Introduction

During the last years, polymer scientists have focused considerable attention on the easy design of multifunctional macromolecular architectures with a specific combination of properties required for their desired end-use applications. One of the possible approaches for building up such architectures is to apply macromolecular co-assembly processes, in particular, the electrostatically driven co-assembly occurring upon the simple mixing of aqueous solutions of oppositely charged polyelectrolytes (PEs), often referred to as interpolyelectrolyte complexation. This process results in the formation of interpolyelectrolyte complexes (IPECs), which represent macromolecular co-assemblies stabilized by a cooperative system of interpolymer salt bonds. IPECs are of considerable interest because of their promising applications in agriculture, water treatment, biotechnology, and medicine.

Up to now, studies on IPECs have mostly been focused on the macromolecular co-assemblies formed by the oppositely charged linear PEs. The significant progress in the controlled synthesis of well-defined polymers achieved during the last years has offered unique possibilities for designing novel macromolecular co-assemblies comprising PE species with nonlinear topologies. These co-assemblies considerably increase the complexity of the IPECs, into which new properties can be imparted.

In this contribution, we consider IPECs resulting from the interaction of the star-like polyionic species, viz., star-shaped PEs and star-like micelles of ionic amphiphilic diblock copolymers, (a) with the oppositely charged linear homopolyelectrolytes and (b) with the oppositely charged double hydrophilic diblock copolymers.

Materials

Star-shaped poly(acrylic acid) (5, 8, 21 arms, DP_n(arm) ≅ 100) or star-shaped poly([2-(methacryloyloxy)ethyl] trimethylammonium iodide) (5.6, 11, 24 arms, DP_n(arm) ≅ 170 ÷ 240) were used as star-shaped PEs. Poly(isobutylene)-block-poly(methacrylic acid) diblock copolymers (DP_n(PIB) = 20, DP_n(PMAA) = 100 ÷ 425) were used as ionic amphiphilic diblock copolymers. Exhaustively quaternized poly(vinyl pyridine)s (DP_n ≅ 35 ÷ 440) and poly(acrylic acid) (DP_n ≅ 35 ÷ 500) were used as linear homopolyelectrolytes. Exhaustively quaternized poly(vinyl pyridine)-block-poly(ethylene oxide) diblock copolymers were used as double hydrophilic diblock copolymers (DP_n(PVPq) = 40 ÷ 70, DP_n(PEO) = 210 ÷ 450).

Results and Discussion

Using a combination of various techniques, viz., turbidimetry, dynamic/static light scattering, analytical ultracentrifugation, small-angle neutron scattering, fluorescence spectroscopy (with the use of pyrene as a probe), cryogenic transmission electron microscopy, we found that, if the certain conditions are met, the interpolyelectrolyte complexation of the star-shaped polyions and star-like micelles of ionic amphiphilic diblock copolymers with the oppositely charged linear PEs or double hydrophilic diblock copolymers can result in the formation of soluble in aqueous media distinctly compartmentalized nanosized complex species. The obtained experimental results strongly suggest that the formed macromolecular co-assemblies have peculiar “core-corona” (star-shaped PEs) or “core-shell-corona” (star-like micelles of ionic amphiphilic diblock copolymers) structure. A hydrophobic core (star-shaped polyelectrolytes) or a hydrophobic shell (star-like micelles of ionic amphiphilic diblock copolymers) of each of the complex species represents an essentially water-insoluble IPEC incorporating the oppositely charged polyelectrolyte components in 1 : 1 charge ratio. In the case (a) of star-like polyionic species interacting with the oppositely charged linear homopolyelectrolyte, a hydrophilic corona is composed of free (excessive) PE branches that are not coupled with the fragments of the oppositely charged linear polyions. In the case (b) of star-like polyionic species interacting with the oppositely charged double hydrophilic diblock copolymers, a hydrophilic corona can be built up only from nonionic hydrophilic blocks of double hydrophilic diblock copolymer (at 1 : 1 charge stoichiometry) or apparently can be mixed and formed by those nonionic hydrophilic blocks and free (excessive) PE branches that do not form interpolymer salt bonds (at charge stoichiometries considerably deviating from 1 : 1).

Conclusions

The main feature of the macromolecular co-assemblies resulting from the interaction of the star-like polyionic species (star-shaped PEs or micelles of ionic amphiphilic diblock copolymers) with the oppositely charged linear homopolyelectrolytes or double hydrophilic diblock copolymers is their pronounced compartmentalized structure. We believe that such novel complex macromolecular architectures of micellar type are very promising and will be in demand for their future applications in rapidly developing nanotechnologies, for expample, as nanocontainers and nanoreactors.

Hybrid Carbonaceous and Plasmonic Nanostructures as Efficient Elements in Energy Conversion Devices

Dong Ha Kim, Yoon Hee Jang, Yu Jin Jang

Department of Chemistry and Nano Science, Ewha Womans University, Seoul, Korea

dhkim@ewha.ac.kr

Introduction

It has been recognized as an urgent task to develop highly efficient and reliable energy conversion devices. Rational design and facile synthesis of nanostructured core elements necessary for the viable function with high efficiency comprise a key aspect to attain this goal. There have been tremendous efforts to suggest target-oriented nanomaterials suitable for solar cell, fuel cell, or secondary battery. Along this line, here we propose that complex nanostructures consisting of metal, semiconductor, and carbon can be programmed and fabricated by unconventional and facile self-assembly processes.

TiO_2 has been widely utilized as electrodes in dye-sensitized solar cell due to its optimum optoelectronic property and stability. A simple strategy to increase the overall cell efficiency is suggested combining surface plasmonic effects of noble metal nanoparticles (NPs). We investigate the effect of different fabrication and integration routes, as well as the morphology of hybrid nanostructures, on the ultimate function of the devices. Next, we suggest a new paradigm to fabricate hybrid carbon nanostructures decorated with highly ordered noble metal NPs (Au, Ag, Pt, Pd) or alloy metals based on a direct carbonization concept of amphiphilic copolymer nanotemplates. A unique feature of note in this method is that amphiphilic copolymer acts as a structure directing agent for controlled nanostructures and a carbon source, simultaneously. Versatile functions of the resulting hybrid nanocomposites were evaluated with a focus on their electrocatalytic activities based on which potential applications as counter electrodes in photovoltaic devices and anodes/cathodes in fuel cell can be anticipated.

Materials and Method

Polystyrene-*block*-poly(4-vinylprydine) diblock copolymers (PS-*b*-P4VP) with polydispersity index of 1.09 was purchased from Polymer Source Inc. The number of average molecular weight of PS and P4VP were M_n^{PS} = 41 Kg mol^{-1} and M_n^{P4VP} = 24 Kg mol^{-1}, respectively. Titanium tetraisopropoxide ($Ti(OCH(CH_3)_2)_4$, TTIP, 97 %) and acetylacetone (Acac) were purchased from Sigma-Aldrich. Platinum chloride ($PtCl_4$), ruthenium chloride ($RuCl_3$), sodium borohydride ($NaBH_4$), perchloric acid ($HClO_4$), and formic acid (HCOOH) were purchased from Sigma Aldrich Inc.

Solar cell was fabricated in the following way. TiO_2 nanodot arrays were fabricated on fluorine-doped tin oxide (FTO) glass substrate and then treated with $TiCl_4$ by immersing into 100 mL of 0.2 M $TiCl_4$ aqueous solution and kept in a 60 °C oil bath for 1 hr, subsequently rinsed with ethanol and annealed at 500 °C for 30 min in air. TiO_2 nanoring arrays were fabricated on previously $TiCl_4$ treated FTO glass substrate. Both of them are sensitized with ruthenium dye (*cis*-diisothiocyanato-bis(2,2´-bipyridyl-4,4´-dicarboxylato) ruthenium(Ⅱ) bis(tetrabutylammonium), N-719, Solaronix) by immersing into 0.2 mM dye/ethanol solution for 24 hrs. Platinum (Pt)-coated FTO glass was used as counter electrode, which was prepared by drop casting of 0.5 mM chloroplatinic acid (H_2PtCl_6)/isopropanol solution and directly sintering at 380 °C for 1 hr in air. Device was assembled by stacking of TiO_2 nanostructure prepared FTO (anode) and Pt-coated FTO (cathode) by insertion of spacer (25-μm-thick hot-melt sealing foil, SX1170-25, Solaronix). An ionic liquid electrolyte (0.60 M BMIM-I, 0.03 M I2, 0.50 M TBP, and 0.10 M GTC in acetonitrile/valeronitrile 85/15 (v/v) (No. ES-0004), purchased from io.li.tec (Germany) was then injected between two electrodes.

Results and Discussion

Titanium sol-gel precursors could be selectively incorporated into P4VP blocks, producing TiO_2 nanodot or nanoring arrays *via* PS-*b*-P4VP inverse micelles and micelles templates, respectively. Two kinds of TiO_2 nanostructures were applied as working electrodes of dye-sensitized solar cells.

Metal/carbon hybrid nanostructures containing both platinum (Pt) and ruthenium (Ru) NPs denoted Pt-Ru/carbon, and metal/carbon hybrid nanostructures containing exclusively Pt NPs were prepared by sequential stacking of UV-stabilized PS-*b*-P4VP inverse micelle nanotemplates followed by calcining at 500oC under an inert atmosphere.

Conclusions

In summary, we have suggested a simple approach for fabricating the TiO_2 nanostructures including nanodot or nanoring arrays from self-assembled DBCP scaffolds. The PCE of thicker TiO_2 films (5 layers) was characterized to be much higher than that of TiO_2 monolayer-thick structures. Furthermore, 5 layered TiO_2 nanoring based solar cells devices exhibited the best behavior.

A unique route for the fabrication of an exquisite configuration of hybrid metal/carbon nanostructures with a distinct electrocatalytic activity toward formic acid oxidation was introduced exploiting consecutive self-assembly and direct carbonization of BCPs.

Introduction

Polymer brushes are formed when polymer molecules are grafted at one end to a surface at a sufficient density to force neighbouring chains to overlap. Repulsive interactions between chains cause them to stretch away from the surface into a brush-like structure. Careful tuning of the interactions between neighbouring chains allows control of the brush conformation. This may be achieved in neutral polymers by changing the solvent quality or temperature, while the charge present on polyelectrolyte brushes allows the manipulation of brush conformation via electrostatic interactions, e.g. by changing the pH or ionic strength.

Surface properties such as adhesion, wettability and affinity for protein adsorption are known to depend upon the presence and conformation of a polymer brush layer at a surface. Therefore, control of the brush conformation in response to external stimuli is highly desirable in the design of smart surfaces.

This work explores the use of applied voltages as a versatile, non-invasive stimulus to remotely control the conformation of charged polymer brushes. Electrical stimuli have a number of advantages over controlling the chemical environment of the brush (e.g. by changing pH or ionic strength). Electrical stimuli are easy to produce, highly repeatable and versatile, and easy to integrate into technological applications. For example, the use of patterning techniques could allow pixelation of the surface, to achieve spatial control over the brush conformation.

Materials and methods

Poly(2-(dimethylamino)ethyl methacrylate) (PDMAEMA) weak polybase brushes were grown from silicon surfaces using atom transfer radical polymerization (ATRP). Ellipsometry and neutron reflectivity were used to study the effect of electrical stimuli upon the brushes by measuring changes in their structure in response to applied voltages. DC voltages were applied in DI water or D_2O, with one electrode connected to the brush-bearing substrate and another parallel electrode a distance away in the surrounding liquid.

Spectroscopic ellipsometry data was fitted using a box model with an effective medium approximation (EMA) allowing calculation of the volume fractions of water and polymer within the layer, as well as the overall layer thickness. Neutron reflectometry data was fitted to extract the polymer brush volume fraction profile corresponding to the best fit to the reflectivity curve.

Results and Discussion

Neutron reflectometry data revealed that the polymer brushes had the Gaussian-terminated parabolic volume fraction profile predicted by self-consistent field theory. Positive voltages caused swelling of the brush while negative voltages in some cases caused de-swelling.

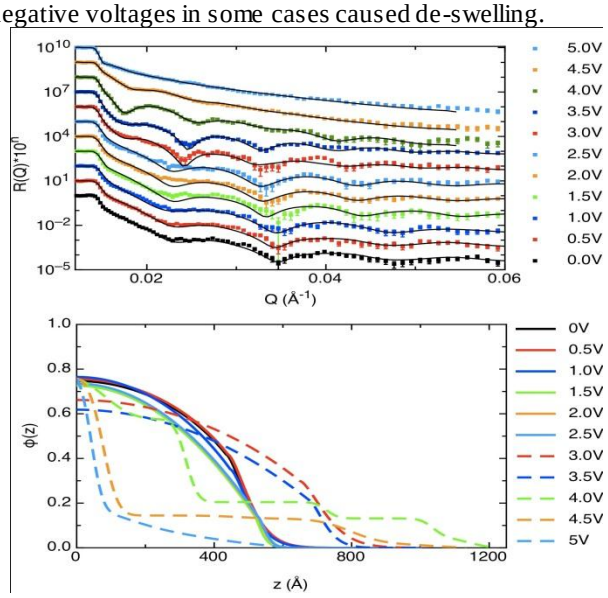

Figure 1. Top: Neutron reflectivity of a 300Å PDMAEMA brush in D_2O as a function of applied voltage, with fits shown as solid black lines. Bottom: Polymer brush volume fraction profiles corresponding to fits shown in (a), and the degree of swelling *S* of the polymer brush as a function of applied voltage (inset)

A full theoretical model is required to describe the behaviour of the brushes, and must take into account the contributions from local pH variations, charged monomers, counterions, and the physical conformation of the chains.

Conclusions

Applied voltages caused changes in the structure of PDMAEMA weak polybase brushes in water or D_2O. The brushes were swollen by positive voltages and were in some cases de-swollen by negative voltages. We have demonstrated the remote control of the conformation of a macromolecular layer. This work opens up a number of possibilities for electronically-addressed smart surfaces.

Fabrication and ordering of noble metal nanoparticles through functional polymers

e-mail: massimo.lazzari@usc.es

Developments in polymer synthesis and functionalization over the last decades provided a wealth of polymer and copolymer structures with well-defined morphology, controlled architecture and functionality that are converting functional polymers in a unique tool for nanotechnological applications. In particular, functional polymers and especially block copolymers [1], may be used either as nanomaterials themselves, as template or scaffold for the preparation of nanostructured materials and also for the polymer-assisted controlled fabrication of well-defined metal or metal oxide nanoparticles (NPs). As an example, different functionalized polymer matrixes were employed to prepare metallic NPs dispersed in polymer medium by *in situ* synthesis technique [2].

In this communication we present our recent results on the use of chain-end functional polymers for controlling the synthesis of noble metal NPs, with some reference to their distribution into block copolymer nanostructured morphologies. In particular, we report on the use of different ω-thiol (a functional group with high affinity for noble metal surfaces) polyacrylonitrile (PAN), poly(methyl methacrylate) (PMMA) and polystyrene (PS) ligands, opportunely prepared by controlled/living radical polymerization [3], as capping agents in the preparation of Au NPs through a one-step procedure.

The influence of molecular weight, polymer concentration and temperature was studied for different systems, also comparing the behavior of the chain-end functional polymers with those of the corresponding homopolymers without any active chain-ends. Polymer ligands and their interaction with the metal surface were mainly studied by FTIR and NMR spectroscopies, whereas TEM, UV-vis spectroscopy and thermo- gravimetric analysis allowed characterizing the metal NPs.

As an example, Figure 1 shows TEM micrographs of Au NPs prepared using $HAuCl_4$ as precursor and $NaBH_4$ as reducing agent in presence of PAN chains, either with thiol as chain-end (1A) or not (1B). In both cases stable particles were formed but only in the presence of PAN-SH size and size distribution could be efficiently controlled.

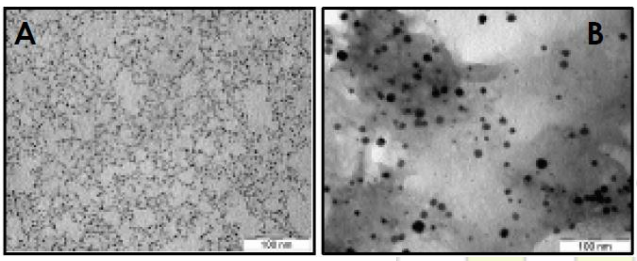

Figure 1. TEM micrographs of Au NPs prepared in presence of PAN ligands: A) PAN-SH, B) PAN-Br.

Similar results were obtained by comparing the behavior of PMMA-SH as capping agent with that of dithiobenzoate terminated PMMA.

Especially in the case of thiol chain-end PSs, a clear dependence of Au NP size and distribution was observed (see examples of Au@PS-SH systems in the insets a and b of Figure 2), and Au colloids with diameter between 1 and around 15 nm could be obtained. NP size and dispersity could be efficiently tuned by changing reaction temperature, PS molecular weight and ratio metal salt precursor to polymer

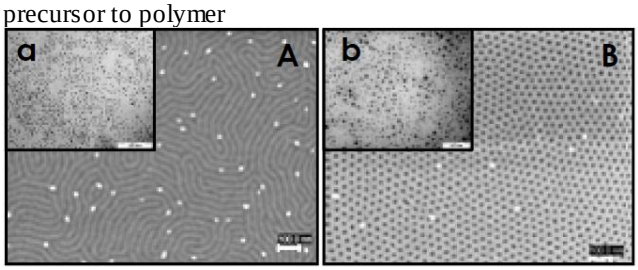

Figure 2. FESEM of thin films of PS-*b*-PMMA with Au@PS-SH NPs (A,B). Inset images show TEM micrographs of Au-capped NPs: a) $Au@PS_{27}SH$, b) $Au@PS_{167}SH$.

Finally, the preparation of block copolymer-based nanocomposites through the addition of such Au@PS-SH will also be reported. Spun-coated thin films were prepared from chloroform solutions of an asymmetric PS-*b*-PMMA block copolymer and different Au@PS-SH NP systems (Figure 2).

In particular, it was observed that depending on the NP concentration and the ligand molecular weight different orientations of the nanostructured morphology could be achieved.

Poly(vinyl chloride), PVC-based composites were prepared by blending PVC with various weight ratios of submicron (i.e. 600 nm) and nano-SiO_2 spherical particles (i.e. 30 nm), which were initially treated with different surfactants: IO7 T7(OH)3 (trisilanol isooctyl polyhedral oligomeric silsesquioxane) [1], IB7 T7(OH)3 (trisilanol isobutyl polyhedral oligomeric silsesquioxane) [1] and DMOAP (N,N-dimethyl-n-octadecyl1-3-aminopropyl-trimethoxysilyl chloride). The degree of dispersion and interfacial compatibility of surface treated SiO_2 particles in PVC matrix was characterized with SEM. The best dispersion of surface modified particles and their compatibility with the PVC matrix was obtained for the silica particles (1% wt) treated with IO7 T7(OH)3, exhibiting a highly ordered 3D silica (600 nm and 30 nm)/PVC organic-inorganic composites layers. The main interest of this study was the investigation of the composites' mechanical and optical properties, which will be presented and discussed in details.

kram@polly.phys.msu.ru

This work is aimed to a development of new polymer composite materials, namely, magnetic field controlled elastomers based on highly elastic polymeric matrices filled with magnetic nano- and microparticles. The novel feature of these materials is the ability to change their properties in magnetic fields and thus, perspective for design of various magnetic field controlled devices.

New elastomers have low Young's modulus (it is of the order of tens of kPa) and occupy an intermediate position between rigid magnetic composites and magnetorheological fluids. In the course of magnetic field controlled structuring of the magnetic filler within polymer matrix new materials demonstrate the following properties:

(a) a unique ability to undergo quick and controllable essential changes in elastic and viscous properties under the action of external homogeneous magnetic fields (magnetorheological effect) . More than 100-fold increase of both storage and loss moduli of the materials has been observed in an external homogeneous magnetic field of up to 0.3 T;

(b) a unique ability to undergo quick and controllable large-scale deformations in external homogeneous and gradient magnetic fields (magnetodeformational effect);

(c) new effect of shape memory or plasticity induced by magnetic field. It is found that in some cases the deformation of the material is virtually fixed by the magnetic field. One may say that the material ''remembers'' its shape in the presence of magnetic field.

In this presentation we show results of experimental and theoretical studies of these properties of new magnetic elastomers, their dependence on the material composition and strength of magnetic fields, as well as demonstrate possibilities of their practical applications.

The main attention is paid to the behavior of magnetic elastomers based on hard magnetic filler, namely, magnetic particles of FeNdB. Viscoelastic properties of these materials are studied by dynamic experiments (shear oscillations on a rheometer). In the figure we show the magnetic field dependences of the storage and loss moduli for the sample containing a mixture of iron magnetic particles (58%) and FeNdB particles (35%). The sample was magnetized in the magnetic field of 15 kOe. The shear plane was perpendicular to the direction of the internal magnetization of the samples and to the applied external magnetic field. The presence of remanent magnetization influences the effect of magnetic field on the elastic modulus. The minimum value of the modulus is reached when the direction of the external field is opposite to the sample magnetization. Thus, the elastic modulus of the magnetic elastomers can be controlled (can be both increased and decreased) by magnetic field.

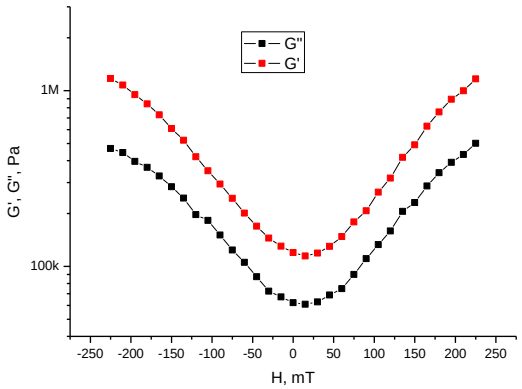

Figure. Dependences of the storage, G', and the loss modulus, G'', on magnetic field.

Introduction: Thin films prepared by the layer-by-layer technique (LbL) are meanwhile known since almost two decades [1]. The benefit of this coating method is the possibility to introduce new functionalities into the LbL-film which can be used as surface modification tool in materials science. This and the facile preparation of LbL films are making the layer-by-layer technique a powerful instrument to create customized surface coatings for different applications. Besides the choice of polyelectrolyte the incorporation of clay nanoplatelets into LbL-films provides a variety of interesting properties like flame retardance, mechanical strength, heat-seal and gas or vapor barriers [2]. The basic principle of an LbL coating with incorporated clay is shown in figure 1.

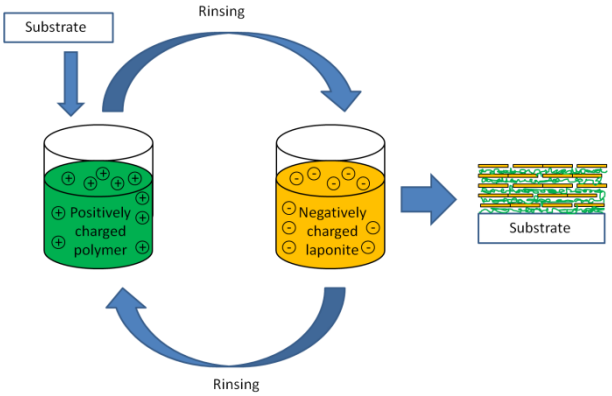

Figure 37: Preparation of a layer-by-layer coating by alternating dip-coating of a substrate, which leads to a "brick-mortar" structure of the film.

The incorporation of biopolymers into LbL-films is, with respect to sustainability, an additional big advantage of this technique. Substrates like cellulose can be modified with e.g. cationic starch and clay nanoplatelets in order to obtain a biodegradable coating. In this study we investigated different approaches to modify a cellulosic model substrate and silicon surfaces with LbL. Well defined cellulose model surfaces were prepared by spin coating and regeneration of trimethylsilyl cellulose films [3,4].

Materials and Methods: Several types of polyelectrolytes including synthetic and natural ones were investigated in order to compare the well known LbL-film forming properties of polyethyleneimine (PEI) and polydiallyldimethylammonium chloride (PolyDADMAC) with that of cationic starch. Mass changes (increase) and layer viscoelastic properties were investigated using quartz crystal microbalance with dissipation technique. The wettability of the surfaces was determined via contact angle measurements. In addition the influence of electrolyte concentration (NaCl) and the type of polyelectrolyte on the growth rate and surface properties were investigated. Finally atomic force microscopy (AFM) gave insights into the surface morphology of the thin film coatings. As an application, selected coatings were used to modify the surface of a commercial cellulose substrate in order to extent the range of applicability of this material.

Results and Discussion: The optical thickness and quartz crystal microbalance data showed a continuous increase of the layer thickness during the coating process. The contact angle measurements revealed alternating values after each coating step, which also confirmed the irreversible adsorption of the film components. Figure 2 is showing AFM images of a commercially available cellulose substrate before and after surface modification by LbL coating. A significant change in surface morphology was observed.

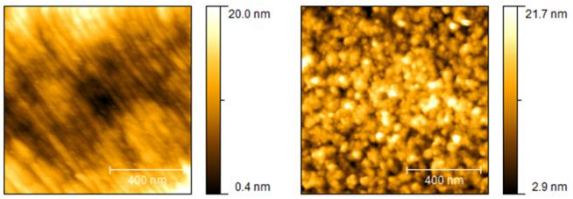

Figure 38: Surface modification of a commercially available cellulose substrate. The left image shows the untreated substrate, whereas the right image depicts the LbL coated surface.

Conclusion: Our research showed the preparation of polyelectrolyte-clay multilayers on different substrates in dependency of electrolyte concentration and polyelectrolyte type. Additionally with the introduction of starch into the film we prepared a biodegradable coating that can be used to increase the barrier properties of e.g. packaging materials.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 214653.

Amphiphilic copolymers combining in their structure hydrophilic ionic and hydrophobic moieties are very interesting in different aspects, particularly, due to their ability to self-assembly in aqueous solution giving rise to diverse nano-structures responsive to environmental changes. Here we present the results of synthesis, characterization and study of stimuli-responsive behavior of novel type of block-gradient copolymers of styrene and acrylic acid.

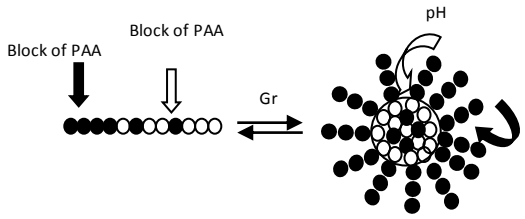

Fig.1. Dynamic micelles formed by block-gradient copolymers.

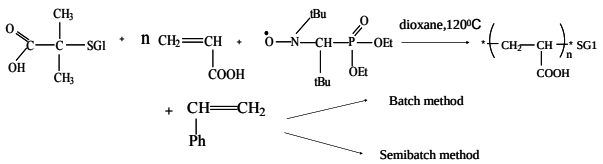
Amphiphilic copolymers each consisting of a (hydrophilic) block of polyacrylic acid and a gradient block of acrylic acid and styrene co-monomer units were synthesized by nitroxide-mediated polymerization. At the first stage we polymerized acrylic acid in the presence of nitroxide SG1 as a control agent and the alkoxyamine (MAMA) as an initiator. At the second stage we used two techniques to obtain different gradient profiles: semi-batch method with different rate of addition of styrene and addition of styrene in one step (batch method). The linear growth of molecular weight as a function of conversion during polymerization proves controlled character of the process.



Constants of copolymerization of styrene and acrylic acid in dioxane are r_1=0,27 (AA) и r_2=0,72 (ST)[1]

The composition of copolymers and local composition along the chains were determined by means of ^{1}H NMR. Molecular weight of methylated copolymers was measured by size-exclusion chromatography.

The rate constant of decomposition of "dormant" adducts: polyacrylic acid-SG1, polystyrene-SG1, copolymer-SG1 and recombination rate constants between nitroxide SG1 and macroradicals - were determined by means of ESR. We found that with the increasing of polarity of solvent the values of constants become higher. This effect opens a new way of activating chains in nitroxide-mediated radical polymerization.

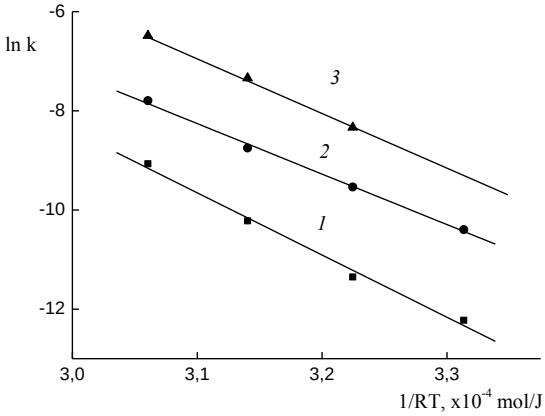


Fig.2. Energy of activation of decomposition of PAA-adducts in dioxane (1), DMF (2) and formamide (3).

The self-assembly of the obtained copolymers in water was studied by DLS and SANS. It was found that the decreasing of pH of solution leads to the increase in the hydrodynamic radius of the micelles. In the presence of salt particles demonstrate the same behavior with changing of pH, but the addition of salt causes the growth of the size of micelles. In contrast to poly(acrylic acid)-block-poly(styrene) copolymers with the same composition which form "frozen" micelles, such block-gradient copolymers can form "dynamic" micelles responding by reversible changes in the aggregation state to variation of pH and ionic strength.

This research was supported by Conseil régional d'Aquitaine and the Russian Foundation for Basic Research (project number 08-03-00269-a).

Self-organization of amphiphilic macromolecules in semidiluted and concentrated solutions.

Valentina V. Vasilevskaya, Anna A. Glagoleva, Mikhail K. Glagolev

Nesmeyanov Institute of Organoelement Compounds Russian Academy of Sciences

vvvas@ineos.ac.ru

It is well-known that in the large majority of real water-soluble polymers many monomer units have a dualistic (hydrophobic/hydrophilic) character, that is, repeating polymer unit, which is usually considered as pure hydrophobic or pure hydrophilic, actually incorporates both hydrophilic and hydrophobic parts concurrently. Interaction between such groups can not be be literally reduced to pure hydrophilic or pure hydrophobic interactions. To eliminate this drawback, we have introduced an extended variant of the HP model that explicitly takes into account the amphiphilic nature of hydrophilic segments [1].

In this model the hydrophilic monomer units are modeling as a "dumbbell" consisting of *H* and *P* beads linked by rigid bonds of a fixed length (Fig.1).

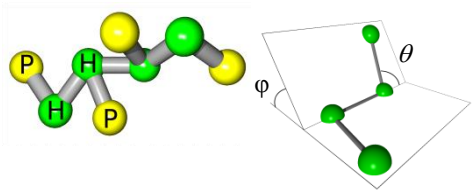

Fig. 1. Schematic representation of the semiflexible model of macromolecule with an amphiphilic monomer unit.

Using this model, we have performed an extensive molecular dynamics simulations of the hydrophobically-driven conformational transitions of macromolecules containing amphiphilic monomer units and found a variety of novel structures in a poor solvent (for review, see [2]).

In this paper we report the results on the computer modeling of self-organization of such macromolecules in semidilute and concentrated solutions.

We studied solution of semiflexible amphiphilic macromolecules with fixed bend angle θ and have found that the conformational state of macromolecules in such systems depends on the macromolecular stiffness and on the way the solution has been prepared. Thus, if the concentration of globules increased from a very diluted solution, the globules remain stable, independent of the macromolecular stiffness, and do not aggregate even in concentrated solutions. On the other hand, if the solvent quality is gradually decreased in a solution with a concentration much larger than that of a semidilute solution, then relatively flexible chains form separate globules, whereas semirigid macromolecules tend to aggregate and form braid-like conformations [3]. The aggregation number and length of complexes can vary and many of them can join with each other.

In the case of macromolecule with both bend angle θ and rotation angle φ fixed, the distribution of aggregates over aggregation number in such a systems is very narrow and moreover, we have found regimes for which the aggregates with the only aggregation number are observed (Fig. 2). The macromolecules in such complexes are interwinded in such a manner that hydrophobic core is protected by hydrophilic shell (Fig. 3) and contour length of the aggregates is equal to the contour length of single macromolecules [4].

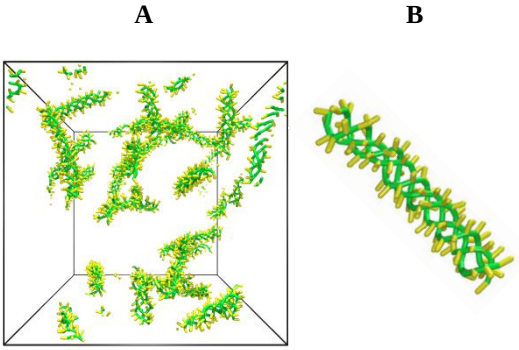

Fig. 2. Snapshot pictures illustrating the aggregate formation of semiflexible macromolecules with fixed bend and rotation angles (a) and aggregate structure (c).

We have studied the concentrated solutions of diblock copolymer containing linear ***H*** and amphiphilic ***HP*** block and found that the phase diagram for such copolymers can be significantly different from that known for the conventional linear diblocks [5].

Introduction: Polymeric nanocomposites, especially with the filler montmorrillonite, have become of predominant interest to the scientific community and industry in the last years [1]. Especially structural details and their relationship to the mechanical, rheological, optical and permeation properties of the nano-composites are of high importance. There are different methods to produce polymer nanocomposites [1]. In this study melt compounding has been applied in order to produce intercalated polypropylene silicate nanocomposites. Isotactic polypropylene (PP) exhibits polymorphic behaviour, which can be distinguished in different modifications. Monoclinic α-form is the most common one for melt crystallized specimen, whereas the trigonal β-form can be produced only under special crystallization conditions or in the presence of nucleating agents [2]. Though much is known about bulk morphology and structure, only very few is known about local structure around agglomerates in PP composite.

Materials and method: For realisation of the melt intercalation a compounding process with an intermeshing co-rotating twin screw extruder Theysohn TSK30/40D (Korneuburg, Austria) and a string die had been used. The selected polymer was the semi crystalline isotactic polypropylene with the commercial indication HC600TF provided by Borealis Inc., Linz, Austria and as filler the smectite clay mineral montmorrillonite with the indication Nanofil 5 provided by Süd-Chemie Inc., Munich, Germany was chosen. This combination of materials was rather incompatible, so therefore additionally a compatibilizer with the indication PP–MA, Scona TPPP 2112 FA, Kometra/D, Schkopan, Germany was required. A high filled mixture with 20 wt.% nano-filler and 20 wt.% compatibilizer was produced in this way. For structural characterization the granulated material was pressed to a plate using a hydraulic vacuum press machine (Collin 200 PV, Dr. Collin Ltd., Ebersberg, Germany). This plate was cut back to a thickness of 10 µm by using a microtom (Histocom, Wiener Neudorf, Austria).
The structure of layered silicates, the arrangement of the silicate platelets, the influence of fillers on spherolithic growth and the changes in polypropylene phase content have been observed by numerous researchers [3]. All of these properties are influenced by the distribution of particles in polymeric matrix. In this paper the authors present a spatially resolved X-Ray diffraction study with sub micron position resolution. The study was performed by applying a 250 nm wide (full width half maximum) X-Ray beam at ID13 beamline at ESRF, Grenoble. From a composite containing agglomerates a thin foil was cut using microtome. In the thin sample agglomerates were visible already in the light microscope. From cutting process visually unaffected agglomerates were chosen for structural characterization. The thin sample was scanned over the area where the chosen agglomerate was located. Phase composition, local composition and interlayer distances were evaluated from the data.

Results and Discussion: In layered silicate reinforced polypropylene produced by melt intercalation more than one defined state was existing. Agglomerates as well as single platelates were coexisting; also different PP-forms could be found. This work shows structural details around an intercalated agglomerate. At the boundary of the agglomerate the interlayer distance sligthly increased and exfoliated single platelets surrounding the agglomerate could be detected. The monoclinic form of PP dominated, however β-PP was found at and near sample positions with high concentration of clay platelets. The degree of crystallinity was lower in areas of agglomerated particles.

Conclusion: Physical properties are strongly influenced by structural details and in this work we present the structural details at a sub micrometer resolution. Further research work is needed to fully understand the effects of the local structure on bulk physical properties.

Poly(ethylene oxide)/sepiolite and poly(ethylene oxide)/sepiolite/Li salt Nanocomposites: Confinement Effects and Preliminary Results on their Performance as Solid Electrolytes

Alberto Mejía, Julio Guzmán, Nuria García, Pilar Tiemblo

Instituto de Ciencia y Tecnología de Polímeros (CSIC), Juan de la Cierva 3, 28006 Madrid, Spain

e-mail: amejia@ictp.csic.es

For over 30 years, poly(ethylene oxide) (PEO) has been used as a matrix in the search and development of a solid polymer electrolyte[1]. In the range of operating temperatures, it is essential to suppress its crystallinity while maintaining dimensional stability. Most research has been focused on extremely confined PEO[2,3,4], however this approach leads to materials with low concentrations of PEO and high non-conducting phase. Our approach consists on using high aspect ratio nanofibers (sepiolite) optimally dispersed in the polymer matrix, with the purpose of achieving solid-like materials behaving as a pseudosolid even above the melting point.

Raw (S) and polyethylene glycol lab-modified (M) sepiolites were melt compounded by extrusion to prepare the nanocomposites with two different molecular weight PEO matrixes (Mw=5000Kg/mol; and Mw=200Kg/mol). The resulting materials were characterized by microscopy techniques, DSC and DMTA. Good compatibility with the matrix is expected for both S and M due to the hydroxylated surface of S and the polyethylene glycol coating on M. Polymer nanocomposites (PNC), with excellent transparencies up to filler levels of 40 wt% and pseudosolid behaviour from 5 wt%, were obtained.

Filler dispersion was checked by SEM and TEM, showing, in general, excellent dispersions (Figure 1).

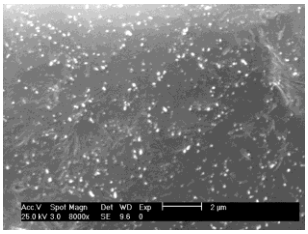

Figure 1:SEM image of 5 wt% M/PEO nanocomposite.

The crystallization behaviour of the PNCs was investigated by DSC and polarized light microscopy (PLM). DSC tests showed that crystallinity remains unaffected even at high sepiolite loadings, while the crystallization temperature (T_c) decreases clearly in M/PEO and does not increase in S/PEO. The unexpected T_c decrease suggests a confinement effect even in the composites with a 5% of M, which is confirmed by the large spherulites detected by PLM. The confinement effect is stronger in M-containing than in S-containing nanocomposites (Figure 2).

The addition of a Li salt completely alters the morphology of the composites: while salts like Li triflate (LiTF) do not strongly affect crystallinity, others like Li sulfonimide (LiTFSI) preclude crystallization and almost amorphous composites are obtained. The ability to avoid crystallization while maintaining a solid-like state above the melting point (T_m) makes these PNCs materials of great interest for the development of transport membranes. Preliminary studies on their performance as solid electrolytes have been made; being able to prepare, by extrusion, films of M/PEO-LiTFSI which are almost totally amorphous but show solid-like mechanical properties and dimensional stability. These NCPs present a Li^+ conductivity of 10^{-4} S·cm^{-1} at 40 ºC.

