films via the alternative adsorption of polyelectrolytes and biomolecules is one of the most important subjects in biomaterials sciences due to the potential application for the construction of bioreactors, biomedical devices, and biosensors. Requirements for their sensitivity and selectivity force to look for new polymer objects with non-linear topology compared to conventional linear polyelectrolytes. Such non-linear polymers are expected to provide enhanced adsorption and improved fixation of biomaterial.

This work deals with multilayered films obtained by self-assembling method of polyelecrolyte deposition (layer-by-layer technique), which are composed from electrochemically active tyrosinase or choline oxidase electrostatically complexed with the star-like polyionic species. As star-like polyionic species we have used (i) star-shaped poly(N,N-dimethylaminoethyl methacrylate)s with the relatively small number of arms (6, 9, and 17 arms) as well as (ii) star-like micelles of poly(styrene)-block-poly(N,N-dimethylaminoethyl methacrylate)s and poly(butadiene)-block-poly(N,N-dimethylaminoethyl methacrylate)s characterized by the larger number of arms, as well as their quaternized with methyl iodide derivatives.

Materials and Methods

Self-assembled films were deposited on graphite supports via layer-by-layer technique for the formation of biosensing surfaces for phenol and choline detection. The films were constructed via subsequent stages of deposition of the polyelectrolyte component onto graphite substrate, washing, adsorption of enzyme molecules via their complexation with the adsorbed oppositely charged polyelectrolyte component, washing and so on. The electrochemical activity of the incorporated enzymes, their kinetic parameters (K_M, V_M) and the stability of self-organized films were studied amperometrically. Electrochemical data were compared with surface topography characteristics obtained by Atomic Force Microscopy and Scanning Electron Microscopy.

Results and discussion

Spatial organization of the polyelectrolyte component appears to have an influence on the properties of self-assembled films containing incorporated enzymes. The comparison between the enzymatic activities of the films constructed from star-like polyionic species and of the films built up from their linear analogues (reference homopolyelectrolytes) demonstrates an increase in enzymatic activities of the films containing polyphenol oxidase and choline oxidase. The effect becomes stronger with the increasing number of arms of the star-like polyionic species.

Enzymatic activities of the films can also be modulated by the small ion composition (Cl^- vs I^-) of the solution of the polyelectrolyte component, which is used at the stage of its deposition. According to amperometrical measurements, pronounced enhance in the enzymatic activity of films was observed with the increasing iodide-anion concentration. This effect appears to strengthen in the series: short linear polycation < star-like polycationic species ~ long linear polycation and, as supposed, is determined by the flexibility of polyelectrolyte chains and their ability to undergo salt-induced change of conformation from expanded to compact one. The adsorption of macromolecules in compact conformation is thought to result in the increasing amount of the polyelectrolyte component adsorbed on the substrate surface, which therefore can potentially bind more enzyme molecules at the following enzyme adsorption stage. The latter leads to higher amount of the adsorbed enzyme in the films, thereby resulting in the increase of their enzymatic activity.

The analytical characteristics of resulting sensor coatings for phenol and choline detection (linear ranges, detection limits, operational stability, sensitivity, etc.) were described in detail and biomedical applications are demonstrated for the analysis of biochemically important enzymes in the samples of whole blood of humans and experimental animals.

Conclusion

The enzymatic activity of self-assembled polyelectrolte-enzyme films built up via layer-by-layer technique can be controlled by varying topology of the polyelectrolyte component and conditions (such as the type of small ions and their concentration), at which its deposition is performed. This finding is thought to be in demand by modern sensor technologies creating highly active and stable sensor coatings.

Introduction: Biopolymers have received increased attention as excipients in pharmaceutical formulations as they are derived from natural sources. Silver has a long history of use in human healthcare and medicine. A number of healthcare products such as wound dressing materials, body wall repairs, augmentation devices, tissue scaffolds, and antimicrobial filters now contain silver. In this study, alginate-nanosilver-anthocyanin hybrid sponges (ANAHS) were prepared by in-situ synthesis of silver nanoparticles in an aqueous alginate solution. Antimicrobial activity and pro-inflammatory cytokine inhibition of ANAHS were investigated.

Materials and Methods: A solution of 1.0 wt/v% alginate and anthocyanin was prepared by dissolving alginate and anthocyanin in a 100ml of distilled water. Silver nitrate (2ml, 5.0 wt/v% in water) was dropped in 100 ml of the alginate and anthocyanin solution. After 1 hour, freshly prepared sodium borohydride solution (2ml, 1.0 wt/v% in water) was slowly added under magnetic stirring. A rapid color change to dark brown indicated the formation of silver nanoparticles. The mixture was stirred for 3 hours at room temperature in order to lead entire reduction. And then, the solution was dialyzed for 2 days to eliminate the salts which were
formed while alginate and silver nitrate were synthesized. The alginate-nanosilver-anthocyanin solutions were freeze-dried. Finally, the ANAHS were prepared by cross-linking of the freeze-dried matrices, washing, and freeze-drying. The ANAHS were characterized by transmission electron microscopy (TEM), X-ray diffraction (XRD), and ultraviolet-visible (UV) spectroscopy. Cytotoxicity of the ANAHS were checked by 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) assay. Pro-inflammatory cytokines 9 (IL-1β, IL-6, and TNF-α) were measured by cell culture of RAW 264.7 cells and enzyme-linked immunosorbent assay (ELISA).

Results and Discussion: The size of nanoparticles in the TEM images of the alginate solution are about 5-20 nm. Figure 1 is TEM images of the ANAHS. Nano-sized silver crystals were spread in the sponge. We confirmed the presence of silver in the ANAHS by
XRD as shown

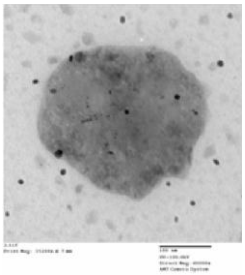

Figure 1. TEM images of silver nanoparticles in the ANAHS

The ANAHS revealed the 97-99% reduction of number of colonies of staphylococcus auseus and klebsiella pneumonia. From results in Figure 3, we confirmed that the ANAHS inhibited the production of IL-1β, IL-6, and TNF-α Conclusively, the ANAHS had a good microbial activity and anti-inflammatory property. They are considered a candidate for the application as wound dressing material.

Characterization and biocompatibility evaluation of novel segmented polyurethanes based on poly(ε-caprolactone)-poly(dimethylsiloxane)-poly(ε-caprolactone)

Marija V. Pergal[1], Vesna V. Antić[2], Gordana Tovilović[3], Jelena Nestorov[3], Jasna Djonlagić[4]

[1]Center of Chemistry, ICTM, Studentski trg 12-16, Belgrade, Serbia; [2]Faculty of Agriculture, Nemanjina 6, Belgrade, Serbia; [3]Department of Biochemistry, Institute for Biological Research, Bul. Despota Stefana 142, Belgrade, Serbia; [4]Faculty of Technology and Metallurgy, Karnegijeva 4, Belgrade, Serbia

Thermoplastic polyurethane elastomers (TPUs) are widely used as biomaterials because of their excellent mechanical properties and good biocompatibility. They are employed in a wide range of medical applications including implantable medical devices, drug-controlled release systems or scaffolds for tissue engineering.[1] TPUs are multiblock copolymers composed of short, rigid polyurethane sequences, hard segments (HS) connected *via* long and flexible chains of soft segments (SS). The thermodynamic incompatibility of the HS and and SS segments at low temperatures results in phase separation and, consequently, in the formation of a domain structure. Their two-phase microstructure imparts excellent mechanical properties. The introduction of poly(dimethylsiloxane) (PDMS) into the polymer chain has the advantage of imparting some of the attractive properties of PDMS to polyurethanes such as high flexibility, excellent thermal, oxidative and hydrolytic stability and low surface energy. [2-4]

In this study a series of novel TPUs based on *α,ω*-dihydroxy-[poly(*ε*-caprolactone)-*block*-poly(dimethyl siloxane)-*block*-poly(*ε*-caprolactone)] (PCL-PDMS-PCL) triblock copolymer, 4,4′-methylenediphenyl diisocyanate (MDI) and 1,4-butanediol (BD), is presented. TPUs were synthesized by a two-step solution polymerization and evaluated for biomedical applications. The triblock prepolymer contained terminal crystallizable PCL blocks and a central PDMS block. PCL is particularly interesting due to excellent water resistance, slow hydrolytic and enzymatic degradation, good biocompatibility and very high flexibility. The combination of the properties of PCL and PDMS makes these block copolymers excellent candidates for surface modifying additives, pharmaceutical and biomedical applications. In the synthesis of the TPUs, the PCL blocks served as a compatibilizer between the non-polar PDMS blocks and the polar comonomers, MDI and BD. The content of hard MDI/BD segments in the polymer chains was varied from 9 to 63 wt%.

The influences of the content and length of the hard segments on the thermal, surface, mechanical properties and biocompatibility were investigated. The structure, composition and HS length were examined using ^{1}H and quantitative ^{13}C NMR spectroscopy. The degree of hydrogen bonding and its influence on the microstructure of synthesized TPUs was analyzed by means of FTIR spectroscopy.

DSC results implied that the synthesized TPUs were semicrystalline polymers in which both the hard MDI/BD and soft PCL-PDMS-PCL segments participated. It was found that an increase in the average HS length (from 1.2 to 14.4 MDI/BD units) was accompanied by an increase in the crystallinity of the HS, storage moduli, hydrophilicity and degree of microphase separation of the copolymers.

Depending on the HS content, a gradual variation in polyurethane surface properties was revealed by AFM and static water contact angle measurements. The *in vitro* biocompatibility of copolymers was evaluated using endothelial EA.hy926 cell line. The cell adhesion and morphology were analyzed by light microscopy. In order to investigate the cell viability and cytotoxic effect of polyurethanes, MTT and LDH assays were used. Protein adsorption on the polyurethane films was also investigated.

Studies of protein adsorption onto polymeric surfaces showed that the adsorption ratio of fibrinogen/albumin for the TPUs, which was adopted as the indicator of biocompatibility, was in the range from 0.306 to 0.513. Since the surface of all samples has adsorbed larger amount of albumin compared to fibrinogen, it can be concluded that all synthesized copolymers have good biocompatibility.

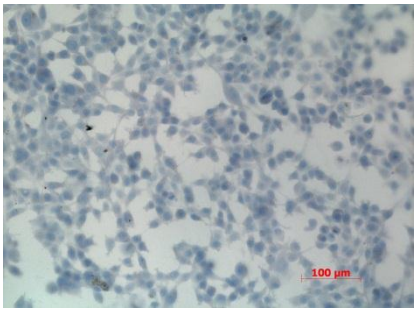

Fig. 1 Photographs of endothelial EA.hy926 cells on the surface of TPU film with 50 wt% soft segment

The copolymer films with high HS content exhibit the best biocompatibility due to a combination of cellular affinity, non-toxic effects to cells and good microphase morphology (Fig. 1). Therefore, their non-cytotoxic chemistry makes TPUs with rougher surface and good microphase separation promising biomaterials for use in implantable medical devices.

alggomez@ictp.csic.es

Amphiphilic copolymers have attracted a great deal of attention in terms of their ability to form self assembled nanosized structures. These polymers are obtained by the polymerization of two or more types of monomers, typically one hydrophobic and one hydrophilic, so that the resulting macromolecule is composed of regions that have opposite affinities for an aqueous environments. Therefore, these systems offer a unique methodology to prepare structures such us polymeric-drug conjugates nanospheres, in which a hydrophobic drug, covalently bound to the macromolecule and isolated from the surrounded aqueous medium by a hydrophilic shell, enhancing the control of the therapeutic action and the biostability of the drug.

The aim of this work has been the incorporation of the ibuprofen (Ibu), ketoprofen (Keto) or naproxen (Nap) molecule onto self assembling 1-vinylimidazole (VI) based macromolecules which led in stable aqueous nanoparticles to be used as controlled drug delivery systems for biomedical applications.

Acrylic derivatives of Ibu, Keto and Nap were synthesised in accordance with the literature[1]. Each acrylic monomer was copolymerized with VI, through free radical polymerization in a range of feed compositions from 20:80 to 80:20. The reaction products were characterized by ^{1}H-NMR, ATR-FTIR, DSC and SEC. The reactivity ratio values for all the comonomer pairs and copolymer compositions of the product obtained were determined by in situ ^{1}H-NMR[2], showing a higher reactivity for the three acrylic derivatives in comparison to the observed for the VI monomer indicating that the polymeric backbones grow with a gradient distribution of the molecular units along the macromolecular chains. These heterogeneous triads distribution of the hydrophobic and hydrophilic segments provide amphiphilic properties to the copolymers synthesised.

The polymeric nanoparticles were prepared by nanoprecipitation method in water (Figure 1).

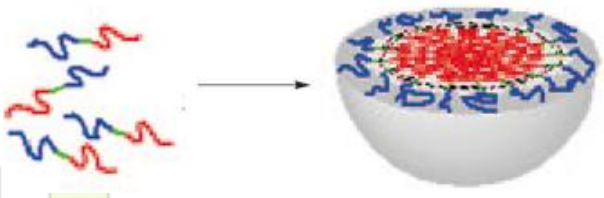

Figure 1. Amphiphilic copolymer micelle formation transforming into a nanoparticle.

Morphology and mean diameter of the particles obtained were determined by Scanning Electron Microscopy (Figure 2) and by Polarization Intensity Differential Scattering respectively. Spherical nanosized particles were observed with mean diameters in a range of 50 to 200 nm, dependent on the microstructure and molar composition of each copolymer system.

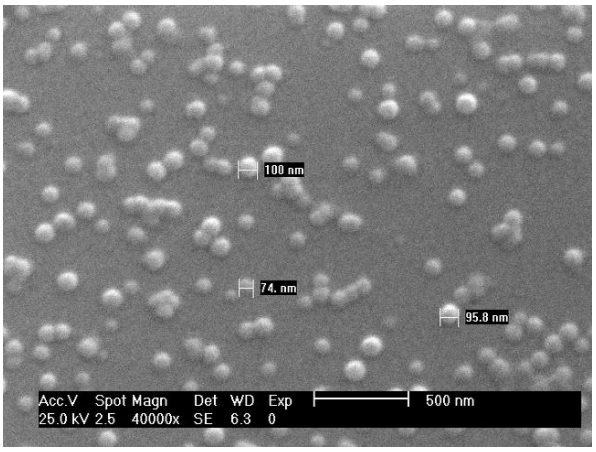

Figure 2. SEM images of p(HKT-co-VI) (20:80).

In vitro drug released from the nanoparticles were determined in pH 7.4 and 10.0 buffers at 37 ºC by HPLC-UV. Both the kinetics and total amount of drug released shown a noticeable dependant on the micelle composition and the physicochemical properties of the surrounding media as a consequence of the existing balance between the chemical natures of the imidazole ended units and the drug molecule content within the polymer backbones.

Finally, the biocompatibility studies analysed through the MTT assay, showed absence of toxicity as a consequence of the release of leachables to the medium in any of the copolymer formulations, which permitted a cellular activity greater than 95% from the second to the seventh day.

All these results shown in this work indicate the potential of these copolymers for obtaining nanoparticles through self-assembling mechanisms which provide a very interesting approach to the preparation of polymer-drug systems for biomedical applications.

Viability and proliferation analysis of culture from human mesenchymal stem cells onto bioinspired collagen membranes for guided tissue regeneration.

Fraga, AF[1]; Tavares, HS[1]; Marques, RFC[1]; Tómas, H[2]; Santos, JL[2];

[1]PROCELL/Brasil; [2]Universidade da Madeira (CQM)/Portugal.

Introduction and Objective: Human mesenchymal stem cells (hMSC) have several advantages in practical and experimental uses due to its easy isolation and purification protocols and principally its capability to differentiate into cells of different tissue. Biomaterials like collagen barriers are current employed in guided tissue regeneration (GTR) for plastic and reconstructive surgery, dental implants and bone graft procedures. Recently, drug and gene delivery systems based on collagen membranes appear as a new promissory treatment for sportive traumas such as muscle and tendon lesions. Human mesenchymal stem cells cultures provide excellent model for these evaluations because have many advantages when compared to *in vivo* methods, and reliable results without unnecessary animal sacrifices. The actual challenges of sportive medicine are trauma in muscle, tendon and cartilage structures where clinical and surgical treatment shows many controversies. The aim of this preliminary study was to evaluate the behavior of human stem cells and proliferation after the initial stage of cell adhesion among collagen matrices, with different compositions, nanostructures and mechanical properties. **Materials e Methods**: After local ethical committee approbation, hMSC from fourth passage with density of $5x10^4$ cells/sample were seeds onto collagen membranes manufactured by PROCELL BIOLOGICS LTDA. The experiments were realized in hex-plicate (n=6) for all biological barrier studied. The cell adhesion and proliferation was analyzed by fluorescent method using Alamar Blue assay. This sensitive method is extremely stable and nontoxic to the cells allowing its continuous cells cultures monitoring over time. Mainly for this reason, this test has been considered superior to classical tests for cell viability such as the MTT test. In order to evaluate morphological aspects, fluorescent labeling by Alexafluor were performed. **Results:** Good cell adhesion behavior of cells on all barriers was observed without any citotoxicity. The best performance for Bilayer group was found after 24h. The cells were monitored every 24h until day 5, when was performed the expression of enzyme Alkaline Phosphatase and the quantification of total protein. These evaluations were also realized at day 10, when was determinate the initial cell differentiation. The proliferation results shows decrease of RFU (Relative Fluorescence Units) after 24h due to environment changing and cell adaptation on the morphologies of each collagen membrane. The results of resasurin increases after 72h and 96h by the proliferation into the porous surfaces (see Fluorescence Microscopy day 3) and decrease after 120h when the cell differentiation starts. The ends of these evaluations are the comparison between Alcaline phosphatase expression and amount of protein for 5 and 10 days. **Conclusions**: The biodegradable collagen membranes Bilayer and Hydroxyapatite coated showed excellent morphology for cell growing. These biomaterials have presented good properties for tissue engineering as scaffold for cells culture from human mesenchymal stem cells as.

Modular And Tunable Polymeric Systems Containing Dual Biologically Active Ions

Introduction

A successful new approach for the treatment of diseases is the combined therapy in which two or more active pharmaceutical ingredients (APIs) that act on the same or different therapeutic target are combined. In the particular case of infectious diseases the success is relatively big because by this way it has managed to reduce the resistance to the treatment as well as other associated diseases [1]. It is well known that quaternary ammonium polymers have antibacterial activity and they have found application in the biomedical field for prophylaxis or treatment of implant associated infections. So, recently we have synthesized hydrophilic quaternary ammonium copolymers for application as foldable intraocular lenses [2].

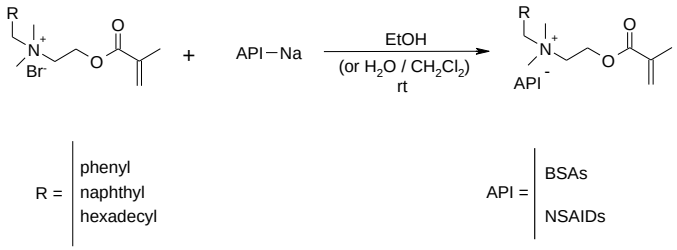
Here, we report the synthesis, characterization and the bactericidal behaviour of dual biologically active quaternary ammonium monomers bearing active pharmaceutical ingredients, like broad-spectrum antibiotics (BSAs) or non-steroidal anti-inflammatory drugs (NSAIDs), as well as their polymeric derivatives. The anti-inflammatory activity and the biocompatibility studies of copolymers and homopolymers by *in vitro* cell cultures were also studied.

Experimental

Monomers were synthesized by applying established procedures [3] as shown in Scheme 1. Polymerization reactions were carried out in solution of dimethylformamide (1M) using AIBN (0.5 wt-%) as a free radical initiator at 50ºC. Copolymers of the dual functional monomer and 2-hydroxyethyl methacrylate (HEMA) were obtained in bulk. Chemical characterization was carried out by nuclear resonance spectroscopy. Drug release profiles from polymeric systems were studied at 37ºC and pH = 7.4 by UV spectroscopy. Antimicrobial activity of monomers and polymers was analyzed against Gram-negative strains of *Pseudomona aeruginosa* PAO1 and *Salmonella typhimurium* LT2, and Gram-positive strains of *Staphylococcus epidermidis* and *Staphylococcus aureus*. The anti-inflammatory activities of extracts of polymeric samples were performed according to the method of Wang et al [4] using macrophages from Swiss male mice. The *in vitro* tolerance cytotoxicity was assessed by the MTT assay using human skin dermal fibroblasts

Results and Discussion

The monomeric compounds were synthesized by one-step ion exchange reaction from the corresponding monomeric quaternary ammonium halide and the sodium salt of the API to give the dual biologically active quaternary ammonium compound in quantitative yield (Scheme 1).



Scheme 1. Synthesis of dual functional monomers.

Polymerization of representative monomers, e.g. the benzyl ammonium ketoprofenate derivative monomer (BK), was successful in giving a corresponding polymer, e.g. poly-BK, and the polymerization yields were in the range 40 to 70 %. Bulk copolymerization reactions of the BK monomer and HEMA with a BK:HEMA ratio of 20:80 (wt %) were carried out to obtain transparent and hydrophilic discs. Ketoprofen release amounted to 80% from poly-BK after 10 days and around 15% from BK-co-HEMA copolymer after 8 days. In the bactericide assays of monomers or polymers it was found that the NSAID counterion had little effect on the anti-microbial activity, giving MIC and MBC values similar to those of the halide counterion. The benzyl ammonium derivative monomers had the highest MIC values and the hexadecyl ammonium derivatives the lowest MIC values, independently of the strain although they were more effective against gram-positive bacteria.

Cellular viability of human fibroblasts in presence of extracts of poly-BK was around 60% indicating that the biocompatibility is compromised; however, fibroblasts viability in presence of the extracts of the copolymer BK-co-HEMA (20:80) at any time was 100% (Figure 1). Anti-inflammatory activity of extracts of the copolymer taken during the first week was around 80% and it decreased for longer times. Macrophages viability was of 100% during the whole period studied.

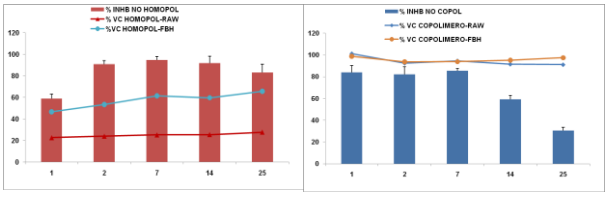


Figure 1. NO release and cytotoxicity against macrophages and fibroblast of poly-BK (left), and BK-co-HEMA (20:80) (right).

vivianeferre040@gmail.com

Introduction - *Arrabidaea chica* is a scrambling shrub which occurs in tropical America whose extract of their leaves contains a 3-desoxiantocianidina, carajurina, which presents activities anti-inflammatory, scarring and antioxidant. The efficiency of crude extract of *A. chica*, involves the stimulus to growth of fibroblasts and collagen synthesis, as demonstrated "in vitro" and "in vivo". Hyaluronic acid (HA) is a glycosaminoglican anionic and non sulfated, widely distributed in connective, epithelial and neural tissues. Several studies suggest that the HA participates in processes that promote the cellular proliferation and migration in the growth of tissues and favors the hydration, which has beneficial effects in cicatrization. These properties, associated to the effects of encapsulation and controlled release produced by hyaluronic acid nano and microparticles, descry more efficient actions in the various stages of the process of healing and their effects in cicatrization.

Matherials and Methods - In this work was studied the influence of two surfactants, Span 80® and Tween 80® in obtaining hyaluronic acid micro and nanoparticles using the method of w/o emulsion, for encapsulation the *A. chica* leaves extract and testify the healing activity. Span 80® was evaluated free and together with Tween 80®, in the proportion 9:1, in both conditions, the concentrations tested were 1 to 5 %. The particles were characterized through its average diameter, polidispersity and morphology. The effects of *A. chica* extract encapsulated were studied in the mouse back tegument through the subcutaneous injection of the same and blood vessels were count to evaluate the healing ability.

Results and Discussion - Was verified that the saturation of the surface of the particles occurred more rapidly when used the lipophilic surfactante Span 80®, better stability of emulsions in the presence of free surfactant was in the concentration of 1% and together with Tween 80®, in the concentration of 3%. Span 80® 1% was choose to produce the HA particles, confirming the utilization already described in the literature. Tests carried out in a culture of human fibroblasts showed that the extract of *A. chica* and empty HA particles had no toxic effect, allowing their use in the testing of healing. In mouse back tegument was find out an increase of blood vessels number when the particles with the *A. chica* extract was employed.

Conclusion – It showed more interesting use Span 80® 1% to obtain the HA micro and nanoparticles. The association between the HA and *A. chica* extracts properties to obtain micro and nanoparticles present characteristics to be employed as inductors in healing process through the increase of blood vessels number.

Synthesis and Characterization of Porous Hydroxyapatite/Polymer Biocomposite Scaffolds

Dajana Kranzelic, Marica Ivankovic, Hrvoje Ivankovic

University of Zagreb, Faculty of Chemical Engineering and Technology, Marulićev trg 19, 10000 Croatia

dkranzel@fkit.hr

Scaffold materials designed from highly porous hydroxyapatite, HAp, derived from cuttlefish bone, and natural (gelatin, alginate) and synthetic (polycaprolactone) biopolymers were prepared and characterized.

In the first stage, complete hydrothermal conversion of aragonite ($CaCO_3$) originated cuttlefish bone (*Sepia Officinalis L.*) to pure HAp, maintaining the original highly porous micro-architecture of bone, was achieved. In the second stage, different concentration of polymer solutions (2-20 wt. %) were impregnated into the HAp scaffolds.

The hydrothermal conversion of aragonite from cuttlefish bone into HAp was confirmed by XRD analysis. The FTIR spectra of HAp/biopolymer composite contain only the characteristic bands of HAp and polymers. There is no evidence of formation of new chemical bonds between HAp and polymers.

In vitro treating with Hank's balanced salt solution (HBSS) for period up to 28 days at 37°C was performed.

Morphological investigations of the prepared composite scaffold performed by SEM revealed the appearance of much more regular sponge-like microspheres (5-10µm) deposited on the original microstructure of HAp converted cuttlefish bone.

The SEM-EDX analysis of the composite surface showed the precipitation of calcium deficient hydroxyapatite (CDHA) and amorphous calcium phosphate (ACP) depending on the nature of precipitation substrate. The chemical analysis of HBSS solution, performed after *in vitro* treating by ionic chromatography method, also indicated calcium phosphate precipitation on the composite surface.

After initial weight increase, HAp scaffold was partially crumbled with weight loss ~6.7 % during 28 days while HAp/polymer composite samples showed weight increase ~7.0 % due to the Ca-P precipitation on composite surface.

These biocomposite materials can be used in delivery of drugs and as growth factors stimulating cellular adhesion, proliferation, and differentiation thus promoting bone and cartilage regeneration.

Polymer Brushes Grafted on Polymer Foils as Platforms for Enzyme Immobilization

Sonja Neuhaus[1,2], *Celestino Padeste*[1], *Nicholas D. Spencer*[2]

[1]Laboratory for Micro- and Nanotechnology, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
[2]Laboratory for Surface Science and Technology, ETH Zurich, 8093 Zurich, Switzerland

sonja.neuhaus@psi.ch

Introduction

Grafting of polymer brushes is a versatile method for surface modification, as the thickness and functionality of the created layer can be varied over a wide range. The flexible extended interface created by the polymer brush significantly enhances the possibilities for enzyme immobilization compared to modified flat surfaces. With the strategy presented in this contribution, polymer brushes with a large variety of functional groups can be produced on an inert but flexible substrate. Different strategies for the immobilization of horseradish peroxidase (HRP) or microperoxidase (MP) were evaluated by assaying the enzymatic activity with colorimetry (Figure 1).