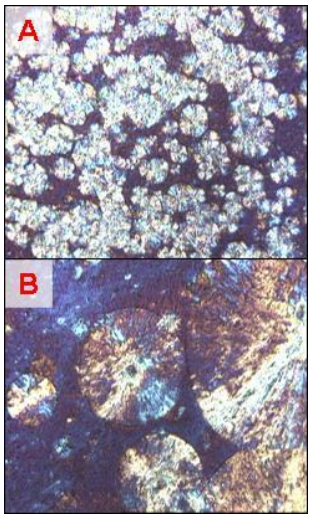

Figure 2:PLM images of A: 20 wt% S/PEO and B: 20 wt% M/PEO nanocomposites

Nanocomposites prepared with Montmorillonite modified by quaternary polyesters

Miroslav Huskić,[1,2] *Majda Žigon*[1,2]

1 National Institute of Chemistry, Ljubljana, Slovenia
2 Center of Excellence for Polymer Materials and Technologies, Ljubljana, Slovenia

miro.huskic@ki.si

Polymer/clay nanocomposites have attracted great interest, both in academia and industry, due to remarkable improvement in mechanical properties, heat resistance, decreased flammability etc. Various clay minerals can be used for this purpose but montmorillonite (MMT) appears to be the most studied so far.

Being hydrophilic by nature, clay minerals are not suitable for direct polymer nanocomposite preparation. Therefore, the surface has to be modified in order to make clay more hydrophobic and to reduce attractive forces between alumosilicate layers. There are several ways of clay modification, however, the most common method is a cation exchange with organic ammonium salts, which differ in a number, length and structure of long chains.[1,2]

Polycations have also been used to modify clay but have not been studied much for nanocomposite preparation[3], which is the subject of this work.

We synthesized polyesters from alkyl diethanolamine with long alkyl chains (N-octyl diethanolamine - ODEA, N-dodecyldiethanol amine – DDEA, and N-hexadecyldiethanolamine – HDEA), and succinic anhydride. Polyester synthesized from HDEA is crystalline at room temperature, polyester synthesized from DDEA is crystalline below -10°C, while P-ODEA is amorphous with glass transition temperature -58°C.

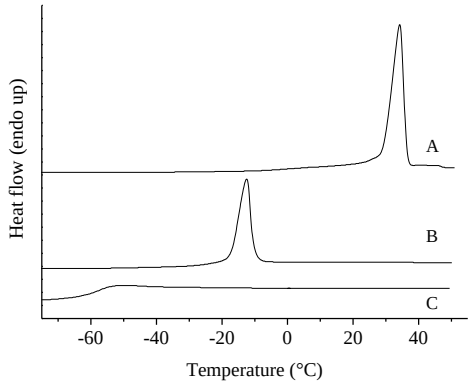

Figure1: DSC curves of polyesters: (A) P-HDEA, (B) P-DDEA, (C) P-ODEA.

The polyesters have been converted to quaternary polyesters by benzylbromide. The reaction was not quantitative and only up to 97% quaternization was achieved with P-ODEA, and up to 90% for P-DDEA and P-HDEA. Quaternization increased glass transition temperature and decreased or prevented crystallization. Polyesters with 40% and 60% quarternization were used for MMT modification. Cation ratio (MMT/polyester) 1:3 was used since our previous experiments showed that this is necessary best modification.[4] During the modification one part of quaternary polyester was bound on MMT while another part was only intercalated. The later was removed by extraction. The modified MMTs before and after extraction were characterized by X-ray diffraction (XRD) and thermogravimetric analysis (TGA). A decrease in interlayer spacing after extraction was observed as shown in Figure 2.

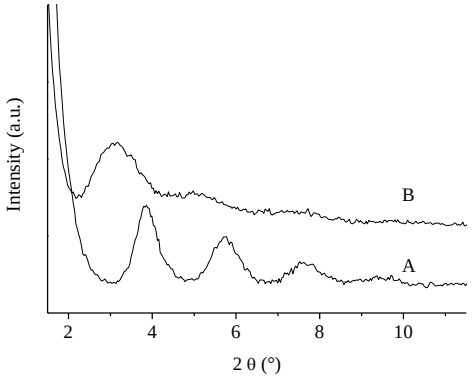

Figure 2: X-ray diffractogram of MMO modified with quaternary P-HDEA, before (A) and after extraction (B).

Unsaturated polyester and epoxy resins were used to prepare nanocomposites with the quaternary polyester modified MMT. The concentration of MMT was 1% to 5%.

Intercalation was determined by XRD and thermal stability of nanocomposites by TGA.

Mechanical properties of nanocomposites were determined by dynamic mechanical analysis (DMA). The modulus was significantly lower when non-extracted MMT was used since the excess polyester acted as a plasticizer.

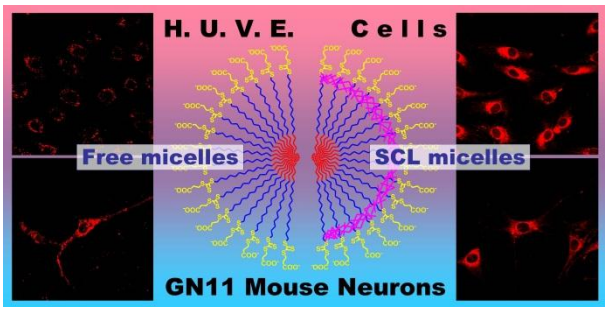
Introduction Nanotechnology sciences have recently benefited from controlled/living radical polymeriza-tion,[1] an extremely powerful tool that has allowed new unexploited results to be reached in polymer chemistry. Among those techniques, RAFT polymerization has been successfully used in the preparation of functional polymeric micelles[2] that can be employed for the delivery of therapeutic agents. This makes it possible to administer lipophilic drugs while protecting unstable molecules from metabolic deactivation.[3,4] Such characteristics, together with a reduced clearance, increase the efficacy of drugs that are usually toxic, thus reducing their effective dose.[5] Polymeric micelles are characterized by a low critical micelle concentration (CMC), which makes them stable under diluted conditions. Nevertheless, their high stability may not be sufficient for the in vivo physiological extreme dilution. Further stabilization can be provided to polymeric micelles by crosslinking processes.[6,7]

Results and Discussion Stable micelles are obtained starting from carboxyl terminated PS-*b*-PMA block copolymer that shows pseudo-amphiphilic properties when dispersed in methanol. Well defined mono-dispersed spherical micelles (20-30 nm) are obtained when the acidic groups carried by the unimers are deprotonated and by using dry solvents. Once assembled, the micelles can be suspended in water by osmosis because their thermodynamic stability. The micelles were also stabilized by Shell Cross Linking (SCL) using triethyleneglycol diacrylate as crosslinker and 2,2'-azobis(2-methylpropionamidine) dihydrochlo-ride as initiator. Because of electrostatic interactions this initiator settles, in its cationic form, only in proximity to the micelle surface initiating there the crosslinking polymerization process. The anionic corona that constitutes the outer shell of the micelles performs a double function: one is to direct the hyperbranching process only at the surface of the particles, the other one is to prevent micelle aggregation by electrostatic repulsion. The improved stability of SCL micelles has been proved by changing the pH of the dispersant media. The free or SCL particles were loaded with the lipophilic marker Nile Red and cell internalization of the carried fluorescent compound was followed with confocal microscopy (CLSM). Different cellular compartments were stained by free or SCL micelles. Free Nile Red loaded micelles stain the membranes while the SCL ones stain the cytosol. This evidences the intracellular stability of SCL nano-particles. Uncrosslinked micelles were also loaded with neutral doxorubicin and administered to doxorubicin resistant cells (LoVo-MDR). CLSM images showed the internalization of doxorubicin into the nucleus. This reveals that the resistance of LoVo-MDR to doxo-rubicin has been overcame. The unimers constituting the micelles were also labeled through thiol conjugation with fluorescein 5-maleimide. This has been made possible by the versatility of the RAFT group that easily affords the thiol function. Cell internalization of fluorescein labeled micelles was followed by CLSM.



Conclusions RAFT polymerization made possible the synthesis of carboxyl terminated PS-*b*-PMA block copolymer. This material showed pseudo-amphiphilic properties when dispersed in methanol and provides stable micelles. Their thermodynamic stability allows their dispersion in water. SCL stabilization increase the intracellular stability of the micelles. These nanoparti-cles are internalized into LoVo-MDR cells delivering doxorubicin. The micelles can also be labeled in their constituent unimers which were covalently bound with fluorescein in order to trace the unimer fate *in vitro*.

1. Introduction

It is well known that monodisperse colloidal microspheres easily self-assemble into hexagonal close packed (*hcp*) arrays on surfaces as a result of capillary forces arising from the evaporation of solvents.[1] Such periodic arrays were used already as shadow masks in colloid lithography (CL) for the deposition of platinum nanomaterials in early 1980 by Fischer and co-workers. [2] Since then, CL has become a simple, versatile, and cost-effective fabrication technique for a large number of researchers in the field of micro/nano fabrication.

Patterned polymer brushes are of increasing importance especially for array based platforms because of their ability to modify surface properties and their potential applications in surface-based technologies, such as protein-resistant coatings, switchable sensors, substrate for cell-growth control, and for separation of biological molecules. [3, 4] Micro- and nano-patterned polymer brushes can be grown via surface-initiated polymerization from surface confined initiator templates, fabricated by various lithographic approaches. [5-9] Among these fabricating approaches, microcontact printing (μCP) is, a simple and convenient technique, accessible to a broad range of researchers, while many of the other patterning strategies remain inaccessible due to the instrumental complexity required. This motivates our current development for new micro- and nano-patterning strategies for polymer brushes.

Here, we exploited a series of robust, but simple and convenient approach of CL using microsphere array as mask, as guiding template, and footprint as restricted geometry, and combining with surface initiated atom transfer radical polymerization (SI-ATRP) to fabricate patterned polymer brush microstructures.

2. Results and Discussion

The appropriate position of colloid microsphere structure could be as mask, as guiding template, and footprint as restricted geometry was shown in Figure 1A-C. The AFM images of subsequent patterning of polymer brush microstructures fabricated from CL and combining with SI-ATRP were given in Figure 1D-G.

3. Conclusions

We have demonstrated prototypically for the first time how colloidal lithography can provide a simple approach to fabricate various patterned polymer brush micro- and nanostructures. Our approaches rely on the spontaneous formation of well-ordered colloidal microsphere arrays that provide lithographic masks or templates for creating patterns of initiator SAMs that can be used for subsequent amplification into polymer brush patterns. The advantages of CL technique for patterned polymer brush fabricating over the aforementioned lithographic approaches that, not only providing commercially available colloid precursor at a relatively low cost, and no complex equipment required to create patterned template with features at a micro and nano scale, but also polymer brush feature are controlled simply by changing the size or chemical functionality of a microsphere.

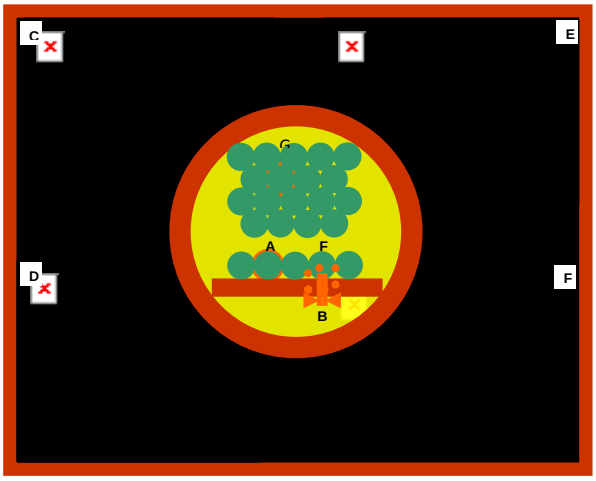

Figure 1, Schematic illustration and AFM images use of colloidal microsphere lithography for patterning polymer brush microstructures (A-C) Appropriate position for lithography. (D-G) Polymer brush microstructures fabricated from CL by using microsphere array as mask, as guiding template, and footprint as restricted geometry, and combining with SI-ATRP.

Penetrants interacting with matrix of polymeric membrane. Problems and perspective.

Ilya V. Vorotyntsev, *Natalia A. Petukhova*

R.Y. Alekseev Nizhny Novgorod State Technical University, N.Novgorod, Russia

postmaster@vorotyn.nnov.ru

Nowadays membrane gas separation is one of traditional physicochemical separation and purification methods such as crystallization, distillation, and sorption. Membrane gas separation is using for separation different binary system, such as N_2/O_2, CH_4/CO_2 and many others. But some systems are characterized by interaction with matrix of polymeric membrane. For example, ammonia in aromatic polyamides, polyheteroarylenes which is characterized by electron acceptors character of active groups of these polymers. Also donor-acceptor interaction in which the penetrants acting as electron acceptor is might be realized in sulphur dioxide – polyeher (ester) ureas system. Hydrogen bonds might be cause of such interaction in hydrogen containing fluorocarbons in polyurethanes. Lots of data of huge gases permeability increasing when they have higher level of humidity might be an example of ion-dipole interaction of water with polymeric matrix of membrane.

Despite the fact of wide and common use of membrane gas separation for above mentioned problems it is needed to explore the process for the case of interaction between the separated gases and membrane matrix. In this case the separation effect might increase or decrease.

In the present work we represent the results of investigation interaction between ammonia and cellulose acetate glassy polymer membrane. Ammonia and some permanent gases permeability were measured [1]. It is shown that ammonia and water interaction with cellulose acetate membrane is of reversible nature.

Features of this process determine the thermo dynamical and kinetic properties of the system penetrant (ammonia and water) – polymer caused by the types and energies of interaction realized in the system.

As we were known the donor-acceptor character of interaction of these polymer membrane matrix/penetrant can be proved by change in IR spectrums of polymer in sorption equilibrium with interacting penetrant, also by high values of partial molar enthalpy of dissolved penetrant.

The inverse gas chromatography was used for determination sorption characteristics of the investigated system. The sorption investigation for the tested systems is complicated due to non-equilibrium state of glassy polymer with micro heterogeneous which is also a swelling material. The partial thermodynamic functions were determined by thermal equation of sorption equilibrium in system of swelling polymers. This thermal equation was obtained by quasi-chemical model of sorption proposed by Laatikainen and Lindstrom. The values of partial molar enthalpy of dissolved ammonia in cellulose acetate were obtained from isotherms data.

IR-spectroscopy was used for proving specific interaction in investigated system. The tested system was obtained by ammonia purge through cellulose acetate up to sorption equilibrium at certain temperature.

The obtained IR spectrums of ammonia – cellulose acetate system is characterizing by significant increase in absorption peak which are not present in cellulose acetate without ammonia.

As a result of above-mentioned investigation the mechanism of penetration of gases interacting with membrane was proposed.

From Bulk to Attograms of Matter: Dynamics and Phase Transitions of Polymeric Materials

A. Serghei[1], *T.P. Russell*[2]

[1] Université Lyon 1, CNRS, UMR 5223, Ingénierie des Matériaux Polymères, F-69622 Villeurbanne, France
[2] Polymer Science and Engineering,University of Massachusetts Amherst, Amherst MA 01003, USA

russell@mail.pse.umass.edu; anatoli.serghei@univ-lyon1.fr

The present contribution is dealing with investigations on extremely small amounts of polymeric materials, i.e. attograms of matter (1 attogram=10^{-18} grams). The project is based on the novel experimental concept of using nano-containers as measurement cells (Fig. 1). Two major objectives are proposed:

(a) development of an experimental platform to address fundamental questions in soft matter physics, such as for instance: "What is the minimum amount of matter necessary to "define" the material properties?".

(b) exploring new routes to enhance the performance of macromolecular systems by means of geometrical confinement and/or external perturbations (i.e. electric fields). The concept of this approach is essentially related to a two-fold effect which is expected for sample amounts in the order of attograms: (i) the degree of disorder characteristic for bulk materials is strongly reduced in the case of small systems; (ii) small external perturbations can generate huge effects when applied on tiny amounts of material.

Different aspects of the polymer dynamics – manifested on time scales spanning more than 10 orders of magnitude (molecular fluctuations, glass transition, capillary flow) – phase transitions as well as material parameters relevant for technological applications (i.e. conductivity, permittivity, ferroelectric activity) will be discussed for polymeric systems having one, two or three dimensions on the nanometric length-scale.

Effect of Organoclay Surface Treatment on the Property Profile of Recycled PET Nanocomposites

M. Kracalik, A. Witschnigg, S. Laske, C. Holzer

Montanuniversitaet Leoben, Department Polymer Engineering and Science, Otto Gloeckel Str 2, 8700 Leoben, Austria

Milan.Kracalik@unileoben.ac.at

Introduction: Nanotechnology was introduced as a new method of improvement of polymer properties in 1995. The technology involves not only incorporation of nanosized particles into the polymer but, more importantly, investigation of interactions between the polymer matrix and the enormously large nanofiller surface [1]. Especially for polymer/clay nanocomposites, the surface effects are responsible for improvement of barrier, mechanical and rheological properties, dimensional stability, heat, flame and oxidative resistance. In comparison with traditional fillers (20–40 wt. % loading), 2–5 wt. % filling of layered clays is sufficient to achieve analogous material improvement [2, 3]. Addition of nanoscaled fillers to recycled polymers represents a promising possibility of properties enhancement [4-6]. Generally, three methods of polymer/clay nanocomposites preparation are used: in situ polymerization, solution mixing and melt mixing. The melt mixing process is technologically the most interesting; nevertheless, satisfactory results with polyethylenterephthalate matrix have not been achieved. In this contribution, recycled polyethylenterephthalate (PET-R) has been compounded with differently modified commercial organoclays. Effects of organoclay surface modification on processing as well as utility properties have been investigated.

Materials and method: Colour-sorted PET-R has been compounded with 6 different organically modified layered silicates. For the compounding process, a counter-rotating twin screw extruder Brabender Plasticorder PL2000 using a string die with consequent granulation using a water bath has been employed. Processing (rotational and elongational rheometry), structural (X-ray diffraction, transmission electron microscopy) and utility properties (differential scanning calorimetry, thermogravimetric analysis, mechanical and flammability testing) of the prepared nanocomposites have been investigated.

Results and Discussion: The efficiency of the organoclay filling manifested itself as a significant increase in melt viscosity in the range of low shear rates. At higher frequencies, the complex viscosity of some PET-R nanocomposites decreased below the value of the unfilled matrix with the same processing history as the nanocomposites. It was already found that the most significant degradation during the processing of recycled PET and organoclay is attributed to chemical reactions between the functional groups of organic modifiers, free water of silicate and the polymer chains [4]. These reactions lead to a decrease in molecular weight, which explains lower viscosity values in nanocomposites at higher shear rates. The level of the mentioned degradation reactions can be assessed by viscosity decrease of the processed PET-R as compared to original PET-R before processing. Compared to the unfilled polymer matrices, all nanocomposites show significant increase in melt elasticity at lower frequencies. In the range of higher shear rates, the melt elasticity of some PET-R nanocomposites decreased below the value of the unfilled PET-R matrix due to degradation mechanism described. Considering rheological behavior in the elongational flow, all the prepared nanocomposites revealed significant increase in the melt strength as compared to unfilled polymer matrices. Results of flammability tests revealed pronounced influence of flamm rate on surface treatment applied in organoclays. Nanocomposites containing organoclays sensitive to degradation during the processing revealed even higher flamm rate than unfilled polymer matrix. On the contrary, filling with organoclays possessing higher thermal stability and lower sensitivity to degradation reactions during the processing led to reduction in the flamm rate. However, all the nanocomposites revealed significant reduction in drop-off effect in comparison with unfilled polymer matrix.

Conclusion: PET-R nanocomposites have been prepared using different organic surface modifications of layered silicate. Selected processing and utility properties have been compared. In the prepared nanocomposites both, the delamination effect (formation of 3D structure) as well as degradation phenomenon (chain scission, generation of low-molecular products) has been detected by dynamic rheological experiments. Using Rheotens equipment, effect of organoclay surface treatment on the melt strength level of different PET-R nanocomposites has been investigated. Tests of flammability revealed strong influence of the flamm rate on the surface modification used in organoclay. However, significant reduction in drop-off effect in all nanocomposite systems prepared has been obtained as compared with polymer matrix without nanofiller.

Effect of two different surfactants on the properties of PET nanocomposites

Itamara F. Leite, Anna Priscilla S. Soares, Oscar M. L. Malta e Suédina Maria de L. Silva

Two types of organic modifiers as alkyl ammonium and alkyl phosphonium were employed in different amount in the organic modification of a purified bentonite clay by reaction ion exchange and utilized as filler in the preparation of poly(ethylene terephthalate)(PET) nanocomposites. PET nanocomposites containing 1 wt% of organoclays were prepared in the Rheometer Torque Haake, operating at 260 ˚C, 60 rpm for 10 min and then analyzed by X-ray diffraction and thermogravimetry analysis. This study allows evaluating the characteristics of the organic modifiers' influence on the intercalation and exfoliation processes in PET. XRD results suggested the obtaining of exfoliated PET nanocomposites when high levels of alkyl ammonium salt were used in the organic modification of purified bentonite. Improvement in the thermal stability also was observed for the sample containing high levels of alkyl ammonium as a result of exfoliated morphology.

Key-words: PET, surfactants, properties, nanocomposites.

Optical Writing in Self-Assembled Azobenzene Block Copolymers and their Blends with PMMA

S. MENGHETTI[1], M. ALDERIGHI[1], F. TANTUSSI[2], F. FUSO[2], M. ALLEGRINI[2], R. SOLARO[1], G. GALLI[1]*

E-mail: gallig@dcci.unipi.it

Introduction

The attainment of ultra-high density (foreseen up to 1 Tbyte/cm^2) optical data storage, e.g., for re-writable DVDs, requires the development of materials able to sustain stable modifications of their optical properties sized on the order of tens of nm, or even less. Besides new materials, research on nanooptical writing demands non-conventional optical schemes able to access sub-diffraction spatial resolution. Block copolymers have a great potential in opto-electronics and data storage applications [1].

To these aims, we synthesized new block copolymers containing azobenzene side groups and then performed nanowriting experiments by using a scanning near-field optical microscope (SNOM) equipped with a polarization-modulation system able to catch details of the optical properties with a spatial resolution in the tens of nm range. These materials exhibit a liquid-crystalline behaviour able to improve the writing stability. The resulting morphology is not strongly influenced by liquid-crystalline order, being mostly governed by the volumetric fraction of the phase-separated blocks. We also prepared blends with PMMA and the block copolymers to dilute the azobenzene content in order to perform nanowriting in the bulk sample.

The relevance of block copolymers and their morphology in the optical writing will be discussed.

Materials and Methods

We synthesized novel block copolymers of an azobenzene-containing polymethacrylate and polymethyl methacrylate, P(MA4-b-MMA)y, with different contents y of the azobenzene block (1–20 mol% MA4) to be used as media for optical writing [Fig.1].

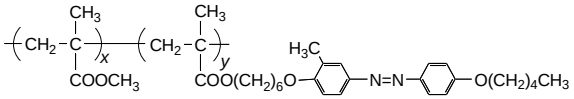

Fig.1 Chemical structure of the block copolymers P(MA4-b-MMA)y (y = 1–20 mol%).

Results and Discussion

The block copolymers are able to self-assemble in nanostructures and the segregation of the azobenzene moieties in nanodomains [Fig.2] permits high stability and high contrast in optical writing at the nanoscale to be achieved in writing/reading experiments in the near field. SNOM writing demonstrates the achievement of a stable optically nanowritten bit [Fig.3].

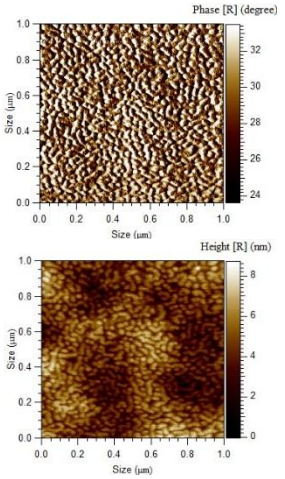

Fig.2. AFM topography (top) and phase (bottom) maps of P(MA4-b-MMA)20.

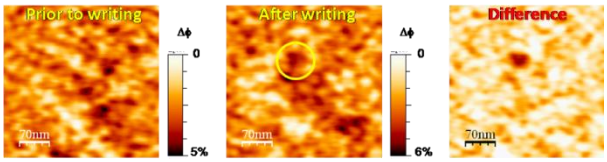

Fig.3. Maps of the optical retardation acquired by PM-SNOM on a P(MA4-b-MMA)20 film before and after optical writing (at the encircled position).

Conclusions

Self-assembled azobenzene block copolymers allow the obtainment of a pure-optical writing and the achievement of a nanoscale size of the imprinted bit.

In azobenzene block copolymer films stable optical modifications can be produced by using pulses as short as 1 ms, with the capability of pure optical writing with sub-100 nm spatial resolution. This may open avenues to ultra-high density information storage media.

Generating Hierarchical Nanostructures in Polymer Surfaces

J.P. Fernández-Blázquez, A. del Campo

Max-Planck-Institut für Polymerforschung. Ackermannweg 10, 55128 Mainz, Germany

e-mail: fernande@mpip-mainz.mpg.de

A generic method to obtain nanostructured surfaces with different topographies upon plasma etching of polymer surfaces is presented. Special effort was paid to the generating of hierarchical structures mimicking structured surface found in nature (i.e. gecko adhesive structures or self-cleaning lotus leaves). A correlation was found between the morphology of the polymer sample (crystallinity, orientation) and the resulting nanopatterns. We propose plasma etching as a templateless method for generating polymer nanopatterns.

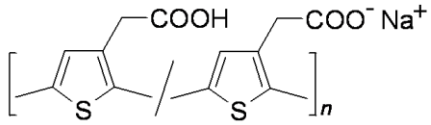
Background & Methods: Conjugated polyelectrolytes (CPs) possess several interesting properties that make them an interesting material for technological use. One of these properties is their spectral characteristics in UV/Vis region which are primarily dependent on the conformation of polymer backbone. Nevertheless, the thermodynamic and transport properties of CPs in aqueous solutions are very scarce although significant portion of UV/Vis spectral studies of CPs' solutions cannot be unequivocally interpreted without known thermodynamic and transport properties. On the other hand, the information about polyelectrolyte conformation in solution can help in interpretation of conductivity studies. This is especially true when polyelectrolyte conductivity is to be interpreted also in terms of conformational changes.

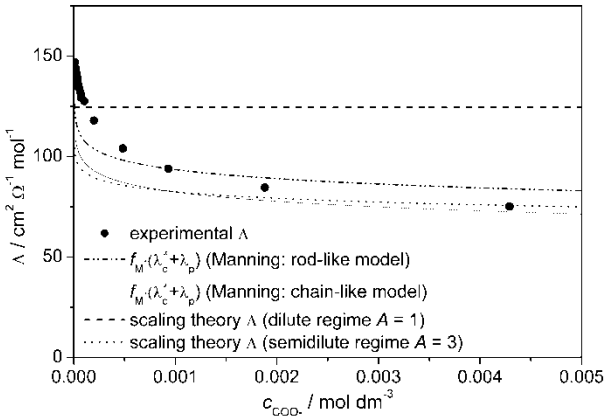
As the compound that could be used in testing various polyelectrolyte conductivity theories poly(thiophene-3-ylacetic acid) (PTAA) was chosen as a typical and often studied representative of CP. For the purpose of conductivity studies the sample of PTAA was carefully dialyzed and neutralized to degree of neutralization α_n = 0.346 with aqueous NaOH solution. For the prepared stock solution of partially neutralized PTAA (PTAA/Na; α_n = 0.346) concentration dependence of electric conductivity of aqueous solutions at 25 °C was measured in dilute concentration regime.



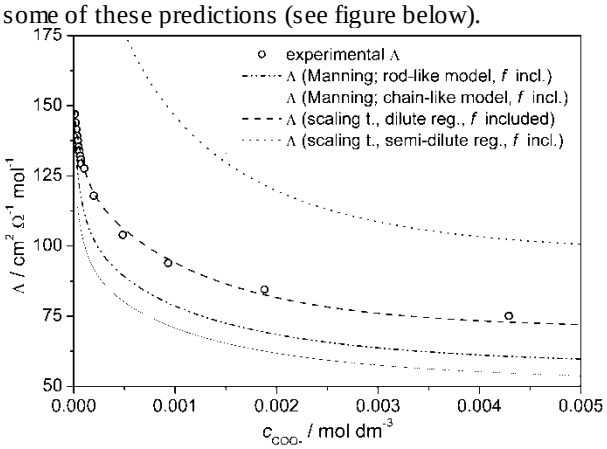
PTAA/Na (α_n = 0.346)

From the obtained specific conductivity the molar conductivity Λ, expressed to one mole of neutralized carboxylic groups, was calculated. Theoretical predictions of Λ were calculated for two Manning's models (rod-like and chain-like) and for scaling theory (for dilute and for semi-dilute regime). In order to correctly take into account fraction of free counterions, *f*, occurring in these theories, the values of *f* were evaluated from the measured transport numbers and electric conductivity. The degree of polymerization, X_n, was estimated to be $X_n \approx 39$ by size-exclusion chromatography measurements. All these data enabled application of theoretical expressions and recalculation of Λ without use of a single adjustable parameter.

Results & Discussion: Measurements of UV/Vis spectra of PTAA/Na indicated no conformational changes of polymer backbone in the concentration range where electric conductivity was measured. Both Manning's and scaling conductivity theories in principle recognizes concentration dependence of fraction of free counterions but through simplifications in their final expressions dependence of *f* on concentration is lost. Consequently, all these theories are practically always used with simplification of constant value of *f*. Results of such calculations for PTAA/Na case are presented in the figure below.



The results obtained by applying all four theoretical predictions in their standard form are rather satisfactory as judged according to their limitations. Incorporating experimentally determined and concentration dependent *f* into existing polyelectrolyte theories drastically changes some of these predictions (see figure below).



Conclusions: Introducing explicit concentration dependence of *f* on concentration can substantially change theoretically predicted Λs of polyelectrolyte. By applying this improvement for the studied case of PTAA/Na almost perfect agreement between measured Λs and those calculated from the scaling theory for dilute regime was obtained without introducing any adjustable parameter.

e-mail: J.G.P.Goossens@tue.nl

Tapes with alternating semi-crystalline thermoplastic/rubber layers with thicknesses varying from 100 nm up to several μm's were prepared by multi-layer co-extrusion. The variation in layer thickness was obtained by varying the thermoplastic/rubber feed ratio. Various microscopy techniques were used to visualize the morphology of the layered systems. The relatively large length scales and the sample preparation make optical microscopy (OM) unsuitable to study the morphology of the multi-layer tapes. Although excellent contrast between the thermoplastic and rubber layers can be obtained, the usually applied, relatively large magnifications limit the use of transmission electron microscopy (TEM) and atomic force microscopy (AFM) to small sample areas. The large range of applicable magnifications makes scanning electron microscopy (SEM) the most suitable technique to study the morphology of the multi-layer tapes. The sample preparation for SEM with a secondary electron (SE) detector is often based on the removal of one of the components, which may induce changes in the morphology. SEM with a back-scattered electron (BSE) detector is a very convenient method to study the morphology over a wide range of length scales, where the contrast between the different layers can be enhanced by chemical staining. Finally, the crystallization behaviour of the semi-crystalline layers, as probed by differential scanning calorimetry (DSC), may provide valuable information on the layered morphology.

Cationized Nanofibrillated Cellulose by Aqueous Free Radical Polymerization: Synthesis, Structure, and Antibacterial Properties

Kuisma Littunen, *Ulla Hippi*, *Jukka Seppälä*

Aalto University School of Chemical Technology, Polymer Technology Research Group, Espoo, Finland

kuisma.littunen@tkk.fi

Chemicals with positively charged groups are known to be antibacterial, offering a nontoxic alternative to common disinfectants.[1] Combining these properties with the large specific surface area of nanofibers could yield safe and efficient antibacterial materials.

Nanofibrillated cellulose (NFC) was modified by polymers containing cationic ammonium groups. Since NFC exists as dilute water dispersions, the polymerization was conducted in an aqueous medium by redox initiated free radical grafting. Cerium ammonium nitrate was used as initiator. This method is known to be efficient for grafting polysaccharides with acrylic monomers while also preserving the nanofibrillar structure.[2]

Three different synthesis routes were investigated (Fig. 1):

- Direct grafting of cationic monomer from NFC
- Grafting NFC with a monomer containing tertiary amine groups, followed by cationization
- Grafting NFC with a monomer containing epoxide groups, amination with a secondary amine, and cationization

Chemical structure of the products was characterized by FTIR, solid-state ^{13}C NMR, and XPS. Antibacterial properties were investigated by bacterial cultivation experiments.

Molecular brushes are composed of a long main chain onto which side chains ("grafts") are attached at regular intervals. The graft copolymers are classified as molecular brushes provided that the distance between the grafts along the contour of the main chain is small in comparison to the characteristic dimensions of the side chains.

In general case the backbone and the grafts can be chemically different, i.e., exhibit different flexibility and solubility properties. Furthermore, the grafts themselves can exhibit chemical or topological complexity. For example, "core-shell" molecular brushes are formed in the case of the block copolymer side chains. Recently, molecular brushes comprising randomly or regularly branched (dendritic) grafts have been synthesized.

The objective of our work was to establish general relationships between architecture of the grafts, types of intra-molecular interactions involved and local and large scale conformational properties of the molecular brushes. This is done on the basis of systematic combination of analytical mean-field and scaling approaches with the numerical Self-Consistent Field (SCF) modeling. Theoretical predictions are compared to experimental observations and results of numerical simulations.

The general features of molecular brushes are determined by crowding and strong steric interactions between the grafts. These interactions (repulsive under good solvent conditions) lead to radial stretching of the grafts, impose the axial tension in the backbone and affect apparent persistence length of the molecular brushes. The latter property is manifested in large-scale conformational properties, e.g. in the gyration radius of molecular brushes.

By comination of scaling and numerical SCF approaches we have proven that the apparent persistence length of molecular brushes with linear grafts comprising $10 \div 10^2$ segments is controlled by the brush thickness (i.e. by the radial extension of the grafts). This finding is in a line with results of computer simulations and with experiments on molecular brushes formed by the grafts of similar length. We have demonstrated, that the effects of induced bending rigidity (which grows proportionally to the square of the brush thickness) are manifested only in molecular brushes with the graft length $\geq 10^3$, that is beyond the up-to-date experimental and computational limits.

Conformations and induced bending rigidity of molecular brushes with dendritic grafts have been considered. These brushes are formed by dendrons attached by the end of the root spacer to the backbone of the brush. We have demonstrated that fairly uniform radial distribution of monomer unit density within the brush thickness is ensured by strong radial fluctuations in the extension of individual dendrons. The effects of induced bending rigidity on the apparent persistence length of dendritic molecular brushes become stronger upon an increase in the number of generations or/and increase in the functionality of the branching points of the dendrons.

Amphiphilic molecular brushes with block copolymer grafts have been considered. In the case of grafts with solvophobic inner block and solvophilic outer block the formation of intra-molecular core-corona cylindrical micelles was expected. We have, however, demonstrated longitudinal instability of the uniform cylindrical core and formation of multi-domain pearl-necklace structures. We predicted a similar type of necklace structure consisting of intra-molecular spherical micelles for molecular brushes with solvophilic grafts and solvophobic main chain.

Concentrational effects in semi-dilute solutions of molecular brushes have been considered on the basis of scaling approach. We demonstrated that in contrast to solutions of linear polymers the solution of molecular brushes exhibits three characteristic concentrational thresholds: the concentration c^* corresponds to the overlap of the macromolecules as a whole, the concentration c^{**} corresponds to crowding of the grafts belonging to different brushes, and only at concentration beyond c^{***} the interpenetation of the internal (proximal to the backbones) regions of different brushes occurs. Remarkably, at $c>c^{**}$ the apparent rigidity of the molecular brushes decreases as a function of polymer concentration in the solution.

A New Approach to Peptides Encapsulation

Barbara Trzebicka[1], *Andrzej Dworak*[1], *Barbara Robak*[1], *Paweł Weda*[1], *Jerzy Silberring*[1,2]

barbara.trzebicka@cmpw-pan.edu.pl

Introduction

In the last decade, an interest in formulations of peptide delivery systems that protect and stabilize biomolecules against enzymatic degradation, significantly increased [1] ."Capsules" made of polymeric materials might serve as protection carriers for biomacromolecules and provide their delivery to the desired place [2-3]. Sometimes it is also convenient to covalently attach biomolecule to the polymer, what is called bioconjugation [4]. Recently, attention has been paid to the thermosensitive materials as precursors of the stimuli-responsive drug delivery systems [5]. It was shown [6-9] that by controlling the process of heating of dilute solution of thermosensitive polymers, stable nanoparticles (mesoglobules) formed by polymer chains could be obtained.

Here we explored the idea of application of the thermosensitivity of poly(*N*-isopropylacrylamide) (PNIPAM) for encapsulation of peptides by their entrapment in PNIPAM mesoglobules or by formation of mesoglobules by peptide-PNIPAM bioconjugate.

Materials and Methods

Two peptides, the nociceptin (FGGFTGARK-SARKLANQ) and a pentapeptide (GFKRG) were synthesized. Both peptides were obtained according to the standard solid phase peptide synthesis (SPPS) and Fmoc chemistry in DMF as solvent [11] on a solid support – *Dansyl NovaTag*™ resin (Merck). Nociceptin was used in the process of physical entrapment in PNIPAM mesoglobules.

PNIPAM (Sigma-Aldrich) of M_n=84000 g/mol (according to our GPC-MALLS measurements in DMF), was used for the formation of mesoglobules with nociceptin, similarly to the protocol described in [10]. *N*-isopropylacrylamide (NIPAM) (Sigma-Aldrich) used for ATRP polymerization of polymer block in bioconjugate was purified by crystallization in hexane. Pentapeptide linked to the resin was modified with 2-bromopropionate groups capable of initiation of the ATRP polymerization of NIPAM. The resulting hybrid bioconjugate was used to obtain stable mesoglobules in water solution above bioconjugate phase transition temperature.

Peptide composition and molar masses were confirmed by ESI-MS. GPC-MALLS was used to measure molar masses and their dispersities of polymers and peptide-polymer bioconjugate. The cloud point temperature of the investigated macromolecules was taken from transmittance, observed by UV spectroscopy, vs. temperature. The size and shape of the obtained particles were determined by the light scattering techniques.

Results and Discussion

Two different peptide encapsulation methods based on the ability of thermosensitive PNIPAM to form stable mesoglobules were investigated. The physical interaction between PNIPAM and nociceptin upon heating of PNIPAM/nociceptin water solution above cloud point temperature of PNIPAM resulted in formation of mixed mesoglobules. The process of mesoglobules formation and influence of the peptide concentration on mesoglobule sizes were followed by the dynamic light scattering measurements. Physical interaction between PNIPAM and nociceptin resulted in formation of much bigger nanoparticles than those formed by the chains of PNIPAM homopolymers.

ATRP of NIPAM initiated by the solid supported peptide resulted in formation of thermosensitive peptide-PNIPAM bioconjugate. During abrupt heating of their water solutions, bioconjugate chains formed stable particles with the peptide encapsulated inside. This method provided a new approach to obtain much smaller particles than physical entrapment of the same peptide amount.

The presented encapsulation methods do not require complicated and tedious reservoir purification before peptide encapsulation and are a promising approach for peptide encapsulation and delivery.