Materials and Methods

Polymer brushes were grown from poly(ethylene-*alt*-tetrafluoroethylene) (ETFE) foils. (Hydro)peroxide radicals for the initiation of a free radical polymerization were created by exposure of the foils to EUV light at the Swiss Light Source (SLS) or by activation with cold, atmospheric-pressure helium plasma [1]. The strong covalent attachment of the grafted chains and the excellent chemical stability of the substrate allowed for modification of the functional groups when necessary. For instance, poly(vinylformamide) brushes were hydrolyzed to yield a weak positively charged polyelectrolyte (PEL) brush and poly(glycidyl methacrylate) (PGMA) brushes were derivatized with metal chelating groups via ring opening of the epoxide.

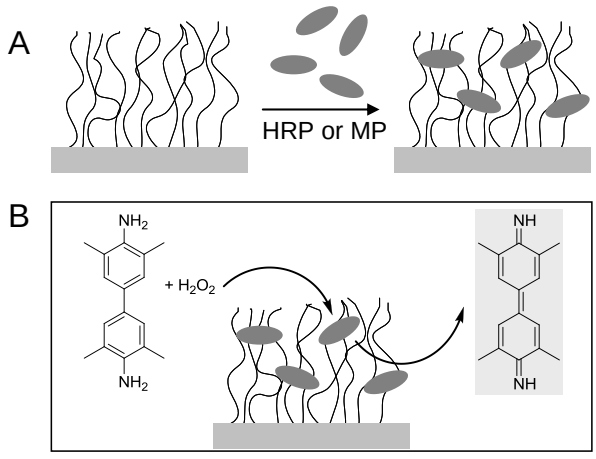

Figure 1: Strategy for testing the activity of HRP immobilized in polymer brushes. A) Immobilization; B) addition of the substrate (tetramethylbenzidine, TMB); enzymatic activity yielded a coloured product which can be quantified colorimetrically.

Results and Discussion

In a first approach, polymer brushes of different wettability and polyelectrolyte character were prepared in order to study the physisorption of enzymes. As an example, MP was loaded into a poly(acrylic acid) brush of variable thickness (Figure 2). Strong enzymatic activity was observed and the polymer brush was stained blue by the reaction product, while the adjacent area consisting of pristine ETFE remained colourless. Therefore, immobilization occurred exclusively in the brush. Moreover, thicker brushes were more intensely stained, indicating that a larger amount of enzyme was immobilized.

Another strategy was focused on the exploitation of metal affinity binding of proteins [2]. To this end, PGMA brushes were derivatized with strong metal chelating groups for the complexation of Cu^{2+} or Ni^{2+}. The contribution of metal affinity interactions to the immobilization of HRP will be assessed by conducting tests in the presence and absence of complexed metal cations.

Conclusion and Outlook

The versatility of the presented polymer brush preparation method was used for studying different parameters affecting enzyme physisorption or enzyme binding via metal affinity interactions. The influence of the local chemistry in the polymer brush on the activity of the immobilized enzyme will be investigated in further studies.

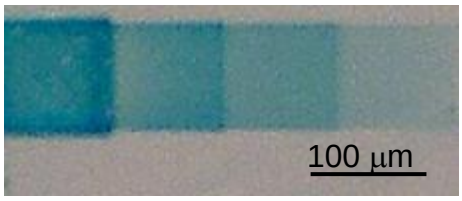

Figure 2: Microscopy image of an array of squares grafted with poly(acrylic acid) brushes. MP was immobilized in the brush and assayed with TMB whereby the brush was stained by the blue reaction product. The staining of the brush decreased with brush thickness from left to right.

Photochemicaly promoted degradation of poly(epsilon-caprolactone)

Katarina Borska, Martin Danko, Ivica Janigova, Jaroslav Mosnacek

Polymer Institute, Center of Excellence GLYCOMED, Slovak Academy of Sciences, Dubravska cesta 9,845 41 Bratislava, Slovakia

e-mail: katarina.borska@savba.sk

Introduction: Studies aimed at controlling of degradation rate of biodegradable polymer materials are of great importance for biomedical or environmental applications[1,2]. Photochemical effects of low molecular weight benzil (1,2-diphenylethandion) doped in biodegradable polyester poly (ε-caprolactone) (PCL) have not yet been studied. The aim of this work was to monitor the photochemical degradation of PCL in the presence of benzil as photoactive dopant using infrared spectroscopy and gel permeation chromatography (GPC).

Materials and methods: Polymer films of 40 μm thickness were casted from chloroform solution on a 10 cm^2 glass plate. The concentration of doped benzil (BZ) in PCL matrix was 7 wt%. Irradiation of polymer films with light of λ> 400 nm was carried out by medium pressure mercury lamp in Spectramate (Ivoclar AG, Schaan, Liechtenstein, 350 to 530 nm) in combination with UV CL SR HPR plastic filter (LLumar, USA). Samples were inserted into the glass finger cooled with water to prevent heating of the sample during irradiation.

The PCL/bz samples were characterized by gel permeation chromatography (GPC) and Fourier transmission infrared spectroscopy (FTIR).

Results and discussion: Benzoyl peroxide is product of photooxidation of benzil in solid polymer matrices after irradiation with light at wavelength λ> 400 nm [3-5]. During the irradiation of the polymer at this wavelength in the air a decreasing of the characteristic stretching band of 1,2-dicarbonyl groups of BZ at 1660-1690 cm^{-1} in the IR spectra was observed (Fig.1).

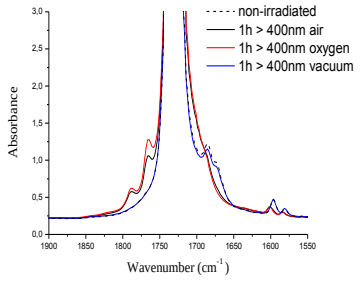

Figure 1: FTIR spectra of PCL/bz films after 1 h irradiation in Spectramate at λ> 400 nm at room temperature.

Nearly quantitative conversion of benzil was visible after 1 h of irradiation. Decay of vibration band of dicarbonyl groups at 1660-1690 cm^{-1} in FTIR spectra was accompanied by the appearance of two new vibrational bands at 1750-1800 cm^{-1} corresponding to benzoyl peroxide.

From FTIR spectra of the films irradiated at λ> 400 nm in the air or under oxygen atmosphere was clear that at higher oxygen concentration the amount of formed benzoyl peroxide was higher. On the other hand, in the film irradiated under vacuum, the benzoyl peroxide related bands did not arise at all. Comparing the elution curves (Fig. 2) showed that the extent of degradation of the PCL increased with increasing oxygen concentration. In contrast, increase in molecular weight with partial gellation due to the recombination of polymer radicals was observed during irradiation under vacuum.

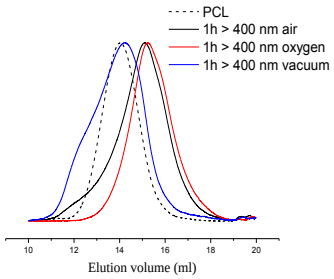

Figure 2: GPC elution curves of PCL/bz films after 1 h irradiation in Spectramate in air, oxygen, vacuum at λ> 400 nm at room temperature.

Based on these observations, we assume that under vacuum the abstraction of hydrogen from PCL chain by benzil in the excited state with subsequent recombination of created macroradicals was occurred. In the presence of oxygen two competitive processes could take place – photoperoxidation of benzil and hydrogen abstraction from the PCL chain. Results showed that increasing oxygen concentration led to higher yield of benzoyl peroxide and thus lower extent of hydrogen abstraction. However, the extent of degradation of PCL was higher. The reason is that even though less macroradicals is formed by hydrogen abstraction by benzil in excited state, in the presence of higher oxygen concentration the macroradicals reacts with the oxygen and subsequent degradation of polymer is occurred. During this process new macroradicals are formed which leads to multiplying the effect of degradation.

nkasyanenko@mail.ru

Introduction

DNA complexes with synthetic polycations are the well-known objects for the manipulation in biotechnology. They are perspective for gene therapy of different diseases, including cancer. Most anticancer drugs have serious negative side effects. The combining of drug efficiency and targeted delivery by means of gene vectors opens up new perspectives in cancer therapy. DNA is the main target for one of the best anticancer drugs cisplatin, *cis*-$PtCl_2(NH_3)_2$. The construction of gene vectors with coordination platinum compounds is of great interest. The use of gene vectors allows avoiding the drug binding to other biological components on the way to reach DNA thus enhancing the selectivity of chemicals.

Materials and methods

Calf thymus and plasmid DNA binding with the coordination platinum compound cis-diamminedichloroplatinum (cis-DDP) in the presence of polycations and DNA-polycation interaction in 0,005 M NaCl were studied by Viscometry, Circular Dichroism, UV spectroscopy, Dynamic Light Scattering, Atomic Force Microscopy, Electrophoresis. Linear polymer polyallylamine (PAA) and graft-copolymer of N-methacryloilamino-D-glycose and N, N-dimethylaminoethylmethacrylate (MAG-g-DMAEM) 30:70 mol. % were used.

Results and Discussion

It was shown that the coordination of cis-DDP to DNA does not prevent the formation of interpolyelectrolyte complex DNA-polycation and the construction of gene vectors. The size of formed nanoparticles estimated by atomic force microscopy and dynamic light scattering showed that the complexation of DNA with cis-DDP does not affect the size of gene vectors.

Conclusions

The formation of gene vectors with the inclusion of anti-cancer drug cisplatin was regarded revealing the new potential in antitumor treatment. Besides, this result indicates that any modification of DNA by the linkage with coordination compounds is possible for further application in nanotechnologies based on DNA packaging.

roberto.scaffaro@unipa.it

Introduction

Biopolymer-based scaffolds can stimulate isolated cells to regenerate tissue with defined size and shape. Consequently, they have been studied as supports for cell transplantation both *in vitro* and *in vivo* [1]. Due to their known biocompatibility and their modular kinetics of degradation, polylactides (PLA) are currently studied as potential materials to obtain three-dimensional structures for tissue engineering applications. In order to enhance their flexibility and resilience, to tune the degradation rate and to promote the surface hydrophilicity of the PLA-based scaffold, studies have been carried out on the possible modification of PLA bulk and surface, including blending and copolymerization with polyethylene glycol (PEG) [2]. In addition to biocompatibility, PEG can be also used to eliminate or at least to minimize the adsorption of proteins via steric repulsion [3]. The study includes the synthesis and the characterization of poly(L,L-lactide)-b-poly(ethylene glycol) diblock copolymers as plasticizers and their effect on the leaching properties and on the hydrophilicity of the polymer matrix to promote cellular affinity. These diblock copolymers were obtained by metal-free ring-opening polymerization of lactide from a ω-hydroxy PEG macroinitiator at room temperature [4].

Materials and Methods

To synthesize PEG-PLA block copolymers, ring opening polymerization (ROP) of L,L-lactide (LA) was initiated from a monohydroxylated PEG segment (polyethylene glycol monomethyl ether, CH3PEG5000 Mn=5 kDa, polyethylene glycol monomethyl ether, CH3PEG2000, Mn = 2 kDa) or dihydroxylated PEG (PEG4600 Mw = 4.6 kDa and PEG200 Mw = 2 kDa) using organic DBU as catalyst. L,L-lactide was gifted by PURAC. The monohydroxylated PEG segment were supplied by Fluka-Chemicals. The dihydroxylated PEG segment and DBU were supplied by Sigma-Aldrich. MALDI-ToF, MS, 'H NMR spectrometry and Gel Permeation Chromatography (GPC) were adopted to estimate the molar ratio between both blocks, the polymerization degree and the molecular weight of the block copolymers. The coexistence and the interactions between the different phases have been evaluated by Differential Scanning Calorimetry (DSC) and Thermogravimetric Analysis (TGA). The morphological characterization of the materials produced was performed by Scanning Electron Microscope (SEM).

Results and Discussion

The GPC results suggest that the polymerization takes place rapidly and that it is possible to achieve the desidered polymerization degree in less than than 30 mins. The polydispersity index, very close to 1.0, indicates that the experimental conditions adopted for performing the synthesis are appropiate to obtain almost single molecular weight copolymers.

Looking at the calorimetric results, it can be observed a strict correspondence between the glass transition temperatures of monohydroxylated CH3PEGs and the corresponding copolymers. In particular, the Tg recorded for CH3PEG5000 is -34.7 °C, close to that found for CH3PEG5000-b-PLLA5000. For CH3PEG2000-b-PLLA2000 it was observed a Tg of -46.4 °C while the Tg of the corresponding PEG is -47.8 °C. As regards the melting temperatures, there is a correspondence between the values recorded for the commercial monohydroxylated PEG used in the synthesis and the values of the first peak of the heating curves of the copolymers. These results indicate that the macroinitiator did not undergo any degradation/modification during the synthesis. TGA data show two distinct degradation peaks associated with the two blocks. In particular, a first peak at 326.3 °C for CH3PEG5000-b-PLLA5000 and at 290.8 °C for CH3PEG2000-b-PLLA2000 that can be attributed to the block of lactide. The onset values recorded for the copolymer with lower molecular weight are, as expected, lower. The second degradation step occurs at about the same temperatures of onset, and may be attributed to the PEG block. The residues measured at 360 °C and at 600 °C confirm the correct proportion between the two blocks.

Conclusions

The copolymers synthesized in the frame of the present work presents properties that are compatible with applications in tissue engineering. Preliminary studies to assess the cytotoxicity of the materials produced are ongoing to evaluate the vitality of SK-Hep1 cells seeded and grown *in-vitro*.

roberto.scaffaro@unipa.it

Introduction

The purpose of this study is to evaluate a method combining melt-blending and leaching techniques for the preparation of a highly interconnected three-dimensional polymeric porous scaffold [1]. More specifically, sodium chloride (NaCl) and poly(ethylenglycol) (PEG) will be used as water soluble porogens to form porous Poly(L,D-lactide) (PLA) and plasticized PLA-based scaffolds, solvent free, designed for applications in field of tissue engineering [2]. This study set out to investigate the effect of processing of polylactide-based blends, on the simultaneous bulk and surface modifications and different pore architectures obtained. The effects on the viability and cell adhesion will be assured too.

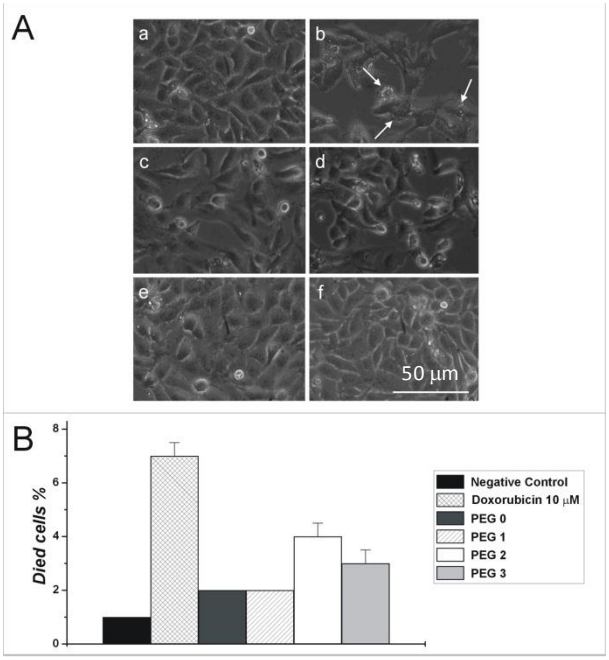
Materials and Methods

Blends of PLA and PEG in the presence of NaCl were prepared by Brabender PLE-330 (operating conditions with T=190°C, t=10 minutes, composition PLA:PEG:NaCl=20:5:75 by weight) and then leached in boiling distilled water for 3 hours. We correlated the pores architecture with the preparation of the materials by changing the molecular weight of PEG. Image analysis - based on the elaboration of SEM micrographs detecting back secondary electrons diffusion (BSED) - were coupled with other analysis methods to ascertain the real pores architecture of the scaffolds. The morphological results were therefore correlated with in vitro adhesion, proliferation and viability tests on human SK-Hep1 hepatocarcinoma cells.

Results and Discussion

The SEM results obtained confirm the feasibility of a method of preparing three-dimensional porous and interconnected structures that combines the techniques of working with molten mixtures of polymeric and composite materials of thermoplastic and leaching.

In order to evaluate the effects performed by different PLA-PEG scaffolds on SK-Hep1 cells viability we have firstly tested if morphological exchange in direction to apoptotic/necrotic phenotypes occur. As shown in Fig. A Sk-Hep 1 cells cultured together scaffolds containing PLA (Fig. A-c) with different molecular weight of PEG (Fig. A-d, e and f) did not show difference with respect to the control (Fig. A-a) in which cells were cultured in absence of scaffolds; on the contrary SK-Hep 1 cultured together Doxorubicin (apoptotic inducer) shown (Fig. A-b) classical morphological exchanges of apoptotic cells. However, a minimal of cell died (<3%), evaluated by Tripan Blue, physiologically occur during SK-Hep 1 cell culture in absence or presence of scaffolds as shown in Fig. B. To further validate this data, was performed an enzymatic assay using a specific substrate for Caspase 3. Fluorocrome extinction kinetic value, here not reported for the sake of brevity, shows that cells grown in the presence of the respective scaffolds do not exhibit caspase activity, because they have not been able to cut the substrate as it has been able to do the positive control, cells SK-Hep 1 in which apoptosis was induced by Doxorubicin 10 μM.



Conclusion

The solubilization of crystalline phase (NaCl) and phase hydrophilic polymer (PEG) has made porous and interconnected matrix biocompatible polylactide (PLA), without the help of toxic solvents, making, therefore, the resulting three-dimensional structures suitable for applications in the field of tissue engineering. Viability and adhesion assays demonstrate that PEG-based scaffolds are well biocompatible to SK-Hep 1. Moreover the treatment of scaffolds with PEG shown to change the adhesive capability, thar are comparable to those obtained when scaffolds are treated with ECM components as type-I collagen.

PLA nanocomposites reinforced by cellulose nanowhiskers: Influence of the preparation on the final properties

B. Ruelle, L. Bonnaud and Ph. Dubois

CIRMAP – Materia Nova

Benoit.ruelle@materianova.be

Keeping in mind environmental problems and the consequence of the fossil resources rarefaction, a new category of materials has been developed over the last years: the cellulosic bionanocomposites which designate biopolymer combinated with cellulosic nanofillers. Besides the low cost of the raw material, the use of cellulose nanoparticles as a reinforcing phase in nanocomposites has numerous advantages such as low density, high availability through the world, high specific properties, reactive surface or biodegradability of the cellulose [1]. However, the cellulose nanoparticles present also some disadvantages, mainly, high moisture absorption, relative low degradation temperature and incompatibility with hydrophobic polymers due to strong hydrophilic interactions between nanoparticles.

The main focus of this work is to characterize polylactide (PLA) nanocomposites reinforced by cellulose nanowhiskers extracted from ramie (CNW) prepared through different ways such as chloroform casting, reactive extrusion and compatibilization of the cellulose surface with PLA chains grafting. The mechanical properties of the different (nano)composites were characterized by DSC and DMA. Their barrier properties were also determined and the degree of CNW dispersion was evaluated by high resolution transmission microscopy.

Introduction

Proton-sponge polymers are known to be part of the best available off-the-shelf materials for gene delivery [1]. However, they suffer from several drawbacks due to their high cytotoxicity. In this sense, it is primordial to design enhanced biocompatible materials which mimic proton-sponge mechanism necessary for buffering the pH and improving endosomal escape efficiency without increasing toxicity.

Our approach is based on the combination of a cationic polymer derived from pyrrolidine and imidazole moieties in order to increase the biocompatibility and the transfection efficiency. For these reasons, it has been developed novel linear copolymers combining *N*-ethyl pyrrolidine methacrylamide (EPA) and 1-vinilimidazole (VI) properties (Figure 1). Throughout this presentation, synthesis, characterization, composition-cytotoxicity relationship and blood compatibility studies of these novel linear copolymers will be reported as well as their evaluation as possible carriers for gene delivery.

Materials and methods

The EPA monomer was prepared as previously reported [2] and the 1-vinilimidazole monomer was purchased from Sigma. Poli(EPA-co-VI) copolymers were obtained by free radical polymerization from molar ratio feed of EPA/VI monomers of 80:20, 50:50 and 20:80 respectively. Microstructural analysis were carried out by ^{1}H-NMR and ATR-FTIR spectroscopy whereas molecular weight, glass transition temperature (Tg) and pH buffering capacity of the (EPA-co-VI) copolymers were determined by Size Exclusion Chromatography (SEC), Differential scanning Calorimetry (DSC) and acid-base titration respectively. *In vitro* cytotoxicity and blood compatibility of the (EPA-co-VI) copolymers were evaluated by MTT, platelet activation, complement system, plasma clotting time, red blood cells aggregation and haemolysis essays following standardized protocols. Finally, w/wo serum media DNA complexation ability with plasmid gaussian luciferase (pGLuc) and transfection efficiency of the pGLuc-(EPA-co-VI) polyplexes were evaluated using 3T3 cells, after 48 hours of incubation. Linear poly (dimethylaminoethyl methacrylate) (10 kDa, PDI: 1.097) [p(DMAEMA)] [3] was used as positive control.

Results and Conclussions

High conversion Poli(EPA-co-VI) copolymers were obtained by free radical polymerization reactions with 70% yield. The ^{1}H-NMR spectra confirmed the structure shown in *Figure 1* for the copolymeric systems with calculated molar fractions of 0.84/0.16, 0.57/0.43 and 0.19/0.43 for 80:20, 50:50 and 20:80 EPA:VI monomeric units respectively. The pK_a values of the copolymers indicate that it was possible to increase the buffering capacity compared to the homopolymer of EPA and are partially protonated at physiological pH.

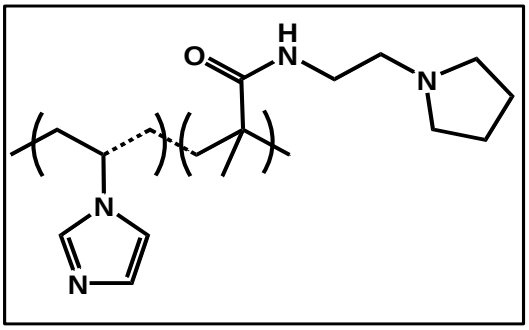

Fig 1. Structure of (*N*-ethyl pyrrolidine methacrylamide-co-1-vinylimidazole) copolymer [Poly (EPA-co-VI].

Finally the Tg values obtained are remarkable higher than the physiological temperature. The Gel Retardation Electrophoresis shows that the copolymers were able to complex with DNA at different N/P ratios, obtaining polyplexes with a proper size for internalization into the cells (200-300 nm), which are stable in solution (10-25 mV). Blood compatibility (data not shown) studies revealed that the copolymers are biocompatible. In addition, MTT assay (data not shown) showed that the cytotoxicity increases when EPA monomer increased in the composition of the copolymer. Finally, the transfection levels (data not shown) obtained after 48 hours in serum free media are higher than the levels reported with the p(DMAEMA), and also significantly higher at high N/P ratios when transfection experiments were carried out in serum media which make these copolymers an attractive transfection reagent for serum-sensitive cell lines.

Introduction

An analysis of the modern evidence of cholesterol enriched micro(nano)domains of plasma membrane, the so-called **rafts**, leads to understanding a crucial role of the rafts in viral entry into cells for no less than 80% cases of known human viruses infections. Since the rafts are natural epicenters (portals) of the enhanced risks for viral interventions, we accept the raft-targeting macromolecular design as one of key strategy for the viral entry prevention [1]. Here we report a synthesis and evaluation of the cholesterol-related anchors (***Chol***) containing polyanions derived from graft-modified alternating copolymers of maleic anhydride within the general formula **1**, fig.1.

Synthesis

The purposed synthesis was carried out by scheme:

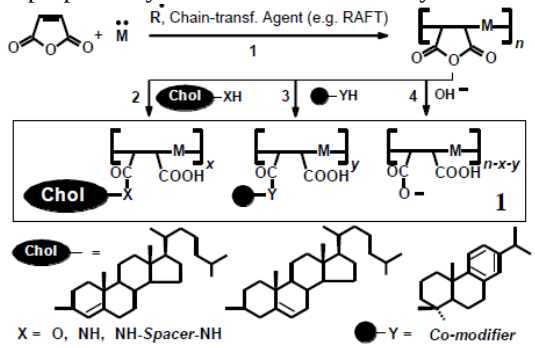

Fig.1. Scheme of synthesis

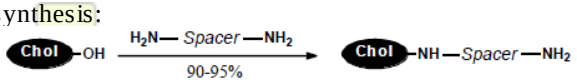
The **step 1** (free radical alternating copolymerization) assigned the –M– nature, polymerization degree and polydispersity; the **steps 2-3** (grafting in anhydrous media) determined the degree of the modification by the ***Chol*** (*x/n*, step2) and, if it was required, by co-modifiers (*y/n*, step3). The **step 4** (hydrolysis in aqueous $NaHCO_3$) resulted in acid salts, the water-soluble anionic polyelectrolytes **1**. The needed ***Chol*** content (>1< several units per macromolecule) was controlled on the step 2. For the etherification (X = O) the *x/n* grade was predictable from the early studied kinetic data [2]. The aminolysis (X = NH/NH-Spacer-NH) provided the needed grade by the initial concentrations $[RNH_2]_0$: [Anhydride units]$_0$ = *x/n* due to a quantitative yield. To regulate a distance between the ***Chol*** and polymeric chain the various spacers were inserted in the ***Chol*** reagents, using, for example, the pre-synthesis:



The products **1** were characterized by element analysis, IR, NMR, GPC data. Final products were carefully purified by multi-cyclic ultra filtration and separated as lyophilized samples suitable for bio-testing

Safety and Antiviral Effectiveness

The evaluations of the synthesized products series **1** demonstrated, that grafting the one ***Chol*** unit per anionic macromolecule (*x* ~ 1-2) resulted in minimal toxicity *in vitro* (CC_{50} >1500 μg/ml, MT4, Hella cells), comparable with one of the non-modified (*x* = 0) precursors, whereas the *x* ~2-4 leaded to ~6-fold more high toxicity. Similar effects were observed at the too much extended hydrophobic chain of the spacer bridge between ***Chol*** and polymer backbone. From the other hand even the minimal content of ***Chol*** at optimal spacers turned the **1** into strong inhibitors of viral infection, in particular, the human immunodeficiency type 1 virus (**HIV-1**). This fact has been confirmed from independent laboratories on experimental models *in vitro* of various viral strains (see the table).

Structure (n~40, -X- = O; *y* =0)		Tox. CC_{50} μg/ml	Activity **IS**= CC_{50}/EC_{50} against the **HIV**-1 strains*				
-M-	*x*		EVK	899	AD8	NL4.3	SF162
	0	1500	14	76	95	63	38
	0.9	1500	-	125	-	-	-
	1.7	1500	-	**300**	**960**	**375**	240
	3.0	600	-	140	-	-	-
	3.6	250	-	< 25	125	100	80
	0	1500	260	-	-	-	-
	1.6	1500	**470**	174	240	190	170
	2.8	370	-	-	160	110	120

**The experimental data were obtained from the laboratories of: Dr. Igor V. Timofeyev (EVK strain SRBC Vector, Koltsovo, Russia); Prof. Alla G. Bukrinskaya (899 strain, Ivanovski Inst. Virol., Moscow, Russia), and Prof. Paul Clapham (AD8, NL4.3, and SF162 strains, Univ. Massachussets Med. Schoool, USA)*

The represented in the table indexes of antiviral selectivity (**IS**), as integrative criteria of antivirals safety-efficiency, reflected the antagonistic tendencies: 1) the safety lowering (enhancement of toxicity for cells), but 2) the antiviral potency amplification with enriching the polymeric molecules by the ***Chol***. It is very interesting, that maximum of IS (5-10-fold increasing) were achieved at very moderate content of the ***Chol***: ~ 1-2 units per polymer **1** molecule. Probably just 1 or 2 cholesten anchor(s) is/are optimum for virus entry blocking without detriment for cells. To understand the specifics of the polymers **1** interactions with the HIV entry mediators (viral env proteins gp120, gp41 and cell receptors CD4, CCR5, CXCR4) within the raft locus, we initiate a computational modeling on base on molecular dynamics and docking techniques.