Some novel applications for biodegradable elastomers

Subbu Venkatraman, Vitali Lipik, Kong Jen Fong, Huang Yingying, Nithya V, Freddy Boey

School of Materials Science and Engineering, Nanyang Technological University, Singapore

assubbu@ntu.edu.sg

Introduction: Although several biodegradable elastomers have been reported (1), very few real applications using such elastomers have been detailed. In our laboratory, we have been targeting a few cardiovascular implant applications that require minimally invasive methods. One such example is an occluder for atrial defects (2, 3).

Cardiovascular occluders are preferably biodegradable and should be inserted via the transcutaneous method, using the femoral artery. As such the device should be compressible into a sheath, and when released should recover to its original shape. Materials for such devices must be predominantly elastomeric.

We evaluated several polymers and designs for this application, including some new polymers synthesized in our laboratory. The selection criteria for the elastomer include good recoverability and biodegradation over 6 months.

Results and Discussion: The table below gives the mechanical and compositional characteristics of various polymers evaluated:

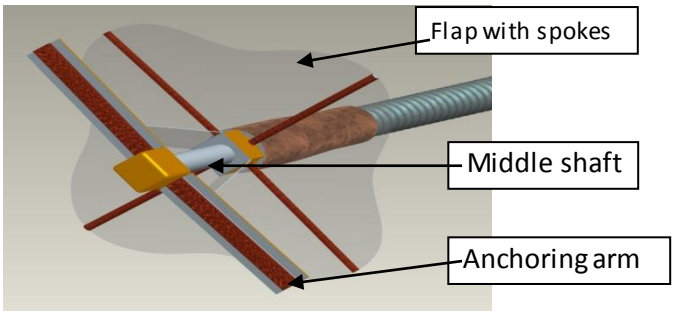
Polymer	Modulus (MPa)	Elongation to break (%)	Recovery @50%	Recovery @150%
PCL	153 ± 23	378 ± 92	45 ± 7	-
PLC	64 ± 9	458 ± 79	86 ± 2	86 ± 1
Copoly B[1]	31 ± 4	307 ± 2	86 ± 1	83 ± 1

[1] Copoly B is a branched copolymer of PLA and PLA/CL.

PCL is a homopolymer (poly (caprolactone)) and PLC is a copolymer of PCL and Poly (l-lactide), PLA; both are commercially available polymers from Purac corporation.Star is a star-branched copolymer of PLA and PCL synthesized in our laboratory.

As can be seen from the table, PLC has good elastomeric properties, although not exhibiting 100% recoverability. In our preliminary studies we evaluated these polymers in the device design, described below.

The device design is a "double-umbrella" design, which allows for two flaps to be opened at the proximal and distal ends, so that the device is anchored at both ends of the defect.



Elastomeric material is needed for the flap as well as for the shaft of the device, as explained below. This device is enclosed in a 10F or 11F sheath (diameters mm and mm) prior to insertion into a femoral artery. The sheathed device is then guided using X-ray imaging to the atrial septal defect, and the sheath withdrawn to release the device. The flaps should open fully within seconds so that the device can be positioned and anchored. Following anchoring, the sheath is withdrawn, and any wire connection to the device is severed.

We have evaluated 3 polymers (PCL, PLC and a PLA-PCL/PLA- PLA branched copolymer in this application. Although all 3 devices could be opened upon unsheathing, the time taken to unfold and the extent of opening were different, and dependent on recovery as well as on modulus. Data showing the speed and extent of opening from the sheath will be discussed.

An animal study in pigs was conducted to show the feasibility of sealing a model defect in the atrial septum1. Data clearly confirm sealing of the defect, as seen from ultrasonic testing of introduced air bubbles, as well as angiographically. Histology revealed very little tissue reaction, while at the same time confirming complete endothelial cell coverage of thedevice in one month.

Amyloid Peptides and Peptide Copolymers: From Self-assembly, Towards Therapeutics

Ian W. Hamley and Valeria Castelletto

Department of Chemistry, University of Reading, Whiteknights, Reading, RG6 6AD, UK

Email: I.W.hamley@reading.ac.uk

There has been great interest recently in the fibrillisation of peptides, especially the amyloid beta (Aβ) peptide which is involved in diseases such as Alzheimer's [1]. We have recently commenced a study of the self-assembly of peptides and peptide copolymers based on a fragment KLVFF, corresponding to the core region of Aβ(16-20). Aβ self-assembly is driven by inter-molecular β-sheet self-assembly into fibrils. A primary objective of our work is to identify fragments that bind to amyloid fibrils and disrupt fibrillisation (aggregation inhibitors based on self-recognition elements [2]). We are also interested in peptides and peptide/polymer conjugates as hydro- and organo-gelators. I will present results on the self-assembly of peptides such as AAKLVFF [3,4] and PEGylated diblock copolymers of these peptides [5,6]. Self-assembly is studied in water for hydrophilic peptides and peptide copolymers and in organic solvents for hydrophobic peptides. Gelation at higher concentration is also discussed. Peptide AAKLVFF is the subject of detailed studies (FTIR, CD, NMR, molecular dynamics simulations) of its self-assembly into nanotubes in methanol and twisted fibrils in water [4,7]. Very recently we have discovered a novel twisted ribbon fibril structure by adding β_2-amino acids to the N terminus of KLVFF to give βAβAKLVFF [8], and the fascinating structural properties of this will be discussed. We have recently examined the binding of this peptide to the amyloid β peptide Aβ(1-42), as part of a project to develop aggregation inhibitors, which may be useful in the treatment of amyloid disease [9]. In addition, we have found that a PEGylated version of this peptide forms spherical micelles in aqueous solution, pointing to the ability to modulate the self-assembled structure by introduction of amphiphilicity [10]. The enzymatic cleavage (using α-chymotrypsin) of the peptide from the PEG3000 chain (between phenylalanine residues) leads to release of unassociated peptide monomers [10]. This nanocontainer delivery and release system could be useful in therapeutic applications. As another example, we have investigated the self-assembly of a novel peptide amphiphile (PA) Matrixyl, with collagen-stimulating properties [11]. It forms self-assembled tape-like structures in aqueous solution as shown in Fig.1. These can be dispersed into amyloid-like fibrils by use of the anionic surfactant SDS.

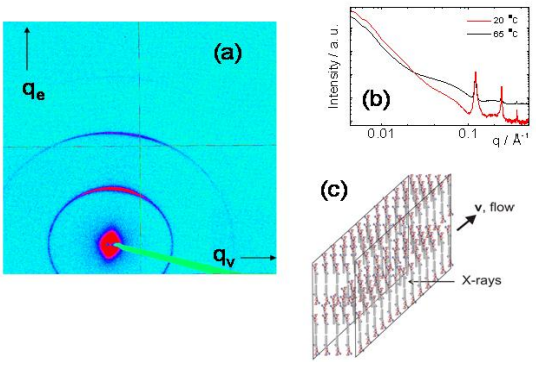

Figure 1. X-ray data and model for Matrixyl self-assembly, (a) Two-dimensional SAXS data from a sample (0.95 wt%) aligned by flow. The oriented Bragg reflections are nearly perpendicular to the horizontal flow (**v**) direction and indicate alignment of PA bilayers perpendicular to the flow direction (i.e. tapes align along the shear axis), (b) One dimensional SAXS profiles showing Bragg peak positions, and the development of diffuse scattering at high temperature, (c) Structural model for the PA bilayers.

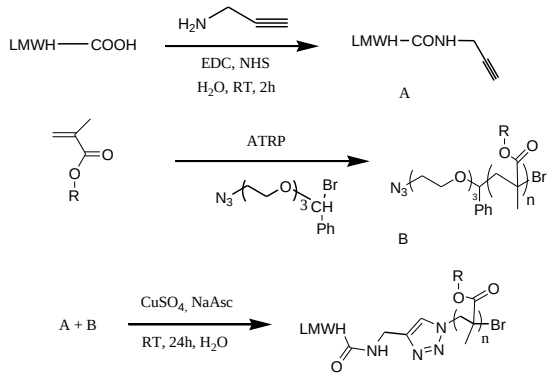
felireyes@ictp.csic.es

Introduction

Combination of synthetic polymers with proteins and polysaccharides in order to develop bioconjugates has enjoyed a significant impact in medicine in recent years due to possess a high content of functional groups that can be utilized for bioconjugation with cell-targeting agents (1). The aim of this work was the preparation of new heparin-polymer bioconjugates via ATRP, carbodiimide chemistry and click chemistry in order to obtain new temperature-sensitive (T-sensitive) heparin-based materials with a controlled architecture that could form self-assembling systems with new properties.

Materials and Methods

Low Molecular Weight Heparin (LMWH) has been functionalized with an alkyne group via carbodiimide chemistry. MEO_2MA, $OEO_{300}MA$ and DMAEMA have been polymerized by ATRP using an initiator-N_3 to get the azide functionalization of the T-sensitive polymer (2). Heparin-alkyne and different azide functionalized polymers have been coupled by click chemistry using a copper catalyzed reaction (3). The polymers used were N_3-p(DMAEMA) and the copolymer N_3-p($OEO_{300}MA$-co-MEO_2MA) (figure 1).



R = 2-(dimethylamino)ethyl, poly(ethyleneglycol)methylether or di(ethyleneglycol)methylether

Figure 1. Scheme of the synthesis. *Experimental conditions:* *(I):* LMWH (1.25×10^{-4} M) / EDC / propargylamine/ NHS = 1 / 10 / 20 / 5mM in distilled water, RT, 2h. *(II):* p(MEO_2MA-co-$OEO_{300}MA$) 50% (v/v) anisole, 60ºC, 2h, MEO_2MA (2.2 M) / $OEO_{300}MA$ / dNbpy / $CuBr_2$/ CuBr / N_3-In = 90 / 10 / 1 / 0.1 / 0.4 / 1. P(DMAEMA) 50% (v/v) anisole, 50ºC, 4h, DMAEMA (2.9 M)/ N_3-In/ CuCl/ $CuCl_2$/ HMTETA = 100 / 1 / 0.4 / 0.1 / 0.5. *(AB):* A (2.5×10^{-3} M) / B / sodium ascorbate / $CuSO_4$ = 1 / 1 / 0.1 / 0.05 in distilled water, RT, 24h.

Azide polymers and alkyne functionalized heparin were characterized by ^{1}H and ^{13}C-NMR, FTIR, SEC and GC techniques. Bioconjugates were characterized by NMR, FTIR and DLS.

Results and Discussion

T-sensitive polymers have been prepared by ATRP. The reactions presented a linear kinetic plot and the polymers were obtained with a low polydispersity. Alkyne functionalization of heparin has been carried out using propargyl amine and EDC/NHS to activate the carboxylic groups of heparin. A characteristic band of the alkyne group is observed at 2100 cm^{-1} in the FTIR spectra (Figure 2).

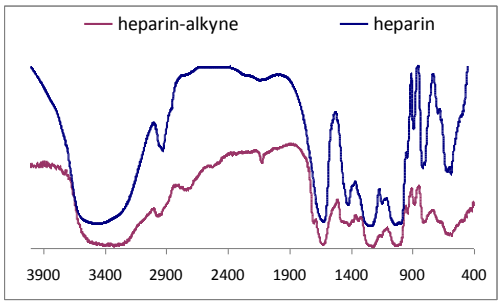


Figure 2. FTIR characterization of LMWH and LMWH-alkyne systems.

T-sensitive polymers have been grafted to heparin by click chemistry. A characteristic peak of triazole ring formed during the click reaction was observed at 7.5 ppm in ^{1}H-NMR spectra.

Low Critical Solution Temperature (LCST) was investigated in heparin polymer bioconjugates by DLS. LCST of the heparin-based bioconjugates decreased when compared with the non-modified T-sensitive homopolymer. This behavior is due to the hydrophilicity of heparin molecule.

Conclusions

T-sensitive heparin-based bioconjugates were prepared using ATRP, carbodiimide chemistry and click chemistry. These new material are very interesting for biomedical applications such as targeted drug delivery (1).

Synthesis of PLA-*b*-PHEA block copolymers as precursors of tubular guides for peripheral nerve repair

B. Clement, T. Trimaille, K. Mabrouk, D. Bertin, D. Gigmes

Université de Provence, Laboratoire Chimie Provence UMR 6264, Av. Esc. Normandie Niemen, 13397 Marseille Cedex 20, France

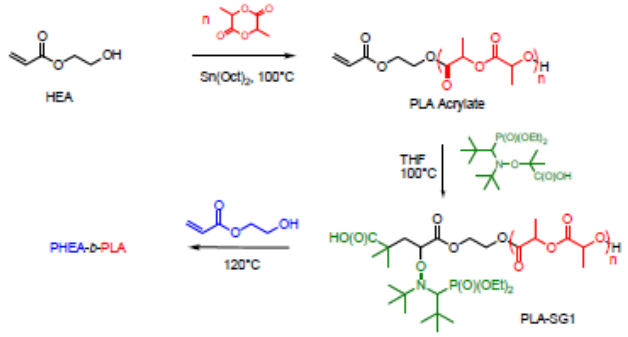
didier.gigmes@univ-provence.fr

Introduction

The use of synthetic polymer materials[1] as guide scaffolds for nerve repair is a promising alternative to natural ones, such as collagen, that present several drawbacks (reproductibility between samples, cost, possible contamination with pathogen agents,…). Among synthetic polymers, poly(2-hydroxyehtyl acrylate (PHEA) is widely investigated in nerve repair, due to its hydrogel-like properties. Aliphatic polyesters such as polylactide (PLA) or polycaprolactone (PCL) are also choice candidates due to their biodegradability[2]. In order to fulfill the criteria of guide scaffolds for nerve repair, we aimed at combining the properties of both kinds of polymers in a single homogeneous material using block copolymers of PLA and PHEA.

Results and Discussion

More particularly, we prepared various block copolymers PLA-b-PHEA in three steps[3] (scheme 1). Typically, an acrylated end-capped PLA (PLA acrylate) was first prepared by ring opening polymerization (ROP) of the D,L-Lactide using 2-hydroxy ethyl acrylate (HEA) as initiator and $Sn(Oct)_2$ as catalyst. The PLA acrylate was further involved in a 1,2-intermolecular radical addition with MAMA-SG1 alkoxyamine, leading to the corresponding PLA-SG1 macroalkoxyamine (2). Finally, Nitroxide Mediated Polymerization (NMP) of HEA initiated from (2) led to the corresponding PLA-b-PHEA (3). The NMP of 2-hydroxyethyl acrylate (HEA) appeared to be well controlled in the presence of free SG1 nitroxide.



Scheme 1 : Synthesis of PLA-b-PHEA copolymers

In order to move a step closer to the clinic, we particularly focused on poly(D,L-lactide)-b-poly(2-hydroxyethyl acrylate) (PLA-b-PHEA) block copolymers and compared them to parent PLA homopolymer. For that purpose, we performed in vitro and in vivo (in rats) degradation studies and assessed Schwann cell adhesion. Over 12 weeks, we observed mass loss and molecular weight decrease. In vitro and in vivo findings were very similar for each polymer tested. The in vivo and in vitro degradation behaviour of such materials were found to be identical, and the PHEA content in the copolymer had a great impact on the degradation mechanism. The most appropriate features for further use as guides in nerve repair were found for PLA-b-PHEA presenting a sufficiently short PHEA block (PLA-b-PHEA of 85/15 wt% composition). Schwann cell adhesion on the latter copolymer substrate was improved, when compared to PLA homopolymer. No cellular death was observed after 7 days of culture.

Then, using a electrospinning process we were able to prepare a micro tube from the PLA-b-PHEA copolymer (figure 1).

Figure 1 : Scanning Electron Microscopy (SEM) pictures of the tube made from PLA-b-PHEA copolymers

Conclusion

We focused in study on the properties of novel hydrophilized PLA based materials, namely PLA-b-PHEA copolymers, in terms of degradation and Schwann cell adhesion. The obtained results show the potential of such biodegradable materials for further use in nerve guides. In vivo rat nerve regeneration experiments are currently under investigations.

e-mail: ivanchev@SM2270.spb.edu

-The presented studies relate to the development of the synthetic approaches to obtaining polymer hydrogels featuring with a "memory" effect to antibiotics of cephalosporine and fluoroquinolone classes, characterization of sorption-desorption properties of the prepared hydrogels and obtaining therapeutic soft contact lenses (SCL) on their basis.

The hydrogels with a "memory" effect were synthesized by reacting 2-hydroxyethyl methacrylate with anionic and cationic functional comonomers using a template method in the presence of a drug extracted after the synthesis and crosslinking agents in high concentrations.
Sorption and diffusion characteristics of water and target drugs in the studied hydrogels are studied. The intrinsic parameters are determined for total, non-specific and specific sorption of the drugs by the hydrogels.
The "memory" effect is expressed as an enhanced drug sorption by the developed hydrogels in comparison with conventional hydrogels of the same composition. This phenomenon is primarily determined by a specific morphology of the hydrogels formed at the template synthesis of the copolymer in the presence of the target drug.
The considered effect is mostly prominent for cationic hydrogels but also observed for anionic and ampholitic ones. The obtained hydrogels with a "memory" effect are also featured with a prolonged drug release compared to the conventional hydrogels.
The nanostructure features of the synthesized hydrogels and effect of cephazoline immobilization at the synthesis upon their structure are studied using a small angle neutron scattering.
The developed hydrogels are shown to be efficient as polymeric carriers for drugs in therapeutic SCL saturated with three different types of drugs. The SCL based on these hydrogels are featured with an advantageous possibility to a controllable drug release into the internal structures of the eye.

Synthesis and characterization by lipase-catalyzed ring-opening polymerization of poly(ε-caprolactone) with different reaction mediums

Erhan Özsağıroğlu, Banu İyisan, Yüksel Avcıbaşı Güvenilir

ozsagiroglu@itu.edu.tr

Introduction

The development of lipase catalyzed ring opening polymerization in organic solvents has an important consideration [1]. Especially, synthesis of poly(ε-caprolactone) (PCL) is one of them because PCL has different kind of applications in biomedical area. In these reactions immobilized *Candida antarctica* lipase (Novozym 435) usually would rather than other kind of lipase enzymes. It provides higher conversions with different reaction mediums.

Previous experiments changed monomer or enzyme concentration in reactions or different solvents at one specified reaction temperature [2-4]. This work examined the effects of different reaction mediums were obtained with chancing of temperature, time and solvent types at the same time. The main purpose of the experiment is observing molecular weight distribution of polymer and understands optimum conditions of reaction mechanism with distinct mediums. Three different reaction temperatures and three different solvent types were studied in the present work. Reactions were carried out 40 ^{o}C, 60 ^{o}C and 80 ^{o}C and n-hexane, toluene and diisopropyl ether were used as solvents. Moreover, experiments were undertaken different time periods which 2h, 4h, 6h, 17h, 24h, 48h, and 72h respectively. Along the all reactions monomer, solvent and enzyme concentrations were same. For 1 ml monomer/solvent solution (0.44 M monomer and 0.56 M solvent) and 10 mg lipase were used in the experiments. All samples were analyzed by GPC and H-NMR to obtain molecular weight, conversion and chemical structures. Thermal behaviors of samples were analyzed by DSC to examine and compare polymers with one to another.

Materials and Methods

Candida antarctica lipase B, Novozym 435, (7000 PLU/g), an immobilized enzyme, was used at all reactions. ε-caprolactone was dried by activated molecular sieves before use. Organic solvents for reactions are n-hexane, toluene and diisopropyl ether.

All samples were analyzed by gel permeation chromatography (GPC). GPC was calibrated by polystyrene standards. THF was used as the eluent at a flow rate of 1 ml/min at 25 ^{o}C.

The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker NMR spectrometer (250 MHz for ^{1}H NMR) and a Varian Inova 500 spectrometer (125.66 MHz for ^{13}C) using $CDCl_3$ as solvent and tetramethylsilane as an internal standard.

Differential Scanning Calorimetry (DSC) was used to analyze changing of thermal transition temperatures of polymer samples. The device model of DSC is Perkin Elmer Diamond.

ε-caprolactone were dried activated molecular sieves and a mixture (1 ml) 0.44 M monomer in n-hexane, toluene, isopropyl ether and 10 mg lipase were used in the experiments. At the end of time, reaction solution was taken and chloroform terminated by adding an excess of chloroform and removing the enzymes by filtration. The chloroform in the filtrate was in large part removed by evaporation and the polymer in the concentrated solution was precipitated in methanol. The samples were dried in an oven. Finally all samples were analyzed by GPC, NMR and DSC.

Results and Discussion

Candida antarctica lipase catalyzed ring opening polymerization of ε-caprolactone were performed in n-hexane, toluene and isopropyl ether at 40 ^{o}C, 60 ^{o}C and 80 ^{o}C with same monomer/enzyme concentrations. Analyses were made and molecular weight distributions versus time and monomer conversion versus time were figured for all solvents and temperatures. Figure 1 shows maximum M_n values for all solutions at 40 ^{o}C, 60 ^{o}C and 80 ^{o}C respectively.

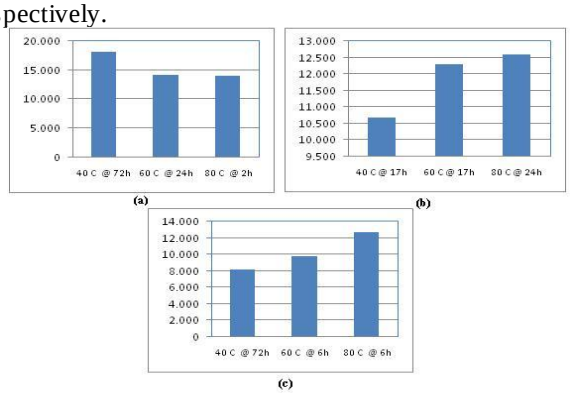

Fig. 1. Maximum M_n values at different reaction mediums (a) toluen (b) diisopropyl ether (c) n-hexane

Conclusions

Rising of molecular weight was resulted from increasing of reaction temperatures. Moreover, solvent types and reaction time has greatest effects on monomer conversions.

Polyesters from Natural Macrolactones for Biomedical Applications

I. van der Meulen[1], *C.E. Koning*[1], *A. Heise*[1], *R. Deumens*[2]

[1] Eindhoven University of Technology, [2] Maastricht University Medical Centre

i.v.d.meulen@tue.nl

Introduction

An interesting new class of materials is derived from macrocyclic lactones, which belong to the class of naturally occurring macrocyclic musks and are frequently used in the fragrance industry. Their eco-friendliness led to an increased demand and the development of improved synthetic routes. The goal of our research is to develop biocompatible synthetic routes to polymers from these natural monomers (Figure 1), investigate their properties and position them among other biomaterials in order to identify possible application areas. This paper will summarize our results on this interesting class of polymers.

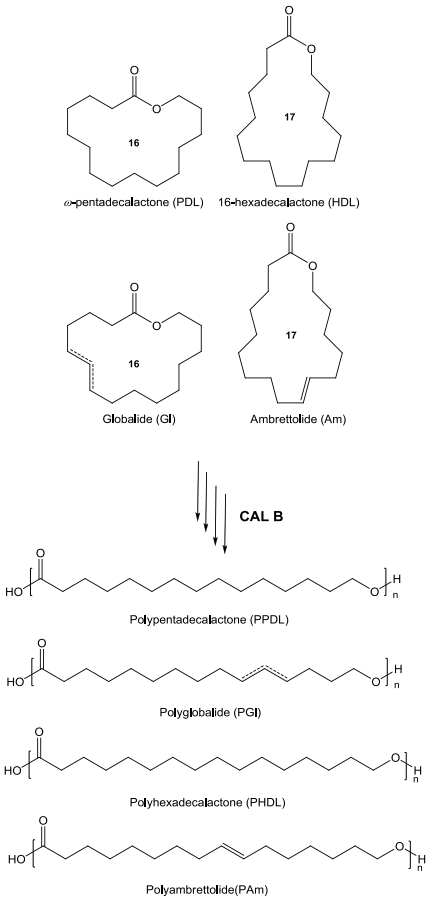

Figure 1: Structures and polymerization of various macrocyclic lactones, which form the basis of a new materials platform.

Results and Discussion

One example of such a biocompatible polyester is semi-crystalline poly(ω-pentadecalactone) (PPDL), which resembles the properties of low density polyethylene (LDPE).[1] Applying enzymatic catalysis we obtained PPDL with exceptionally high molecular weight of >300,000 g/mol (M_w). These were spun into fibers (Figure 2) revealing a tensile strength of around 0.7 GPa after elongation.[2]

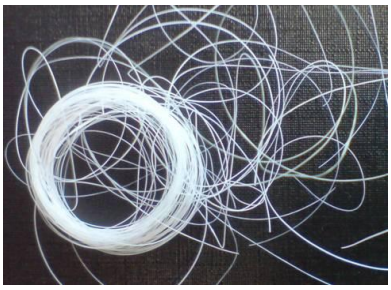

Figure 2: Fibers obtained from high molecular weight poly(ω-pentadecalactone).

The interesting structural features and properties of polymers derived from macrolactones prompted us to investigate their potential for biomedical products. Polymers were obtained via enzymatic ring opening polymerization from unsaturated macro-lactones such as globalide and ambrettolide.[3] Biocompatibility tests confirm that these polymers can be classified as non-toxic. While initially semicrystalline, thermal cross-linking of the polymers via the main chain double bonds in the solid-state produced fully amorphous materials. The degradation of the homo-polymers in buffer solution revealed the high hydrolytic stability of the materials, which can, however, be modulated by copolymerisation. By choosing the right conditions of the polymerization process and the post-polymerization methods, properties such as crystallinity, material strength, degradability (rate and percentage) and hydrophilicity can be controlled.

Conclusion

Applying this highly applicable biocompatible synthetic route to synthesize polyesters, a platform of new biomedical materials is created in which material properties can easily be tuned for the desired product.

Developing and Evaluating Mucoadhesive Polymers and Mucosa-Mimetic Materials

Vitaliy Khutoryanskiy

University of Reading, Reading School of Pharmacy, Whiteknights, PO Box 224, Reading RG6 6AD, United Kingdom

v.khutoryanskiy@reading.ac.uk

Introduction: Mucoadhesion is defined as interfacial force interactions between polymeric materials and mucosal tissues, the moist surfaces lining the walls of various body cavities such as gastrointestinal, respiratory and reproductive tracts as well as the mouth, the eyes and the nasal cavities. [1]. In this communication we will discuss our experiments on design and evaluation of various mucoadhesive dosage forms and polymeric materials able to mimic mucosal tissues.

Materials and Methods: We have studied the mucoadhesive properties for a number of polymers such as linear and weakly cross-linked poly(acrylic acid) (PAA), chitosan, various copolymers of [2-(methacryloyloxy)ethyl]trimethylammonium chloride (MADQUAT) as well as their blends with cellulose ethers. Interactions between polymers and porcine gastric mucin in solutions were studied by dynamic light scattering, zeta-potential measurements, transmission electron microscopy and turbidimetric titration. Mucoadhesive properties were studied by tensile (detachment) technique for solid dosage forms and flow-through method for liquid and semi-solid dosage forms

Results and Discussion: Investigation of the solution behaviour of chitosan and amphiphilic copolymers of MADQUAT in mixtures with porcine gastric mucin revealed a complex nature of specific interactions including electrostatic attraction, hydrogen bonding and hydrophobic effects [2, 3]. The strength of these interactions was found to be dependent on the structure of polymers and environmental conditions (solution pH, presence of inorganic ions and organic molecules). Studies of interactions between polymers and porcine gastric mucin in solutions allowed understanding and predicting mucoadhesive properties of dosage forms.

Mucoadhesive films were formulated based on blends of poly(acrylic acid) (PAA) and chitosan with cellulose ethers [4, 5]. It was demonstrated that careful selection of solution pH allows avoiding phase separation in PAA-cellulose ether blends caused by interpolymer complex formation and helps preparing homogeneous materials by casting technique. It was established that the mucoadhesive properties of the films are highly dependent on the component ratio in the blends and reduced with cross-linking of polymers.

Mucoadhesive tablets were prepared based on chitosan, half-acetylated chitosan, weakly-cross-linked poly(acrylic acid) (Carbopols®) and their blends with hydroxypropylmethylcellulose (HPMC) using direct powder compression. Mucoadhesive properties of tables were found to depend on the degree of deacetylation in chitosan, presence of model drug (ibuprofen) in the tablets and polymer ratio for Carbopol®/HPMC.

Weakly cross-linked derivatives of poly(acrylic acid) or Carbopols® in addition to excellent mucoadhesive properties exhibit unique gelation behaviour, which can be easily triggered by changes in solution pH [1]. We have shown that formation of gels in situ depends on the type of Carbopol® (71G, 940, 971PNF, 974PNF and 980NF) and presence of inorganic ions in solutions. The applicability of these polymers to provide a retention effect on the surface of ocular mucosa has been demonstrated.

Two types of hydrogels have been prepared as materials mimicking animal mucosal tissues using the following approaches: (1) Layer-by-layer (LbL) deposition of poly(acrylic acid)-methylcellulose complexes on glass surfaces with their subsequent cross-linking by thermal treatment [6, 7]. It was demonstrated that LbL approach allows preparing ultrathin hydrogel coatings with highly controlled thickness. (2) Three-dimensional copolymerisation of 2-hydroxyethylmethacrylate with 2-hydroxyethylacrylate, N-vinyl pyrrolidone, sorbitol methacrylate, and N-acryloyl glucosamine [8, 9]. Both types of hydrogels were evaluated as potential substrates to mimic mucosal tissues in experiments with mucoadhesive tablets based on Carbopol®940 and its blends with HPMC. The adhesive properties of these materials were also compared with porcine buccal mucosa, glass, polypropylene, polystyrene and polytetrafluoroethylene. It was demonstrated that synthetic hydrogels have some potential to mimic porcine buccal mucosa and the degree of their swelling, mechanical properties and chemical nature of polymers have a strong effect on the ability of these materials to mimic mucosal tissues.

Conclusions: Hydrophilic functional polymers show an excellent potential for developing mucoadhesive dosage forms for drug delivery and materials mimicking animal mucosal tissues.

e-mail:filippov@imc.cas.cz

We report a rigorous investigation of detailed structure of nanoparticles that were already proved as a successful drug delivery nanocarrier. The basic structure of the drug conjugates consists of HPMA copolymer bearing anticancer drug doxorubicin (Dox) bound via the pH-sensitive hydrazone bond and a
defined amount of cholesterol moieties differing in their hydrophobicity (Figure 1, Table 1).

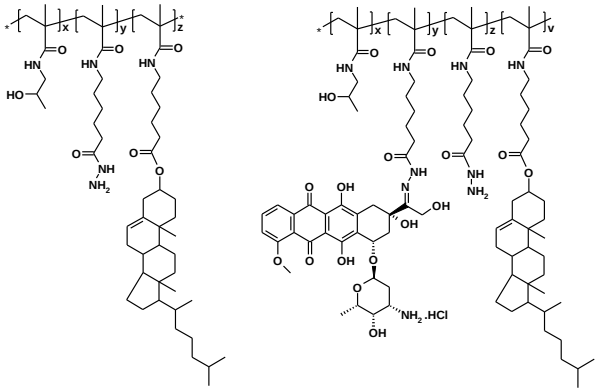

Fig. 1. The Chemical structure of conjugates.

Our study of dilute solutions of conjugates in phosphate buffer at pH5.0 and 7.2, examined by dynamic and static light scattering (DLS/SLS), small-angle X-ray and neutron scattering (SAXS and SANS), prove that the content of cholesterol has a strong influence on the system. We established that the presence of any amount of cholesterol results in formation of anisotropic nanoparticles (Figure 2).

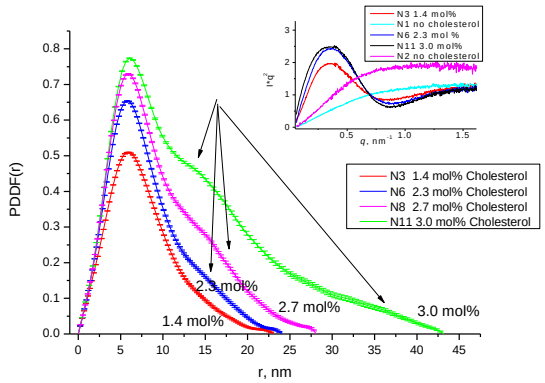

Fig. 2. Pair-distance-distribution function for the polymer N3, N6, N8, N11 at pH=5.0. Inset: Kratky plot for some polymers.

Obtained results show that the size and anisotropy of the nanoparticles grow with increase of the amount of cholesterol moieties i.e. the higher content of cholesterol groups, the higher asymmetry of a nanoparticle (Figure 3).

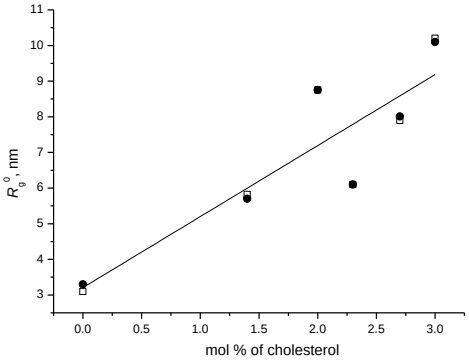

Fig. 3. The gyration radius R_g^0 extrapolated to infinite dilution as a function of cholesterol content .(●) pH=5.0; (□) pH=7.2

The similar tendency have hydrodynamic radius R_h^0 and aggregation number N_{aggr} determined by DLS and SLS methods. SAXS and SANS experiments allowed us to determine the three-dimensional low-resolution structure of the nanoparticles composed of HPMA-cholesterol conjugates (Figure 4).

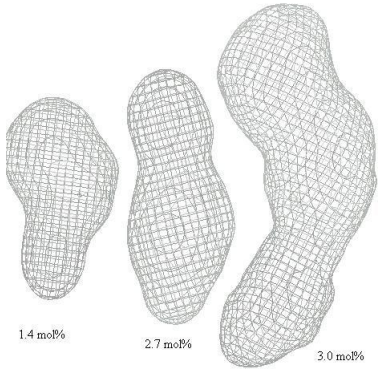

Figure 4. Ab-initio reconstructed molecular structure of nanoparticles with different content of cholesterol moieties.

Photo cross-linked and pH-sensitive polymersomes as bionanoreactors

Introduction:
Polymersomes consist of amphiphilic block-copolymers, which form vesicles upon a self assembly process. They show a higher mechanical and chemical stability than lipid vesicles and a great potential in synthetic biology or as drug delivery systems. The higher stability also leads to a complete loss of diffusion traffic through the polymer membrane. Usually this is overcome by incorporating transmembrane proteins into the polymersome wall. In contrast to this approach, we combine photo cross-linkable and pH sensitive monomers within the hydrophobic part of our amphiphilic block-copolymer.[1] The pH sensitivity of the polymersomes will lead to a triggered swelling and thus changes in diffusion behaviour of the membranes.

Materials and Methods:
We adapted the well-known pH-sensitive poly(ethyleneglycol)$_{45}$-block-poly(diethylaminoethyl-methacrylate)$_{81}$ (PEG_{45}-b-$PDEAEM_{81}$)[2] and integrated the photo-crosslinker 3,4-dimethyl maleic imidoethyl methacrylate[3] (DMIEM) in the hydrophobic part of the block copolymer. This resulted in a PEG_{45}-b-PDEAEM-s-PDMIEM block-copolymer with 10 mol% of DMIEM.

Results and Discussion:
The resulting polymers yielded polymersomes of approximately 100 nm in size, if produced via self-assembly in water. A production of vesicles using electroformation resulted in giant vesicles of sizes up to 100µm. (Fig. 1)

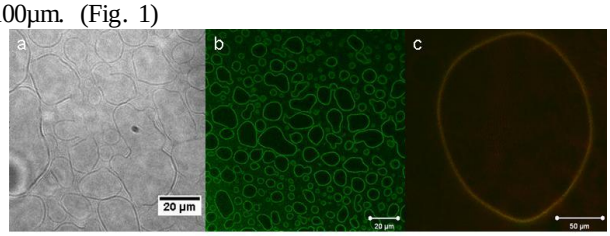

Figure 40: Bright field image of large polymersomes (a), fluorescence images of large (b) and giant (c) polymersomes

So far, only vesicles produced without electroformation showed effective cross-linking. These cross-linked vesicles show a definite pH sensitive behaviour around pH 7 by swelling in size. To check the permeability of the membrane, a solution of rhodamine B was subjected to an acidic solution of cross-linked vesicles and subsequently dialysed in basic conditions. Here, some dye still remained in the sample, while a blank sample of pure rhodamine B did not show any remaining dye after 2 days of dialysis proving effective dye enclosure (Fig. 2).
As a next step the polymersome was used as carrier for larger guest molecules. Therefore, an acidic solution of the starting polymer was mixed with dye-labeled and maltose-decorated polyethyleneimine (PEI-Mal)[4] hyperbranched polymer as a guest molecule. Upon switching to basic pH values, the PEI-Mal was partially incorporated into the vesicles. The remaining non-incorporated guest molecules were removed via dialysis. Again, a comparison with a dialysis of a pure PEI-Mal solution was carried out and revealed remaining, e.g. encapsulated, guest molecules (Fig. 3) in the polymersomes.

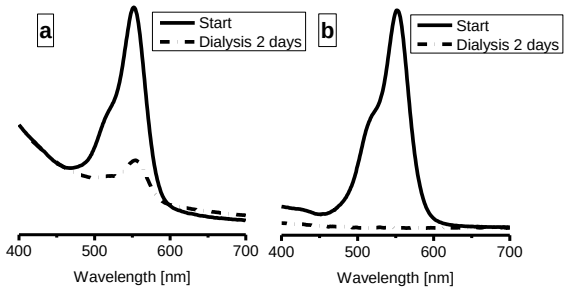

Figure 41: Dialysis with UV-Vis monitoring of rhodamin B entrapped in the vesicles (a) and pure rhodamine B (b).

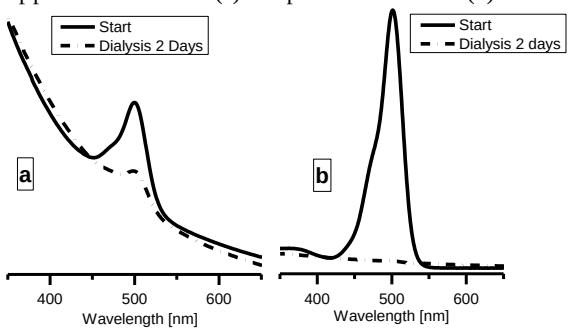

Figure 42: Dialysis with UV-Vis monitoring of dye labelled PEI-Mal entrapped in the vesicles (a) and as pure solution (b)

Conclusions:
We established a polymersome-based carrier system which enables controlled diffusion traffic through the membrane. Furthermore, large guest molecules can be incorporated into the vesicles. In further studies we want to apply our pH sensitive polymersomes as synthetic bionanoreactors for real biological questions by introducing enzymes into the polymersomes and inducing an enzymatic reaction at its substrate.

The introduction of chirality within dendritic architectures has been attracted significant attention. Naturally occurring chiral building blocks such as amino acids, carbohydrates or oligonucleotides as well as synthetic monomers have been used to construct different types of chiral denrimers. Several potential applications of these chiral dendritic structures have been also envisaged such as molecular recognition processes, sensor technologies and catalysis.[1]

Here we introduce a facile and simple method to synthesize novel chiral dendrimers, which respond to enantioselective enzymatic modification as a function of their chiral composition.