Conclusion

The proposed raft targeting strategy through the cholesten – modified polymers synthesis is promising way toward new antiviral agent developments.

Protein Nanoreactors for Atom Transfer Radical Polymerization

K. Renggli, G. Kali, N. Bruns

Department of Chemistry, University of Basel, Klingelbergstrasse 80, CH-4056 Basel, Switzerland.

Kasper.Renggli@unibas.ch

Chemical reactions can be confined to nanoscale compartments by encapsulating catalysts in hollow nanoobjects. Such reaction compartments effectively become nanoreactors when substrate and product are exchanged between bulk solution and cavity (Figure 1). Nanoreactors hold promise for applications ranging from selective and size-constrained organic synthesis to biomedical advances (e.g., artificial organelles, biosensing) and as analytical tools to study reaction mechanisms.[1]

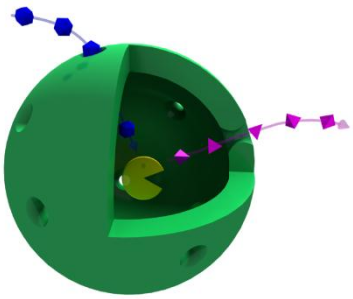

Fig. 1: Schematic of a nanoreactor, where substrate and product are exchanged between bulk solution and cavity.

Atom transfer radical polymerization (ATRP) has emerged as one of the most powerful synthetic techniques in polymer science. Similarly to other controlled radical polymerization (CPR) methods, it allows the synthesis of polymers with predetermined molecular weight, narrow molecular weight distribution, as well as desired composition and molecular architecture.[2] ATRP is a metal complex-mediated reaction with copper-based catalysts being most commonly used. Recent advances have provided access to polymers with protein-reactive end groups synthesized by ATRP and other CPR methods. Conjugates have also been prepared by polymerizing directly from the proteins. To the best of our knowledge, preparation of protein catalyst conjugates for ATRP have not yet been reported.

In our work we successfully grafted ATRP catalysts into the thermosome (THS), an archaeal chaperonin, and used the resulting conjugates as nanoreactors for ATRP polymerization. THS possesses built-in lids that cover the central cavities (Figure 2). The gated pore is large enough (up to approximately 10 nm in diameter) to allow the uptake of guest molecules into the cavity. The lids are formed by helical protrusions at the tip of the apical domain of the subunits. Their opening and closing proceeds in a two stroke-cycle, in which one ring opens in a cooperative movement while the other ring closes. The conformational changes are driven by the hydrolysis of ATP. Depending on the experimental conditions, fully closed or open conformations are obtained as well. THS uses an iris-like conformational change, where apical and intermediate domains rotate in a coordinated manner to close off access to the central cavity.

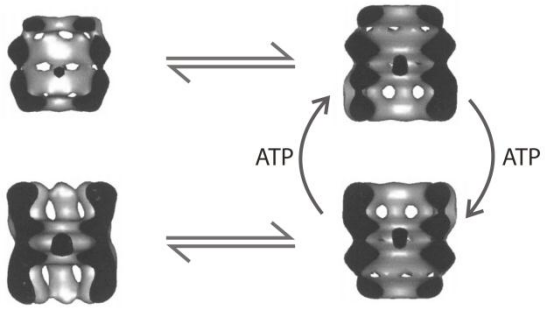

Fig. 2: Cut away models of a thermsosome based on cryo-electron microscopy data.[3]

Here we present an easy and efficient way to couple copper-based catalysts to THS. The resulting nanoscale catalyst enables ATRP in pure water and greatly enhances control over the polymerization.

Introduction

Poly(α-hydroxy acids), which includes poly(lactic acid) (PLA), poly(glycolic acid) (PGA) and their copolymer poly(lactic-*co*-glycolic acid) (PLGA), are some of the most widely used synthetic polymers in biomedical applications. Due to its biocompatibility and biodegradability, PLGA has been widely employed in the areas of surgical sutures, controlled release and tissue engineering (for example in orthopedic devices, where high mechanical strength and toughness are required). However, the hydrophobicity and the lack of functional groups on the surface of PLGA are general drawbacks, which restrain its applications. For example, the absence of recognition sited for cells on its surface, which affect cell attachment and growth, represents a limitation for the use of PLGA in tissue engineering. Furthermore, the lack of functional groups prevents the use of unmodified PLGA in directed adhesion and targeted drug delivery applications. Recent works on different poly(α-hydroxy) acids have demonstrated that both oxygen and ammonia plasma treatments modify their hydrophilicity and morphology, leading to an enhanced cell affinity.

Materials and Methods

This work deals with the surface modification of PLGA films by means of nitrogen/hydrogen mixtures plasmas. N_2/H_2 plasmas are often utilized for the introduction of amino groups onto polymeric substrates such as poly(ethylene) and poly(styrene). However, the effect of such kind of plasmas on biodegradable poly(α-hydroxy acids) has not been studied. Chemical modifications were monitored by contact angle measurements, attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR) and X-ray Photoelectron Spectroscopy (XPS). Morphological modifications were assessed with atomic force microscopy (AFM) analyses. Finally, the density of the inserted primary amino groups was determined by means of fluorescence labeling with fluorescamine.

Results and Discussion

XPS analysis confirms the introduction of N-containing functional groups owing to plasma exposure of the PLGA films. In fact, the N1s peak appears in the spectrum of the treated sample. From XPS results, some considerations about the efficiency of the plasma treatments can be drawn:

1. The N/C ratio (which is equal to zero for untreated PLGA) ranges between 0.027 and 0.045, depending on the adopted operating parameters. From a quantitative point of view, these results are similar to that obtained previously with NH_3 plasma.
2. The N/C ratio increases by increasing the N_2 flow, the power input and the treatment time

The introduction of nitrogen containing functionalities results in an increased hydrophilicity of the PLGA films, as assessed by the decrease of the water contact angle.

A reliable methodology for the quantification of primary amino groups onto plasma treated polymeric materials is their labelling with fluorescamine, a non-fluorescent compound that selectively reacts with primary amino groups yielding a fluorescent product. The fluorescence intensity of the treated sample (measured at 475 nm) allow us to determinate, by difference with that of the untreated one, the surface density of primary amino groups. As previously reported, mixtures with N_2/H_2 ratios of 1:2 and 1:3 are more efficient for the introduction of primary amino groups. For these mixtures we obtained an amino groups surface density of about 1.3 groups/nm^2.

The morphological changes on the PLGA film surface owing to the plasma treatment were evaluated by means of AFM analyses. A surface patterning owing to the plasma exposure can be easily detected. The formation of such surface structures, probably deriving from differential etching of the PLGA surface, is potentially interesting for biomedical applications because of, for example, surface roughness and topography can influence cell attachment and proliferation onto solid substrates.

Conclusions

We investigated the chemical and morphological changes owing to N_2/H_2 plasma treatments of PLGA films, with particular attention to the quantification of the inserted primary amino groups. Our results demonstrates the possibility of a chemical functionalization of PLGA with NH_2 groups, which can influence the cell behavior on the modified polymer or can be exploited for chemical grafting of bioactive molecules. Morphological changes owing to the plasma treatment were also detected.

Effect of Photo, Thermal and Biodegradation on Molar Mass and Crystallization of Polylactide

lausanbl@upvnet.upv.es, alamo@eng.fsu.edu

Introduction. A large number of external agents can affect the degradation of polylactide (PLA) such as temperature, water, weathering, microorganisms, radiation etc. Degradation occurs mainly via chain excision, monitored by the decrease in molar mass. The present work investigates the effect of a thermal treatment on the crystallization kinetics of PLA in reference to those of the virgin resin. The temporal decrease of molar mass and crystallization kinetics are also investigated as a function of exposure to both photo and soil-degradation processes for extended times. A major feature of this work, with respect to prior studies, is the simultaneous study of the three major degradation routes in the same specimen for longer degradation times than previously reported.

Materials and Methods. The material studied is a commercial polylactide copolymer with ~ 4% D-content manufactured by Natureworks, PLA2002D (Minnetonka, USA). Different types of samples were analyzed, the original pellets, melt pressed plates, photodegraded plates and plates degraded in soil. The plates were prepared from the original pellets by melt compression in a Collin 6300P hydraulic press at 210ºC in five pressure steps. The biodegradation was studied in soil for up to 60 months according to ISO 846-1997. Test specimens were collected from 1 to 60 months exposure and kept in a desiccator for 2 days before analyzing. Photodegradation test was carried out using an accelerated exposure system, Suntest XLS+ (Atlas) at 478 W/m^2 with a Xenon lamp with solar filter for simulating sunlight exposure in a maximum of 5100 hours of sample exposure. Specimens were collected from 400 to 5100 hours (corresponding to the Spanish average radiation exposure from 1.7 to 21.4 months) The molar mass was measured by Gel Permeation Chromatography (GPC), the crystallization and melting of the samples by Differential Scanning Calorimetry (DSC), and the linear growth rates by Optical Microscopy (OM) coupled with a Linkam hot stage.

Results and Discussion. The decrease of the number-average molar mass (M_n) with the degradation time has been assessed for all the degradation processes. The first degradation step is thermal, it takes place during melt compression of the initial pellets. The pressing procedure at 210 °C caused a very large reduction of the initial molecular weight, ~ 40% decrease (from 222K to 135K). Interestingly, the time dependence of the decrease of molar mass during biodegradation is different than for photodegradation. The temporal variation of the molar mass of soil-degraded specimens follows an exponential behavior ($M_n = M_{no}\, e^{-kt}$) where M_{no} is the initial molar mass and k the rate constant of degradation. In spite of different biodegradation conditions, the same exponential temporal functionality was reported for hydrolysis and compost biodegradation studies (1,2). Conversely, the molecular weight of specimens tested during photodegradation follows a power law relation with molecular weight ($M_n = M_{no} - At^k$). Although the algebraic variation of M_n with time in PLA photodegradation was not given in prior works, literature data obtained in similar conditions were fitted with equivalent power law functionality, in support of a difference in rate dependence between the soil and photodegradation processes. The photodegradation of PLA is faster than via soil degradation.

The effect of decreasing molar mass from both bio and photo degradation on cold crystallization temperatures (T_c) and on the linear growth rates (G) of specimens crystallized isothermally from the melt has been also studied. T_c obtained from the second DSC heating scan displays the same slight decreasing dependence with increasing time or decreasing molar mass for bio and photodegraded samples, indicative of a faster crystallization. Moreover, the linear growth rates of isothermally crystallized samples from the melt in a large range of T_c are increasing with molecular weight, as expected from the main contribution of the transport term in nucleation. The change of G with molecular weight follows for both processes a power law, characteristic of semicrystalline polymers in a wide range of molecular weights ($G = K\, M^{-1.4}$). A slightly lower value of K for photodegraded samples indicates that although chain excision is the major degradation mechanism, the functional groups generated differ in some extent. Lower values of G for photodegraded samples than for bio at equivalent molecular weights conforms to the presence of anhydride groups in specimens from the former degradation type (evidence obtained by FTIR) (3). These groups act as defects lowering the crystallization rate. Anhydride groups are absent in the biodegraded specimens. The kinetic G data have been analyzed according to secondary crystallization theory.

Conclusions. Photodegradation is a faster process than biodegradation. Differences in linear growth rates at equivalent molecular weights give evidence for characteristic functional groups in photodegraded samples, absent in other types of degradation.

Chitosan and layered silicates bionanocomposites of preparation to be used as drug carrier vehicle

Itamara F. Leite[1], Samilla F. de Oliveira[2], Thaís Maria A. Marinho[3], Oscar L. Malta[4] e Suédina M. de L. Silva[5]

[1,2,3,5]Universidade Federal de Campina Grande, [4]Universidade Federal de Pernambuco

Biopolymers (chitosan) and clay minerals (montmorilonite) are common ingredients in pharmaceutical products. Although they are frequently used in their pure form, a single polymer or clay mineral often does not meet all the requirements. A way to further extend their applications is to modify biopolymers by incorporation of inorganic fillers to obtain bionanocomposites with improved properties, especially for pharmaceutical applications. Recently, the field of polymer layered silicate bionanocomposites has attracted much attention for drug delivery applications. The unique properties of the polymer layered silicate bionanocomposites such as easy degradation, biocompatibility and tunable mechanical properties are essential for pharmaceutical applications.

Chitosan (CS) is widely used as a drug delivery vehicle for control release of therapeutic agents. This polymer has been extensively used in recent years due to be non toxic and exhibit high mechanical strength, hydrophilic character, good adhesion beyond its low cost. On the other hand, the montmorillonite (MMT) is widely used in the modification of the biopolymer chitosan, since this mineral belongs to smectite family and is a promising layered silicate as delivery carrier for various drug molecules. Moreover, the negatively charged edges on the layers of MMT could interact with cationic polymer like chitosan (CS) to form unique polymer layered silicate materials having a large inter-planar spacing; and superior capability to intercalate drug molecules into the interlayer space of the (001) plane. Recently, synthesis of micro and nanocomposites with clay minerals was proposed as a novel approach to modify some of the properties of polysaccharide (chitosan), including swelling, hydrophilicity, mechanical and thermal behavior and bioadhesion. These modifications permit to obtain films of chitosan/layered silicates bionanocomposites with improved thermal and mechanical properties for use as a drug carrier vehicle.

Chitosan was obtained from Polymar (Fortaleza/Brazil) with degree of deacetylation at about 86%. A sodium Bentonite named Argel 35 was supplied by Bentonit União Nordeste (Campina Grande/Paraíba/Brazil) to the form powder with the cation exchange capacity (CEC) of 92 meq/100g.

In this work, bionanocomposites of chitosan and natural bentonite were prepared by solution intercalation using different concentrations, 5:1 and 10:1, respectively. At first a chitosan aqueous solution was prepared by dissolving powdery chitosan corresponding to desired weight ratio in 300mL of 1% (v/v) acetic acid and stirring for about 2h/45°C. A 1wt% clay suspension was also prepared by dispersing clay powder in distilled water and stirring for 10min at 50°C prior to use. The chitosan solution was then slowly added to the clay suspension at about 50°C and 1200 rpm. During the mixing process, the weight ratio of chitosan to clay was from 5:1 and 10:1 in order to control the chitosan loading level in the silicate layers. The reaction mixture was stirred for 4h, separated by filtration three times. Then the bionanocomposites films were dried at 50°C for 24h.