In this study, first an azide functional 2,2-bis(methylol)propionic acid (bisMPA) dendrimer with 24 chain end functionality were synthesized. Then *(R)* and *(S)*-1-(4-ethynylphenyl) ethanol) were obtained via enantioselective enzymatic reductions and used as enantio-pure building blocks. These molecules bear both an alkyne functionality (for click reactions) and a chiral enzyme sensitive unit, i.e. phenyl ethanol, (for enzyme responsiveness). The periphery of the azide functional dendrimers was decorated with these building blocks via the copper(I)-catalyzed azide-alkyne cycloaddition ("click" reaction) (Figure 1). In these cycloaddition reactions, different ratios of enantio-pure building blocks were utilized changing from (R:S) 100:0 to 0:100. This resulted in chiral dendrimers with different chiral surface functionalities. When exposed to *(R)*-selective CALB enzyme (Novozyme 435) in an esterification reaction with vinyl acetate, the chiral composition encoded in the periphery of the dendrimers was successfully read-out by the enzyme, measured as the extent of the esterification reaction. The chirality of the dendrimers and the dependency of the enzymatic response to chirality are depicted in Figure 2 and Figure 3 respectively.

The development of new medical therapies involving the cellular delivery of biomolecules strongly depends on the development of efficient vehicles for encapsulation and cellular delivery. Watersoluble polypeptides are a good alternative to oil-based synthetic polymers for biomedical applications because they are biodegradable, have low toxicity, are monodisperse, and can be produced from cheap and renewable substrates at a large scale. Furthermore, functional designs can take direct inspiration from naturally evolved proteins.

For the particular case of nucleic acids delivery, viruses are the obvious benchmark. Viral capsid proteins present domains that display different functionalities necessary for an effective co-assembly with the nucleic acids (e.g. colloidal stability, self assembly and electrostatic binding). A good candidate for mimicking the functionality of viral coat proteins are unique polypeptides: these present a modular design that can be built by genetic engineering allowing insertion of independent functionalities in a linear sequence.

In this study we reported the cloning, production and characterization of one of these unique polypeptide carrying colloidal stability and DNA binding blocks (fig 1).

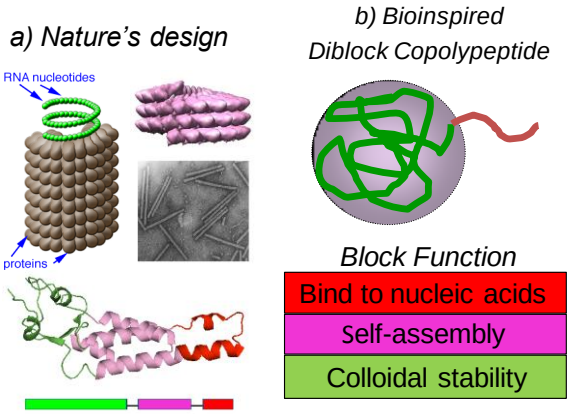

Figure 43. Biomimetics of nucleic acid-protein complexes A) Tobacco Mosaic Virus-RNA assembly B) Design of our virus-inspired diblock asymmetric copolypeptide.

The DNA binding properties were characterized by Dynamic Light Scattering and Atomic Force Microscopy (fig 2 & 3). It was found that this unique polypeptide results in controlled coating of single DNA molecules, as is the case for viral capsid proteins. The present design is intended to be a framework for adding further functional blocks to make further steps in mimicking the functionality of viral capsid proteins. Next to the above mentioned functionalities, also a high efficient production route towards this polypeptide is reported.

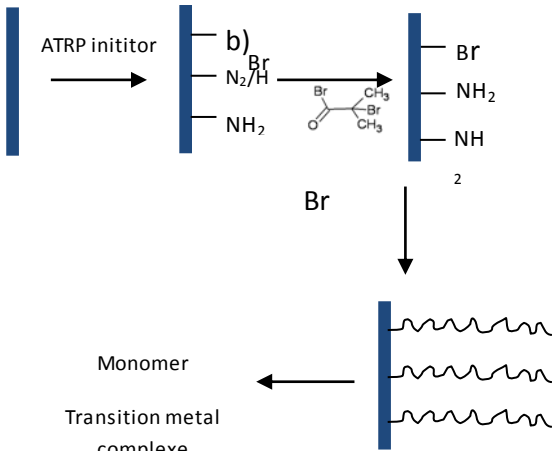
Jessie.casimiro@u-psud.fr

Control surface contamination by microorganism is of great concern in a variety of areas such as food packaging, medical devices, hospitals and so on. To reduce or prevent microbial adhesion, new polymer surfaces must be developed. In this context, we investigate a new theme which deals with the modification of polymer materials containing carbohydrate molecules. [9, 10, 11] The aim of the study is to attach covalently glycopolymers or potential antimicrobial polymers on films of polyethylene terephthalate (PET) or polypropylene (PP) in order to study the biocidal or anti-fooling properties. Indeed, grafting glycopolymers on PP fibers have brought anti-fooling properties. [12]

The surfaces are prepared in several steps:



Preparation of materials

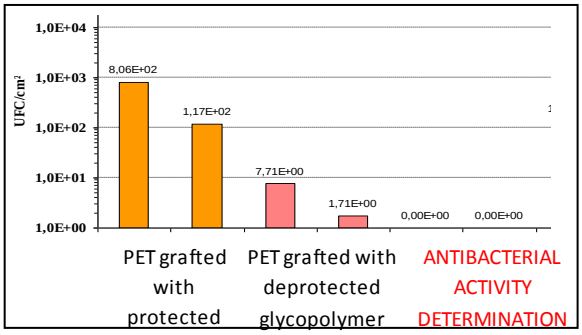
Step 1: Incorporation of primary amino groups by N_2/H_2 or NH_3 plasma treatment. The pretreatment by plasma exhibits many benefits for the surface modification, which enables to introduce functional groups at the surface without any modification of the chemical and mechanical properties of the material during the process.

Step 2: Insertion of Atom Transfer Radical Polymerization (ATRP) initiator

Step 3: Grafting from surface polymerization method of a monomer in order to control the molecular weight distribution on the surfaces. ATRP parameters of glycomonomers are studied in solution before carrying polymerization on surfaces.

Step 4: Microbial adhesion tests of modified surfaces with *Bacillus Subtilis* and *Lactoccocus Lactis* as bacterial strains.

Several analytical techniques such as X-ray photoelectron spectroscopy (XPS), Atomic Force Microscopy, size exclusion chromatography of polymers obtained in solution have been used to characterize the modified surfaces. The first step was to optimize plasma parameters in order to have a high density of primary amino group on the surfaces. Then several monomers have been studied especially a glycomonomer from galactose. Protected and deprotected glycopolymers polymerized on PET surfaces exhibit anti-fooling properties toward *Bacillus Subtilis*.



Results of counting of Bacillus Subtilis after 3 hours of adhesion at 30 °C on modified PET

Polymers containing quaternary ammonium salt or fluor have also been successfully polymerized by a grafting from method on PET films. Monomers from glucosamine are under consideration to mimic antimicrobial properties of chitosan.

e-mail : jayhkim@yonsei.ac.kr

Core-shell type nanofibrous scaffolds were prepared using coaxial electrospinning. Poly(ε-caprolactone) (PCL) and chitosan with Levofloxacin was used as shell and core respectively, so the antibiotics Levofloxacin electrospinning would be useful for medical applications to treat acute rhinitis. PCL was used to control the release of Levofloxacin with time. SEM, TEM, and fluorescence microscope were used for the surface characterization of the core-shell fiber and the diameter measurement of the fiber core and of the total fiber. The core-shell interface was smooth and its structure was clearly visible by TEM. The total fiber diameter was about 200 nm while the core diameter was about 100 nm. 20 mg of nanofibrous scaffolds were soaked in PBS solution at 37 ℃ and the release of Levofloxacin with time was monitored by UV adsorption measurement at 331.20 nm. Since the PCL shell allowed the controlled release of Levofloxacin without an initial burst, the antibiotics-loaded core-shell type nanofibrous scaffolds show promise for treatment of wounds cause by acute rhinitis.

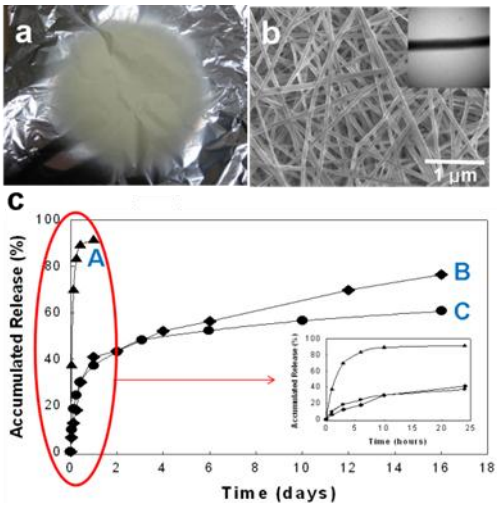

Fig.1 (a) Digital photo image of core-shell type nanofibrous scaffolds after coaxial electrospinning. (b) SEM and TEM images of core-shell type nanofibrous scaffolds. (c) Antibiotics release behavior of (A) PCL + gelatine + antibiotics nanofibrous scaffolds with single nozzle electrospinning, (B) PCL / chitosan + antibiotics nanofibrous scaffolds with dual nozzle electrospinning, (C) PCL / only solvent + antibiotics nanofibrous scaffolds with dual nozzle electrospinning.

Vinyl Sulfonate Terminated Polyglycidol for Biomedical Applications

haamann@dwi.rwth-aachen.de

During the last decade, polyglycidols and their derivates have gained much attention in biomedical applications due to their high functionality, solubility in aqueous media and biocompatibility.[1-3] Formation and application of synthetic materials in contact with biological matter remains a substantial challenge in today's biomaterial research. Therefore the combination of peptides/proteins or polypeptides with synthetic materials has gained raising interest during the last couple of years. Various reactive groups have been studied for the synthesis of polymer-peptide conjugates, e.g. maleimides or acrylates. Recently we reported the synthesis of a vinyl sulfonate terminated, linear and star-shaped polyglycidol as well as their high reactivity towards amines in organic and aqueous solution.[4-6]

In this presentation, the use of vinyl sulfonate terminated, star-shaped polyglycidol for various biomedical applications will be highlighted.

One application of the vinyl sulfonate terminated, star-shaped polyglycidol is the generation of reactive fibers in the sub-micron range for tissue engineering by electrospinning from functionalized polyglycidol/poly(ε-caprolactone) blends as shown in figure 1.[7]

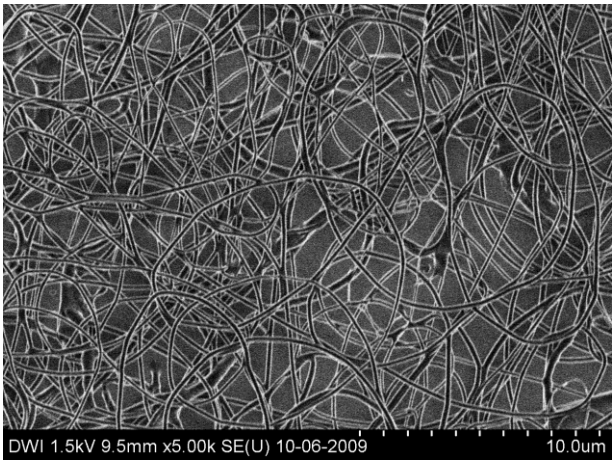

Figure 1: Electrospun fibers from polyglycidol/poly(ε-caprolactone) blends

These fibers can be further equipped with bioactive compounds using the high reactivity of the functionalized polyglycidol as shown exemplarily by reaction with an amine-group containing, fluorescent dye as shown in figure 2.

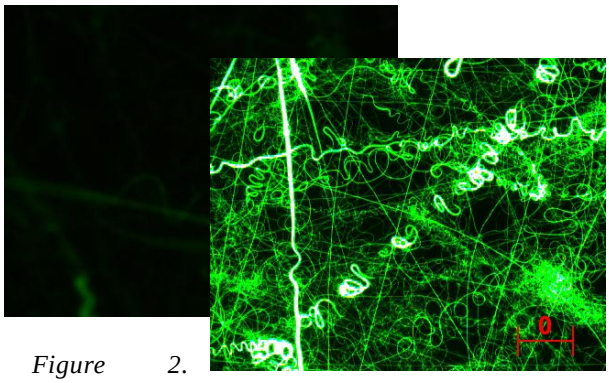

Figure 2. Fluorescence image of fibers from PCL/sPEEGE blends with no specific end groups (back) and vinyl sulfonate end groups (front) at the sPEEGE after incubation with (*R*)-(-)-4-(3-amino¬pyrrolidino)-7-nitro-benzofuran in water.[7]

Additionally, results including the use of vinyl sulfonate terminated polyglycidols for the formation of hydrogels and for hydrophilic surface coatings to minimize the unspecific protein adsorption will be presented.

Biosynthesis – Structure – Property Relations for Branched Polysaccharides as Revealed by Two-Dimensional Macromolecular Size/Branch Chain-Length Distributions

Francisco Vilaplana, Mitchell A. Sullivan, Jovin Hasjim, Robert G. Gilbert

Centre for Nutrition and Food Sciences, University of Queensland, 4072 Brisbane, QLD, Australia

f.vilaplana@uq.edu.au; franvila@kth.se

Introduction

Branched polysaccharides based on repeating glucose units, especially starch and glycogen, are fundamental energy storage molecules in plant and animal tissues, with significant influence on nutrition and human health. In addition, starch serves as a basic raw material for numerous industrial applications. Obtaining (bio)synthesis/(bio)degradation – structure – property relations of these molecules is fundamental to understand their functionality in biological systems and to tailor their properties through (bio)synthetic and physico-chemical modification. The structure of these polysaccharides involves a hierarchical organization at different levels: (1) the individual branches, (2) the whole branched macromolecules, and finally (3) supramolecular organizations such as crystalline and amorphous lamellae in starch, or α and β particles of glycogen [1]. Starch and glycogen are homopolymers of anhydroglucose, where the α-D-glucopyranosyl monomeric units are lineally extended by (1→4) linkages and branches are formed by (1→6) bonds at the branching points. However, this simple monomeric structure turns into a very complex branched macromolecular architecture that has defied complete characterization.

An unambiguous structural characterization of complex branched macromolecules requires multidimensional distributions based on the size and number of branches, and the position of these branches within the macromolecule [2]. Current available characterization procedures, such as size separation techniques coupled to multiple detectors (e.g. differential refractive index, viscometry or light scattering) only provide one-dimensional projections. Two-dimensional structural distributions based on macromolecular and branch size are presented here, obtained by offline multidimensional size-exclusion chromatography (SEC) and enzymatic debranching. The implications of such 2D distributions on the properties and (bio)synthetic pathways will be discussed for native rice starch, high-amylose starches, and glycogen.

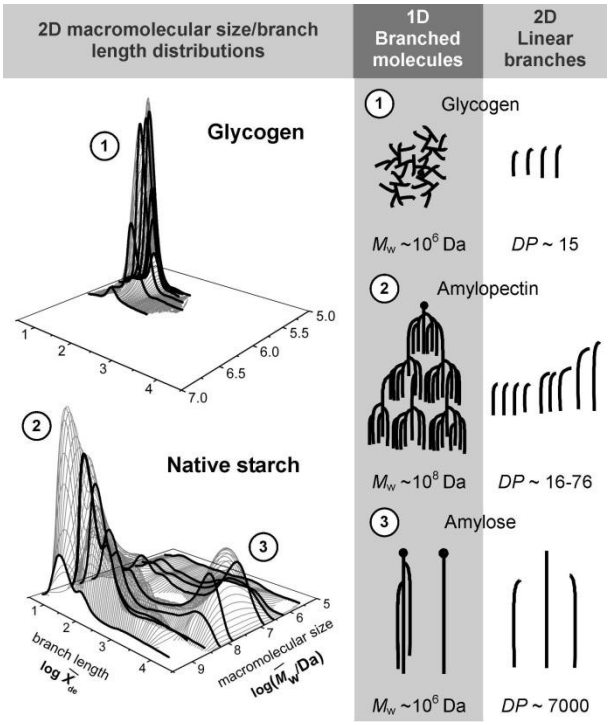
Materials and methods

Commercial oyster glycogen (Sigma Aldrich, MI, USA), native starch from Malaysian rice flour (MRQ74, MARDI, Kuala Lumpur, Malaysia), and high-amylose maize starches (RMS, Gelose 50 and Gelose 80, Penford Food Ingredients Co., CO, USA) were used.

The 2D distributions were obtained by an analytical procedure combining size fractionation by preparative SEC, enzymatic debranching with isoamylase, and analysis of the branched and debranched fractions by analytical SEC with multiple detection (refractometry, viscometry and light scattering) [3].

Results and discussion

The 2D macromolecular size/branch chain-length distributions show distinct topological features for the macromolecular populations found in glycogen and native starch (see Figure). Glycogen shows a symmetrical monomodal peak, related to a single and homogeneous population of branches independent of macromolecular sizes. Starch, on the other hand, exhibits a complex surface with different peaks and foothills that differ in macromolecular size and branch length, corresponding to the main amylopectin and amylose populations, and also minor hybrid components (e.g. amylopectin with extra-long chains, intermediate components). Different starch varieties and mutants (e.g. high-amylose starches with longer branches and proven nutritional benefits) exhibit variations in the relative presence of these distinct macromolecular populations in their 2D distributions.



These 2D distributions reveal new knowledge on the biosynthetic pathways for glycogen and starch, with important future potential for biomedical, nutritional and industrial applications.

Compositionally-tunable surface nanostructuration of microspheres obtained from a self-stabilizing copolymerization of methylmethacrylate and vinylpyrrolidone

*Inmaculada Aranaz, Helmut Reinecke, Carlos Elvira, Alberto Gallardo**

Instituto de Ciencia y Tecnología de Polímeros, ICTP (CSIC). Juan de la Cierva 3, 28006 Madrid

gallardo@ictp.csic.es*

Introduction

Polymethylmethacrylate (PMMA) particles have been used in both biomedical and technological applications.12 They are commonly prepared by different heterogeneous polymerization processes being the use of surfactant molecules needed to stabilize the PMMA particles. Amphiphilic polymers as polyvinylpyrrolidone (PVP) 3 are typical surfactants used for this purpose. PVP has also many technological and biomedical applications. In this work, it is shown that MMAbased microparticles can be easily prepared in a simple and non demanding onepot procedure from copolymerization in methanol of MMA with VP, the monomeric precursors of the solid core and the polymeric surfactant mentioned above. This copolymerization leads to a high compositional heterogeneity, which actually allows the technology described in here.

Materials and Methods

Copolymerizations of MMA and VP were carried out under stirring (60º C, 24 hours,AIBN) by standard free radical reactions in different solvents (methanol, 1propanol, ethanol or dioxan). Emulsion drops formed in the reaction were hardened under vigorous magnetic stirring by slowly dropping water on the emulsion. The solutions were centrifuged and the centrifugate was resuspended in pure water. Three compositions have been studied, labeled as *MV21*, *MV11* and *MV12*, which corresponds to MMA initial feed molar fractions of 0.33, 0.5 and 0.67 respectively. Composition was determined by 1HNMR. Particles morphology and size was determined by SEM and by using a particle size analyzer.

Results and Discussion

Copolymerizations of MMA and VP on alcohols leads to a phase separated system. The high compositional heterogeneity of the reaction allows the partitioning of the copolymer chains between two phases as a function of their composition (MMArich and VPrich Chains forming the dispersed and continuous phases respectively). This emulsion can be easily hardened by adding water (Figure 1). The final result is a hydrophobic solid particle stabilized by some amphiphilic chains rich in VP. Thus, this copolymerization of MMA and VP is selfstabilizing. SEM analysis at higher magnification has shown a surprising irregular surface nanostructuration. Interestingly, changes in feed compositions leads to different sizes of the nanostructurated domains. As the amount of VP increase in the feed, these structures are bigger. Thus, the morphology is somehow compositionally driven (Fig 2).

Table 1. Samples composition and particle characterization.

Sample	f_{MMA}-copolymer phase-1[a]	f_{MMA}-copolymer phase-2[a]	Average diameter of particles[b], µm	PSD (D_w/D_N)
MV21-Me	0.79	0.41	5.570	1.91

MV11-iPr	0.73	0.54	nd[c]	nd[c]
MV11-d	No phase separation		nd[c]	nd[c]

Me: MeoH, Et: EtOH, iPr: 1-propanol

a)Molar fraction of MMA in the copolymer as obtained from the NMR analysis.
b)Average diameter of the particles measured by using a Coulter.
c) nd: no-determined

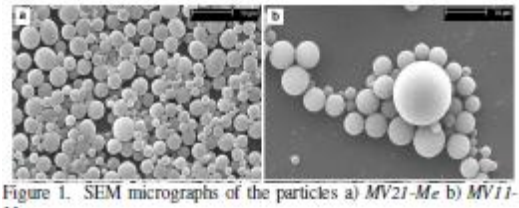

Figure 1. SEM micrographs of the particles a) *MV21-Me* b) *MV11-Me*

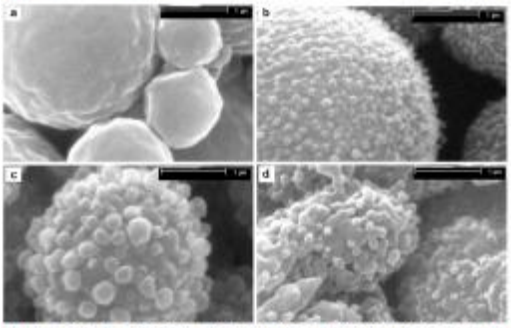

Figure 2. Details of particles surface a) *MV21* -Me b) *MV11-Me* c) *MV12-Me* d) *MV11-d.*

Conclusion

This work shows that the differential reactivity of MMA and VP may also be an opportunity in polymer chemistry. A simple onepot procedure based on the copolymerization reaction of both monomers yields solid microspheres in water. These microspheres have exhibited an irregular surface nanostructuration with a size domain that is controlled by the comonomer composition in the copolymerization.

Introduction

The initial cellular events that take place at the biomaterials interface mimic to a certain extent the natural adhesive interaction of cells with the extracellular matrix (ECM). In fact, cells cannot interact directly with foreign materials, but they readily attach to the adsorbed layer of proteins such as fibronectin (FN), vitronectin (VN), fibrinogen (FG), representing the so-called soluble matrix proteins in the biological fluids. Upon longer contact with tissues many other ECM proteins, such as collagens and laminins (LN), will also associate with the surfaces, affecting the cellular interaction. The concentration, distribution, and mobility of the adsorbed protein layer on a surface play a fundamental role in the biofunctionality of a synthetic material and are clue factors to understand the biological response of a substrate. This work investigates ECM protein dynamics at the cell-material interface (FN, FG, VN, LN). Protein adsorption, cell adhesion and signaling and matrix remodeling are investigated after adsorption of model polymer substrates with controlled chemistry and surface stiffness.

Materials and Methods

The substrates employed are based on the random combination of monomers, which have either (i) a vinyl backbone chain with the side groups $–COOCH_2CH_3$ and $–COOCH_2CH_2OH$, or a vinyl backbone chain with the side groups $–COO(CH_2)_xCH_3$, with x=0, 1, 3, 5. Their copolymerization gives rise to a substrate in which the surface density of –OH groups can be varied without modifying any other chemical functionality of the system in the first case and with tailored surface stiffness in the second one. Plasma polymerization was also used for x=1 after different times. Surface properties were assessed by means of contact angle and X-ray photoelectron spectroscopy.

Protein adsorption (FN, FG, VN, LN) was performed from solutions of different concentrations (from 2μg/ml to 20 μg/ml) at different time points (from 10s to 2h). The amount of adsorbed protein on the substrates was obtained by western blot. AFM and ELISA were used to obtain protein conformation and distribution on the surfaces.

MC3T3-E1 cells were obtained from the Riken Cell Bank and cultured on the previously protein-coated substrates in serum-free conditions. Cell adhesion, actin cytoskeleton formation, intracellular signaling and matrix remodeling were correlated with the state of the protein layer on the material surface.

Results and discussion

The adsorbed amount of both FN and LN depends non-monotonically on the -OH density in the substrate, and protein surface density shows a minimum at approximately OH_{50}. Both higher and lower concentrations of hydroxyl groups in the substrate result in higher amounts of the adsorbed protein. The situation is completely different when either FG or VN is adsorbed on the same family of substrates. The amount of adsorbed protein diminishes monotonically as the OH density increases. The conformation of the adsorbed proteins can be directly observed by AFM. FN and FG tend to organize on the material surface, giving rise to protein fibrils. By contrast, cross-shaped molecules are observed for LN (which shows the change of conformation of the molecule upon adsorption) and globular aggregates are observed after VN adsorption (Figure 1).

On the other hand, the family of surfaces with different length of the side group (x=0-5), adsorbed the same FN density but in different conformations between x=0 (isolated molecules) and the other surfaces (well-interconnected network is formed). Consequently, this allows one to dispose of a set of substrates with stiffness as the main parameter able to influence the cellular behavior. Also, the conformation and amount of adsorbed FN was different on polymer surfaces obtained by plasma polymerization of x=1 after different times.

Cell behavior depends not only on the underlying chemistry, but also on the matrix protein used. Excellent adhesion is found for the more hydrophobic surfaces when using FN, FG and VN –even if they show different behavior in terms of conformation. By contrast, optimum cell interaction is found for OH_{50} if LN is used instead. Moreover, cellular reorganization of the adsorbed proteins depended on surface chemistry and was correlated to the state of the previously adsorbed protein layer and linked to the mechanical actions that cells exert on the substrate. To do that, the distribution of focal adhesion sizes was calculated. Larger focal plaques were found on those substrates on which reorganization took place more efficiently. Additionally, matrix secretion was related to reorganization abilities.

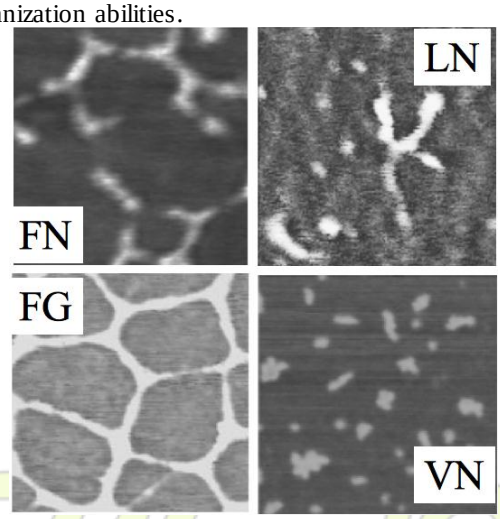

Figure 1. AFM images of ECM proteins adsorbed on substrates with controlled –OH groups from a solution of concentration 20 μg/mL.

Thermo-Responsive Self Assembled Nanoparticles from Elastin-Like Recombinamers

Laura Martín, Carmen García-Arévalo, F. Javier Arias, Matilde Alonso, J. Carlos Rodríguez-Cabello

GIR Bioforge, Universidad de Valladolid, CIBER-BBN, Paseo de Belén 11, 47010 Valladolid, Spain

e-mail: lmartin@bioforge.uva.es

In recent years, much interest has been focused on the performance of tailored stimuli-responsive self-assembled nanoparticles in aqueous solution due to their many important applications such as thickeners, coatings, drug- and gene-delivery systems, chemical or biological sensors and nanoreactors. Elastin-like recombinamers (ELRs) are made of pentameric repeat amino-acid sequences (Val-Pro-Gly-Xaa-Gly), where Xaa is any natural amino-acid except proline, or its permutations providing tunable physicochemical properties and excellent biocompatibility. This has led to extensive biological and nanotechnological applications of ELRs [1]. The absolute control over the design of ELRs allows facile manipulation of their stimuli-responsive properties and other physical and functional characteristics. Biosynthesis allows the production of strictly monodisperse polymers with no possibility of randomness in the comonomer distribution.

ELRs have shown their ability to form smart, self-assembling, protein-like micellar systems with controlled structure and function, which could be useful for drug targeting in therapeutic applications [2]. In this regard, we have biosynthesized different amphiphilic elastin-like di- and triblock corecombinamers in order to study the effect of the amino-acid composition and distribution. They are a combination of two different stimuli-responsive blocks. The first block is a pH-responsive smart polymer, and the other is a thermo-responsive polymer with no pH responsiveness [3]. We have changed the arrangement and length of the both blocks while keeping other parameters, such as the molecular weight or mean polarity, constant. The structure of the nanoparticles was investigated as a function of the temperature and concentration using turbidimetry, DLS and SLS, DSC and TEM amongst others in aqueous solution at neutral pH showing different nanostructures with several diameters The control over the molecular weight and the hydrophilic-to-hydrophobic ratio affords different nanostructures as micelles or vesicles with several sizes as well as control of the temperature at which self-assemble occurs (Figure 1).

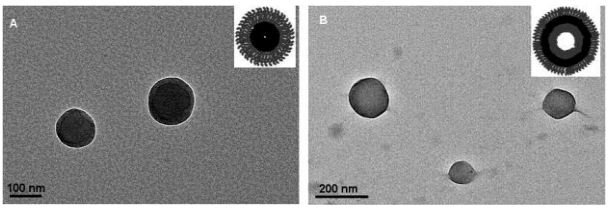

Figure 1. TEM images of micelles (A) and vesicles (B) obtained by self-assembling from elastin-like corecombinamers.

The potential of ELRs to self-assemble in response to environmental changes as pH, temperature or salt content makes them very attractive for the construction of nano-devices for use as controlled delivery and stimuli-responsive systems or advanced nanobiotechnological applications.

Lysine Dendrimers and their Conjugates and Complexes with Amyloid-like Peptides

I.Neelov

Institute of Macromolecular Compounds, RAS, St.Petersburg, Russia

i.neelov@mail.ru

Introduction: It was shown recently[1] that charged dendrimers (PAMAM, PPI) could inhibit amyloid aggregation or even disrupt existing mature amyloid fibrils. There are also evidence that some short fragments of amyloid peptides could prevent amyloid aggregation both in full length amyloids (Aβ1-40 and Aβ1-42) and in their fragments [2]. Our goal is to understand physical mechamisms of both types of inhibition through molecular simulation of interaction of dendrimer with amyloid (or simplified amyloid-like) peptides. The lysine dendrimers are less toxic than widely used PAMAM and PEI dendrimers and thus they could be more suitable for biomedical applications and in particular for possible cure of Alzheimer's and other neurodegenerative diseases.

Materials and Methods: In present work we performed simulation of poly-L-Lysine dendrimers and their hybrids and complexes with short amyloid-like peptides. Method of molecular dynamic simulation with full atomic details (Amber99 forcefield) was used for this goal. One lysine dendrimer of 3.5 generation with 16 positively charged NH3+ terminal groups (or its hybrid with amyloid-like peptides attached to terminal groups were placed in periodic box with 7000-8000 explicit water molecules (TIP3P model). The same number of negative counterions Cl- were added to system for compensation of dendrimer charge. Complexes of lysine dendrimer or its hybrid with 8 amyloid-like peptides were studied also. We used KFFE tetrapeptides as simplest model for amyloid-like peptides. All calculations were performed at temperature T=300K. The length of each molecular dynamics trajectory was equal to 100ns. Computational package OpenMM [3] for computer simulation of molecular systems with full atomic details on graphical processor units (GPU) was used.

Results and Discussion: Structural parameters (gyration radius, asymmetry and distribution of density for all atoms and for terminal groups) around the centre mass of molecule were calculated for lysine dendrimer and hybrid of lysine dendrimer of generation 3.5 with KFFE tetrapeptides.

Time dependence of gyration radius of dendrimer was used to determine the relaxation and equilibrium parts of trajectory. Dendrimer of generation 3.5 is rather asymmetric and chemical attachment of KFFE peptides in hybrid structure doesn't influence the size and shape of dendrimer but slightly increase distance of terminal group from centre.

Adsorption of free KFFE peptides on dendrimer and on hybrid structure occurs rather quick and irreversible. Binding of adsorbed peptides to hybrid structure is stronger than to dendrimer itself. For dendrimer the adsorbed peptides are on the surface of dendrimer while for hybrid structure there are two maxima of peptide distribution around it. Adsorbed peptides are more extended than free peptides in water which help further adsorption of additional free peptides from solution. Distribution of counterions is also bimodal with maxima at the same positions as for adsorbed peptides. In the case of hybrid most number of contacts are between chemically attached and adsorbed peptides.

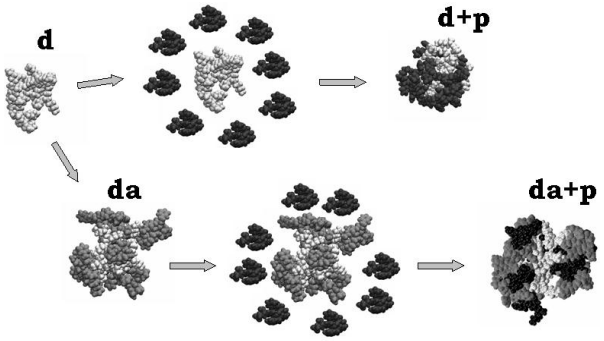

Fig.1 **d** – lysine dendrimer (light gray); **da** - hybrid of dendrimer (light gray) with chemically attached KFFE tetrapeptides (dark gray); **d+p** –complex of dendrimer (light gray) with adsorbed peptides (black); **da+p** – complex of hybrid (light gray+dark gray) with adsorbed KFFE tetrapeptides (black). Two nonamed pictures are initial conformations of dendrimer (or hybrid) and free tetrapeptides before their complexation to **d+p** or **da+p** structure correspondingly

Conclusions

Protonated lysine dendrimers and their hybrids with short peptides could adsorb significant amount of amyloid-like peptides due to strong electrostatic interactions. This spherically symmetric aggregation of amyloid-like peptides on dendrimers and hybrid structures could prevent own aggregation of free peptides in column-like linear structures (fibrils) and even lead to disruption of already existing mature amyloid fibrils.

Introduction: Poly(ester amide)s (PEAs) are a class of synthetic polymers whose importance in the biomedical field has increased in the last years. PEAs gather in the same entity the best properties of polyamides (good mechanical and thermal properties) and polyesters (biodegradability).[1] PEAs containing α-amino acids and α-hydroxy acids (e.g., L-lactic acid) in their structure also demonstrated their potential in biomedical applications.[2] Such PEAs release normal metabolites (α-amino acids and α-hydroxy acids) in the human body upon degradation, and for this reason the toxicity induced by these materials is very low. Because both acid and basic natures of the degradation products, a neutralization effect occurs, thus avoiding an accentuated decrease in the pH, which can cause undesirable host reactions.[3] Besides, the presence of the α-amino acid opens the possibility of these materials being degraded also enzymatically, increasing their biodegradability.

This work reports the synthesis of PEAs by an interfacial polycondensation method between diamines derived from glycine or L-phenylalanine,[3] and diacyl chlorides derived from L-lactic acid oligomers.[4] The obtained PEAs were characterized in terms of chemical structure (FTIR and ^{1}H NMR spectroscopies), thermophysical (TGA, mDSC) and thermomechanical (DMTA) properties. The biodegradation behaviour in PBS (pH=7.4) at 37ºC was also evaluated. The influence of the α-amino acid lateral group in the properties (thermal, mechanical, biodegradation) of the final PEAs was studied.

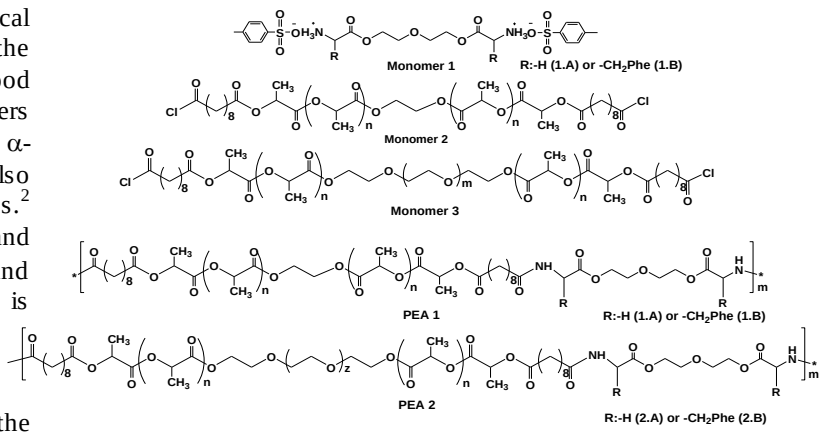
Materials and Methods: The synthesis of the diamine monomers (Monomer 1.A and Monomer 1.B) was carried out by a Fischer esterification in the presence of p-toluene sulfonic acid monohydrate as catalyst.

L-LA diacyl chlorides (Monomer 2 and Monomer 3) were obtained from the reaction between L-LA hydroxyl terminated oligomers and sebacoyl chloride.

PEAs were synthesized by interfacial polymerization between the diamines derived from the α-amino acids and the diacyl chlorides derived from L-LA oligomers, using sodium carbonate as proton acceptor. The system of solvents was water/dichloromethane. Scheme 1 presents the structure of the monomers and of the synthesized PEAs.

Results and Discussion: Both FTIR and ^{1}H NMR analysis demonstrate that PEAs were successfully obtained.

The TGA results indicate that the PEAs containing L-phenylalanine in their structure are thermally more stable than those containing glycine.



Scheme 1- Representation of the monomers and PEAs structure.

This behaviour can be attributed to the presence of the aromatic ring, which gives additional thermal stability to the PEAs.

It was observed that PEA 2 (2.A and 2.B) exhibits a lower glass transition temperature (T_g) when compared to the PEA 1 (2.A and 2.B). This is due to the higher density of ether linkages present in PEA 1.

It was observed that PEAs 2 degrade faster than PEAs 1. This is a consequence of the higher hydrophilicity of PEAs 1, due to the presence of poly(ethylene glycol). The PEAs containing L-phenylalanine (PEAs X.B) degrade slower than the PEAs containing glycine (PEAs X.A). This can be attributed to the additional hydrophobicity given by the aromatic ring in L-phenylalanine.

Conclusions: PEAs based on α-amino acids and α-hydroxy acids were successfully synthesized by interfacial polymerization. The pendant group of the α-amino acid has important influence in the thermal properties as well as in the hydrolytic degradation behaviour.

The University of Melbourne,
Parkville, Victoria 3010, Australia

gsuch@unimelb.edu.au

Introduction. Recently there has been significant research in the area of intelligent polymeric delivery systems for application in drug and gene therapy. Such polymeric carriers must have finely controlled and responsive properties to allow efficient and selective delivery of therapeutics within the body. One technique that has generated interest for synthesis of polymer capsules is the layer-by-Layer (LbL) technique due to the simple and versatile nature of this approach. The LbL technique is based on the serial adsorption of species with complementary interactions and can be performed on a diverse range of templates. LbL assembly on particles and subsequent template removal to form polymer capsules has generated particular interest for use as polymer carriers.

Recently, we combined click chemistry with LbL to develop new ultrathin films and capsules.[1] This approach involved assembling an alkyne-modified polymer with a corresponding hydrogen-bonding partner. After assembly, the alkyne groups were used to covalently stabilise the film by reaction with a bifunctional azide crosslinker. When these materials were incubated in phosphate buffer, the hydrogen bonding was disrupted, allowing the non-functionalised polymer to be removed. In this way single-component films and capsules could be engineered.

Herein, we report the application of the technique to design poly(*L*-glutamic acid) (PGA) capsules. We have demonstrated how these capsules can be used to load a model anticancer drug doxorubicin (DOX) in a controlled dose and position within the film (**figure 1**).[1] We have also shown that the drug-loaded capsules are active *in vitro* and can be used as an approach to partially bypass multidrug resistance.[2] The simple yet modular nature of this technique provides exciting new opportunities for the design of nanoengineered materials.