The influence on the amount of bentonite in the morphology, thermal and mechanical properties of the chitosan bionanocomposites were evaluated. Pure chitosan and chitosan/bentonite bionanocomposites films were characterized by infrared spectroscopy, X-ray diffraction, thermogravimetric analysis and mechanical tests. The morphology of the nanocomposites was affected by the ratio of chitosan/bentonite. Nanocomposites with intercalated morphology were obtained predominantly when the ratio of chitosan to bentonite was 5:1, while that the ratio 10:1 of chitosan/bentonite favored the formation of nanocomposites with exfoliated morphology predominantly.

Introduction

Bone cements, or surgical cements, are polymeric biomaterials which are tolerated by the human body. These materials are used in clinical applications such as prosthesis fixation or procedures to treat spinal fractures (Percutaneous Vertebroplasty and Kyphoplasty). These cements are made mostly of two phases: a solid phase of Poly (methyl methacrylate) PMMA powder, benzoyl peroxide (BPO) and a contrast agent for X-rays as zirconium oxide and, a liquid phase formed by methyl methacrylate monomer (MMA), which polymerizes in situ during surgery, hydroquinone and an activator such as N, N-dimethyl-p-toluidine. A very important element in the conformation of this kind of cements is the contrast agent used, which is essential for the bone cement to be radiologically detectable. The addition of inorganic molecules within the polymer matrix produces that the mechanical strength and fracture toughness of cement decreases due to the incompatibility between them. These problems can be overcome by superficial modifications of zirconium oxide with plasma polymerization of MMA. Plasma polymerization can be used to modify diverse substrates without altering the bulk mechanical properties of the substrates although polymers obtained by this technique are significantly different from those produced by conventional techniques.

Materials and Methods

Zirconium oxide particles were modified with plasma polymer of methyl methacrylate (PPMMA). The modification was performed in an inductively coupled methyl methacrylate plasma reactor with 50 W (13.56 MHz) for 4 h and, 100 W for another 4 h at 5 X 10-1 Torr. The modified zirconium oxide particles were characterized by water contact angle, Fourier transform infrared (FT-IR), thermo gravimetric (TGA) analysis and Scanning Electron Microscopy.

Results and Discussion

The water contact angle results shows that surface of modified zirconium oxide particles were slight hydrophobic (56°+ 5) compared to the unmodified particles (0°). This behavior is due to the deposition of PPMMA. The FT-IR analysis of modified particles showed the presence of carbonyls at 1726 cm-1 (Figure 1) which indicates the presence of PPMMA; this was confirmed with TGA analysis which shows a 1 % of mass weight loss between 450°C and 340 °C which can be addressed to the degradation of the PPMMA (Figure 2).

Three-Dimensional Porous Biocompatible and BiodegradableScaffolds Based on PHAs

Julien Ramier, Estelle Renard, Valérie Langlois, Daniel Grande

"Complex Polymer Systems" Laboratory, Institut de Chimie et des Matériaux Paris -Est, 2 rue Henri Dunant, 94320 Thiais, France

E-mail: grande@icmpe.cnrs.fr

Introduction

Polyhydroxyalkanoates (PHAs) represent a class of aliphatic biopolyesters produced by different microorganisms as energy and carbon supply when they are subjected to stress conditions (limiting oxygen, nitrogen or other compounds)1,2. These biopolyesters possess interesting properties for various applications in the biomedical field as sutures, drug carriers, but also as scaffolds for tissue engineering, thanks to their tunable mechanical properties, and mainly due to their biocompatibility and biodegradability. Among the family of PHAs, poly(3-hydroxybutyrate) (PHB), poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBHV), and poly(3-hydroxybutyrate-co-3-hydroxyhexanoate) (PHBHHx) are increasingly used as bio-based systems involving in vitro and in vivo studies.

To engineer three-dimensional scaffolds with thin fibers as the extracellular matrix, the electrospinning technology is generally used to produce nanofibrous mats (Figure 1, as an example). Under the action of a strong electrical field, a jet of a concentrated solution is formed, stretched and the as-made fibers are collected3.

Three-dimensional nanofibrous scaffolds exhibit a high porosity, and a high specific surface which leads to better interactions with cells4. In our work, PHB, PHBHV, and PHBHHx have been electrospun in order to investigate the biological properties associated with the corresponding fibers. Additionally, block copolymers of PHBHV and PLA have been synthetized under microwave irradiation in order to develop different mats with tunable degradation properties.

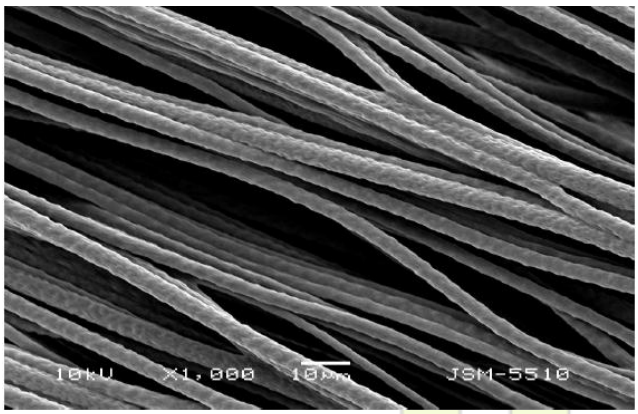

Figure 1. SEM micrograph of PHA nanofibers produced by electrospinning

Results and discussion

Nanofibrous PHA-based scaffolds were engineered by the electrospinning technique with concentrated solutions of the different PHAs in $CHCl_3$ and a $CHCl_3$/DMF mixture. Due to the low dielectric constant of $CHCl_3$ (4.8), highly viscous solutions were used, thus leading to the formation of fibers with a diameter between 3 and 4 µm. Because of a higher dielectric constant (36.7), DMF was added as a cosolvent to the $CHCl_3$ solution: the conductivity of the solution was significantly increased, and one such system enhanced the effect of the electrical field.

Indeed, the more conductive the solution, the higher the charge capacity of the solution, and the stronger the stretching forces, thus leading to the decrease of the fiber diameter. SEM analyses display PHB, PHBHV, and PHBHHx nanofibers with an average diameter of 900 nm. These mats with oriented nanofibers were formed with a smooth surface and a very homogeneous structure.

Among the different properties that distinguish a nanofibrous three-dimensional polymer scaffold and a polymeric film, wettability is of paramount importance.

Because of the higher specific surface of a nanofibrous mat, the water droplet is in contact to a larger surface. Therefore, the hydrophobicity of the PHA surface associated with a three-dimensional fibrous scaffold was higher than that of a two-dimensional flat surface.

This assertion was illustrated through the increase of the water contact angles of all PHAs.

In order to develop different scaffolds with tunable degradation properties, block copolymers based on PHBHV and PLA with various compositions were synthesized under micro-wave irradiation5,6. The LA polymerization was initiated by a PHBHV macroinitiator (M_n = 12000 g.mol^{-1}, I_p = 1.9). Using alow [LA]0/[PHBHV]0 initial ratio, the complete melting of the mixture turned out to be difficult, thus leading to quite moderate conversions. After a polymerization time higher than 5 minutes, the monomer conversion did not increase. Microwave-assisted procedures allow for fast and efficient reactions: in the system under investigation, the initiation efficiency was higher than 0.9.

Acknowledgements

Introduction

Tissue engineering has failed, up to date, to provide with satisfactory devices for bone regeneration. Two of the main factors that are hampering the general application of tissue engineering devices are:

i) Adverse effects of degradation products

ii) Long times required to produce an implantable construct

Inorganic filled polymer matrices have the potential to overcome these shortcomings. Inorganic components allow the tailoring of the resorption kinetics of the polymer matrix to the desired rate while improving the biocompatibility and promoting a faster integration with the hard tissue.

In this paper we propose the fabrication of porous scaffolds that include a polymeric matrix based on polyvinylpyrrolidone (PVP) with polyethyleneglycol dimethacrylate (PEGMA) and an inorganic filler based on hydroxyapatite (OHAp).

Materials and Methods

1-Vinyl-2-pyrrolidone (VP) (Aldrich) and polyethyleneglycol dimethacrylate (EGMA) (Acros) were chosen as the organic components for the preparation of the copolymer system. Composites materials have been prepared through a bulk polymerization induced thermally at 40°C using 1wt% azobis(isobutyronitrile) (AIBN) as free-radical initiator and a solution of chitosan as crosslinker under nitrogen atmosphere. OHAp particles were added to the monomer mixture prior to induce the polymerization.

The ceramic component added in different ceramic/polymer weight ratios: 0/100, 15/85 and 30/70. After washing the composites, the highly porous scaffolds were produced using a freeze-drying technique.

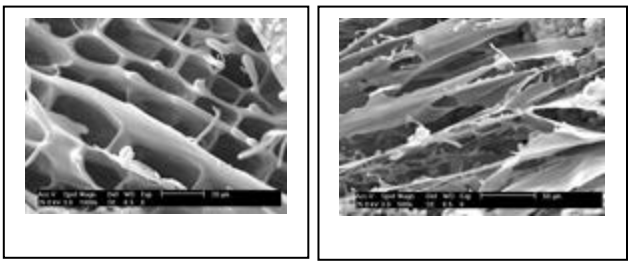
The prepared composites were frozen at a controlled rate (0.9 °C min^{-1}) to −20 °C and held for 90 min, The frozen suspensions were subsequently sublimed at 0 C for 20h under a vacuum of less than 100mTorr

The specimens were characterized by thermogravimetric analysis (TGA), ^{1}H nuclear magnetic resonance (NMR), attenuated total reflectance Fourier transformed infrared spectroscopy (ATR-FTIR), X-ray diffraction (XRD), and scanning electron microscopy (SEM).

Results and Discussion

TGA was the first analysis performed on the specimens, a weight loss between 316 and 480ºC can be observed for each of the compositions analyzed which corresponded to the decomposition and volatilization of the polymer component on heating. From the weight loss ceramic/polymer final ratio of the specimens were calculated. Ceramic/polymer weight ratios obtained are: 17/83 and 34/66. The deviation from the ratios utilized for the synthesis was lower than 3% confirming the reliability of the employed system.. FTIR was used to study the incorporation of both VP and PEGMA and OHAP in the system while NMR spectra confirmed the formation of the crosslinked polymers. XRD spectra of the specimens confirm that the only crystalline phase was hydroxyapatite. No secondary phases were formed during the processes of polymerization and frezze drying.

Development of highly porous scaffolds by a freeze-drying approach was used in this work due to the advantage of this method in employing only water upon freezing as a porogen. Freeze-drying conditions consisting of a relatively high freezing temperature (−20°C) and a rather slow rate of cooling (less that 1°C/min) were chosen to achieve the formation of highly connected ice crystals of rather large size. After sublimation of these ice crystals under vacuum at 0°C, sponges with an inner morphology (pore size, shape, distribution, interconnectivity, etc.) that mirrored the structure of these ice crystals were obtained



Left. Polymeric porous scaffolds(0/100). Right. Composite scaffold (15/85).

All scaffolds were highly porous and interconnected, and appeared to be relatively homogeneous throughout the bulk of the scaffold. A fairly uniform pore structure can be observed for ceramic free specimens (0/100) while the introduction of the ceramic seems to yield specimens with smaller pore interconnections.

Conclusions

Highly porous PVP/PEGMA/OHAp scaffolds containing different amounts of OHAp, with an interconnected pore structure, were produced in this study.

The freeze-drying technique proved to be an easy, versatile, effective and contaminant-free technique to produce scaffolds for tissue engineering

Chitosan and layered silicates bionanocomposites of preparation to be used as drug carrier vehicle

Itamara F. Leite, Samilla F. de Oliveira, Thaís Maria A. Marinho, Oscar L. Malta e Suédina Maria de L. Silva

Biopolymers (chitosan) and clay minerals (montmorilonita) are common ingredients in pharmaceutical products. Although they are frequently used in their pure form, a single polymer or clay mineral often does not meet all the requirements. A way to further extend their applications is to modify biopolymers by incorporation of inorganic fillers to obtain bionanocomposites with improved properties, especially for pharmaceutical applications. Chitosan (CS) is widely used as a drug delivery vehicle for control release of therapeutic agents. This polymer has been extensively used in recent years due to be non toxic and exhibit high mechanical strength, hydrophilic character, good adhesion beyond its low cost. Recently, synthesis of micro and nanocomposites with clay minerals was proposed as a novel approach to modify some of the properties of polysaccharide (chitosan), including swelling, hydrophilicity, mechanical and thermal behavior and bioadhesion. These modifications permit to obtain films of chitosan/layered silicates bionanocomposites with improved thermal and mechanical properties for use as a drug carrier vehicle. In this work, bionanocomposites of chitosan and natural bentonite were prepared by solution intercalation and the influence on the amount of bentonite in the morphology, thermal and mechanical properties of the chitosan bionanocomposites were evaluated. Pure chitosan and chitosan/bentonite bionanocomposites films were characterized by infrared spectroscopy, X-ray diffraction, thermogravimetric analysis and mechanical tests. The morphology of the nanocomposites was affected by the ratio of chitosan/bentonite. Nanocomposites with intercalated morphology were obtained predominantly when the ratio of chitosan to bentonite was 5:1, while that the ratio 10:1 of chitosan/bentonite favored the formation of nanocomposites with exfoliated morphology predominantly.

Synthesis and biocompatibility studies of P(HEMA-co-DMAEMA) based scaffolds obtained by cryopolymerization

Introduction

Cryopolymerization is a clean processing technique that produces highly hydrophilic and elastic porous materials. The method consists in the polymerization by a cryogenic treatment of a system potentially capable of forming a gel where the crystals of the frozen solvent are used as porogen agents. Structures obtained with this technique posse an elevated chemical and mechanical stability. A variety of polymeric cryogels have been prepared but the cryopolymerization technique has not been applied for the preparation of composite scaffolds for bone/cartilague tissue engineering up to date.

Scaffolds for tissue engineering should combine mechanical properties that resemble those of the tissue to be regenerate, porosity that allows cell seeding, cell migration and proliferation and extracellular matrix production and the ability to carry and release signaling molecules that induce or maximize cell phenotype

The goal of this project is the production of scaffolds that spread the range of applications of the cryopolymerization technique into the field of tissue engineering. The preparation of composite scaffolds based on 2-(Dimethylamino) ethyl Methacrylate (DMAEMA), 2-hydroxyethyl methacrylate (HEMA) and α-tricalcium phosphate (α-TCP) and the response of cultured human osteoblastic cells and human mesenchymal stem cells to the prepared cryogels are described in the current paper.

Materials and Methods

The selected monomers, 2-hydroxyethyl methacrylate (HEMA,) and 2- (Dimethylamino) ethyl Methacrylate (DMAEMA,), were purified through sequential extraction steps and vacuum distillation to remove impurities. Sodium persulfate, $Na_2S_2O_8$ was used as a REDOX initiator, and N,N,N´,N´-Tetramethylethylene diamine (TEMED) as an activator. α-TCP with an average particle size of 7.8 μm, was chosen as ceramic component.

Cryogels were prepared by free radical copolymerization in an aqueous solution at -20ºC. Drying of the cryogels was performed by direct freeze-drying. The obtained specimens were washed by immersion in distilled water for 2 h.

Total monomer amount was optimized at 10%. HEMA/DMAEMA ratio (25/75-50/50-75/25) were prepared with and without a 5% weight of TCP. Biocompatibility was tested with osteoblasts and MSCs isolated from bone marrow stroma. They were expanded until 90% confluent, then cultured on the different cryogels for 7, 14 and 21 days. Cell viability was assessed, after 96h, through the alamar blue assay. The cell distribution and morphology were determined by histological techniques. Expression of type-I collagen and alkaline phosphatase (ALP) were analyzed by immunohistochemistry.

Results and Discussion

This study explores the use of the cryopolymerization technique for the manufacture of scaffolds for bone tissue engineering. The challenge is to produce an appropriate pair surface-structure that favours new tissue ingrowth while maintains the integrity of the scaffold. The obtained dry scaffolds are rigid porous bodies with pore sizes up to 1 mm. Greater porosity (75%) and pore sizes (1 mm) were obtained for specimens containing a 25% of HEMA. Swelling ability is greater for 25/75 specimens, up to 500%, than for any other composition. DMAEMA is a pH sensitive monomer and conferred this property to all the prepared compositions influencing their swelling ability. i.e. 25/75 specimens swelled 5 times more at pH 2 than at pH 10. The Molecular weight between crosslinks decreased with the increase of the HEMA amount. α-TCP content did not affect significantly the aforementioned properties. However XRD diagrams shows that α-TCP did not converted into HA during the preparation of the cryogels

Cell response to scaffolds is strongly dependent on the material composition as well as on the cell type, for that reason, in this work, the biocompatibility of the manufactured scaffolds was studied using two different types of cells. After 96h, human osteoblasts and mesenchymal stem cells, had adhered and proliferated on the materials' surface. Material colonisation could be observed along the 21 days of culture, inferring their biocompatible profile. Expression of type-I collagen could be detected whilst the early osteogenic differentiation marker- ALP, expression appeared to be positively correlated with the increase of α-TCP.

Conclusions

Scaffolds with a 75% of porosity and pore sizes up to 1mm can be obtained with the cryopolymerization technique. It is possible to incorporate highly reactive α-TCP into these scaffolds.

Biocompatibility assays indicate that the materials tested are biocompatible, showing vital cells adhering to the materials, proliferating and giving evidence of early expression of biochemical markers of osteoblastic phenotype.

Cryopolymerization is a clean technique that yields promising porous structures for scaffold based bone engineering applications

DOPA Crosslinked Biopolymers

L. Pastor-Pérez, Z. Shafiq, V. San Miguel and A. del Campo

Max Planck Institute for Polymer Research, Ackermannweg 10, Mainz, 55128, Germany

e-mail: lourdes.pastor@mpip-mainz.mpg.de

Abstract : *3,4*-Dihydroxyphenylalanine (DOPA) residue and its derivatives are known to play a crucial role in the adhesive and hardening properties of mussel adhesive proteins. As such, DOPA can be regarded as an effective and biocompatible crosslinker that can replace chemically synthesized cross-linking reagents to form stable and biocompatible hydrogels. We report about the crosslinking reactions of DOPA with different biopolymers under different experimental conditions (type of polymer, pH and oxidant concentration).

Novel caged RGDs for photocontrol of cell attachment to artificial surfaces

M. Wirkner[(1)], *A.J. García*[(2)], *A. del Campo*[(1)]

[(1)]Max-Planck-Institut für Polymerforschung. Ackermannweg 10, 55128 Mainz, Germany
e-mail: wirkner@mpip-mainz.mpg.de

[(2)] Woodruff School of Mechanical Engineering and Petit Institute for Bioengineering and Bioscience, Georgia Institute of Technology, 315 Ferst Drive, Atlanta, GA 30332-0363, USA

The ability to trigger or turn 'on/off' material properties with external stimuli in order to control biological responses is critically important to biotechnological and biomedical applications. One such application is the use of light to trigger cell adhesion to synthetic materials by controlling the presentation of the bioadhesive arginine-glycine-aspartic acid (RGD) oligopeptide.
New caged cyclo[RGDfK] peptides, able to phototrigger cell attachment at defined volumes, have been developed. Cyclo[RGDfK] cell-adhesive peptide was modified by introducing a 3-(4,5-dimethoxy-2-nitrophenyl)-2-butyl or a 7-(diethylamino)-4-(hydroxymethyl)-coumarin ester photolabile caging groups at the carboxylic side chain of the aspartic acid. In their caged forms, the peptides do not show affinity for binding integrins at the cell membrane. Light of different wavelengths allows the selective release of the cages from the peptide structures and hence restores their activity, allowing in-situ site and temporal control of cell attachment. Cell-repellent materials modified with the caged peptides (OFF state) can therefore become cell-adhesive after irradiation (ON state) with the appropriate wavelength and intensity.

In a different approach, we focus on light-triggered cell release from surfaces based on the use of photocleavable linkers which couple the RGD ligand to the surface. Upon light exposure, the linker is cleaved by means of a photolytic reaction, thereby un-tethering the RGD peptide from the surface and releasing adhering cells (OFF state). Therefore we are able to specifically promote cell adhesion to materials with the ability to precisely deactivate or detach the cells at later time points or spatial locations. Our approach represents a more specific and controlled alternative to enzymatic or temperature-driven changes in substrate hydrophobicity. It is applicable to any material, provided proper linker design, and provides direct control over the molecular interactions involved in cell adhesion.

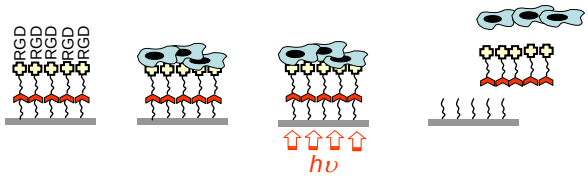

Figure 1: Working principle of phototriggered release particularized to cell detachment from surfaces using photocleavable linkers with an intercalated cage.

Two novel Poly-ether-ether-ketone (PEEK) applications for bone repair: assessment of dental implants and craniotomy closure devices.

barbara.perez@uah.es

Introduction

Poly-ether-ether-ketone (PEEK) is a non-absorbable biopolymer widely used in the manufacture of several medical devices, such as trauma, orthopaedic or spinal implants. Due to its mechanical properties (e.g. elastic modulus), which are similar to bone, this biocompatible material has been tested in two possible clinical applications, involving opposite mechanical stress: closure of craniotomies and dental implants.

Material and Methods:

New Zealand white rabbits (n=6) underwent a 1.5 cm^2 craniotomy, and PEEK device (FC05, NEOS Surgery SL) was used to fix the removed bone fragments in their anatomical sites. Intracranial part of the device was in direct contact with the dura, and the subcutaneous part was placed over the dome. Bone healing was monitorized at day 30 (n=3) and 60 (n=3). Histopathologic studies were carried out to analyze the effects on the dura, and immunohistochemical techniques were performed to study the presence of macrophages. PEEK dental implants (Ilerimplant) were placed on 12 patients and Osstell values were measured to assess the performance of the device, according to the standard odontological procedures.

Results:

Despite of the common nature of both devices, PEEK dental implants did not accomplish the experiment. All patients showed an Osstell value below the acceptable limits, commiting the long-term-viability of the implants.

All animals reached the end of study, while only 1 of 6 presented subcutaneous infection, being attributable to surgical procedures. Histopathological examination at 30 and 60 days showed a good behaviour of PEEK, with normal morphology and dura without significant changes. The device allowed proper bone healing, evidenced at day 30 by the appearance of normal trabecular bone in the defect area, surrounded by a connective tissue from the subcutaneous area. Osteoid substance and new bone formation were observed, especially at day 60. Immunohistochemical studies confirmed the presence of macrophages surrounding the biomaterial.

Conclusions:

-PEEK dental implants are not as efficient at long term as traditional devices, probably due to the strong mechanical forces that occur in the jaw. However, these implants could be a low-cost alternative to temporal devices.

-The use of PEEK for bone fixing after craniotomy maintains the normal morphology of the meninges, and allows proper bone healing.

Acknowledgments:

Bone fixation devices have been granted by NEOS Surgery SL (Barcelona, Spain). Dental implants have been granted by Ilerimplant (Spain).

The present work was supported by grant BIOAVAN PSS-300000-2008-01

Sol-gel synthesis of silica-chitosan hybrids for bone regeneration

M. Suarez[1,2], *E. M. Valliant*[3], *Julian R. Jones*[3]

Introduction

Bone and cartilage injuries compromise significantly the quality of life and significant socio-economic increasing problem, rising from an increasingly aged population and degenerative diseases or traumatic accidents. Chitosan is a copolymer of linked β(1→ 4), 2-amino 2-deoxy-D-glucose, and 2-acetamidodeoxy-D-glucan, which has been used for these applications as it is biodegradable, non-toxic and possesses antibacterial properties. For bone regeneration, polymers alone do not have sufficient compressive strength. Ceramic and glasses are too brittle. Interactions between inorganic and organic components are necessary to obtain a bioactive material that will degrade congruently. Hybrids provide this potential.

In this work, silica-chitosan hybrid biomaterials were synthesized by a sol-gel technique. Chitosan was covalently crosslinked with 3- glycidoxyproyltri-methoxysilane (GPTMS) in order to improve its physical and mechanical properties. The influence of the synthesis pH on the interaction between chitosan and GPTMS and on the bioactivity behavior was studied. Organic-inorganic hybrid with good mechanical properties was obtained and a clear effect of the pH value on these properties was found.

Materials and Methods

Chitosan (CS) solutions were prepared in wt% in distilled water at pH 2 and 5 fixed with 2 M hydrochloric acid. Then GPTMS (crosslinking agent) was added into the solution in a 1: 0.25 molar ratio of chitosan: GPTMS. Structural characteristics of the hybrid were investigated using FTIR. The chemical shifts of the ^{29}Si of powdered samples were measured with a solid-state nuclear magnetic resonance (NMR) spectrometer. The morphology of the surface and the cross-section of the hybrids were characterized using FEG-SEM. Hybrid samples were immersed in simulated body fluid (SBF) for up to 672 h and the solutions were analyzed by Inductively Coupled Plasma optical emission spectrometer (ICP-OES) to determine the Si, Ca and P concentrations in solution. Compression tests were performed using an Instron-type tensile testing machine (Instron 5866).

Results and Discussion

Chitosan is one of the most widely known natural polymers for biomedical applications due to its biocompatibility, biodegradability and low toxicity. In this study organic-inorganic hybrids were prepared using a sol-gel process since it is an effective method to be used for the synthesis of an inorganic network in an organic matrix at low temperature. Hybrids were formed with a range of mechanical properties from rigid to flexible depending on the content of polymer used (Figure 1). All of them were completely transparent, indicating a good integration of the organic and inorganic components. From the FTIR spectra (Figure 2), Si-O stretching bands were observed for chitosan-GPTMS-TEOS hybrids at 1110-1000 cm^{-1}, suggesting the formation of Si-O-Si bridging bonds on hybridization. The appearance of the Si-O-C bands at 795 cm^{-1} is seen in the hybrid monolithic spectra but are not visible in the pure chitosan spectrum, indicating that there is a definite interaction between the polymer and the silica components. The SEM image demonstrated that the hybrids were organized on the nanoscale with a homogeneous morphology and with silica nanoparticles being embedded within the chitosan matrix. This microstructure was dependent on the polymer content. The amount of soluble silica released from the hybrids after 1 month of soaking in SBF is shown in Figure 3. The physical interaction exists between GPTMS and chitosan at pH 2 produce a larger amount of silica releasing from the hybrid. The working pH influences in the mechanical properties. Compressive testing showed a Young´s modulus up to 2 times greater at pH 5 than at pH 2.

Figure1. Images for rigid (a) and flexible (b) materials

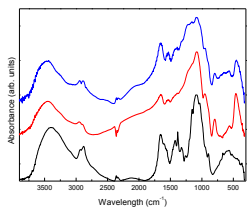

Fig. 2. FT-IR spectra of pure CS (black line), SiO_2: CS (65:35) (red line) and SiO_2: CS (35:65) (blue line).

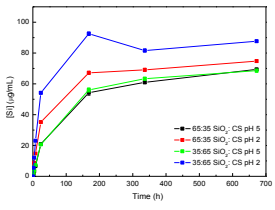

Fig. 3. Dissolution profiles for monoliths SiO_2: CS (65:35) pH 5 (black line), SiO_2: CS (65:35) pH 2 (red line), SiO_2: CS (35:65) pH 5 (green line) and SiO_2: CS (35:65) pH 2 (blue line) after soaking in SBF up to 672 h.

Conclusions

Class II organic-inorganic hybrids based on silica and a natural polysaccharide, chitosan, have described. The kind of interaction between chitosan and GPTMS has an influence in the degradation behavior and in the mechanical properties of the hybrids.