Materials and Methods. The synthetic details of the PGA capsules and PGA-DOX capsules have been described in previous work.[1,2] The main techniques used to characterise these materials included flow cytometry, ellipsometry and both confocal and fluorescence microscopy.[1]

Results and Discussion. In this work we have demonstrated alkyne-modified PGA can be assembled in alternation with poly(*N*-vinyl pyrrolidone) (PVPON) and then subsequently crosslinked with a bifunctional azide. At physiological pH, the PVPON is no longer held in the film by hydrogen bonds and thus is removed. This process can be performed on either a planar or colloidal surface, however on a colloid the sacrificial core can be removed to form a PGA capsule.

A PGA conjugate was also synthesised with both doxorubicin and alkyne functionality. It was demonstrated this conjugate could be successfully incorporated into the capsule in a specific position or dose (**figure 1**), thus allowing control over the drug loading within the capsule. The DOX loaded capsules were shown to have regular spherical morphology with uniform fluorescence due to loaded DOX. Each layer was found to load approximately 25 μg of DOX. It was also demonstrated the PGA-DOX capsule degraded in the presence of protease. This PGA-DOX capsule was found to successfully kill cells in vitro, however at a similar concentration the PGA-DOX conjugate did not effect cell viability.[1] This was thought to be due to the different uptake mechanism of the LbL carrier as compared to the polymer conjugate.

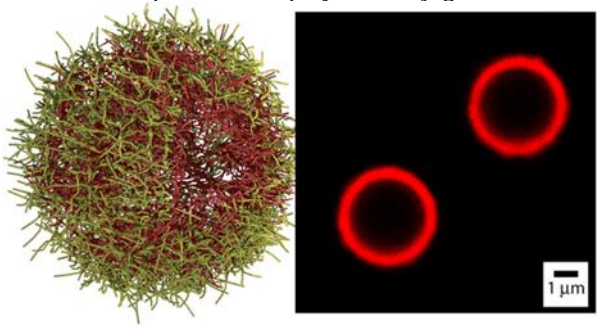

Figure 46: Schematic of a layer-by-layer (LbL) capsule and a fluorescence image of a doxorubicin loaded PGA capsule.

In later work these capsules were used to partially bypass multidrug resistance in DOX resistance cells as compared to free DOX.[2] Due to the different uptake of the capsule relative to the free drug, the DOX within the capsule could access the cell while the free DOX was excluded. In the latter case, free drug was removed by p-glycoprotein on the surface of the cell while the DOX within the capsule is protected.

Conclusion. This modular capsule design allows tunable drug loading and release of active drug once in a cell. Residual alkyne groups within the capsule also allow the possibility for post modification with antibodies or stealth materials. Thus it is expected these nanoengineered materials will have significant impact in areas such as drug or gene delivery.

Introduction. Due to its exceptional properties, stainless steel (SS) is widely used in the daily life (food industry, household appliances, surgery …)[1]. However, it is unable to prevent bacteria from adhering, proliferating and forming a resistant biofilm when ageing. Therefore, surface modification is needed for providing durable antibacterial properties. Various techniques are used for imparting such biocidal properties to the support such as (i) the deposition of biocidal metals (such as silver and copper) or inorganic oxides (TiO_2 anatase) by plasma[2], chemical vapor deposition (CVD)[3] or sol-gel procedures[4], (ii) the coating of the surface by paints containing antibiotics or other biocides[5], (iii) or the deposition of biocidal (bio)polymers such as antibacterial peptides or synthetic polymers containing ammonium groups[6]. Provided that the biocidal polymers are anchored to the support, they impart long tasting antibacterial properties which are highly desirable for the durability of the functionality[6].

Results and discussion. Very recently, we reported on an all-in-one approach to prepare refillable antimicrobial films[7] using the layer-by-layer (LbL) deposition of polyelectrolytes. Specifically designed biocidal multilayered polyelectrolyte films that bear 3,4-dihydroxyphenylalanine (DOPA), known as an adhesion promoter to inorganic surfaces, were deposited onto SS. DOPA was incorporated in the polycationic chains by radical copolymerisation of *N*-methacrylated DOPA with the quaternary ammonium salt of 2-(dimethylamino)ethyl methacrylate (DMAEMA+). In order to boost the antibacterial activity of the polycationic layer, $AgNO_3$ was added to the aqueous solution of P(DOPA)-*co*-P(DMAEMA$^+$), which resulted in the in-situ formation of silver based nanoparticles, Ag^0 and AgCl, sources of biocidal Ag^+. The layer-by-layer deposition of aqueous P(DOPA)-*co*-P(DMAEMA+)/AgCl/Ag^0 suspension and aqueous solution of poly(styrene sulfonate) provided high antibacterial activity against Gram-negative *E. Coli* bacteria.
Although this surface modification is highly efficient, it requires the LBL deposition of about 60 bilayers that makes the process difficult to scale-up at the industrial scale. In the present communication, we will demonstrate how the same copolymers can impart AB properties to the SS surface using only 1 or 2 layers. Novel nanohybrids are first prepared in water before being deposited on the surface.

Conclusions. The method of formation of these nanohybrids, their deposition and the characterization of the modified surface will be discussed in detail in this talk. This novel water-based approach is convenient, simple and is promising for scalable applications. It might also be used for coating other organic and inorganic surfaces in order to impart them robust AB properties.

Acknowlegments. The research was partly supported by BELSPO in the frame of IUAP VI/27 and Région Wallonne, ArcelorMittal and ULg through the PPP program BIOCOAT. C.D. is “Maître de Recherche” of the F.N.R.S. (Belgium), and thanks the F.R.S.-F.N.R.S. for financial support.

a_nematollahzadeh@yahoo.com

Abstract

Human Serum Albumin (HSA) imprinted nano-layer of polydopamine was produced through oxidative polymerization of dopamine on HSA modified porous silica support. The coating thickness was controlled by the reaction time and, therefore, varied within 0-12 nm. The samples were characterized by elemental analysis, FT-IR, DSC, SEM, TGA, physisorption and thermoporometry. The characterization confirmed the success of the evolution and deposition of dopamine onto the silica pore surface. Batch rebinding experiment exhibited that the molecularly imprinted polymer (MIP) with 8.7 nm coating thickness in comparison with the thinner and thicker coatings, adsorbs much more the target protein. The chromatography evaluation of the materials packed in HPLC column showed that HSA imprinted polydopamine offering good mechanical stability adsorbs practically all the target protein from the HSA solution or human plasma.

Introduction

Preparation of artificial systems capable of molecular recognition and capture could uniquely be achieved by molecular imprinting technique. Generally, the technique involves the arrangement of functional monomers around template molecules in a porogenic solvent. The complex is subsequently polymerized. After removal of the template, specific cavities, which are complementary in shape, size and chemical functionality to the template, are left within the polymer matrix. These specific cavities can selectively rebind the target molecules. Surface imprinting on solid porous particle presented in this article was on the basis of mussel-inspired surface chemistry for multifunctional coatings reported by Lee et al. [1,2] Recently, we developed a general technique to obtain a hierarchically structured protein imprinted porous polymer beads by using silica porous particles as sacrificial solid support for protein recognition and capture.[3]

In this study, therefore, we present a general technique to fabricate protein imprinted composite microparticles through direct coating of DA on the pore surfaces of porous silica particles for use as stationary phases in liquid chromatography.

Materials and methods

Dopamine (DA) was purchased from Sigma-Aldrich. Tris-HCl and silica particles were received from Merck. The silica was rehydroxylated prior to use. The surface area and pore volume of the silica were measured by N_2 gas sorption (Nova-Quanatchrom4000e).

The method involves three steps including 1) immobilization of HSA on the silica pore surface, 2) polymerization of DA on the pore surface in presence of HSA and 3) removal of the template. Ten samples (5 imprinted and 5 non-imprinted) were prepared at 5 different reaction time intervals (3, 6, 12, 24 and 48 h)

Results

Different characterizations techniques (FT-IR, DSC, SEM, and TGA) confirmed the success of the evolution and deposition of dopamine onto the silica pore surface. Figure 1 shows the SEM images of bare silica and DA coated and imprinted silica. In Fig. 2A time dependency of the PDA thickness and mass evolution on the silica surface is shown. Batch rebinding experiment exhibited that 8.7 nm coating thickness which was achieved within 24 h reaction time (MIP24h) adsorbs much more target protein than the corresponding NIPs.

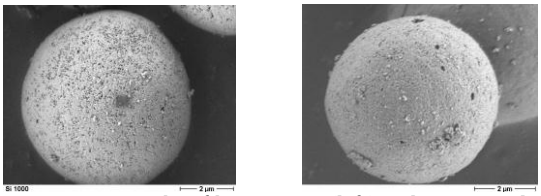

Fig. 1 SEM micrographs of bare Si1000 (left) and DA coated silica (right) particles all having an approximated mean diameter of 5 µm.

The chromatography evaluation of the materials packed in HPLC column showed (Fig. 2B) that the MIP24h adsorbs practically all the target protein from the HSA solution or human plasma, as well.

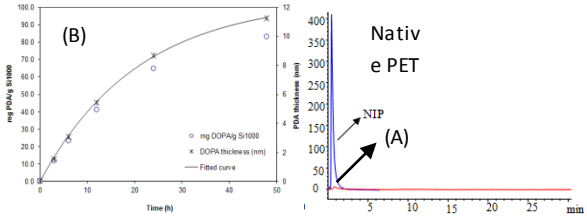

Fig. 2 Time dependency of the PDA thickness and mass evolution on the silica surface obtained by TGA (A), Chromatographs of Human Plasma 100× diluted in the HSA-MIP and NIP (B)

Conclusion

Surface imprinting on a porous solid support is an effective approach to overcome the mass transfer resistance, in particular within protein imprinted polymer, offering high mechanical robustness and a simplified procedure for producing HPLC stationary phase which can be immediately used for HPLC packing for the protein separation purposes.

Development and Characterization of Antimicrobial PCL Fibres for Surgical Suture Applications

L. Botta[1], *R. Scaffaro*[1], *M. Sanfilippo*[1], *G. Gallo*[2], *A. M. Puglia*[2]

[1] Dipartimento di Ingegneria Industriale, [2] Dipartimento di Scienze e Tecnologie Molecolari e Biomolecolari
Università di Palermo, Viale delle Scienze, 90128 Palermo (Italy)

luigi.botta@unipa.it; roberto.scaffaro@unipa.it

Introduction

Actually, the preparation of antimicrobial surgical sutures is under the consideration of both academia and industry. The main problem is to find a good compromise between the effectiveness and the production costs.
Antimicrobial properties can be granted to a surgical suture by different methods that may modify or not the structure of the polymer. In all the cases it is necessary that the process does not significantly change the mechanical properties of the material.
The methods currently used for production of surgical sutures with antimicrobial properties are essentially two: coating and grafting. These methods require several steps after the spinning of the filament and, generally the use of solvents to provide the suture with antibacterial properties.
Polycaprolactone (PCL) is a synthetic biodegradable aliphatic polyester widely used for biomedical applications, such as controlled-release drug delivery systems, absorbable surgical sutures and three-dimensional scaffolds for use in tissue engineering [1].
The chlorhexidine (CHX) is a broad-spectrum antimicrobial agent belonging to the bis(biguanide) family. It is used primarily as a topical antiseptic/disinfectant in wound healing, at catheterization sites, in various dental applications and in surgical scrubs [2].
Aim of this work is to develop a method for preparing PCL monofilament with antimicrobial properties for surgical suture applications by incorporating CHX during the melt extrusion of the PCL monofilament. The effect of CHX content and of the cold drawing on antimicrobial and mechanical properties of the prepared monofilaments was investigated. Moreover, the release of CHX from the fibres was investigated too.

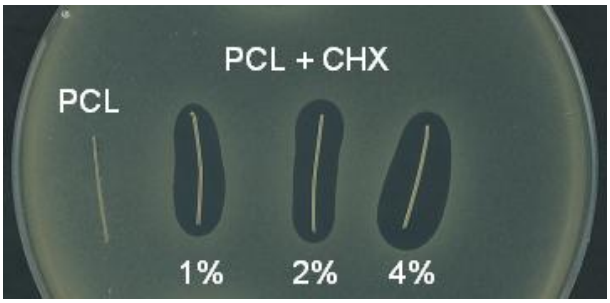
Materials and Methods

Both PCL and CHX (diacetate salt hydrate) used in this work were commercial samples supplied by Sigma Aldrich.
PCL has been compounded with CHX at different concentrations (1%, 2%, 4%) by using a counter rotating twin screw compounder with a thermal profile of 40-50-70-100 °C. The fibres were spun by using a capillary rheometer operating under a constant extrusion speed; the final diameter of the as spun fibres was about 250 µm.
The antimicrobial activity of filaments was determined by agar diffusion method evaluating the presence of inhibition zones against two Gram-positive (*M. luteus*, and *B. subtilis*) and a Gram-negative (*E. coli*). Moreover, bacterial growth in presence of the antimicrobial fibres was determined by plate counting test.

Results and Discussion

All the filaments containing chlorhexidine showed a clear zone of inhibition against both Gram-positive and Gram-negative bacteria. On the contrary, the pure PCL shows no antibacterial activity as reported in figure 1 for the assay against the *M. luteus*.

The effectiveness of the antibacterial properties of the filaments was also evaluated by inhibition tests in a liquid



MIP

medium. The measurements of the bacterial growth revealed, in full agreement with the agar diffusion tests, that the pure PCL did not show any antibacterial activity. On the contrary all the samples added with chlorhexidine inhibited the growth of the bacterial mass.
The off-line cold drawing of the fibres induced an obvious decrease of their diameter and an increase of the mechanical properties with particular reference to the load at break. Both inhibition tests showed that also the drawn fibres clearly exhibit a strong antibacterial activity.
The evaluation of CHX release showed that, as expected, the amount of released antimicrobial agent raised on increasing the content added to the fibres. Moreover, the drawn fibres released a lower amount of chlorhexidine if compared with as spun ones.

Conclusions

This work reports a method to prepare antimicrobial PCL fibres for surgical suture applications. In particular, an antimicrobial agent, i.e. CHX, was incorporated in PCL during the melt extrusion of the monofilaments. The filaments were cold drawn in order to increase their mechanical resistance. Both as-spun fibres and drawn ones clearly exhibit a strong antibacterial activity.

yunus.saricay@wur.nl

-Introduction. Enzymatic cross-linking has been reported to improve the food functionality (foam, emulsions, gels) of the commercially important whey proteins[1-2]. However, the relation between the mesoscale physical properties and the functionality of cross-linked "protein-polymers" has so far not been elucidated.

Materials & Methods. A Ca^{+2}-depleted-α-lactalbumin type III was supplied from sigma and used without any purification. Horseradish peroxidase type VI-a, hydrogen peroxide solution of 30% (w/w) in H_2O were purchased from Sigma-Aldrich.

Results & Discussion. In order to characterize the mesoscale properties of enzymatically cross-linked proteins, we here study the details of peroxidase-catalyzed cross-linking of the whey protein α-lactalbumin, with peroxide as a co-substrate. Crucial to our study is the integration of on-line characterization of the cross-linking chemistry (via UV-spectroscopy) and on-line characterization of the particle formation process (via dynamic light scattering) (Fig.1)

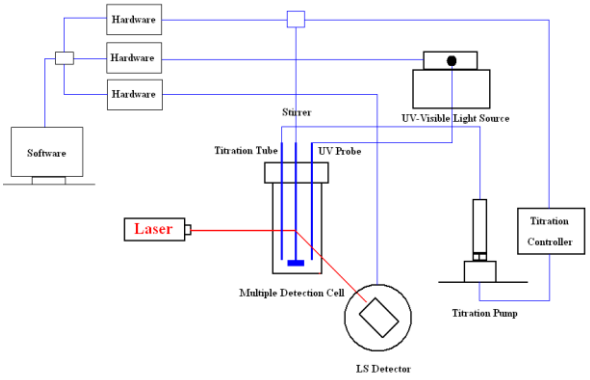

Figure.1. Scheme of multiple detection system.

We find that for our system, cross-linking is limited by the lifetime of the enzyme that is gradually inactivated by excess peroxide. For a 1 % (w/w) starting concentration of α-lactalbumin, we find final sizes for cross-linked products of about 25-30 nm (Fig.2).

Off-line analysis combining Size-Exclusion Chromatography and Light Scattering shows that the relation between the solution size and molecular weight of the reaction products is $R \sim M^{a}$, with an exponent a ≈ 0.6, indicating a very open structure of the cross-linked proteins, with molecular weights up to $M_w \approx 10^7$ Da (Fig.3).

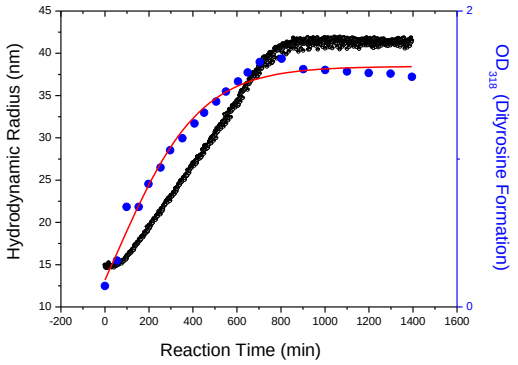

Figure.2. LS intensity and absorbance at 318 nm of reaction mixture of 1 % α-lactalbumin incubated HRP at pH 6.8 in 0.1 M NH_4Ac as a function of reaction time during online characterization of peroxidase-mediated cross-linking reaction

The open structure may be related to the rather low functionality of the monomer that contains only 4 reactive tyrosines.

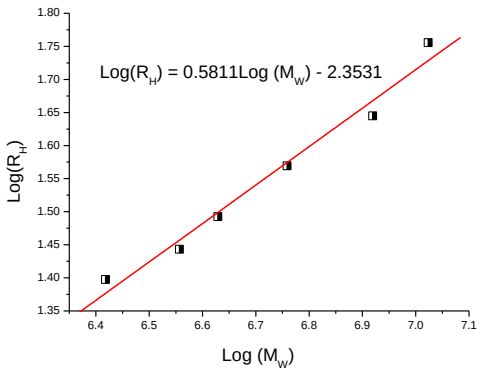

Figure.3. Double logarithmic plotting of hydrodynamic radius vs molecular weight of protein polymer fractions.

Conclusion. We achieved to characterize peroxidase-meadited cross-linking of α-lactalbumin in terms of cross-linking chemistry and particle formation process in order to relate mesoscale physical properties to functionality for the engineered protein structures with controlled size and architecture.

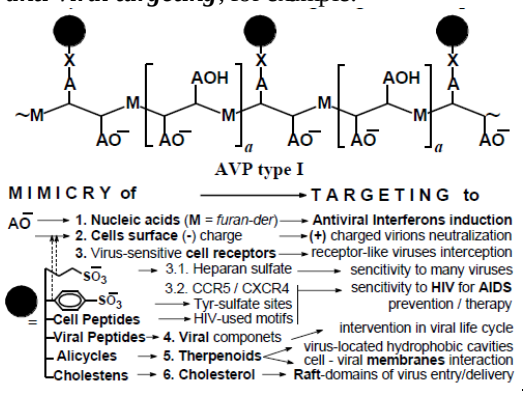
e-mail: serbin@ips.ac.ru

The problem and objective

Polymeric macromolecules construct a fundament for all biologic systems: cell organisms, and cell parasites, including the viruses. But small molecules (**SM**) are incapable for adequate functionality, and SM drugs industry is covered by same objective law. SM cannot be effective blockers for many macromolecular targets, and blocking only sub-molecular small-scale sites fatally promote a drug resistance of mutated viruses. This fundamental course directs our efforts for systematic development of antiviral polymers (**AVP**).

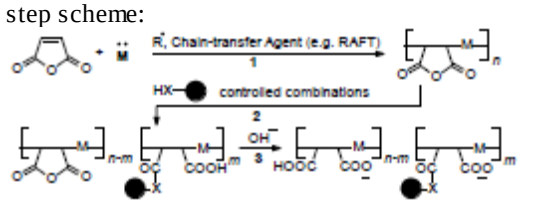
Strategy

To achieve the maximal antiviral efficiency with lowest precondition for a drug resistance the polymer-cooperative approach was studied on base of controlled combining the variable polymeric backbone nature with various kinds of virus-targeting side vectors (**VTV**), designed on the principle: ***from virus bio-acceptors mimicry toward the anti-viral targeting***, for example:



Synthesis

One of the most advanced approaches to the AVP is the tri-step scheme:



The **step 1** (free radical alternating copolymerization of maleic anhydride with suitable monomers) regulates the –M– nature, polymerization degree and polydispersity; the **step 2** allows to introduce the variable designated VTVs = in required combinations, and the **step 3** leads to the correspondent acid-anionic polyelectrolytes, biocompatible, soluble in aqua (bio) media, and maximally safe for toxicology criteria.

Antiviral Effectiveness

1. ***Imitation of nucleic acids (NA)*** by the AVP-acids leaded to NA-like induction of interferon and immune-stimulating preventive protection against lethal doses of viruses: *eastern equine encephalomyelitis-, tick-born encephalitis-, rabies-, Crimean hemorrhagic fever-, meningo-encephalomyelitis* etc. These effects were registered on immune competent experimental models (*in vivo*) [1], but not on cell cultures (*in vitro*).

2. ***Cell surface negative charge mimicry*** only via the slight anionic carboxy-acid manner resulted in slow-downing the electrostatic driven attachment to cells of viral particles, for example the HIV-1 virions, *in vitro*.

3. ***Virus sensitive cell receptors mimicry*** amplified this effect by imitation of strong anionic sulfo-acids, relative to heparan sulfate, the cellular receptor, used by many human viruses to entry into cells. Sulfated Tyr residues, take place also in chemokine receptors CCR5 / CXCR4 within the amino acid moieties used by HIV-1 (R5/R4 strains). The sulfated AVP blocked the viral entry in cells, evidently recorded as a dual protection against both human cytomegalo- and HIV-1 viruses [2]. The next generation of synthetic pseudo receptors was constructed as AVP modified by polypeptide fragments of the CCR5 or CXCR4, and the obtained substances possessed more strong protection *in vitro* against HIV- 1, including strains resistant to SM drug, AZT [3].

4. ***Viral components mimicry*** tested recently on an example of conjugates of AVP with 15-33 amino acid motifs of HIV-1 gag matrix (p17) protein, leaded to VTV interfering with the latest stage of HIV-1 reproduction, post-replication self-assembly of the viral particles [4]. And now this approach is under study.

5-6. ***Membrane tropic agents mimicry*** using variable alicyclic and cholesterol-related VTV. The AVP containing a cholesten anchor, targeted to the cholesterol-enriched "raft" domains of membranes (epicenters of virus entry - delivery risks), strongly inhibited HIV-1 and related strains replication *in vitro*.

The adamantane, norborna(e)n, and dinorbornen containing AVPs were effective against influenza (A,B) HIV-1/2, *herpesviridae*, and other viruses, including the SM drug (e.g. rimantadine) resistant strains [5]. To understand the polymer-cooperative effects a computational modeling-analysis was applied.

Conclusion

The polymer-cooperative strategy allows essentially amplify the antiviral effectiveness and to overcome / prevent the drug resistance of viruses.

Non-linear viscoelastic models for random coil polysaccharide solution rheology over a broad range of concentrations.

Wilco M.H. Verbeeten

Departamento de Ingeniería Civil, Área de Mecánica de los Medios Continuos y Teoría de Estructuras, Universidad de Burgos, C/ Villadiego s/n, E-09001 Burgos, Spain

wverbeeten@ubu.es

Introduction: The investigation deals with the modelling of the flow behaviour of aqueous random coil polysaccharide solutions using non-linear viscoelastic models. Up to date, most researchers and scientists use General Viscous Fluid models to describe the rheology of such biological macromolecular solutions, *e.g.* the Cross model. Although these types of models do an excellent job in modelling steady state simple shear viscosity, they are unable to describe the other three phenomena of viscoelasticity, *i.e.* time dependence, normal stresses in shear, and different behaviour in shear and elongation. Furthermore, these models are not able to describe satisfactorily the linear viscoelastic behaviour measured by dynamic oscillation experiments. Thus, when more complex flows have to be analyzed, *i.e.* flows where material elements experience various types of deformations in a transient sense rather than steady state, these General Viscous Fluid models do not suffice and more complex non-linear viscoelastic models are necessary.

Materials and Methods: A mastercurve can be constructed from experimental steady state shear data over a broad range of concentrations, from the dilute to the semi-dilute solution regime. Shift factors can be determined for the experimental data to transpose data and the linear relaxation spectrum to different concentrations, similar to the time-temperature-superposition. In the limit of small deformations, polymeric fluids show a linear viscoelastic response, which can be accurately described by a multi-mode Maxwell model. For larger strains, polymeric fluids show non-linear viscoelastic behavior, which is modeled by three non-linear viscoelastic models of the differential type: the Phan-Thien Tanner (PTT) model, the Giesekus model, and the eXtended Pom-Pom (XPP) model. The zero-shear viscosity as a function of the concentration can be described over the entire concentration range, both dilute and semi-dilute solution regimes, by a simple combination of two concentration dependent terms with different slopes. The concentration dependent term can now be divided into a part that corresponds to the relaxation time and to the plateau modulus.

Results and Discussion: The experimental linear viscoelastic and steady state shear data of various random coil polysaccharide solutions, *i.e.* polysaccharide guar galactomannan, aqueous phosphopolysaccharide "viilian" solution excreted by *Lactococcus lactis* subspecies *cremoris* SBT 0495, and aqueous *Propionibacterium acidi-propionici* polysaccharide solution, can be quantitatively predicted by the multimode Phan-Thien Tanner, Giesekus, and eXtended Pom-Pom non-linear viscoelastic models over a broad range of concentrations, from dilute to semi-dilute regimes, using a single set of parameters. Transient shear viscosity data is quantitatively and first normal stress coefficient is qualitatively predicted for a galactomannan guar solution.

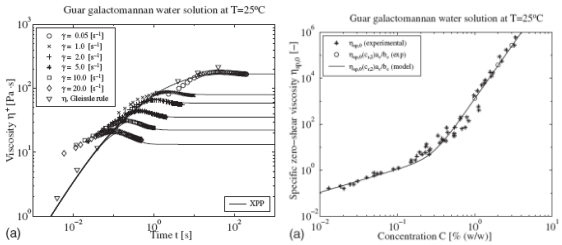

Figure 47: *Numerical and experimental data for a guar galactomannan solution in water at 25°C.*

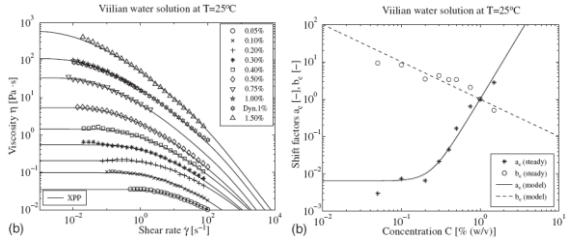

Figure 48: *Numerical and experimental data for a phosphopolysaccharide viilian solution in water at 25°C.*

Conclusions: Due to their proven performance in finite element simulations, these non-linear viscoelastic constitutive equations could help to improve predictive modelling of time-dependent complex flow problems for polysaccharide solutions. However, as a previous step, the performance of additional rheological experiments in simple flows, *i.e.* transient and steady-state extensional measurements, is recommended.

Porous Protein based Scaffolds produced using a Freeze-Thawing Technique

Harald Kirsebom[1*], *Linda Elowsson*[1,2], *Madeleine Durbeej*[2] *Bo Mattiasson*[1]

[1] Department of Biotechnology, Lund University, Lund, Sweden
[2] Department of Experimental Medical Science, Unit of Muscle Biology, Lund University, Lund, Sweden

* Email: Harald.Kirsebom@biotek.lu.se

Introduction

Scaffolds which can sustain mammalian cell cultivation in a 3D environment are interesting for research and as potential material which can be implanted into patients. In this study cryogelation, e.g. freezing combined with chemical crosslinking, has been utilized to produce highly porous and permeable scaffolds from proteins. Cryogelation has previously been shown to be a suitable technique to produce highly porous protein-based materials either through chemical reactions or through non-covalent interactions[1, 2].

Using proteins for the preparation can raise the possibility of immunological responses if the material is implanted into a patient. In order to avoid this reaction one could use proteins from the patient to form an autologous scaffold. Blood or plasma is biological fluids which is generally present in large amounts from most patients. In this study blood or plasma of bovine origin were used as model systems in an attempt to fabricate autologous scaffolds[3].

Materials and Method

Scaffolds from blood or plasma were produced by diluting bovine blood or plasma with PBS buffer or water at a volume ratio 1:1. The mixtures were then kept on ice and subsequently glutaraldehyde was added to a final concentration of 0.25 % (w/v). Thereafter 0.5 ml aliquots of the mixture were frozen at -12 °C for 16 h. after which the samples were thawed at room temperature and washed with water before the samples were reduced using 0.05 M sodium borohydrid in carbonate buffer pH 9.2.

The mechanical properties of the produced materials were analyzed using unconfined compression and the elastic modulus was calculated in the linear range. The porous structure and the pore wall texture were analyzed using scanning electron microscopy after the samples had been critical point dried.

Prepared blood or plasma based scaffolds were then evaluated for biocompatibility through cultivation of myoblasts. Prepared scaffolds were cut into 1 mm disc and sterilized with iso-propanol and the washed with PBS. Prior to cell seeding the discs were equilibrated in cultivation media. For each disc $0.5x10^6$ myoblasts were seeded. The cells were grown in proliferation medium for three days after which the medium was changed to differentiation media. Cell viability was assayed using XTT and the myogenic phenotype of the cells was confirmed using immunofluorescence stainings.

Results and Discussion

Cryogelation of both diluted blood and plasma yielded highly porous and permeable materials. Freezing of blood or plasma mixtures causes the formation of ice crystals which expels any soluble or suspended material. Hence a two phase system is formed in which the solid ice phase acts as pore forming agent while a chemically stable crosslinked protein network is formed in the liquid water phase. Scaffolds from plasma were obtained both from dilution of water or PBS while for blood only PBS was possible to use. Diluting blood with water will change the osmolarity and thus cause lysis among the red blood cells. Undiluted blood or plasma was not possible to use since the high protein content resulted in fast gelation after glutaraldehyde were added. In order to form a interconnected and porous material, gelation must occur after freezing[4] and thus blood and plasma had to be diluted.

Both plasma and blood scaffolds exhibited pores in the range 10-80 µm which were studied using SEM. The pore walls of the plasma-based scaffolds exhibited a smooth texture while the blood-based material was highly uneven due to the red blood cells (Figure 1).

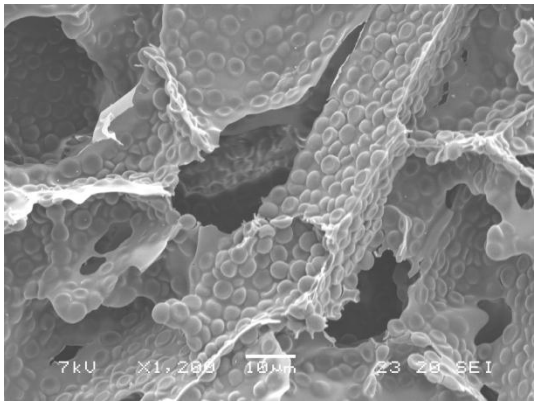

Figure 1: Scanning electron micrograph of a scaffold produced through cryostructuration of bovine blood. The intact red blood cells are clearly shown to be embedded into the pore walls.

The plasma and blood based scaffolds were shown to support cell attachment and proliferation and cell numbers increased during cultivation in proliferation medium. Furthermore, the immunofluorescense stainings confirmed that the cells maintained their myogenic phenotype during the whole cultivation time.

Galactomannan in Imidazolium-Based Ionic Liquids

E. Sultan, A. Bussard, E. Fleury and A. Charlot

Université de Lyon, INSA de Lyon, CNRS, France

aurelia.charlot@insa-lyon.fr

Introduction- The development of polysaccharide-based materials has attracted considerable attention due to their various properties in addition to their renewable character. In this frame, guar gum is a relevant building-block since it combines an easy availability, a low cost, biodegradability, hydrophilicity and viscoelasticity. Guar is a neutral polysaccharide extracted from the seeds of *Cyamopsis tetragonoloba*. Belonging to the galactomannan family, it is constituted of a β-1,4 mannose backbone with randomly distributed α-1,6 galactose moieties (Fig. 1).

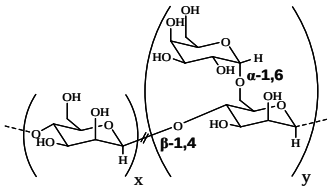

Figure 1. Chemical structure of guar

It is widely used in the food, paper, textile, petroleum, personal care and biomaterial industries. Various synthetic methods can be applied to guar chemical modifications [1] to obtain attractive materials. However, guar is difficult to be solubilised in common solvents due to the existence of strong hydrogen bonds. The use of organic solvents at high temperature leads to guar chain degradation. The solubilisation in aqueous medium generates suspensions of swollen guar particles and no homogeneous solutions (Fig. 2). Thus, there is a strong need to find eco-friendly and efficient solvents to expand the applications of guar. In this context, ionic liquids (IL), a group of salts liquid at low temperature, appear as promising "green" solvents [2] due to their high chemical and thermal stability, non flammability, negligible vapor pressure, as well as their good dissolution capability of sugar.[3] In this work, we investigated the ability of different imidazolium-based IL derivatives to solubilise guar gum with in particular a rheological analysis. Moreover, we illustrated the potential of IL as reactional medium to perform homogeneous guar chemical modifications such as esterification and copper-catalyzed azide-alkyne cycloaddition (CuAAc).

Material and Methods -Guar gums were provided by Rhodia (mannose/galactose = 1.3). EMIMAc, AMIMCl (Aldrich) and EMIMMP (Solvionic) were dried before chemical reactions. Other reagents were performed from Aldrich and used as received. The dissolution of guar in IL was performed under N_2, during 16 h at 50°C under stirring. The guar-based hydrogels by CuAAc in EMIMAc were performed as previously described in water.[1(b)] The viscosity of guar solutions in IL as well as the gelation process were analysed with a AR1000 controlled stress rheometer by using an aluminum cone/plate geometry (diameter 60 mm, angle 2°). Esterification reactions with maleic anhydride, acetic anhydride, butyric anhydride were performed under N_2, at 50°C during 4h by using 5 molar eq. between esterifying reagent and AGU unit. The products were isolated by precipitation into isopropyl alcohol and characterized by IR and by NMR spectroscopy.

Results and Discussion- We have shown the ability of various hydrophilic imidazolium derivatives with low melting points such as 1-ethyl-3-methylimidazolium methyl phosphonate (EMIMMP), 1-allyl-3-methylimidazolium chloride (AMIMCl) and 1-ethyl-3-methylimidazolium acetate (EMIMAc) to act as good solvents for guar (M_w = 50-300 kDa) without any chain degradation (Fig. 2).

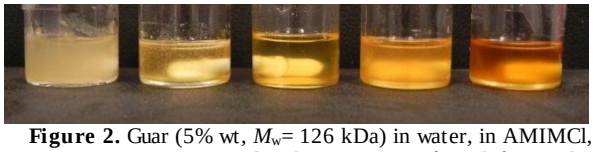

Figure 2. Guar (5% wt, M_w= 126 kDa) in water, in AMIMCl, in EMIMMP, in BMIMCl and in EMIMAc (from left to right)

The rheological properties of guar in IL and in particular the influence of temperature allowed us to determine activation energies (Arrhenius law). The high values obtained for guar/IL solutions compared to water "suspension" reflect strong physical LI/guar and guar/guar interactions. The results also demonstrated that interactions are closely dependant on the IL chemical structure (Table 1).

sample	EMIMAc	Guar in EMIMAc	EMIMMP	Guar in EMIMMP
Ea (kJ/mol)	37	43.9	31.7	42.6
sample	AMIMCl	Guar in AMIMCl	Guar in water	
Ea (kJ/mol)	61.4	64.5	10.1	

Table 1. *Activation energies for pure IL and guar dissolved (5% wt-M_w = 126 kDa) in different IL compared to dispersion in water*

Besides, we evidenced that both AMIMCl and EMIMMP constitute suitable medium to obtain homogeneously esterified guar derivatives, not described in the literature before. Also, we successfully performed CuAAc coupling in EMIMAc between diazido crosslinker and alkyne fonctionalized guar to obtain chemical networks and we have shown that the gelation process as well as the elasticity differ from those obtained in water.[1(b)]

Conclusion- Taking advantage of the efficiency of hydrophilic imidazolium-based IL to solubilise guar, we obtained attractive rheological properties and we prepared a range of homogeneously modified guar derivatives with no noticeable chain degradation.

Hierarchically self-organized PS-*b*-P4VP Honeycomb films with reversible pH-responsive wettability

P. Escale, M. Save, C. Derail, L. Rubatat and L. Billon

IPREM / EPCP, UMR 5254, Université de Pau et des Pays de l'Adour, FRANCE

laurent.billon@univ-pau.fr

Self-organized porous polymer films with pores ordered into a hexagonal pattern can be elaborated by a fast evaporation method under humid atmosphere, also called "Breath Figure" approach. [1] Honeycomb (HC) films have been fabricated from a variety of polymers using the appropriate experimental conditions for each class of polymer. [2-4] The elaboration of smart honeycomb surface with thermo or pH-responsive wettability has been proposed using poly(*N*-isopropyl acrylamide) or PS-*b*-PAA based copolymers [5-6]. In these previous studies, no reversibility of the wettability was shown.

Moreover, self-assembly of diblock copolymers are able to create a nanophase separation within the walls of the honeycomb films, which was observed by microscopy techniques and/or small angle neutron scattering.[7,8] One of the advantage of nanophase separation is that the first block confers the sufficient hydrophobicity required for the elaboration and stability of HC structure whereas the second block can provide an additional functional property.

Here, we aim to elaborate hierarchically ordered porous film from a pH-sensitive diblock copolymer able to create an inner nanostructuration while tuning the surface wettability. We report the self-assembly of well-defined high molar mass polystyrene-*b*-poly(4-vinyl pyridine) diblock copolymer (PS-*b*-P4VP), synthesized by nitroxide-mediated polymerization (NMP), into honeycomb-structured porous film prepared by simple evaporation method under humid conditions (Figure 1).

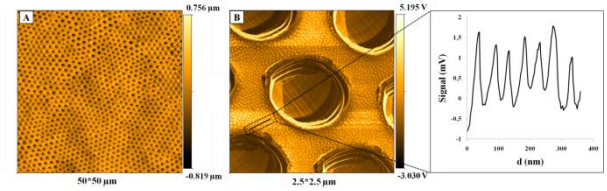

Figure 1. AFM phase images (**A** and **B**) of PS-*b*-P4VP honeycomb recorded at different scales and **(C)** variation of the signal intensity versus the distance for a cross-section of 400 nm.

Then, these films are peeled-off in order to form pincushion structures. The wettability and the impact of the pH-responsive behavior are studied by measuring the contact angle for the two honeycomb and pincushion films (Figure 2)

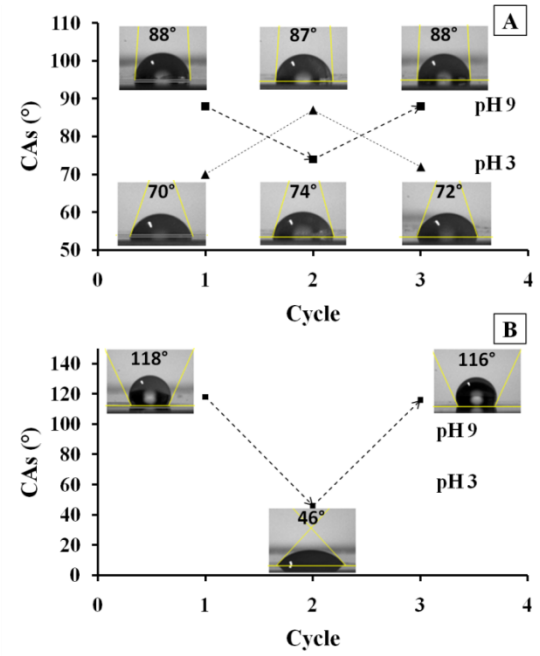

Figure 2. Reversibility of contact angles of a water droplet deposited onto **(A)** PS-*b*-P4VP honeycomb film and **(B)** peeled off PS-*b*-P4VP HC film.

First, an increase of the hydrophobicity is demonstrated when pH is tuned in a large range of values for hierarchically structured honeycomb films. The same behavior can be described with a stronger exaltation of the hydrophobicity when honeycomb films are peeled-off due to the presence of pillars which increase the roughness of the films.

Lipase Catalyzed Synthesis of Biopolyester and Related Clay-based Nanohybrids

H. Öztürk Düşkünkorur[1,2], E. Pollet[1], P. Debeire[1], V. Phalip[1], L. Avérous[1]

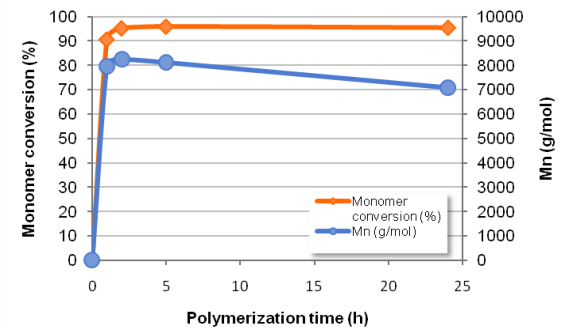
[1] Université de Strasbourg, France; [2] Istanbul Technical University, Turkey

eric.pollet@unistra.fr

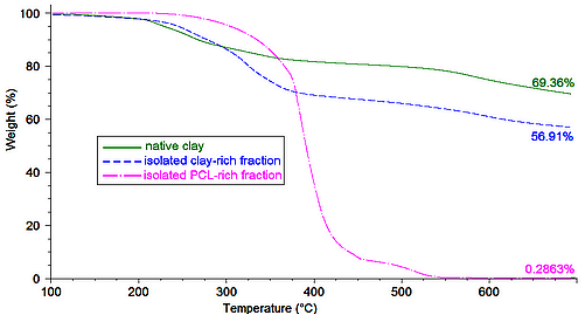
Introduction: Enzymatic ring opening polymerization (ROP) of lactones attracts attention as a new trend of biodegradable polyesters synthesis due to its non-toxicity, mild reaction requirement and recyclability of immobilized enzyme [1]. Beside the enzyme-catalyzed synthesis of biopolyesters, key researches are conducted nowadays on the elaboration of composites materials in combination with inorganic (nano)particles. Thus far, the majority of enzymes studied for polyester synthesis have been from the lipase family. Among these lipases, lipase B from Candida Antarctica (CALB) has proven to be a dominant catalyst for these reactions [2]. In parallel, the use of clays as inorganic porous supports to immobilize enzymes has also been described. Interestingly, the use of such nanoclays as lipase carriers can bring numerous advantages such as the high specific surface availability, the high water uptake capacity, and the excellent mechanical resistance of these materials [3]. The objectives of this study is to develop original catalytic systems based on lipases which are efficient for polyester synthesis and allowing the preparation of hybrid materials based on clay nanoparticles grafted with such polyesters.

Materials & Methods: For this, ε-caprolactone (ε-CL) polymerization catalyzed by CALB was carried out in the presence of montmorillonite and sepiolite clay.
The unmodified and organo-modified forms of these two nanoclays were also used to physically adsorb CALB. The obtained catalytic systems have been tested and their efficiency has been compared. The polymerization kinetics and resulting products were characterized with NMR, SEC, DSC and TGA analyses.

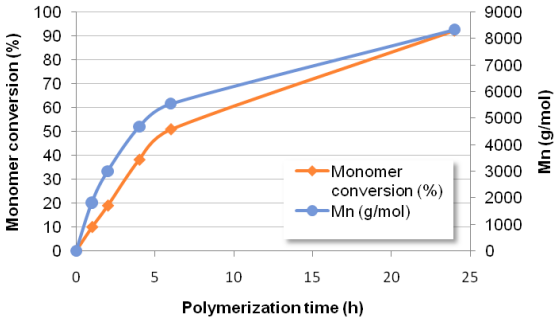
Results & Discussion: Monitoring the monomer conversion and PCL molecular weight versus time shows that the presence of nanoclays does not change the reaction kinetic, the monomer conversion being higher than 90% within 2 hours. However, the addition of clay leads to lower Mn values.



Such decrease in molecular weight depends on the added amount of montmorillonite and attests for the participation of clay hydroxyl groups in the polymerization. Analyses showed that organic/inorganic nanohybrids were obtained through polymer chains grafting and growth from the hydroxyl groups of the clay. Indeed, TGA analyses of the isolated clay fraction evidenced the presence of grafted PCL chains.



Both montmorillonite and sepiolite nanoclays were also used as carriers for CALB immobilisation. Interestingly, activity tests showed that organo-modification of the clay surface allowed to improve lipase immobilization leading to catalytic systems with higher activity.



Nevertheless, polymerization kinetic was slower for nanoclay-immobilized lipases compared to commercial catalytic system.

Abstract

Intelligent polymers are pure or composed material will origin intelligence and self-comparative specialty against all instigations. Shape memory polymers are kind of intelligent materials which are reverse able to the origin shape. Instigators are controllable tools for productive work which tempretural, electronic and magnetic instigator is input and strain and mechanical work is output. According to development of intelligent polymer application, scientists newly use intelligent polymers for produce instigators. Instigators are tools which under influence of instigation get involved in strain. In fact instigators in responding to order or control signs work out. The amount of works which instigators do and the used energy are extremely depends on the way instigation. Hydro gels are kind of intelligent polymers; they have various applications in medicine. The most specialties are: hyrophilically, water absorption and softness which really similar to live weave. Natural hydro gels (collagen, alginate, and fibrin) shows good biomaterial. A crucial point is to make sure of being no non- reacted monomers in the system before apply. Hydro gel behaves both in solid and liquid. This specialty caused classification to 2 parts which is base on side gropes: neutral and ionic. According to physical and structural properties they can be divided to continuous polymer network and phantom. They also can be homo polymer or copolymer networks. In addition they can be classified non-shaped, half crystal, hydrogen bond structure, super molecule structure and association of colloid networks (hydro gel may have shown swelling behavior depend on media). The polymers are physiological responder hydro gels. In last 3 decades, scientists paid more attention to analysis and development in hydro gels responding to the physiological media. Responding to media due to the changes in pH, temperature, ionic power nature and combination of swelling elements shows different enzyme or chemical reaction. Mostly responding networks has critical point which usually transfer happens there. This hydro gel is unique because of different mechanism for drug blocking and other system. Another rare specialty for responding gels is the reversibility of polymer networks which have been changed. In this research we worked on analysis and development of this substructure mechanism of artificial nervous. According to achievements in this filed we can claim to find certain cure of demyelination and degeneration diseases of CNS, like MS and ALS and another diseases of CNS, like Alzheimer and dementia.

Hydrogels Based on Poly(vinyl alcohol)/Phosphoester and Poly(ethylene glycol)/Phosphoester for Biomedical Applications

Tăchiţă Vlad-Bubulac, Ana-Maria Oprea, Diana Serbezeanu, Corneliu Hamciuc

e-mail: tvladb@yahoo.com

Introduction: Biodegradable polymers have attracted considerable attention in the very recent years. Their potential applications in biomedical and ecological fields have been generated a great deal of effort in developing new polymeric structures with a biodegradable backbone, having excellent combined properties such as biocompatibility, antifouling properties, tunable mechanical properties, no toxicity, potential functional versatility which allows introduction of bioactive molecules and extensive modification of the physical, chemical and biological properties etc. [1–3]. Actually, the development of novel, stable and economical advanced drug delivery formulations based on hydrogels, which are well known to reduce the problems of conventional dosage forms, is an important topic in the field of biomaterials science [4]. The present work focuses on the synthesis and characterization of new polymers with phosphoester functions obtained by polycondensation reaction of poly(vinyl alcohol) (PVA) or poly(ethylene glycol) with different phosphonic dichlorides. These compounds were used to prepare hydrogels for biomedical applications.

Materials and Metods:

Starting materials (poly(vinyl alcohol) of variable molecular mases, poly(ethylene glycol) 1000, phosphonic dichlorides, chondroitin sulphate (CS), epichlorohydrin, metoprolol) were purchased from commercial sources and were used as received.

Results and Discussion:

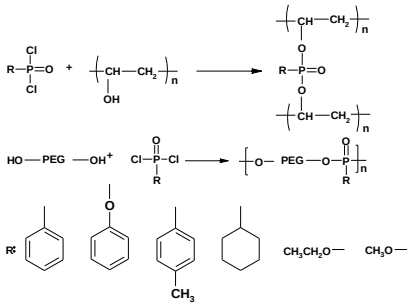
In the first step, the phosphorylated materials, poly(vinyl alcohol)/ phosphoesters and poly(ethylene glycol)/phosphoesters were synthesized by polycondensation reaction using dimethylformamide as solvent (scheme 1). The products were reacted with chondroitin sulphate and then crosslinked with epyclorohydrin. Basic structural characterization was performed and specific investigations for hydrogels were conducted.

Swelling studies were performed for all formulations and carried out by direct immersion in phosphate buffer solution (pH=7.4). The hydrogels samples were maintained for 24 hours at 37 ^{0}C, periodically removed from the solution, gently wiped with a soft tissue to remove surface solution, weighed and than placed back into the vessel as quickly as possible. The swelling degree at equilibrium was calculated according to the equation:

$$Qmax\ (\%) = (Wt - Wd)/Wd\ 100.$$

To determine the kinetics of solvent diffusion into the matrices (swelling) the following equation was used:

$$F_t = \frac{W_t}{W_{eq}} = k_{sw} t^{n_{sw}}$$



The drug loading method was performed by soaking or equilibration of superporous hydrogels samples in phosphate buffer solution (pH=7.4) with metoprolol tartrat for their complete swelling. The dissolution medium was pH 7.4 phosphate buffer solution. During dissolution testing, the media was maintained at 37 ± 0.5 ^{0}C. The concentrations of the drugs were calculated based on calibration curves determined for drug at specific maximum absorption wavelengths.

The in vitro release of metoprolol from PVA-P-CS hydrogels was carried out in intestinal pH conditions at 37 ^{0}C. The percent released is higher in case of hydrogels with an increased CS content, dependence between percent drug released and hydrogel compositions being seen. The highest cumulative metoprolol release obtained at the end of releasing period (6 hours) was 36% for 50/50 APV-P-CS composition.

Conclusion:

The PVA-P-CS hydrogels, crosslinked by epychlorohydrin provide advantages of all the components, PVA, phosphoester and CS moieties and they have potential use in controlled drug release.

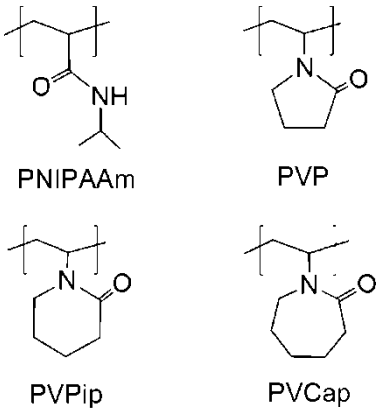
The Missing Lactam – Thermoresponsive Poly(*N*-vinylpiperidone)

Dr. Cecilia Ieong[1], *Dr. Rachel K. O'Reilly*[1]

University of Warwick[1]

n.s.ieong@warwick.ac.uk

In recent years, there has been significant interest in the development of stimuli-responsive materials as they have shown great promise in various biomedical applications.[1] In particular, temperature-responsive polymers (materials which undergo phase changes in response to a temperature trigger) have gained much current attention.



The discovery of poly(*N*-isopropylacrylamide) (PNIPAAm) as a thermoresponsive polymer in the 1950s has sparked interest in search for new classes of these 'smart' materials.[2] Amongst the numerous types of thermosensitive polymers, PEG-based polymers[3] and polyamides (such as poly(2-oxazoline)s[4], poly(*N*-vinylpyrrolidone) (PVP) and poly(*N*-vinylcaprolactam) (PVCap)[5,6] have been the most extensively studied. In particular, PVCap has received much attention due to its biocompatibility.[7] Despite the vast amount of scientific literature on the polymerization and the thermoresponsive behaviour of the 5- and the 7-membered ring poly(*N*-vinyllactam)s, there has been very little work on the 6-membered ring analogue.

In this talk, we will present a new type of thermoresponsive polymer, poly(*N*-vinylpiperidone) (PVPip) prepared by reversible-addition fragmentation chain-transfer (RAFT) polymerization using a xanthate as a chain-transfer agent.[8] All these polymers exhibited sharp and molecular-weight-dependent cloud points (CPs) with no apparent hysteresis. These water-soluble PVPip homopolymers could also be chain-extended with a hydrophobic monomer to afforded well-defined amphiphilic, thermosensitive diblock copolymers. The self-assembly and tunable thermoresponsive behaviour of these block copolymers will also be discussed.

The excellent thermoresponsive behaviour together with the promising cytotoxicity studies of the new materials demonstrated that these polymers possessed huge potential as novel biomaterials. More importantly, the possibility of incorporating PVPip into the existing family of thermosensitive materials, *e.g.* by copolymerization, suggested that the significance of this work might be much more far-reaching.

Introduction

Administration of drugs is often limited by problems of insolubility, inefficient distribution, enzyme hydrolysis, lack of selectivity and side-effects raising health concerns. Hollow capsules prepared by the layer-by-layer assembly of oppositely charged polyelectrolytes on a colloidal template, following by its decomposition, have recently emerged as attractive vehicles in the field of drug delivery.[1] For drug delivery applications, a prerequisite is to use biocompatible and biodegradable polyelectrolytes for the construction of the shell.[2,3] In this context, we proposed to develop tailor-made capsules from biocompatible and biodegradable polysaccharides able to entrap hydrophilic and hydrophobic drug molecules in the aqueous core and in the wall, respectively. In this presentation, we will describe an original approach to prepare in mild conditions polysaccharide capsules able to encapsulate poorly water-soluble molecules in the multilayer shell.

Materials and Methods

Materials. Chitosan Protasan with a degree of *N*-acetylation (DA) of 0.09 and a molar mass of M_w of 372000 g/mol was kindly provided by FMC BioPolymer AS, Novamatrix (Norway). Hyaluronic acid under the sodium salt form, having a molar mass of M_w of 200000 g/mol, was purchased from MEDIPOL Distribution (Switzerland). All other chemicals were purchased from Sigma-Aldrich-Fluka. The quaternized derivatives of chitosan were prepared according to literature procedures.[4,5] The alkylated derivatives of hyaluronic acid were synthesized as previously described.[6]

Polysaccharide capsules preparation. Microcapsules were prepared using calcium carbonate particles as a sacrificial template according to a procedure described previously. Incorporation of the hydrophobic molecules was performed by their pre-complexation with hydrophobically modified HA.

Results and Discussion

For the synthesis of tailor-made capsules, we selected hyaluronic acid (HA) as the anionic polyelectrolyte, due to its unique physico-chemical and biological properties that make it a particularly interesting candidate for the development of novel biomaterials for biomedical applications. In spite of its highly hydrated nature and weak polyacid character, we established the feasibility to obtain capsules consisting of HA and poly(allylamine).[2] As our goal was to obtain fully biodegradable capsules, we replaced PAH by biocompatible and biodegradable biopolymers that can form polyelectrolyte complexes with HA. We successfully prepared capsules based on HA and poly(L-lysine) (PLL) as polypeptide but shell cross-linking was required to improve capsule stability.[3] Interestingly, by replacing PLL by quaternized chitosan derivatives (QCHI), stable capsules could be obtained without cross-linking the shell,[7] which has the advantage of avoiding side reactions that may occur with the encapsulated drugs during the cross-linking reaction.

Based on these results and our previous work showing the very high affinity of hydrophobic molecules for the hydrophobic nanodomains formed by alkylated derivatives of HA in aqueous solution or in multilayer films[6], we then investigated the preparation of capsules able to entrap poorly water-soluble molecules in the polyelectrolyte shell. The LbL assembly of hydrophobically modified HA and QCHI on calcium carbonate particles followed by core decomposition afforded stable capsules. As expected shell loading with hydrophobic molecules pre-complexed with hydrophobically modified HA could be achieved making these capsules promising candidates for the solubilisation and delivery of hydrophobic drugs.

Conclusion

In summary, the present work establishes for the first time the feasibility of hydrophobic shell loading of polysaccharide capsules. The unique physico-chemical and biological properties of the polysaccharides used for the shell construction, and the close control over shell drug loading makes these capsules versatile candidates as carriers for hydrophobic drugs.

Non-monotonic variation of polymer size with increasing confinement

Debasish Chaudhuri and Bela Mulder

Affiliations: FOM Institute AMOLF

e-mail: chaudhuri@amolf.nl

Abstract:

A number of recent experiments have provided detailed observations of the configurations of long DNA strands under nano-to-micrometer sized confinement.
We therefore will revisit the problem of an excluded volume polymer chain confined between two parallel plates with varying plate separation. We'll show that the non-monotonic behavior of the overall size of the chain as a function of plate-separation, seen in computer simulations and reproduced by earlier theories, can already be predicted on the basis of scaling arguments. However, the behavior of the size in a plane parallel to the plates, a quantity observed in recent experiments, is predicted to be monotonic, in contrast to the experimental findings.

We analyze this problem in depth with a mean-field approach that maps the confined polymer onto an anisotropic Gaussian chain, which allows the size of the polymer to be determined separately in the confined and unconfined directions. The theory allows the analytical construction of a smooth cross-over between the small plate-separation de Gennes regime and the large plate-separation Flory regime. The results show good agreement with molecular dynamics simulations in presence of Langevin heat bath, and confirm the scaling predictions.
We will also show a direct comparison between our simulations and two recent experiments on confined DNA measuring the projected radius of gyration as a function of inter-plate separation.

Poloxamines for injectable scaffolds with osteogenic activity

Carmen Alvarez-Lorenzo[1], *Ana Rey-Rico*[1], *Maite Silva*[2], *José Couceiro*[2], *Angel Concheiro*[1]

e-mail: carmen.alvarez.lorenzo@gmail.com

Introduction

Current research on bone regeneration tries to optimize the healing while making the treatment more economically affordable and patient-friendly (injectable scaffolds). Small polyamines, such as spermidine, spermine, ornitine and putrescine, have appeared as an alternative to the expensive recombinant growth factors for inducing the differentiation of mesenchymal stem cells into osteoblasts (1). The aim of this work was to explore the potential of poloxamine block copolymers (Tetronic®) for combining the osteoinductive capability of amine-bearing synthetic molecules with the administration by minimally invasive techniques. These X-shaped copolymers bear four PEO-PPO arms connected to a central ethylenediamine group (Figure 1) and exhibit self-aggregation and in situ gelling under physiological conditions (2). Cytocompatibility, sol-to-gel transitions and osteogenic activity tests were carried out with three poloxamines and the results compared to those obtained in the presence of rhBMP-2.

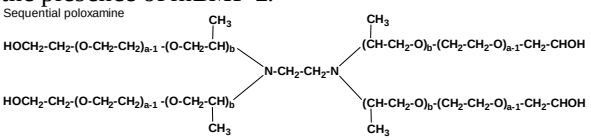

Figure 1. Poloxamines T908 (a=454.5; b=86.2), T1107 (a=238.6; b=77.6) and T1307 (a=286.4; b=93.1).

Materials and Methods

Osteoblast viability. SAOS-2 cells (HTB-85, ATCC) were cultured in D-MEM with 10% w/v FBS. 200,000 cells/well (1.5 ml) were seeded in 24-well plate and 0.5 ml polymer solution (20% w/w) was added. The plates were incubated at 37ºC for 72 hours and a calcein/propidium iodide staining was carried out.

Oscillatory rheology. The storage (G´) and the loss (G´´) moduli of 20% w/w poloxamine solutions in phosphate buffer pH 7.4 and D-MEM were evaluated before and after being autoclaved (121ºC, 20 min), using a Rheolyst AR-1000N rheometer at 5 rad/s from 15ºC to 45ºC with a heating rate of 2ºC/min (cone 6 cm diameter and 2.1 degrees; TA Instruments, UK).

ALP assay and histochemical analyses. Mesenchymal stem cells (StemPRO®, Invitrogen, Spain) were cultured in MesenPRO RSTM medium (Gibco, Invitrogen, Spain) and seeded ($3 \cdot 10^4$ cells/well, 2.5 ml) in 6-well plates. 200 µL of copolymer dispersions (20% w/w) containing or not rhBMP-2 (0.037 mg/ml) were placed into the upper compartment of 6-well plate Transwell® permeable supports. The amounts of copolymer and rhBMP-2 into each well were 40 mg and 7.4 µg, respectively. Negative and positive controls were carried out with cells in culture medium and in osteogenic differentiation medium, respectively. Plates were incubated at 37 ºC with 5% CO_2. To carry out the alkaline phosphatase (ALP) assay, cells were lysed, exposed to freezing/unfreezing cycles, and centrifuged. Each sample (50 µl) was incubated with ALP substrate (150 µl) in 96-well plates at 37ºC for 30 min and the absorbance read at 405 nm (BIORAD Model 680 Microplate Reader, USA). ALP activity measurements were normalized by the protein content. Cell proliferation was quantified with MTT assay. Alizarin red staining was used to detect the mineralization of the matrix and Oil Red O staining was performed to detect adipogenic activity and mature adipocytes. Chondrogenic differentiation was tested using Alcian blue staining.

RT-PCR analysis RNA was extracted at days 7, 10 and 14 using TRIzol (Invitrogen, Spain) and reversed transcripted into cDNA using Maloney murine leukemia virus (M-MLV) reverse transcriptase and random hexamers (Invitrogen, Spain) A semiquantitative RT-PCR method was used by assessing PCR products during the exponential phase of cDNA amplification. The generated cDNA was amplified by using primers for CBFA-1, ALP, and collagen type I, and GAPDH.

Results and Discussion

SAOS-2 cells viability was above 90% after being 24 hours in contact with 20% w/w T908, T1107, and T1307 medium. Below 20ºC, the poloxamine solutions behaved as free flowing liquids and were easily syringeable owing to their low viscosity. The gel temperature was around 25ºC for T1107 and T1307, and 33ºC for T908. At 37ºC, all systems behave as gels with storage modulus ranging between 10^3 and 10^5 Pa. Autoclaving did not modify the rheological behaviour.

The ALP activity of the cells cultured in the osteogenic medium showed a maximum at day 7. ALP activity of T1107 solely and T1307 with rhBMP-2 was no different to that of negative control. Cells cultured with T908 and T1107 gels loaded with rhBMP-2 exhibited an ALP activity pattern that resembled that obtained with the osteogenic medium. By contrast, the ALP activity of cells cultured with T1307 gel loaded with rhBMP-2 initiated at day 3, remained practically constant up to day 14, and then decreased. The highest ALP activity at day 7 was obtained for T908 gels with or without rhBMP-2. Poloxamine solely gels led to an initial proliferation of mesenchymal stem cells (1 week), followed by differentiation to osteoblasts (2-3 week). Such an intrinsic osteoinductive effect of poloxamines was confirmed by histochemical and RT-PCR analysis.

Conclusions

The osteogenic activity of poloxamines offers novel perspectives in the field of fracture healing, overcoming safety and cost/effectiveness concerns associated to the large scale clinical use of recombinant growth factors.

The key factors driving *in vivo* immobilization of proteins to PHA

Nina Dinjaski[1], *Jose Luis Garcia*[1], *M. Auxiliadora Prieto*[1]

[1]CIB-CSIC, Ramiro de Maeztu, 9, 28040 Madrid, Spain

-Introduction

Polyhydroxyalkanoates (PHAs) are biodegradable polymers, produced by different bacterial species, with important industrial and medical applications as bioplastic and potential biomaterial. PHAs are accumulated intracellularly in form of granules protected by a lipid monolayer interspersed with amphipatic phasins from highly hydrophilic cytoplasm. *Pseudomonas putida* strains contain two phasins PhaI and PhaF that is a modular bi-functional protein. PhaF behaves as a structural and also as DNA associating protein. The C-terminal region is similar to nucleoid associated proteins and plays a crucial role in granule localization within the cell and segregation during the cell division. It ensures the equal distribution of granules between daughter cells (Galán *et al*., 2011). The N-terminal region works as a functional domain (BioF domain) able to bind PHA granules and, in harmony with PhaI, acts as a major structural protein. The *BioF protocol* was established as protein immobilization/purification system based on the use of polyhydroxyalkanoate (PHA) granules and their associated phasins (Moldes *et al*., 2004). After fermentation under optimal PHA production conditions, the granules carrying the BioF-proteins fusions can be isolated from the crude cell lysate by a simple centrifugation process and directly used for some applications (Moldes *et al*., 2004). In this work, generated BioF fusions were transferred and expressed in *P. putida* KT2442 strains in the presence and absence of the natural phasins to determine the roles of these key factors for protein immobilization to PHA. The efficiency of the BioF system has been tested by using a reporter BioF-fusions. Host strains have been engineered by site-directed gene replacement, which has the environmental advantage of generating antibiotic marker-free strains. Our work provides new evidences about the minimal genetic modifications that make it suitable for producing environmental friendly active bioplastics.

Materials and Methods

In order to test the BioF system and determine localization of both N- and C-terminal region of PhaF *in vivo*, expression of their fusions with GFP was analyzed by confocal microscopy Laser Confocal espectral (CLSM) Leica TCS SP2-AOBS. Furthermore, DNA was stained with 2 µg/ml (DAPI), while the PHA granules were stained with 1 µg/ml Nile Red to analyze co-localization with C- and N-terminal region respectively. PHA-immobilized protein was extracted as described before (Moldes *et al*., 2004) and analyzed by SDS-PAGE. PHA monomer composition and cellular content were determined by GC-MS. Samples were subjected to methanolysis in the presence of 15% (w/v) sulfuric acid, and resulting methyl esters of monomers were analyzed by gas chromatography. *P. putida* strains KT42F (PhaF mutant) and KT42I (PhaF and PhaI mutant) have been engineered by site-directed gene replacement using the pK18*mobsacB* vector, which has the environmental advantage of generating antibiotic marker-free strains. The heterogeneity of the cell population concerning the PHA production was performed using Flow citometry (flow cytometer Coulter EPICS XL). Analysis was done as described before (Galan *et al*., 2011).

Results and Discussion

The role for the C-terminal and N-terminal domain of PhaF phasin of *P. putida* KT2442 was investigated by confocal microscopy and flow-cytometry studies. Our results confirm the co-localization of the fusion protein GFP::C-PhaF and nucleoid in wild type and PhaF minus cells, independently of the presence or absence of the PHA granules, demonstrating its DNA associating properties. Furthermore, PHA granules produced in the wild type cells, which contain native PhaF protein, co-localised with the nucleoid and GFP::C-PhaF reporter. However, PHA granules produced in the KT42F (PhaF minus) mutant strain were localised independently of the nucleoid and GFP reporter system. This definitively demonstrated the association of PHA granule to the chromosome driven by PhaF protein. Visualizing GFP::N-PhaF proved its co-localization with PHA granules in wild type as well as in both mutant strains when grown in PHA producing conditions. It confirms its granule binding function. However, the PHA production in the strains KT42F (PhaF mutant) and KT42I (PhaF and PhaI mutant) was reduced to 50% and 10%, respectively, when compared to the production of the wild type strain, making them non optimal hosts for expression of BioF system. When complemented with PhaF, KT42F strain recovered wild type phenotype. Furthermore, KT42I strain recovered phenotype of wild type when complemented simultaneously with both PhaF and BioF. Consequently, PhaF and, BioF or PhaI, were identified as essential requirements for BioF system host strains for optimal PHA production yields.

Conclusions

1. BioF tag or its fusion derivatives can replace PhaI role in *P. putida*.

2. The optimal host *P. putida* strain for the BioF system should express i) the whole protein PhaF and ii) PhaI or BioF tag

Polymeric Bio-Functionalisation to Generate Enzyme-Responsive Biomaterials

Paul D. Thornton and Andreas Heise

Dublin City University, School of Chemical Sciences, Polymer Chemistry Group, Glasnevin, Dublin

Paul.d.thornton@dcu.ie

Introduction

Proteolytic enzymes have been identified to play key roles in disease states making them valuable targets for therapeutic programs. We disclose methodologies in which commercially available polymers can be adapted to possess an actuating component sensitive to the presence of targeted proteolytic enzymes. Enzyme activity stimulates a material response that may be employed in 1) drug delivery or 2) protease detection systems. In the first instance a protease-responsive release mechanism that employs a molecular gate to entrap payload molecules is described. Selective proteolysis of the specific peptide sequence results in the triggered release of payload molecules on-demand. A second protease-responsive mechanism details the peptide modification of water soluble poly(allylamine) (PAA) to generate a material capable of self-support when dissolved in water. Enzymatic disruption of the dipeptide sequence generates polarity within the structure, enabling polymer dissolution in water and offering a visible response to enzyme activity. nter your text here making certain it is in a two-column format. Please use this template only.

Materials and Methods

Material modification was achieved by synthesising peptide components directly using stepwise peptide synthesis. HBTu and DIPEA were used as coupling agents and DMF was the chosen solvent. Prior to each additional amino acid coupling piperidine and potassium carbonate were employed to remove Fmoc and acetyl protecting groups respectively. Analysis of the biomaterials produced utilised GPC, NMR, HPLC, ATR-FTIR and TGA. The release of payload molecules was analysed by confocal microscopy and UV-VIS spectrophotometry. Type the abstract title in upper and lower case letters (do not use all capitals letters) in the indicated line spanning both columns.

Results and Discussion

1) Highly Specific Dual Enzyme-Mediated Payload Release from Peptide-Coated Particles

The triggered release of macromolecular guest molecules from polymer microparticles coated with a bioactive peptide shell (Fmoc-EAAR) was demonstrated by utilising terminal Fluorenylmethyloxycarbonyl (Fmoc) groups as molecular gates.[1] Specific enzymatic hydrolysis of the peptide sequence, by elastase but not the control enzyme chymotrypsin, removes the bulky peptide-terminating Fmoc groups from the particle shell, permitting the selective release of previously entrapped guest molecules through the newly created openings. Two-stage payload release was demonstrated by coating the particles with both Fmoc-EAAR (elastase cleavable) and Fmoc-EGGR (thermolysin cleavable) (Figure 1). The system offers highly selective responsiveness and adaptability to be applied to a wide range of organic and inorganic polymeric particles of varying size ranges.

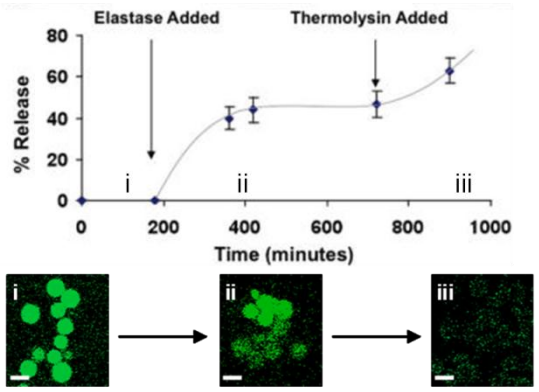

Figure 1: Payload release profile (top) and confocal images detailing enzyme-controlled release.

2) Bio-Functionalisation to Enzymatically Control the Solution Properties of a Self-Supporting Polymer

The solubility of PAA in water can be altered by the partial addition, and subsequent cleavage, of acetyl protected alanine to alanine-modified PAA.[2] Successful proteolysis by elastase generates polarity, allowing the polymer to dissolve in water, offering a visible response to the specific enzymatic activity. It is anticipated that system of controlling polymer solubility may be further employed for the label-free detection of a range of proteases or the release of guest molecules.

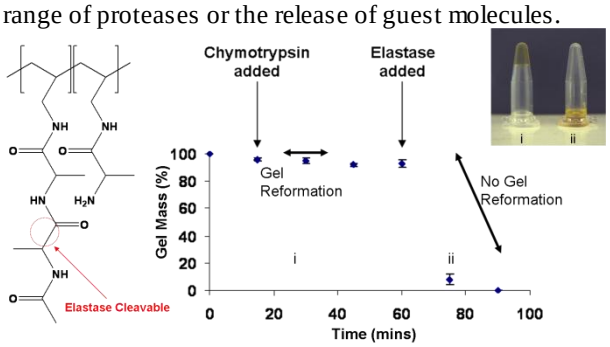

Figure 2: Left Functionalised polymer capable of self-support. Right Targeted proteolysis disrupts the structure.

Conclusions

The work presented discloses methods of polymer modification to offer materials that possess a degree of biological functionality. Possible applications involve the use of polymers in drug delivery and biodiagnostics.

A modern trend to miniaturization of bioanalytical, diagnostic and informatic functional devices down to molecular level requires development and use of nanosize elements of various chemical structure and morphology obtained mainly by direct chemical synthesis. The presentation considers three types of such hybrids and composites.

First, macroscopic solid porous and nonporous matrices have surface modified with nanothick uniform layers of various polymers (fluorinated polymers, polyanilines, etc.) and contain specific functional groups on the surface [1]. The peculiarity of preparation of such composites and their application are considered on the examples of the system for facile separation of biomacromolecules (nucleic acids [2], proteins [3], etc.) and enzyme immobilization [4].

Secondly, the presentation considers a series of bioanalytical systems where the used markers are molecular dyes, fluorophores and in particular fluorescent nanocrystals immobilized on various polymer [5] including nanoscale matrices [6] and full-size or mini-antibodies as bioligands. The efficiency of the system is demonstrated on the examples of various immunoagglutionation assays, flow cytometry, visualization of cells including tumor cells, tissues.

Thirdly, the presentation considers hybrid hydrogels based on linear water-born polymers (poly-N-vinylpirrolidone [7], poly-N-vinylcaprolactam [8], etc.) and nanosize inorganic particles (SiO_2, Si, Au, Fe_3O_4) [9]. The latter acts as cross-linker of the system and also may bring specific function (magnetic, optical, etc.) to resulting hybrid hydrogels. The hybrid hydrogels are formed under mild conditions and show high elasticity and mechanical strength. Their use as biomaterials is discussed.

e-mail: miheres@doctor.upv.es

Introduction:

Metals are the most common materials used in medical implants for hard tissues due to their excellent mechanical properties. [1] However, metals have some severe limitations.[2] For example, their capacity of osseoinduction, the corrosion process that suffers in biological medium releasing metallic particles that reduce the osteoblast activity.[3] Moreover, metals can not incorporate biological or organic components as peptides or drugs. The incorporation of biological compounds and drugs to metals could be a way to obtain multifunctional prosthesis and to increase its biocompatibility.

One way to avoid these problems and to make metal implants able to delivery drugs and peptides is to create a biocompatible and bioactive coating. [4] The sol-gel process is an available technique for coating the surface of the metal. In this method, a metal alkoxide undergoes hydrolysis in the presence of water with an acid or basic catalyst. The silanols produced then condense forming a SiO_2 network. It is possible to obtain organic-inorganic coatings throw the sol-gel method by using metal alkoxides with organic chains.

The aim of this work is to prepare and evaluate sol-gel coatings. Different organic-inorganic coatings have been synthesized using as methal alkoxides vinyltrimethoxisilane (VTES), 3-glycidoxypropyl trimethoxysilane (GPTMS) and tetraethoxysilane (TEOS). The physic-chemical characterization of the materials was done and reported. This paper is focus in the biological characterization of the hybrid coating.

Materials and Methods

Synthesis of the sols
Two set of materials was prepared: VTES / GPTMS and VTES / TEOS, with different compositions. The sol was prepared by acid catalysis method, isopropanol as solvent and 0.1M nitric acid (HNO_3) in order to obtain an acid pH. The water was incorporated from the nitric acid solution in stoichiometric ratio. The molar ratio of VTES/GPTMS were 4:1; 1:1; and 1:4 and the molar ratio of VTES/TEOS were 9:1, 4:1, 7:3. The sol solutions were stirred for about 1h and set for another hour at room temperature before use.

Curing process of the sol
The curing process for VTES/GPTMS was 15 min.50ºC, 15 min. 100ºC, 45 min 140ºC. The curing process for VTES/TEOS was 15 min.50ºC, 90 min. 100ºC.
Characterization of the coatings
The chemical composition of the coating was investigated by Fourier Transformed Infrared (FTIR). The study of the cure process was done by FTIR and Differential Scanning Calorimetry (DSC). The contact angle was measured. The hydrolytic degradation of the materials was characterized. Finally, the cell response using human adipose tissue-derived mesenchymal stem cells (AMSC) in contact with the materials was studied.

Results and Discussions

The characteristic bands of the inorganic network and the presence of the organic groups was found in all spectra. The study of the VTES/GPTMS show that the increase of the quantity of GPTMS in the formulation leads to an increase of active epoxy rings in the surface of the material.

The study of the cure process was done by FTIR and DSC. Optimal cure temperatures and times were obtained for each set of materials in order to maximize Tg, adhesion and mechanical properties.

Variations of the wettability and the hydrolytic degradation ratio ware detected in different formulations of VTES/TEOS, as more TEOS is added more wet and degradation ratio is registered.

The proliferation and the induction of bone formation of AMSC has been reported for each set of materials, showing the high possibilities for using them in tissue engineering.

Spray Dried Hydroxyapatite-Chitosan Biocomposites

Tuğba Başargan and Gülhayat Nasün-Saygılı[*]

[*] Chemical Engineering Department, Istanbul Technical University, Turkey

nasun@itu.edu.tr

Introduction

Hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$, HAp) is a bioceramic used in the biomedical applications [1]. HAp-polymer composites are used to maintain bioactive properties and development in mechanical properties [2]. Chitosan is a natural polymer degrading to non-harmful and non-toxic compounds in the body [3]. Chitosan has gained great interest as a result of their biological activities such as antimicrobial, hypocholesterolemic, immunity enhancing, antitumor effects, drug delivery,accelerating calcium and ferrum absorption [4]. HAp-chitosan microsphere-based material may be used for bone-grafting and delivery of therapeutic agents [5]. It is claimed that HAp-polymer microspheres are perfect to the delivery of cells, proteins and drugs for the cure of defective tissues and their regeneration [6].

The aim of this study was to synthesize HAp-chitosan microspheres by spray drying technique.