Hemoglobin Binding From Human Blood Hemolysate With Poly(glycidyl methacrylate) Beads

*Evrim Banu Altıntaş, Deniz Türkmen, Veyis Karakoç, Handan Yavuz and Adil Denizli**

Hacettepe University, Department of Chemistry, Biochemistry Division, Ankara, Turkey

denizli@hacettepe.edu.tr

Introduction: Hemoglobin (Hb), a tetrameric protein composed of two pairs of different subunits, is the iron-containing oxygen transport metalloprotein in the red blood cells in mammals and other animals[1]. The proteomic studies to identify low-abundance protein profiles and biomarkers in human blood have been largely affected by the high abundance of some proteins like Hb. It is estimated that 85% of the protein mass in human serum is comprised of only a few proteins[2]. The high-abundance proteins make detection of low-abundance proteins difficult, no matter which proteomic method is used[3,4]. Typical methods that have been published to bind Hb include tangential flow filtration, fast performance liquid chromatography, hydrophobic interaction chromatography, ion exchange chromatography and molecular recognition[5-10]. Recently, immobilized metal affinity binding has shown great potential in the binding studies and several types of metal affinity carriers have been applied to binding studies[11]. So far, no one study has been published using IMAC to deplete Hb from human blood for analyzing the proteome of human blood.

We used iminodiacetic acid (IDA) immobilized poly(glycidyl methacrylate) [PGMA] beads with chelated Cu^{2+} ions as a model carrier capable of selective binding of Hb from human plasma. PGMA was used as the basic matrix because of its known good mechanical strength, stability at neutral pH values even in wet conditions and high reactivity of the epoxy groups for surface immobilization. Epoxy-derived carriers seem to be almost ideal systems to develop very easy protocols for biomolecule immobilization[12,13].

Materials and Methods: IDA was covalently attached to the PGMA beads (1.6 µm in diameter). Cu^{2+} ions were chelated via IDA groups on PGMA beads for affinity binding of hemoglobin (Hb) from human blood hemolysate. The PGMA beads were characterized by scanning electron microscopy (SEM). The PGMA-Cu^{2+} beads were used in the Hb binding-elution studies. The effect of Hb concentration, pH and temperature on the binding efficiency of PGMA-Cu^{2+} beads was performed in a batch system.

Results and Discussion: Non-specific binding of Hb to PGMA beads in the absence of Cu^{2+} ions was very low (0.39 mg/g). The maximum Hb binding was 130.3 mg/g. The equilibrium Hb binding increased with increasing temperature. The negative change in Gibbs free energy ($\Delta G° < 0$) indicated that the binding of Hb on the PGMA-Cu^{2+} beads was a thermodynamically favorable process. The ΔS and ΔH values were 102.2 J/mol.K and -2.02 kJ/mol, respectively. Significant amount of the bound Hb (up to 95.8%) was eluted in the elution medium containing 1.0 M NaCl in 1 h. The binding followed Langmuir isotherm model with monolayer binding capacity of 80.3-135.7 mg/g. Consecutive binding-elution experiments showed that the PGMA-Cu^{2+} beads can be reused almost without any loss in the Hb binding capacity. To test the efficiency of Hb depletion from blood hemolysate, eluted portion was analyzed by fast protein liquid chromatography. The depletion efficiency for Hb was above 97.5%.

Conclusion: Proteomics research is a long-established part of biochemistry[14]. The depletion of high abundant proteins is often significant in diagnosis and therapy. The results obtained in this depletion study are consistent with published studies. We reached the Hb depletion amount up to 95.8%. In the light of this study we believe that the PGMA-IDA-Cu^{2+} beads offered the promising strategy with good depletion specificity and efficiency of Hb.

Biodegradable Fibrous Polymer Materials and Composites Prepared on the Basis of Plant Biomass

Andrzej Okruszek

Institute of Technical Biochemistry, Faculty of Biotechnology and Food Sciences, Technical University of Lodz, Stefanowskiego 4/10, 90-924 Lodz, Poland

andrzej.okruszek@p.lodz.pl

Within the Project "Utilization of biomass for the preparation of environmentally friendly polymer materials" various kinds of plant biomass are employed for the preparation of biodegradable fibrous polymer materials and composites by biotechnological methods, involving enzymatic or microbial processess. The major intermediates in the preparation of final products are cellulose nanofibres, tactical polylactide and biodegradable aliphatic-aromatic copolyesters.

For the preparation of cellulose nanofibres, a cellulose rich plant biomass is being utilized, including grass and straw of various cereals or other agriculture useful plants, as well as waste fibres from textile industry (cotton, linen). The biomass is first pretreated with physical and/or chemical methods including boiling, steam-explosion or treatment with certain chemicals. Multienzyme complex obtained from *Aspergillus* niger mould is utilized as the main enzymatic tool.

The synthesis of tactical polylactide is being performed by chemical polymerization of L,L-lactide, prepared from L-lactic acid. The latter is obtained by stereoselective fermentation of plant biomass, after its saccharidification by appropriate enzymes (*Aspergillus niger* preparations). The stereoselective microorganisms (bacteria) used for the fermentation were selected by classical microbiology methods from the environment. In this case patatoes, cereal grains or beet pulp are utilized as starting biomass.

The third path involves utilization of various oil-plant biomass, which on sequential treatment with lipase preparations obtained from *Mucor circinelloides* and *Mucor racemosus* moulds (structurization, hydrolysis) and appropriate chemical reactions (cycloaddition process, catalytic hydrogenation) are transformed into oligodiols/polyols with glyceride backbone. These will be copolymerized with appropriate reagents in order to produce new biodegradable aliphatic-aromatic copolyesters. The polyesters will be utilised for preparation of various fibrous polymers and composites.

The fibrous materials and composites prepared within this Project on the basis of abovementioned intermediates will be further utilized for obtaining new functional textiles and nonwovens with potential sanitary or technical applications, such as sweat-absorbing textile inserts, sanitary textiles, filtration materials, geotextiles and agrotextiles. Within this Project the processes of ageing and controlled biodegradation of prepared materials will be studied, as well as the conditions of their recycling and possible use of degradation products in agriculture.
The poster presents information about Project "BIOMASS" which is being realized within the time
frame 2009-2013 by the Consortium composed of eight research groups from Poland.
The Project (POIG 01.01.02-10-123/09) is partially financed by the European Union within the European Regional Development Fund

Bioactive Alginate Based Drug Delivery Microgels For Skeletal Tissue Engineering

Luis Rojo[1], *Helene Autefage*[1], *Seth McCullen*[1], *Eileen Gentleman*[1], *Molly M. Stevens*[1,2]

[1]Department of Materials and [2]Department of Bioengineering, Imperial College London, UK.

Introduction: Development of musculoskeletal tissue requires the orchestration of cells, growth factors, scaffold, and physiological stimuli within a highly defined 3D architecture[1]. There is significant interest in the development of novel systems that can control the temporal-spatial delivery of soluble factors, whilst maintaining a 3D structure in which the cell population can receive appropriate physiological stimulation[2]. This work is focused on the preparation of bioactive alginate-poloxamer interpenetrating microparticles loaded with recombinant human transforming growth factor β3 (TGFβ3) to be used in musculoskeletal tissue regeneration. *In vitro* studies were performed to assess the viability of chondrocytes (C), chondroprogenitors (CP) and mesenchymal stem cells (MSCs) growing within pelleted alginate-poloxamer condensates. We also assessed the formation of cartilaginous matrix by culturing cells in alginate-poloxamer condensates for 3 weeks *in vitro*.

Materials and methods: Sodium alginate macromolecules were grafted with GRGDS pentapeptide and the microstructure and degree of modification was determined by ^{1}HNMR. Alginate-poloxamer microparticles loaded with model protein or TGFβ3 growth factor were prepared by w/o inverse emulsion and external gelation using $CaCl_2$ and $SrCl_2$ as crosslinking agents. Morphology and particle size distribution were examined by SEM and laser scattering respectively. *In vitro* model protein bioactivity, encapsulation efficiency and release profiles were determined by Ghaderi-Carlfors and BCA assays, respectively. Pelleted cell-microgel condensates were prepared by centrifugation of precultured bovine CP (10^6cells/ml) mixed with the alginate particles and cultured for three days. Cell viability was assessed using the LIVE/DEAD assay. Effect of cell type and alginate-poloxamer condensates on *in vitro* chondrogenesis was assessed via histological examination, by embedding condensates in paraffin, and staining 10 µm sections for proteoglycan production with Alcian Blue (AB) and for cell nuclei and extracellular matrix deposition via Hematoxylin and Eosin (H&E).

Results: GRGDS peptide prepared by conventional solid-phase was obtained in 87% yield and > 95% purity. The experimental efficiency of alginate modification was calculated by considering the resonance signals of the corresponding GRGDS protons (14H, 3.76 – 1.01 ppm) and alginate protons (2H, 4.46-3.82 ppm). The molar fraction of GRGDS moieties was found to be 0.09 indicating that the macromolecular chains consist mainly in guluronic-co-manuronic units with carboxylate groups available for the characteristic crosslinking reactions mediated by divalent cations, with 9 % of pendant GRGDS peptide moieties.

Alginate-poloxamer microparticles were prepared by a w/o emulsion method and model protein encapsulated within. As observed by SEM imaging, spherical and fairly homogeneous particles were observed with average size of 5 µm (Figure 1). Reconstituted particles in PBS showed swollen morphology during soaking leading to an enlarged particle diameter up to 25 µm as determined by laser diffraction measurements.

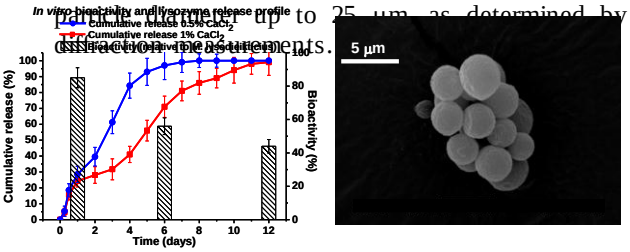

Figure 1. Bioactivity and lysozyme release profile (left) and SEM examination (right) from alginate-poloxamer particles prepared by w/o inverse emulsion method.

Drug release studies showed a 64% loading efficiency for the model protein with a tunable release profile during the first month. Additionally, protein released showed that 85% of the natural protein activity was conserved (Figure 1). Histological staining revealed significant differences in AB staining in a cell-specific manner, indicating that CP cells were able to synthesize a rich proteoglycan matrix compared to both C and MSCs cells (Figure 2). MSC-alginate poloxamer condensates yielded a poor cartilage like tissue with minimal matrix deposition.

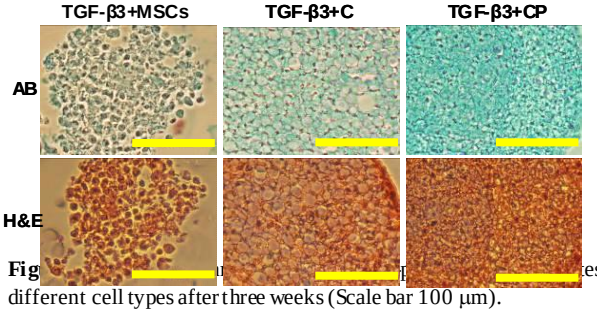

Figure 2. [illegible] with different cell types after three weeks (Scale bar 100 µm).

Conclusions: GRGDS cell adhesion peptides were covalently grafted onto alginate molecules for the preparation of novel poloxamer-alginate micro-scaffolds that deliver soluble factors in a temporal-spatial manner. These are potentially promising growth factors delivery systems enabling high encapsulation efficiency, tuneable protein release profiles and viability of entrapped cell condensates as useful for skeletal tissue engineering applications. Histological examination revealed cell-specific differences in proteoglycan staining intensity and distribution, suggesting that CP cells may be an optimal cell source of musculoskeletal repair and regeneration of cartilage.

Introduction

Multi-resistant bacteria are nowadays an increasing problem especially in the medical sector. Therefore the demand for new antibacterial solutions is rising. To overcome the problem of excessive bacterial growth and contamination, one approach may be, to equip surfaces with antibacterial coatings.

The problem with common antimicrobial coatings is that these coatings often release their active compound into the environment. This causes two negative effects: 1. the antimicrobial effect is lost over time and 2. the long term effect resulting from the development of bacterial resistance and associated health risks etc. is not known. Therefore it is desirable to develop non-leaching coatings. Antibacterial polymers may be one solution.

The polymers developed herein are able to overcome these problems and can be used as non-leaching antimicrobial coatings.

Materials and Methods

In this work we present the functionalisation of poly(vinyl amine) (PVAm) to generate new non leaching antibacterial candidates. PVAm is a weak cationic polyelectrolyte and possesses the highest known cationic charge density for a technical polymer. Due to the high cationic charge density it shows very good adsorption behaviour to glass, metal and negatively charged surfaces (e.g. cellulose). Here, PVAm was further derivatised to display antibacterial properties.

The resulting products were characterised on the molecular level using NMR and Raman spectroscopy. The modified amphiphilic polymers were then coated onto surfaces and the antimicrobial effect was studied. Through variation of the degree of functionalisation of the amine groups with alkyl chains and quaternary ammonium groups, the influence of the hydrophilic/hydrophobic balance on the antimicrobial effect was investigated.

We assume that the alkyl chains and cationic groups self-assemble during the reaction and build up microstructures in the polymer. Samples with the same composition and different microstructure were prepared by simultaneous or sequential addition of functional epoxides to poly(vinyl amine) (PVAm).

Results and Discussion

Amphiphilic multifunctional poly(vinyl amine)s were synthesised and characterised by ^{1}H-, ^{13}C-NMR and Raman spectroscopy. The degree of functionalisation was adjusted by changing the ratio of functional epoxides to amine groups. The amphiphilic polymers thus obtained showed a good antibacterial effect against *E. coli*. From the antibacterial tests it can be concluded that the antibacterial action takes mainly place during the cell division (under growth conditions). It was found that the antibacterial activity increased with increasing degree of functionalisation with quaternary ammonium groups, and decreasing degree of functionalisation with alkyl chains.

The antimicrobial effect was investigated in dependence of the polymer microstructure.