Materials and Methods

Phosphoric acid (0.12 M)-chitosan (%1 wt in %2 aqueous acetic acid) mixture was added to $Ca(OH)_2$ (0.2 M) solution drop by drop at 40 ^{0}C. During the addition of acid mixture, the pH was maintained at 9 using dilute acetic acid and NaOH. After the mixture addition, the reactants were stirred for two hours more and then suspension was aged for 15 h at room temperature. The precipitate was separated from the supernatant liquid by decanting and volume was restored again by adding distilled water. The slurry was fed into a laboratory scale spray dryer at a flow rate of 500 mL/h. The inlet temperature of hot air was set to 160 $^\circ$C. For comparison, HAp sample was also prepared in the absence of chitosan using a similar way. Synthesized HAp and HAp-chitosan samples were structurally characterized using FTIR, SEM, XRF, BET and XRD. Crystallite size of the composite was calculated with TOPAS 3 software [7]. Particle size measurements were made using ZetaPals.

Results and Discussion

The XRD patterns of the samples (Fig. 1) confirmed the formation of HAp in the samples. Nano-crystalline apatite and low degree of crystallinity were observed in the samples [8-10]. Crystallite sizes of the composite were found 40.8, 10.3 and 14.3 nm when 002, 211 and 310 peaks were used, respectively [7]. According to FTIR spectra (Fig. 2) HAp-chitosan composite was successfully synthesized. After polymer addition, CH_2 (2920-2858 cm^{-1}) and amide II (1570 cm^{-1}) bands of chitosan appeared on the composite which confirmed the formation of HAp-chitosan composite.

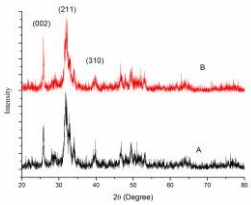

Fig. 1. XRD patterns for **A** HAp **B** HAp-chitosan.

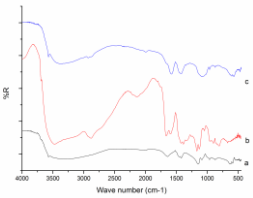

Fig. 2. FTIR spectra of **A** HAp **B** Chitosan **C** HAp-chitosan.

According to XRF analysis result, the Ca:P molar ratio of HAp and HAp-chitosan powders were 1.665 and 1.721, respectively. The particle size was found 2.7 µm. BET surface area of HAp and HAp-chitosan samples were found 78.59 and 94.82 m^2/g, respectively.

Fig. 3 indicates SEM graph of HAp-chitosan composite. Most of the granules were solid particles and the particle distribution was not uniform.

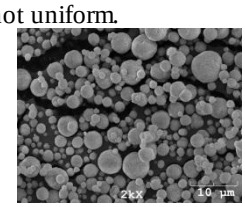

Fig.3 SEM graph of HAp-chitosan.

Conclusions

In this study, HAp-chitosan microsphere was prepared using spray dryer. This composite may be a potential material in biomedical fields.

Introduction:
Heparin is a natural polymer widely used in medicine especially during the treatment of cardiovascular diseases since it is a potent blood anticoagulant. In case of emergency, e.g. massive haemorrhage the anticoagulant activity of heparin has to be quickly stopped by the administration of a heparin reversing agent. Currently protamine sulfate, an allergenic protein is used for this purpose.

Materials and Methods
We are reporting the studies on a new polymeric substance, a cationic dextran derivative, which is able to form complexes with heparin. Dextran is a blood-compatible polymer which is also frequently applied in medicine. By substituting dextran with glicydyltrimethylamonium chloride (see reaction scheme below) a cationic polymer was obtained that binds to heparin with an efficiency similar to that with protamine[1].

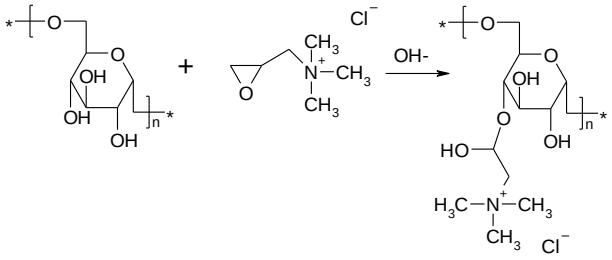

Figure 50 Schema of reaction used to obtain cationic dextran

The binding process and the complex formed were studied using UV-Vis spectroscopy, DLS and zeta potential measurements.

Results and Discussion:
Cationic dextran derivative was found to bind heparin in PBS solution. This binding is based on attractive electrostatic interaction between anionic heparin and cationic dextran. The efficiency of this processes strongly depends on the degree of cationic modification and is similar to binding of heparin by protamine, however, the size of heparin-dextran complexes is larger than that of heparin-protamine complexes (ca. 10 μg). Moreover, preliminary studies on the influence of different levels of modified dextran on the heparin activity in the rat blood using various coagulation tests were performed. They have shown a decrease in clotting time after administration of cationic dextran to heparinized rats.

Conclusions:
The preliminary data obtained show that the cationically-modified dextran may reduce anticoagulative heparin activity both under in vivo and in vitro conditions.

e-mail: migiannotti@ub.edu

Introduction. Nanopharmaceutics composed of a carrier and a protein have the potential to improve the activity of therapeutical proteins. Therapy for lysosomal diseases is limited by the lack of effective protein delivery systems that allow the controlled release of specific proteins to the lysosomes. Here, we address this problem by developing functional polyelectrolyte-based nanoparticles able to promote acidic pH-triggered release of the loaded protein. Complexes formed by self-assembly between proteins and natural or synthetic polyelectrolytes do not require harsh preparation methods and have been the focus of many recent studies.[1] Chitosan and its derivatives are cationic polymers at low pH and can interact and form complexes with proteins that bare a negative charge at pH<pI, whereas derivatives like quaternized chitosan bare positive charge and are soluble at physiological pH. α-galactosidase A (α-GAL) is a lysosomal enzyme, which deficiency leads to the Fabry disease and results in the lysosomal accumulation of globotriaocylceramide within various tissues and cells, in particular the vascular endothelium.[2] To date, the only strategy to treat this disease has consisted in ERT with exogenously administered α-GAL.[3] As an alternative, we developed functional TMC-based PEC nanocarriers with α-GAL, prepared by self-assembly via simple aqueous solution mixing and ionotropic gelation. We characterize their physicochemical properties, stability against time and temperature, behavior against the variation of the medium pH as well as intracellular trafficking and fate in human endothelial cells.[4]

Materials and Methods. Chitosan middle-viscous was used to prepare *N*,*N*,*N*-trimethyl chitosan chloride (TMC) following a two-step synthesis procedure.[5] The product was characterized by 1H NMR. Potentiometric titration was used to analyze chitosan and TMC buffering capacity (free amine moieties that can be protonated). The polyelectrolyte complexes (PECs) between TMC and the negatively charged protein α-GAL were prepared by self-assambly, adding a solution of TMC (buffer HEPES 10 mM, pH 7.4) at various concentrations (100 to 24.5 μg ml^{-1}) to the protein dissolved in the same buffer, in a volume ratio 70:30. For the cases where penta-sodium triphosphate (TPP) was used, the polianion was previously dissolved in the protein solution. Average size, polidispersity index (PDI) and Z-pontential values were determined by dynamic light scattering (DLS). TMC was conjugated to the florescent dye Atto 647N NHS ester, to visualize the nanoparticles under total internal reflection fluorescence (TIRF) microscopy (for single particle tracking) and for further *in vitro* studies. Atomic force microscopy (AFM) was used to characterize the PECs morphology and their behavior upon pH variations. Cellular uptake of the fluorescent nanoparticles by HMEC-1 cells was followed flow citometry and confocal laser scanning microscopy (CLSM).

Results and discussion. Ionically crosslinked colloidal polyelectrolyte complexes (PECs) between TMC and the lysosomal protein α-GAL were successfully obtained by self-assembly in a simple way. These α-GAL nanocarriers are homogeneous in size, as well as stable and active under physiological conditions. A relatively high protein load (around 50 wt %) per particle was achieved. The enzymatic activity of the α-GAL was not significantly affected by the encapsulation process, ensuring the integrity of the protein during and after the procedure. Finally, a rapid PEC internalization and further accumulation in lysosomal compartments of human endothelial cells was demonstrated. Following a pH drop from physiological (around 7.5) to endosomal/lysosomal (4.5-5.5) values, the PECs dissociated and released the protein (Fig. 1). Altogether, our results demonstrate that the α-GAL nanocarriers are stable and active under physiological conditions and traffick to lysosomal compartments of human endothelial cells, where the acidic conditions can trigger the release of the protein. As such, these nanocarriers represent a valuable and promising alternative for lysosomal enzyme replacement therapy with improved efficiency in Fabry disease and other lysosomal storage diseases.

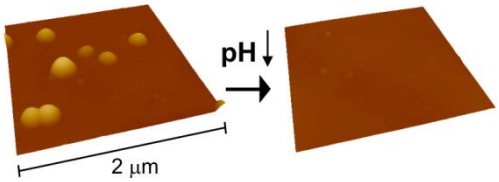

Fig. 1. 3D representations of AFM images (height, tapping mode) of TMC/α-GAL PECs on an HOPG substrate at pH 7.5 and after HCl addition (pH 3.9).

Modeling of Nanotubes Penetration through a Phospholipid Bilayer

Sergey Pogodin[1], *Nigel K. H. Slater*[2] *and Vladimir A. Baulin*[1,3]

[1]Departament d'Enginyeria Quimica, Universitat Rovira I Virgili, Av. dels Països Catalans 26, 43007 Tarragona, Spain, [2]Department of Chemical Engineering and Biotechnology, University of Cambridge, Pembroke Street, Cambridge CB2 3RA, United Kingdom, [3]ICREA, Passeig Lluis Companys 23, 08010 Barcelona, Spain

msupsg@yandex.ru

A great efficiency to penetrate into living cells is attributed to carbon nanotubes due to a number of direct and indirect observations of the nanotubes inside the cells. However the exact mechanism of such penetration still remains unknown. We performed series of computer simulations in order to study one of the possible ways of the nanotubes inside the cells, namely the spontaneous translocation through a pure phospholipid membrane induced by thermal motion.

With use of Single Chain Mean Field technique we simulated phospholipid membrane at the coarse grained level, which had been shown to represent adequately the key thermodynamic properties of the DMPC bilayer in the fluid phase [1]. A carbon nanotube was modeled by a cylinder, which diameter and surface affinity to the hydrophobic core of the membrane was varied between different sets of the simulations. Performing perpendicular insertion of the nanotube inside the membrane we were obtaining, as output of our simulation, the values of equilibrium free energy of the system at every position of the nanotube (Fig. 1), and mean field snapshots of the bilayer reorganization around its' tip (Fig. 2).

We began with consideration of the nanotubes with uniform surface properties [2]. As we found out, they hardly are able to cross the phospholipid membrane without an application of external force due to the presence on their way of energy barrier of order 40 kT and higher, depending on the nanotube size and hydrophobicity. While relatively hydrophilic nanotubes meet the positive barrier which is difficult to overcome by thermal motion, the hydrophobic ones are exposed to strong attraction to the phospholipids tails which is high enough to entrap them within the hydrophobic membrane core. The nanotubes with the intermediate hydrophobicity are exposed to the both effects. To pass through the membrane they have to overcome the steric repulsion from it due to the pore formation in the bilayer, as well as the attraction to the membrane's core.

Comparison of the energy curves (Fig. 2) of the nanotubes with uniform surface properties suggests that alternation of hydrophobic and hydrophilic regions on the nanotubes surface can reduce considerably the energy barrier of translocation. We have shown [3] that the periodical patterning of the nanotube with distinct hydrophobic and hydrophilic bands can significantly facilitate their penetration through the phospholipid bilayer. Such a patterning may occur naturally in biological systems upon the spontaneous self-assembly of biomolecules onto the surface of the nanotubes.

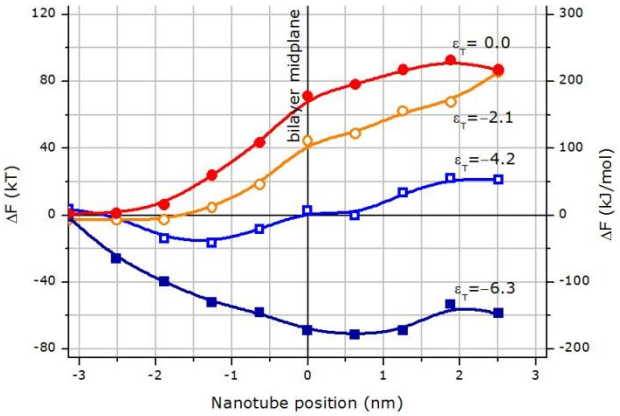

Fig. 1. Free-energy cost of the nanotube insertion into the phospholipid bilayer versus the tube position. For the nanotube with diameter 1.0 nm and hydrophobicity increasing from curve ε_T=0.0 to ε_T=-6.3.

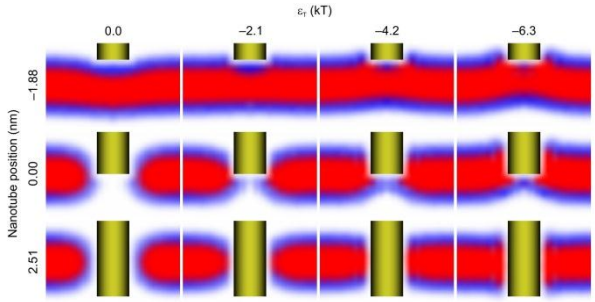

Fig. 2. Mean-field snapshots of the nanotubes insertion into the phospholipid bilayer.

Zinc oxide protects etch&rinse adhesive resin-dentin hybrid layers from MMPs degradation.

Toledano M, Yamauti M, Suarez P, Quintana M, Osorio E, Osorio R.

Aim of the study: Demineralization of dentin collagen matrix by acids may represent a suitable collagen scaffold to be remineralized; in the presence of minerals.Demineralized exposed collagen can undergo degradation by endogenous matrix metalloproteinases (MMPs). Effective inhibitors of matrix metalloproteinases may be included in resin-dentin bonding interfaces to protect the seed crystallite-sparse collagen fibrils of the scaffold, from degradation before they could be re-mineralized. MMPs mediated collagen degradation in the different bonded interfaces has to be determined.

Methods: An in vitro assay with dentin beams was performed. Dentin beams were obtained and immersed in: 1) 10% phosphoric acid (PA) and impregnated with Single Bond resin or 2) Clearfil SE Bond (SE) primer and impregnated with SE bonding resin. 2% of $ZnCl_2$ or 10% of ZnO nanoparticles were added to resin mixtures. Four dentin beams were tested for each condition.

Dentin beam specimens were incubated in 500 µl of media artificial saliva at 37°C for 24 h, 1 and 3 wk. Supernatants were analyzed for the release of collagen degradation product (C-terminal telopeptide of type I collagen -ICTP-) using a radioimmunoassay. Values were analyzed by ANOVA and SNK multiple comparison ($P<0.05$).

Results and discussion: Mean and standard deviation of ICTP values and multiple comparisons results are in the table. Identical numbers in each row indicate no significant difference. In each column values with identical letters indicate no difference.

		24 h	1 wk	4 wk
Phosphoric acid		53.33 (8.3) 1A	210.11(11.20)2A	212.3(17.89) 2A
Phosphoric acid	SB	0.84 (0.03) 1B	1.49 (0.33) 2B	2.52 (0.80) 2B
	SB- 2% $ZnCl_2$	1.09 (0.10) 1B	0.97 (0.12) 1B	1.74 (0.76) 2B
	SB- 10% ZnO	0.48 (0.05) 1B	0.83 (0.05) 1B	0.60 (0.05) 1C
SEB-Primer		10.02 (1.20) 1C	41.54 (5.32) 2C	50.97 (6.54) 1D
SEB-Primer	SEB-Bond	1.37 (0.22) 1B	0.30 (0.12) 2E	0.59 (0.09) 2C
	SEB-Bond- 2% $ZnCl_2$	1.71 (0.32) 1B	2.94 (0.11) 2B	5.04 (0.87) 3E
	SEB-Bond- 10% ZnO	0.92 (0.20) 1B	1.35 (0.10) 2B	1.91 (0.54) 2B

Conclusions: Addition of 10% of zinc oxide particles serves as effective and stable inhibitor of dentin MMPs in resin/dentin hybrid layers created with the tested etch&rinse system. MMPs degradation of collagen is strongly reduced in resin infiltrated dentin.

Preparation and Characterisation of Glycopolymers by CCTP and Click Chemistry

*Yanzi Gou and David M. Haddleton**

Department of Chemistry, University of Warwick, Coventry CV4 7AL, United Kingdom

D.M.Haddleton@warwick.ac.uk

Introduction

Glycopolymers are important in many biological processes such as inflammation, cell-cell contacts and fertilisation.[1] For catalytic chain transfer polymerisation (CCTP), very small amount of chain transfer agent is needed to prepare low molecular weight oligomers and under well-chosen conditions, nearly all polymer chains will have an unsaturated vinyl bond at the chain end for post-functionalization.[2] Huisgen copper-catalysed azide–alkyne cycloadditions (CuAAC) click reaction has been used in the design of novel polymeric materials, bioconjugation, synthesis of lead discovery libraries, tagging of live organisms and proteins and labeling of DNA.[3, 4] In this study, CCTP and CuAAC have been combined to prepare glycopolymers with low molecular weights, which are very difficult to synthesize by other living polymerisation techniques.

Materials and Methods

3-Tri-methylsilanyl-prop-2-yn-1-ol was purchased from Alfa Aesar and used without further purification. Copper(I) bromide (Aldrich, 98%) was purified according to the method of Keller and Wycoff.[5] Triethylamine (TEA) (Fischer, 99%) was stored over sodium hydroxide pellets. All other reagents and solvents were obtained from Aldrich and used without further purification. All reactions were carried out by using standard Schlenk techniques under nitrogen. NMR spectra were obtained on Bruker DPX300 and Bruker DPX400 spectrometers. All chemical shifts are reported in ppm relative to tetramethylsilane, referenced to the chemical shifts of residual solvent resonances (^{1}H and ^{13}C). MALDI-TOF spectra were obtained on a Bruker UltraflexII TOF and analyzed using FlexAnalysis software. The MALDI contains a 337 nm wavelength N2 at a maximum repetition rate 50 Hz. The system is kept inside a vacuum at 5×10^{-6} Torr to avoid contamination of the sample reading.

Results and Discussion

Preparation of alkyne-containing double clickable polymers via CCTP. A series of TMS-protected polymers **(2)** were prepared using CoBF as catalyst and AIBN as initiator, **Figure 1**. Double clickable scaffolds **(3)** can be obtained by deprotection to remove the TMS groups with tetrabutylammonium fluoride (TBAF) and acetic acid in THF at ambient temperature. MALDI-TOF spectrum, **Figure 2,** shows the composition, structure and PDi of the double clickable polymers.

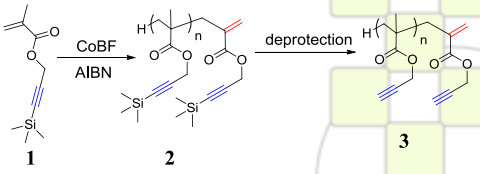

Figure 1. Preparation of polyalkyne scaffolds via CCTP.

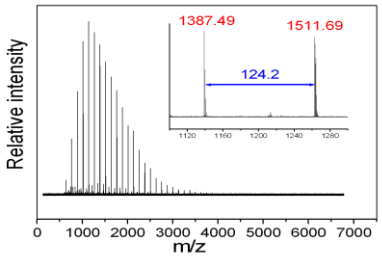

Figure 2. MALDI-TOF spectrum of polymer **(3)**.

Glycopolymers synthesized by CuAAC click reaction. Sugar azides were prepared by one-step reaction from unprotected sugars.[6] Fucose glycopolymers were synthesised by CuAAC, **Figure 3**, **Figure 4**, as were mannose and galactose glycopolymers.

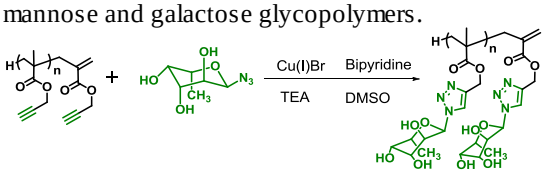

Figure 3. Synthesis of fucose glycopolymer via CuAAC.

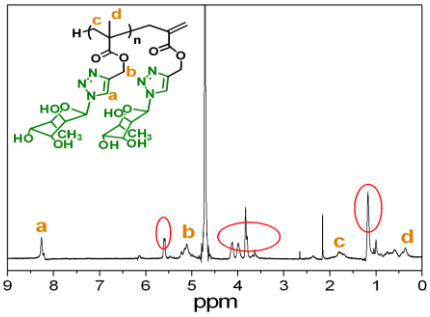

Figure 4. ^{1}H NMR of fucose glycopolymer

Conclusions and References

A series of glycopolymers have been synthesised in a modified way by combining CCTP and CuAAC. The interaction of them with specific lectins is being investigated.

Recognition and Release of Biological Catechols in NIPAM-Based Copolymers Bearing Phenylboronic Acid Receptors

Nicolas Martin, Sophie Norvez, and Ilias Iliopoulos

Matière Molle et Chimie, ESPCI ParisTech – CNRS, UMR-7167
10, rue Vauquelin, 75005 Paris, France

sophie.norvez@espci.fr

Responsive polymers like poly (*N*-isopropyl-acrylamide), PNIPAM, have been widely used for the preparation of stimuli sensitive systems with potential applications in drug transfer and delivery. A comonomer bearing the phenylboronic acid (PBA) functionality may be designed to recognize diol-containing biological molecules, *e.g.* catechol derivatives like dopamine or noradrenaline. Since PNIPAM is a thermosensitive polymer, PNIPAM-*co*-(acrylamido-PBA) copolymers (PNB) will exhibit both temperature and diol responsiveness. In this work, the reversible association *via* boronic ester formation between PBA-bearing NIPAM-based copolymers and biological catechols was investigated at physiological pH by experiments in the UV–visible range.

Alizarin Red S (ARS), considered here as a model for biological catechols, was chosen as an optical reporter in the visible range for the boronate ester formation (Figure 1). Dialyses experiments and numerical analysis of UV-visible titration curves resulted in the quantitative determination of the host-guest binding constants. Above the phase transition temperature of the NIPAM-based thermosensitive copolymer, the binding constant decreases significantly more than in the case of non thermosensitive copolymers. Temperature-controlled released of the dye was associated to the coil-to-globule transition of NIPAM-based copolymer [1].

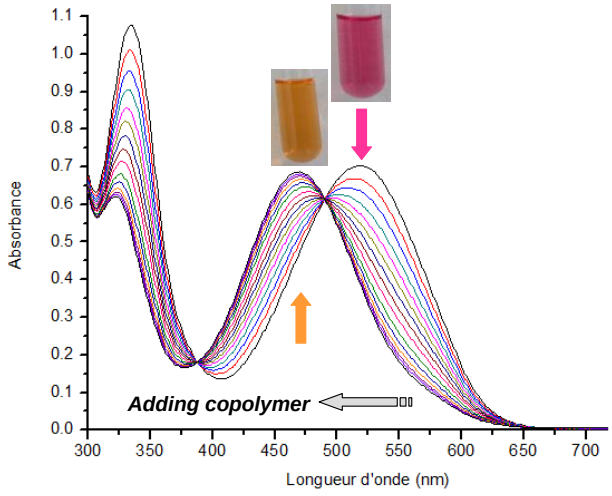

Figure 1: Quantitative study of the recognition of ARS by PNB copolymer.

Polycatechols, like tannins, are other attractive molecules because of their biofunctional properties, in particular anti-oxidative. Tannic acid (TA) is a bio-resourceful fully degradable polyphenol extracted from plants. Only a couple of studies have dealt with the TA-PNIPAM interaction, a weak association acting through hydrogen-bonding between hydroxyl groups of the phenols and amide groups of the polymer, as well as through hydrophobic interactions. In this work, turbidity studies as well as competitive experiments highlighted a very strong interaction between tannic acid and NIPAM-based copolymer bearing phenylboronic acid residues. This was in particular attested by the disappearance of the LCST of PNB (Figure 2). This huge interaction is likely rooted in the multivalent character of the polyphenol, which may bind to multiple chain sites through boronate ester formation.

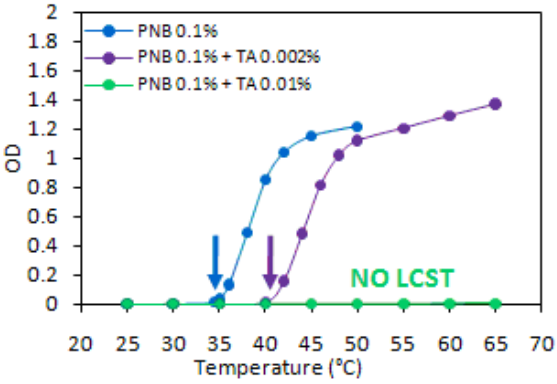

Figure 2: Disappearance of the LCST of PNB copolymer in presence of tannic acid (TA).

It is envisioned that the affinity between tannic acid and NIPAM-*co*-PBA copolymers may serve to the controlled release of catechols of significant biological importance, like dopamine or others.

Istanbul Technical University, Department of Chemical Engineering, 34469 Maslak, Istanbul, Turkey

iyisanb@itu.edu.tr

Introduction

Lipase is a kind of hydrolase that catalyze the hydrolysis of fats in living cells. They are also used in organic synthesis as a catalyst to produce organic compounds. In addition to that, their hydrolytic effect in water can be changed into ester synthesis in non-aqueous media. By utilizing this special behavior, lipases are used to catalyze ring opening polymerization (ROP) of lactones. A seven-membered lactone called ε-caprolactone (ε-CL) is used as a monomer to produce poly (ε-CL). Although novozym 435 (immobilized form of candida antartica lipase B) can catalyze ROP of ε-CL efficiently, because of the cost reasons, chitin immobilized lipase was prepared for polycaprolactone synthesis in this study [1,2].The reason why chitin was chosen as a support material for immobilization in this study is that it is a cheap, ubiquitous and nontoxic material, also it has high protein affinity and this property makes chitin a demanding support for enzyme immobilization [3,4].

In this study, chitin was immobilized to lipase by two different methods: physical adsorption and crosslinking with glutaraldehyde. To evaluate prepared catalysts for polycaprolactone synthesis, polymerizations reactions were carried out simultaneously with the same conditions by both chitin immobilized catalysts (physically immobilized and crosslinking with gluteraldehyde) and novozym 435. Among chitin immobilized lipases, crosslinking with gluteraldehyde showed higher catalytic activity. To reach optimum polymerization conditions, chitin immobilized lipase crosslinking with gluteraldehyde was used in further polymerization reactions. Effect of temperature, polymerization time and enzyme concentration on molecular weights (Mn) of polycaprolactone was investigated in this study. Also, reuse of chitin immobilized lipases was examined.

Materials and Method

Novozym 435 and free form of lipase enzyme (Novozymes CALB L) was purchased from Sigma Aldrich Company. ε-caprolactone (%99) was provided Alfa Aesar and stored under dry nitrogen over molecular sieves (3A^{o}). Toluene was supplied from Merck Company. Gluteraldehyde solution, chloroform and Chitin from crab shells were purchased from Sigma Aldrich Company.

First part of the experiments was immobilization of lipase. Gluteraldehyde pretreated chitin was prepared by adding chitin into 50 ml %0.2(v/v) gluteraldehyde/phosphate buffer solution (ph7,0.015M). Then this suspension was stirred (160 rpm) for 1 hour at 25 ^{o}C. The gluteraldehyde pretreated chitin was filtered and washed with distilled water. Secondly, determined amounts of CALB enzyme solution was diluted by phosphate buffer (ph 7, 0.015 M). 400 mg chitin and gluteraldehyde-pretreated chitin supports were suspended in prepared diluted enzyme solutions. Enzyme-support suspensions were stirred (160 rpm) for 5 hours at 25 ^{o}C. Immobilized enzymes were characterized by scanning electron microscopy.

In the second part of the study, polymerization reactions were performed at different temperatures (60 ^{o}C, 70 ^{o}C, 80 ^{o}C) in toluene (toluene to ε-caprolactone ratio, 2:1(v/v)) under dry nitrogen. At a specified time, reaction was terminated by adding chloroform and enzyme was separated by filtration. Chloroform in the filtrate was largely evaporated and resulted solution was precipitated in methanol. Polymer was filtered and dried at 35 ^{o}C.

Characterization of the resulting polymers was performed by GPC, FTIR and ^{1}H-NMR. Molecular weights and polydispersity were determined by GPC using Agilent 1100 HPLC system.

Results and Discussion

In figure 1, for 24 hours and at 70 ^{o}C, comparison of three enzymes mentioned above with respect to Mn can be seen.

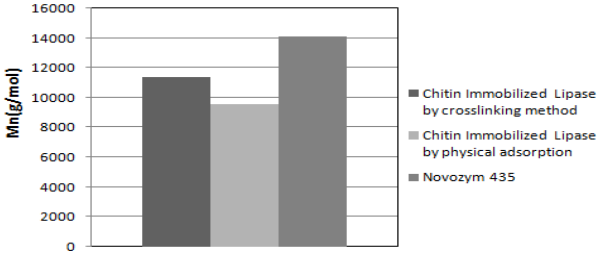

Figure 1. Comparison of enzymes with respect to Mn

Conclusions

Temperature, polymerization time and enzyme concentration had important effects on molecular weights (Mn) of polycaprolactone. Also, in comparison to novozym 435, although polymerization reaction was slower by chitin immobilized lipase, polydispersity were reduced by this type of catalyst.

The development of polymer/chromophore conjugates is particularly attractive in many fields such as bioimaging. Indeed, polymers bring many advantageous features to the conjugates. First, they contribute to the solubilization of the hydrophobic organic chromophores in biorelevant media. In addition, highly fluorescent probes are obtained through the coupling of many chromophores on the same polymer backbone. Finally, multifunctional polymers can also be used to immobilize other entities like bioactive moieties (bioconjugates).

Using well-defined multifunctional polymers synthesized by RAFT polymerization [1-2], we developed biocompatible conjugates bearing a controlled number of chromophores that can be excited in the red or the near–infrared where absorption of light by the biological media and tissues is low.

Figure 51: Schematic representation of the polymer/chromophore (F) conjugates

.

In particular, high two-photon absorption (TPA) chromophores were covalently bound onto the polymers since two-photon excitation is highly localized and thus allows high 3D resolution imaging with low out-of-focus photodamages or photobleaching [3-4].

After a thorough characterization of the mono- and two-photon optical properties of the conjugates, their cytotoxicity as well as their internalization into live cells were evaluated using flow cytometry and confocal fluorescence microscopy.

Introduction

Incorporation of cellulosic fibers into polymers matrices offers the possibility to design new composite materials with reduced environmental impact, due to the biodegradability, renewability and low cost of natural fillers. The properties of these composites are strictly depending on the interactions at the interface between the components. To improve the interfacial adhesion and fiber dispersion into the polymer matrix, either addition of modified components or introduction of reactive groups can be advantageously employed [1]. The present study is focused on the preparation and characterization of new binary and ternary polyester/cellulose composites with enhanced properties and processability for packaging applications.

Materials and Methods

Poly(lactic acid) (PLA) (Hycail HM 1011, MFR[190 °C/2.16 Kg]= 2-4 g/10min), ethylene-vinyl acetate-glycidylmethacrylate (EVA-GMA) (Elvaloy AS DuPont), polycaprolactone (PCL) (CAPA 680, Solvay) were used as polymer components. Cellulose fibers (CF) of different length (Technocel 165 and 500-1, Neuchem) were used as filler. Binary and ternary composites (PCL/CF, PLA/CF, EVA/CF, and PLA/EVA-GMA/CF) were obtained by melt mixing in a Brabender Plasti-corder internal mixer at 150/180 °C (60 rpm, 10 min). The various systems were then examined by SEM, RX, FT-IR, DSC, TGA, DMTA and tensile tests.

Results and Discussion

Composites of PCL with CF were compatibilized by adding cellulose modified with butyric acid (CFB). SEM analysis of these samples pointed out an improved adhesion between PCL and fibers as compared to uncompatibilized PCL/CF composites. DSC and XRD analyses showed that the PCL crystallinity decreased from 68% to 50% by increasing the CFB content (0-10 wt%) due to miscibility effects [2] (**Figure 1**).

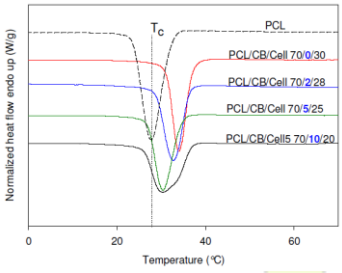

***Figure 1**. DSC cooling thermograms of PCL and PCL/CF composites*

The properties of PLA/EVA-GMA blends and PLA/EVA-GMA/CF ternary composites were investigated as a function of composition. For the blends the values of elastic modulus followed the model of Coran and Patel [3]. Tensile strength of blends decreases with increasing EVA-GMA content due to the lower strength of EVA-GMA, while elongation at break increased exponentially (**Figure 2**).

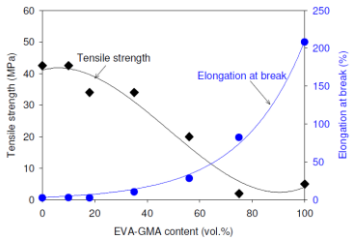

***Figure 2.** Tensile strength and elongation at break of PLA/EVA-GMA blends*

SEM microscopy pointed out a higher compatibility between cellulose and PLA/EVA-GMA matrix blends over all the composition range, as compared to PLA/CF composites (**Figure 3**). This effect was accounted for by the reaction of epoxy groups of EVA-GMA with the OH groups of cellulose and OH/COOH groups of PLA.

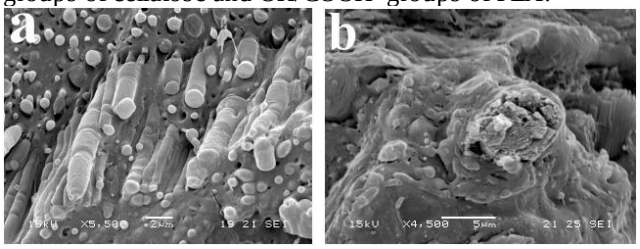

***Figure 3.** (a) PLA/EVA-GMA 50/50; (b) PLA/EVA-GMA/CF*

Moreover, a nucleating effect of cellulose fibers on the crystallization of PLA was observed with formation of transcrystalline morphology. Enhanced mechanical properties, i.e. tensile strength, elastic modulus and elongation at break, were also recorded for ternary composites.

Conclusions

For all examined systems the interfacial adhesion and properties are improved both in the presence of modified cellulose (CFB) and reactive polymer (EVA-GMA). In the case of ternary composites PLA/EVA-GMA/CF the phase morphology and mechanical properties can be advantageously modulated by varying the ratio of polymer components.

Synthesis and (Bio)Conjugation of Polypeptides from *N*-Carboxyanhydride (NCA) Polymerization

Jin Huang[a], *Gijs Habraken*[b], *Andreas Heise*[a,b]

andreas.heise@dcu.ie

Introduction: Recent developments in the ring-opening polymerization of N-carboxyanhydrides (NCA) allow the synthesis of well-controlled polypeptides.[1] A very common and convenient method of NCA polymerization is the initiation by primary amines (amine mechanism). We investigated the effect of reaction parameters like temperature and pressure on this approach with respect to structural control and reaction kinetic. Secondly, we will present our results on the lateral as well as end-group (bio)functionalization of synthetic polypeptides for example for the synthesis of glycopeptides.

Results and Discussion:
We have systematically investigated the polymerization of various amino acid N-carboxyanhydrides (NCAs) at 0 °C.[2] Detailed MALDI-ToF analysis of homo-polymerizations clearly confirms that frequently occurring end-group termination and other side-reactions are absent at 0 °C. The polymerization is thus controlled and homo and copolypeptides with low polydispersities around 1.1 can be obtained. The controlled character of the low temperature NCA polymerization was further verified by the successful multi-block copolymer synthesis from polypeptide macroinitiators (Figure 1).

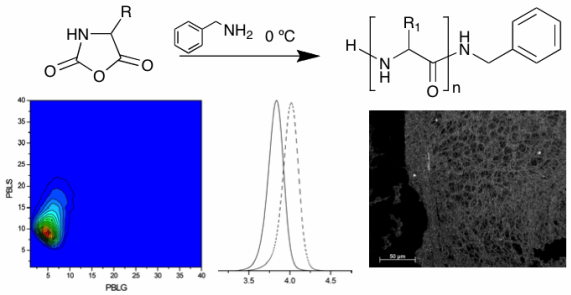

Figure 1. NCA polymerization at 0 °C: MALDI-ToF contour plot of copolymerization of benzyl-L-glutamate (BLG) and benzyl-L-serine (BLS) NCA confirming randomness of monomers (left), GPC traces of P(BLG-*b*-BLS) synthesis by macoinitiation (center) and optical microscopy picture of P(BLG-*b*-BLS).[2]

Based on these experimental procedures functional polypetides were targeted by using efficient thiol chemistry and azide-alkyne click reactions.[3,4] The latter was applied for the synthesis of glycopeptides. In the initial polymerization poly(DL-propargylglycine) and poly(BLG–*co*–DL-propargylglycine) were synthesized to yield well-defined polypeptides with polydispersity indices below 1.3. The subsequent glycosylation was achieved by Huisgen [3+2] cylcoaddition ('click' reaction) with azide-functional galactose (Figure 2). FTIR, NMR, SEC and MALDI-TOF analyses verified the successful glycosylation and suggest a high efficiency of the click reaction. Upon glycosylation a transition from β-sheet to random coil was observed for the homopolymer in the solid state. The homo-glycopeptide was found to be water-soluble and to form aggregates in water above a critical concentration of 0.079 mg/mL. Selective lectin binding experiments confirmed that the glycopeptides could be used in biorecognotion applications. The fact that no labile bond was used to link the alkyne to the amino acid allows to apply common amino acid deprotection chemistry on the glycopeptides as was shown for the γ-benzyl-L-glutamate copolymer. The isosteric linkage thus improves the chemical and potentially metabolic stability while retaining biological activity.

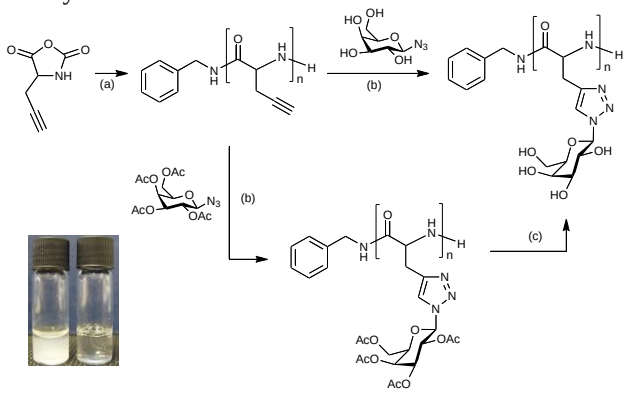

Figure 2. Synthesis of glycopeptides by NCA polymerization und subsequent glycosylation by 'click' chemistry. The inset shows positive reaction with lectin RCA_{120} (left, turbid) and negative control with lectin Con A (right).[4]

Microbial depolymerization processes are categorized into two classes, exogenous type depolymerisation processes and endogenous type depolymerisation processes. In an exogenous depolymerization process, molecules reduce molecular weight by trancation of monomer units from their terminals. Polymers subject to exogenous depolymerization processes include polyethylene (PE). The mechanism of PE biodegradation is based on two essential factors, gradual weight loss of large molecules due to β-oxidation and the direct consumption or absorption of small molecules by cells. A mathematical model based on those factors was proposed to study PE biodegradation [1, 2, 3, 4].

Polyethylene glycol (PEG) is also subject to exogenous depolymerization processes. The mathematical techniques originally developed for the PE biodegradation was extended to study the biodegradation of PEG. Problems were formulated to determine degradation rates based on the weight distribution of PEG with respect to molecular weight

before and after cultivation of a microbial consortium E-1, and transition of the weight distribution was simulated [5, 6, 7, 8].

Unlike exogenous type depolymerization processes, molecules are cleaved at arbitrary positions in endogenous type depolymerization processes. A mathematical model for endogenous depolymerization process was proposed to study enzymatic depolymerization process of PVA [9, 10]. Mathematical model originally proposed for enzymatic degradation of PVA was extended to study enzymatic hydorolythis of polylactic acid (PLA) [11, 12].

Techiques in studies on biodgradability of xenobiotic polymers based on numerical simulation and experimental outcomes will be described, and results will be introduced.

Abstract

Lignin is biopolymer that belongs to the main components of wood. The modification in the chemical structure of lignin of rubber wood chip, Soda-Anthraquinone and total chlorine free bleached lignin content was monitored by SEM and FTIR spectroscopy. FTIR spectroscopy is an important tool for lignin characterization based on several major vibration bands associated with generally found chemical groups. In wood treated by soda pulping, there was a progressive increase in the lignin content, which is evident from increase in the relative intensities of lignin associated bands and a corresponding decrease in the intensities of carbohydrate bands. In contrast, there was a decrease in the lignin content of TCF bleached pulp. Less than half of the surface lignin was removed during bleaching process, with the oxygen stage and the final peroxide stage being the most effective. The SEM result also shows that the surface lignin remaining on TCF-bleached lignin was remnant from native rubber wood lignin having tetra functional branch points, which was never released from wood fibers, but it had undergone several structural changes during cooking.

Introduction

Cellulose is a polymer β-(1-4) linked glucose units. By contrast to synthetic polymers where crystallization is an entirely separate process from the synthesis, the nature of cellulose biosynthesis is such that cellulose crystallites are synthesized at the same time as the polymer by an array of synthetic complexes embedded with a specific orientation with respect to the cell membrane. Biosynthesis by the arrays (rosette complexes[1]) arranges cellulose chains in parallel along the length of the crystallite, rather the than the more thermodynamically favorable anti-parallel form[2]. As a result of this modern view of cellulose biosynthesis, and careful analysis of x-ray diffraction of powder (isotropic) samples, we view cellulose as a nanocrystalline (microfibrilar) solid rather than a semi-crystalline solid[3]. This stiff crystalline material is embedded in an amorphous matrix consisting of lignin and other cell wall polysaccharides. The anisotropic arrangements of the microfibrils (texture) within plant tissue is a key means by which plants may modulate their mechanical properties with little or no change in chemistry or nanostructure.

There is a renewed technological interest in natural fibres due to a dawning molecular scale understanding of biosynthesis and generation of texture[1], and the potential to economically unlock glucose locked within the crystalline microfibril. In our work we examine the response of these structures to mechanical deformations, both from the perspective of understanding mechanical performance, but also the physical changes to the packing of cellulose chains within the cellulose microfibril.

Materials and Methods

Palm nut fibres are the by-product of palm cooking oil and represent a considerable source of unexploited biomass[4]. Hemp fibres are used commercially for reinforcement of composite materials and textiles[5]. These materials have been selected because it is relatively easy to isolate single fibres for presentation to the x-ray beam and provide an interesting contrast in cellulose texture.

Small and wide angle X-ray scattering (SAXS and WAXS respectively) patterns have been collected on a two-dimensional X-ray detector from single hemp and palm nut fibres. Both measurements were made on a Bruker Nanostar instrument - operational details of the instrument may be found on its web-site[6].

Results and Discussion

The azimuthal SAXS and WAXS profiles indicate two different cellulose arrangements in the palm and hemp fibres. Azimuthal profiles of WAXS are interpreted in terms of a rectangular cellular cross-section, while the cross section of the hemp fibre would seem to be largely cylindrical. In the palm fibres the cellulose microfibrils are largely arranged in a helix around the fibre axis. The angle of this helix with respect to the fibre axis is approximately 35°. In the hemp fibres the microfibrils are arranged largely parallel to the fibre axis.

Radial averages of WAXS measurements and the Scherer equation (assuming pure size broadening of diffraction peaks) were used to calculate the lateral dimensions of the cellulose microfibril. The picture of a rectangular cross-section is consistent with the view of cellulose biosynthesis. The palm fibre microfibril is smaller than that of the hemp fibre. The relatively homogenous electron density of all cell wall polymers means that SAXS is of limited use in determining cellulose nanostructure. SAXS data is consistent with long voids in the fibre aligned largely with microfibril direction.

Conclusions

SAXS and WAXS provide, non-destructively, information about the arrangements of cell wall polymers in single fibres. Thus both measurements and the analysis outlined here are suitable and provide complementary information for the *in-situ* studies of structural re-arrangements of fibres during tensile deformation using the synchrotron radiation. These studies, which are currently underway, should provide an interesting contrast, in the case of the palm fibres it will be the cellulose helix which is deformed, and in the case of the hemp fibres the tensile stress will be applied largely along the direction of the cellulose crystallite.

Introduction

Designing novel synthetic agents that are able to affect cellular membrane properties and induce a controlled permeabilization while keeping the integrity of the membrane is a major challenge for academic chemistry and biophysics, applications in pharmaceutical research, and biotechnologies.

In this context, we developed an original family of polymeric membranar permeabilizers. Their originality lies on a unique structure with single or geminated crown-ethers located on each three carbons along the main chain (Scheme 1). This particular stereochemistry induces absolutely unusual inter-substituents distances.

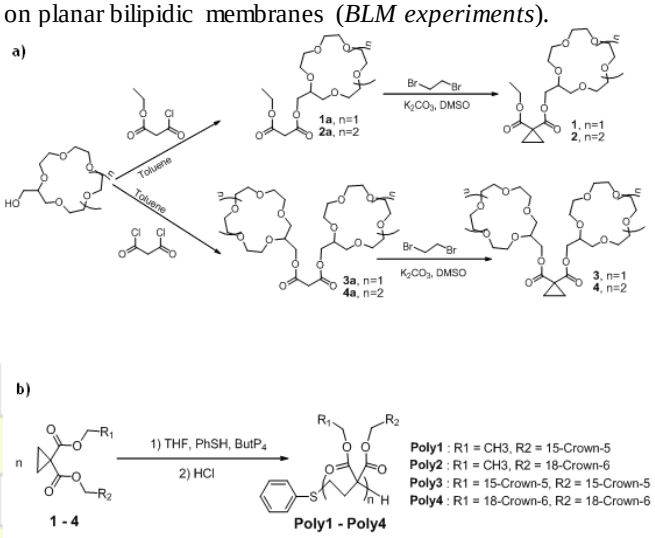
The communication reports the synthesis of four monomers **(1)-(4)** differing by the number and size of crown-ether substituents and the corresponding polymers. Their ion binding properties as well as their ability to permealize bilipidic membranes have been investigated.

Materials and methods

The polymers were obtained via the anionic ring-opening polymerization of the substituted cyclopropane-1,1-dicarboxylate monomers (scheme 1). A controlled polymerization was obtained by using a procedure we recently developed based on tetrameric phosphazene base $ButP_4$ in association with a protic precursor to the initiator.[1,2]

The binding efficiencies of the polymers and their monomeric analogs towards Li^+, K^+ and Na^+ were evaluated from distribution equilibria of the respective salt complex between an aqueous phase and an immiscible organic solvent.

The membrane permeabilization ability of synthesized polymers was investigated by conductance measurements on planar bilipidic membranes (*BLM experiments*).



Scheme 1: monomers (a) and polymers (b) synthesis pathways

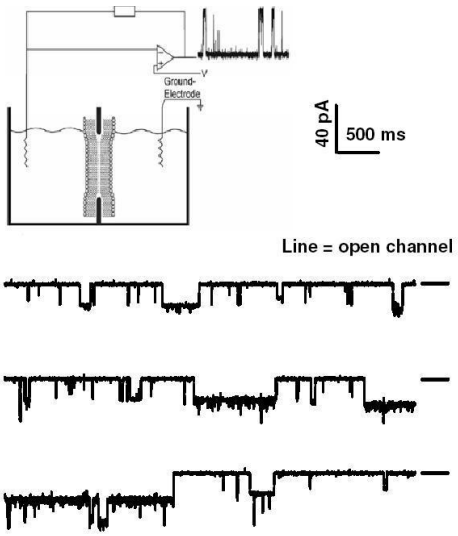


Figure 1: *BLM experiments*; (up) experimental set-up; (down) some current traces obtained with Poly(1) at 40 mV. The current jumps are characteristics of the closure and opening of well-defined pores within the bilipidic membrane.

A conventional set-up for BLM conductance measurements uses two chambers that are filled with buffer (Figure 1). The membrane is located between both chambers. The current flowing through pore in the BLM in response to an applied voltage is then recorded and used to obtain insights on the pore conductance.

Results and discussion

To span a bilipidic membrane, polymers have to be around 3-7 nm. Four oligomers corresponding to **poly(1)-poly(4)** has been successfully synthesized with a good control of molecular weights ($6.10^3<M_n<10^4$ g/mol) and narrow polydispersity index (<1.2). Results obtained on the complexation of metallic cations indicate a strong polymer effect and the possibility of obtaining sandwich structures. Finally, BLM experiments revealed no pore formation in presence of monomers, whereas well defined pores could be observed in presence of the corresponding oligomers (Figure 1).

Conclusions

Original polymeric membrane permealizers with crown-ethers located on each three carbons along a polymer backbone has been developed and studied. Their activity on biological membranes is now under investigation.

Synthesis of monodisperse linear poly(oxazolines) with minimised structural defects as model compounds for elucidating cell membrane properties

Bryn Monnery[1], *Sunil Shaunak*[2], *Maya Thanou*[3], *Joachim Steinke*[1]

Correspondence: j.steinke@imperial.ac.uk

-Linear poly(ethylenimine) is an important polymer in the field of gene delivery as it is widely used as a cationic model gene delivery vector [1, 2]. However it is extremely cytotoxic, and this toxicity is related to the molecular weight of the polymer [3, 4, 5]. Synthesis of linear PEI (l-PEI) is typically carried out by the cationic polymerisation of a 2-alkyl-2-oxazoline followed by hydrolysis (see figure 1).

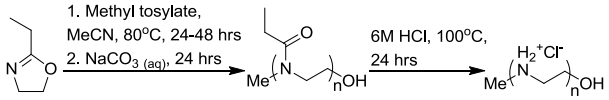

Figure 1: Commercial synthesis of l-PEI hydrochloride salt[6].

The current state of the art polymerisation of oxazolines was reported by Park and Kataoka [7] and shows low polydispersity up to a molecular weight of ~ 10 kDa. However, applying this methodology to higher molecular weights leads to a broadening of the molecular weight distribution by a chain transfer- coupling mechanism (see figure 2).

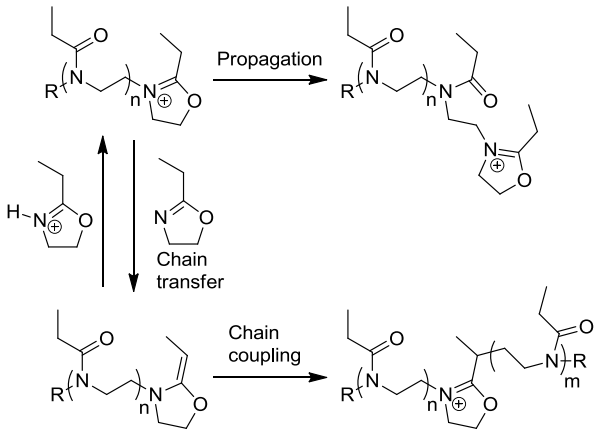

Figure 2: Competing propagation (nucleophilic substitution) and chain transfer (elimination) reactions, followed by chain coupling (alkene competing with the monomer). R = CH_3 or H (re-initiated polymers)

Optimised reaction conditions could be identified further suppressing chain-transfer lowering PDI values, for example at ~ 25 kDa polymers with PDI values of 1.03 instead of ~ 1.30 (see figure 3). This allowed us to synthesise higher molecular weight poly(oxazolines) than previously possible whilst retaining a very narrow molecular weight distribution.

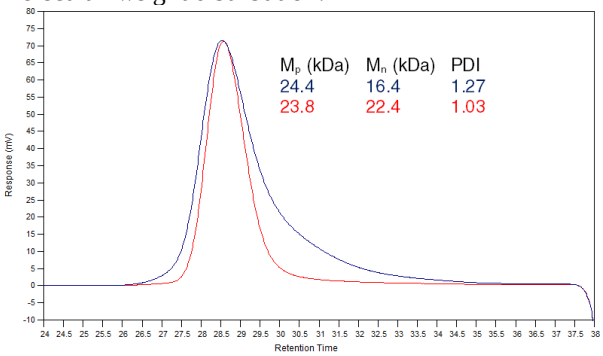

Figure 3: M_p = ~ 24 kDa poly(2-isopropyl-2-oxazoline) via (blue) the methodology of Park and Kataoka[4], and (red) the current work. Eluograms in DMF (1% TEA/ 1% acetic acid) of one drop of the crude reaction mixture in 1 ml DMF.

Polymers with a DP of around 250 have been synthesised without detectable chain transfer. Even higher molecular weight poly(oxazolines) with narrow PDI can be accessed in this way, though chain-coupling is present and crude product samples require an additional purification step via affinity chromatography. Our polymers are currently being employed to generate a rigorous data set which will allow us to determine the structure-activity relationship of l-PEI in regards to its cytotoxic properties.

Proteins as mechanophores in damage self-reporting polymeric materials

N. Bruns, Samuel Lörcher, Thomas Winkler

Department of Chemistry, University of Basel, Klingelbergstrasse 80, CH-4056 Basel, Switzerland.

nico.bruns@unibas.ch

Living organisms have developed ways to detect and report damage of their tissue. This is usually accomplished by nerve signals, e.g., in the form of pain, or by optical signals, e.g., by the dark red color of a bleeding wound. The indication of damaged tissue is crucial for an organism in order to start to protect the respective body part. In technical applications, polymer-based materials are often used as load-bearing materials because they are lightweight, possess excellent mechanical properties and are easy to manufacture into any desired shape. Fiber-reinforced composites in particular find application in the aerospace, the automotive and the sporting goods sector. However, common polymers and composites do not visualize damage to alert the user of impeding danger. In order to avoid accidents, man-made polymeric materials that detect and report small scale structural damage before catastrophic failure occurs are highly desirable.

We have doped polymers and fiber-reinforced composites with engineered proteins. Microcracks and delamination defects due to strain or impact are reported by the proteins in the materials through a local change in the fluorescent properties of the proteins, e.g. a change in fluorescence resonance energy transfer (FRET) [1] or the vanishing of fluorescence [2]. These signals can be observed by fluorescence microscopy and other fluorescence methods.

Synthesis and Characterization of Redox and pH-sensitive Poly(aspartic acid) Hydrogel

B. S. Gyarmati, Á. Némethy, T. Gyenes, A. Szilágyi

Soft Matters Team, Department of Physical Chemistry and Materials Science, Budapest University of Technology and Economics, H-1521 Budapest, Hungary

e-mail: aszilagyi@mail.bme.hu

Hydrogels have been studied extensively because of their unique bulk and surface properties, as well as their responsiveness to external stimuli. Hydrogels play an important role in various biomedical applications, especially in the development of controlled drug delivery systems. Besides the stimuli responsive attribute, biocompatibility and biodegradability of the controlled drug delivery system is also important. Drug delivery systems aim to be compatible with the drug and control the rate of its release at the targeted biological disease site with little or no damage to the surrounding tissues [1]. Polymer gels based on amino acids may fulfill these requirements.

A novel preparation route was developed to synthesize chemically cross-linked poly(succinimide) (PSI) and poly(aspartic acid) (PASP) gels [2]. Several natural compounds were selected as cross-linkers. In this study we focused on PSI and PASP hydrogels containing redox sensitive cross-linkers. The resulting redox and pH sensitive gels were investigated and the interconversion between thiols and disulfides are produced in different conditions. This phenomenon is a key step in many biological processes, as well as being applicable in injectable polymeric implants.

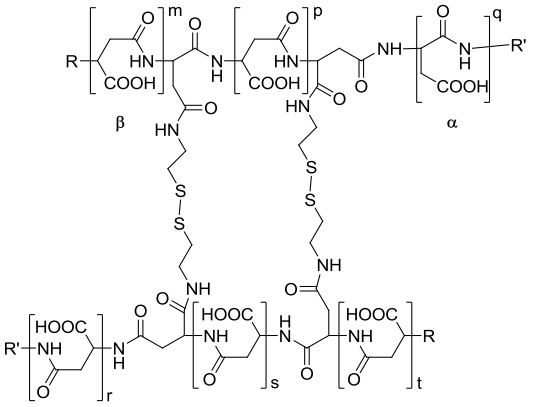

Figure 1. Chemical structure of the poly(aspartic acid) hydrogels with redox sensitive cross-linkers.

In case of cysteamine modified PASP, gelation can be carried out by oxidation. Gelation time strongly depends on the polymer concentration, but less on the modification ratio. To determine gelation time oscillation rheometry measurements were carried out. Storage modulus increased rapidly during oxidation, and gelation time determined from these measurements. Thiol and disulfide groups were characterized by Raman microscopy and it was proven that sol-gel transition occurs because of thiol-disulfide transformation in redox reaction.

With a combination of two kinds of cross-linker – redox sensitive and inert cross-linker – we could synthesize PASP hydrogel with well defined, adjustable swelling properties. The hydrogels could respond with a volume change when the environmental properties, such as the pH or redox potential, were varied.

Swelling degree of poly(aspartic acid) gels showed strong pH-dependence. They show an abrupt change at about the pKa values of poly(aspartic acid) so this property arises because of the polymer and it is independent from the cross-linkers.

Redox sensitivity was also characterized by measuring swelling degrees. Swelling - shrinking response of the hydrogels, due to the cleaving and reforming of the disulfide bonds, could be observed through several cycles. Relative change in swelling degree can be controlled by the gel composition. Elastic moduli of gels also change in the redox reaction.

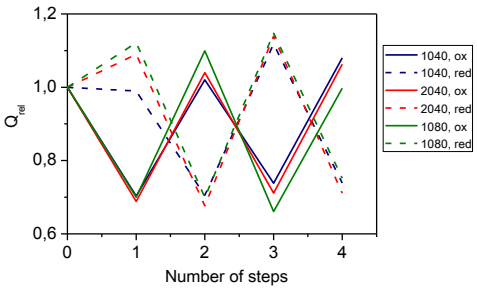

Figure 2. Repeatable swelling and shrinking of redox sensitive gels through several reduction and oxidation cycles.

Redox and pH sensitive nanogels were also synthesized. By applying these nanoparticles in drug delivery the disadvantage of macroscopic gels with slow response to environmental parameters could be overcome [3].

Introduction

Poly(2-oxazoline)s are a perfectly suited class of polymers for the preparation of well-defined (co-)polymers, allowing the integration of a wide range of functionalities. Due to their known biocompatibility poly(2-oxazoline)s have the potential to find a wide range of applications in biological systems. The incorporation of manifold conjugation sites in the polymer can be achieved by both side group and end group functionalization, whereby the polymer properties can be tailored by the nature of the side chains. Besides a defined structural design by preparation of hydrophilic and hydrophobic blocks as well as the fine-tuning of the crystallinity, functionalized side chains can be utilized for subsequent efficient modification reactions, e.g. for "click chemistry", allowing the introduction of sugar-moieties, peptide sequences as well as specific dye molecules.

Results and Discussion

Here we report the synthesis of a series of copoly(2-oxazoline) consisting of 2-ethyl-2-oxazoline as hydrophilic monomer as well as 2-decenyl-2-oxazoline (DecOx), a hydrophobic double bond containing monomer (Figure 1). The incorporation of DecOx was varied from 10 to 60% yielding water-soluble and insoluble copolymers.

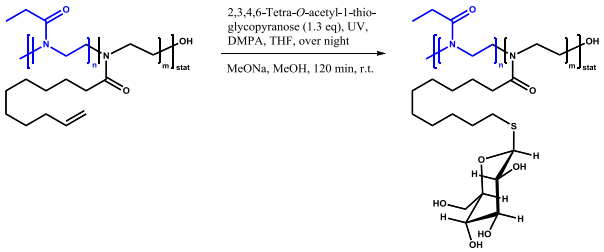

Figure 1. Schematic representation of the preparation of glycopoly(2-oxazoline)s using the thiol-ene approach.

Applying thiol-ene "click" reactions the corresponding glycopolymers were prepared and subsequently studied systematically in terms of their LCST behavior resulting in a decrease of the cloud point temperature with increasing sugar content in water. The overall hydrophobic copolymers and glycopolymers respectively, were used for the preparation of functional nanoparticles. To be able to study their cellular uptake these copolymers where labeled with fluorescein as well as fluorescein 5(6)-isothiocyanate prior to the nanoparticle formation by the nanoprecipitation technique. The particle size could be varied by the concentration used as well as the applied method encompassing the dialysis and dropping technique, respectively. Furthermore, the cellular uptake of the particles was revealed by confocal laser scanning microscopy (Figure 2).[1]

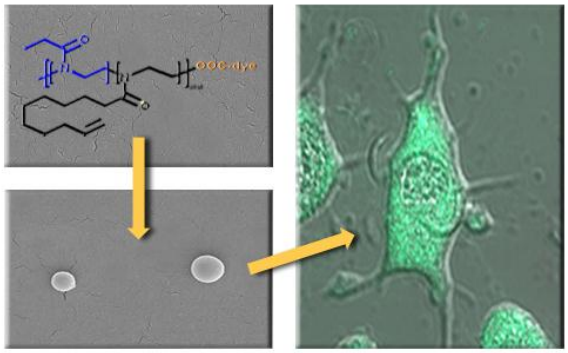

Figure 2. Confocal micrograph of fibroblasts incubated for 24 h with fluorescein labeled nanoparticles.

In addition, bulk (co-)polymerizations of the fatty acid based DecOx as well as thiol-ene reactions in environmentally friendly solvents could be performed demonstrating the green character of this copolymer system.

redouan.mahou@epfl.ch

Introduction: For the last three decades, sodium alginate (Na-alg) based hydrogels have become one of the most studied systems for cell immobilization. Such hydrogels are obtained by ionotropic gelation of Na-alg in presence of Ca^{2+}or Ba^{2+}. However, these hydrogels suffer from mechanical stability deficiency, limited durability, and permeability drawbacks. Frequently used coating or reinforcement with polycations requires multi-step processes and can have a negative impact on the biocompatibility. Our approach aims at combining ionotropic gelation of alg and covalent cross-linking of poly(ethylene glycol) (PEG) derivatives in one step and designing a process which yields alginate-PEG hybrid microspheres (Alg-PEG-M).

Methods: Alg-PEG-M and PEG-M were prepared at 37°C under physiological conditions employing a coaxial airflow droplet generator (Fig.1)

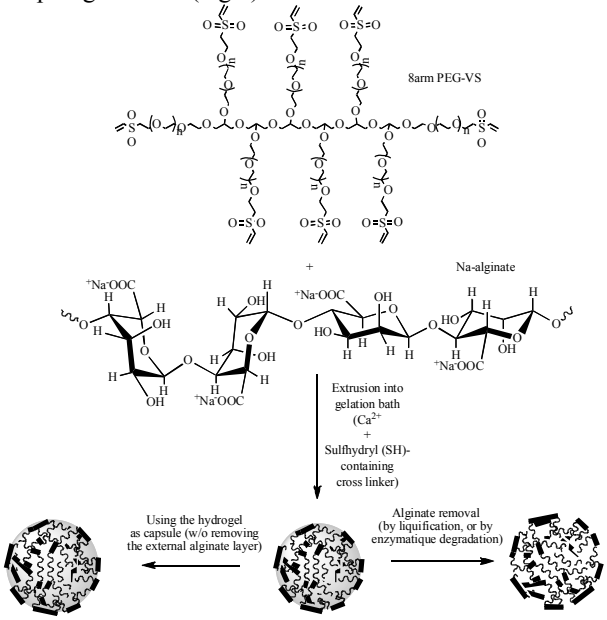

***Fig. 1**: Formation process. Both Alg-PEG-M (left) and PEG-M (right) were obtained spherical and uniform.*

Results and Discussion: Minimum swelling and maximum mechanical resistance of Alg-PEG-M were obtained for the molar ratio thiol/VS=2.75 (Fig. 2).

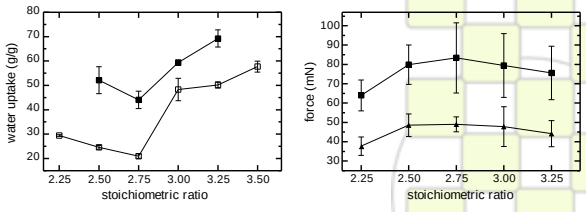

***Fig. 2**: Swelling (left) and mechanical resistance (right) of Alg-PEG-M as a function of the molar ratio thiol/VS.*

The initial precursor concentration influenced swelling and mechanical resistance. Increasing the concentration of PEG-VS creates a denser and more rigid network. Dissolution of Ca-alg slightly raised the resistance to compression (Fig.3). The permeability of the hydrogels could be tailored by adequate choice of the arm length of PEG-VS. The MWCO was tuneable in a range of 70 to 150 kg/mol.

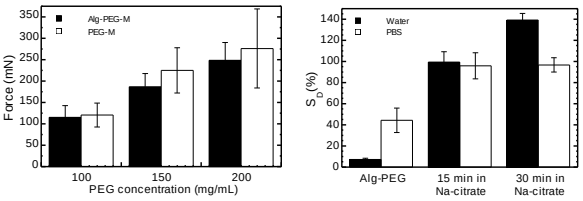

***Fig. 3:** Mechanical resistance to 80% compression for different initial PEG-VS concentrations (left), before and after Ca-alg liquefaction. Swelling degree of Alg-PEG-M after gradual dissolution of Ca-alg (right), in water and in PBS.*

In vitro cytotoxicity tests did not reveal cytotoxic effects for different cell lines after incubation with Alg-PEG-M at different concentrations (Fig.4).

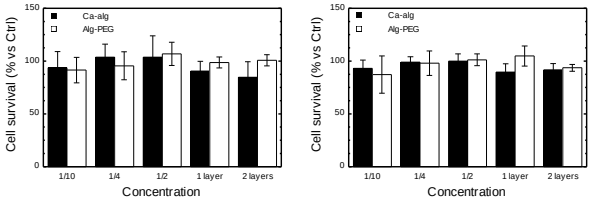

***Fig.4.** Cell survival after 24 h of incubation (percentage compared to the control). EC219 rat endothelial cells (left) and ECp23 murine endothelial cells (right).*

The immune response, cytokine production, after intraperitoneal implantation into mice was comparable to the control and pure Ca-alg microbeads. No significant increase was observed for IL-6, IL-10, IL-12p70, MCP-1, TNF and IFN. Encapsulated human islets continued insulin secretion.

Conclusions: Combining of ionotropic gelation of Na-alg and chemical cross-linking of PEG-VS in a one-step process yields hybrid Alg-PEG-M with well-controllable physical properties. Significant toxic effects were observed neither *in vivo* nor *in vitro*. Overall, microsphere properties are in a range as requested for biotechnological, biomedical, and pharmaceutical applications.

Degradation of Polyglycidol in Aqueous Solution by UV light

Alicja Utrata-Wesolek, Roza Trzcinska, Barbara Trzebicka, Andrzej Dworak

Centre of Polymer and Carbon Materials, Polish Academy of Sciences, M. Curie-Sklodowskiej 34, 41-819 Zabrze, Poland

alicja.utrata@cmpw-pan.edu.pl

Introduction:
In recent years, great interest in polyglycidol (PGl) based materials has increased considerably. Systems based on different molecular architectures of PGl such as block, hyperbranched, arborescent and graft copolymers have been obtained [1-3]. PGl chain modification has also been used to obtain thermoresponsive polymer materials, including hydrogels, nanogels, micelles and nanoparticles [4-6]. These thermoresponsive PGl materials can be used in biotechnology and medicine for controlled drug and genes release, bioseparation and surfaces for cell culture. Although the interest to use the PGl to obtain materials for aforementioned application is recently strongly growing, its degradation has not been previously investigated.
Here, we report the photodegradation of PGl in aqueous solution under the UV irradiation at 254 nm. The experiments were carried out in air at a constant temperature and the photodegradation of polyglycidol was compared to that of poly(ethylene oxide) (PEO), the most widely studied polyether. The mechanism of polyglycidol degradation under UV light was proposed.

Materials and Methods: The PGl was synthesized via coordination polymerization as described in [7]. PEO with a M_n = 300,000 g/mol, supplied by Aldrich was used as received.
The degradation of PGl and PEO aqueous solutions were carried out using a UVILITE LF 215S 2x15 W lamp (UVItec, Cambridge, UK) at 254 nm. The polymer solutions were irradiated vertically, 4 cm from the lamp (the intensity of the incident light was 25 mW/cm^2).
The polymers and their degradation products were characterized by SEC-MALLS (DAWN EOS, Wyatt Technologies), NMR (Bruker Ultrashield 600 MHz) and FTIR (FTS-40A, BIO-RAD).

Result and Discussion: The PGl was obtained through the anionic-coordination polymerization of ethoxyethyl glycidyl ether in the presence of partially hydrolyzed diethyl zinc as a catalyst. When the synthesis was complete, the ethoxyethyl groups were removed by hydrolysis under acidic conditions to yield a linear PGl. The molar mass of the polymer was 270,000 g/mol and the dispersity of the polymer (M_w/M_n) was equal to 2.5. PEO with molar mass of 300,000 g/mol and a dispersity of 2.0, was used to compare its photodegradation process to that of polyglycidol.
Aqueous solutions of PGl with concentrations of 2% and 8% and a 2% aqueous solution of PEO were exposed to UV irradiation at 254 nm. The change in the molar mass and molar mass dispersity of PGl and PEO was measured using SEC-MALLS. During irradiation of PGl, the shape of the chromatograms changed from monomodal to bimodal whereas the chromatograms of PEO remained monomodal throughout the entire irradiation. In all of the chromatograms, the lack of signals at higher elution volumes pointed to the absence of low molar mass oligomers as photodegradation products. This could indicate that UV irradiation of PGl solutions led to the fragmentation of the polymer chains, which occurred through scission around the midpoint of the polymer chain but not at the polymer chain end. Regardless of the polymer type or polymer concentration, the molar mass of degraded PGl and PEO gradually approached the limiting value of 17,000 g/mol and 14 000 g/mol, respectively. During the irradiation of the polymer solutions, a strong acidification was observed. The observed decrease in the pH of the PEO solution appeared to be more significant than for PGl.
To determine the structure of the degradation products of PGl and PEO created during UV irradiation at 254 nm, FTIR, ^{1}H NMR and ^{13}C NMR analyses were performed. During the irradiation of PGl formats, esters and α-hydroxyesters were formed whereas degradation of PEO led to formation of formate, ester and formic acid ions. A mechanism accounting for the main routes of polyglycidol photooxidation is proposed.

Conclusions:
The irradiation of polyglycidol in aqueous solution with the UV light at 254 nm caused damage to the macromolecular chains via chain scission around the midpoint. The molar mass of polyglycidol decreased significantly due to irradiation and reached a limiting value. The degradation of polyglycidol was accompanied by strong acidification. Based on the degradation products detected by NMR and FTIR spectroscopy, a mechanism of the photodegradation of PGl was proposed.

DNA complexes with charged compounds, that are useful for nanotechnology

Kasyanenko N., Dribinsky B., Puchkova A., Sokolov P.

Department of Molecular Biophysics, Faculty of Physics, St.-Petersburg State University

nkasyanenko@mail.ru

Introduction

DNA is a polyanion with a high charge density and unique properties (high stiffness, complementarity of base pairs, reversible denaturation). This molecule is the attractive, useful and convenient object of manipulation in the field of nanotechnology. Its interaction with cationic molecules cause the formation of different structures, including gene vectors, self-assembled ordered structures, as well as templates for nanowires.

The investigation of DNA reversible packaging in a solution (so-cold DNA condensation) induced by various agents has a long history. Nevertheless now this is of a great interest in connection with the absence of complete clarity in molecular bases of DNA condensation and due to the development of new nanobiotechnologies. For example, DNA packaging is the main step in gene transfer into target cells. Polycations and DNA form compact interpolyelectrolyte complexes (IPEC) in a solution. So synthetic polycations are known as perspective agents for the non-viral gene delivery. They exhibit many advantages over other DNA transporting means because of their ease of production, nonimmunogenicity, low risk of side effects, simplicity of DNA–polymer complex formation. DNA condensation is a collapse of swollen molecular coils into small dense particles. Since DNA is a highly-charged polyanion, the key question is how the electrostatic interaction between charged monomers changes from repulsive to attractive.

In our previous articles the key distinction in DNA organization before condensation induced by trivalent metal ions and polycations was discussed [1-3]. The model system (DNA + oligocations) can provide the more understanding of difference between influence of polycations and small multivalent ions on DNA conformation in a solution.

Materials and Methods

Calf Thymus DNA, poly- and oligolysine, spermine and spermidine (Sigma) were used. The influence of di-, tri-, penta- and oligoions as well as polycations (polylysine) with a degree of polymerization 270 and 350 on DNA conformation in a solution was studied. DNA conformational changes are examined by the methods Atomic Force Microscopy (NanoScope 4a, Veeco), Dynamic Light Scattering (PhotoCor, Russia), Low Gradient Viscometry, Flow Birefringence, Circular Dichroism (Mark IV, Jobin Ivon).

Results and Discussion

It was shown that some polycations (polylysine 270 and 350) as well as multivalent cations (La3+, hexammine cobalt (III) (CoHex), spermidine, spermine) facilitate DNA packaging in a solution into toroids. Small multivalent ions cause the change in DNA tertiary structure via intramolecular linkage with remote phosphate groups and formation of compressed coil with mutually oriented segments of macromolecule before DNA packaging. In contrast to that polycations do not induce any reorganization of DNA structure prior to condensation. In our research the influence of number of positive charges, the length of oligocation chain and the disposition of charges on polymer chain on DNA conformation. As a result of DNA interaction with multivalent ions in a solution the discrete nanoparticles (100-200 nm) were registered.

DNA complexes with charged compounds can also be used as templates for the fabrication of nanowires. It was shown that DNA complexes with silver ions provide the further silver DNA-nanowire formation on silicon surface. The method of DNA metallization is based on the reduction of silver ions on DNA bundles by means of silicon substrate.

Conclusions

High molecular DNA is a good material for the creation of nanostructures like gene vectors and nanowires. Self-organizing structures on the base of DNA complexes with charged compounds in a solution can be interesting also as model systems for the understanding of conformational properties of main biological macromolecule during functioning in vivo and in vitro.

Viscoelastic and thermal behavior of polyurethane films prepared as shape memory polymer

Cansu Citak, Isık Yavuz, Mirey Bonfil, F. Seniha Güner,

Istanbul Technical University, Department of Chemical Engineering, Maslak 34469 Istanbul, Turkey

e-mail: guners@itu.edu.tr

Shape memory polyurethanes are the typical thermo-sensitive shape memory polymers, which were extensively studied in the near past decades. A shape memory polyurethane has two phases on its structures that are hard and soft segments, these segments make up phase separation. The soft segment forms reversible phase and also, it determines the shape recovery temperature.

The aim of this study is to characterize some viscoelastic and thermal properties of the polyurethane films showing shape memory property. Castor oil (CO) and polyethylene glycol (PEG) are used as polyol sources, and hexamethylene diisocyanate is used as diisocyanate component in the preparation of the films. Dibutyl-tin-dilaurate, 1,4-buthane diol and triethanol amine are used as catalyst, chain extender and crosslinking agent, respectively. The films are prepared in various CO/PEG weight ratios (50/50, 60/40, 70/30, 90/10 and 100/0); (1) with cross-linker and catalyst (WC-wc), (2) with cross-linker and without catalyst (NC-wc), and (3) without cross-linker and catalyst (NC-nc). The crystallinity of the polyurethane films is determined by using wide angle X-ray scattering. Crosslink density (υ_c) and average molecular weight between two crosslinks (M_c) are determined by the equilibrium swelling method according to the Flory-Rehner equation. The thermal and viscoelastic properties of the samples are characterized by differential scanning calorimeter (DSC), thermal gravimetric analysis (TGA) and dynamic mechanical analysis (DMA).

The crystallinity of the polymer decreases, on the other hand, the number of the crosslink center increases with increasing CO content. The glass transition temperatures (T_g) of all polyurethanes are below room temperature, consequently they are rubbery at ambient temperature. The T_g increases with increasing CO/PEG ratio. As shown in Figure 1, the polyurethanes synthesized without crosslinker show the lowest T_g for the same CO/PEG ratio except the sample prepared at 70% CO content.

An intersection point is obtained for all TGA curves at 415±10°C. Increasing the CO content in polymer structure caused a rapid decrease in the weight (increase the weight loss) of the polymer at the intersection temperature. The degradation pathway depends on the ratio of CO/PEG used in the polymer synthesis.

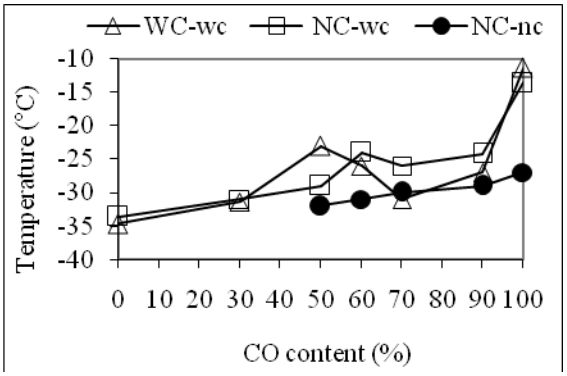

Figure 1. T_g of the polyurethanes

According to the DMA results, the polyurethanes synthesized without catalyst and chain extender have less chain mobility than the other polyurethanes containing same amount of CO, since the hight of the tan D peak is the smallest value (Figure 2). This may be due to the relatively high crystallinity of these polyurethanes compared to the samples having same CO content. This result is supported by XRD measurements.

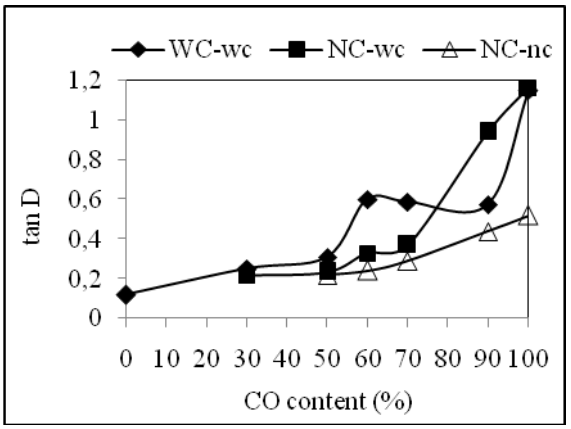

Figure 2. The value of tan D peak

Wavelength-Responsive Polymer Materials

V. San Miguel, A. del Campo

Max-Planck Institut für Polymerforschung. Ackermannweg 10, 55128 Mainz, Germany

e-mail: sanmigue@mpip-mainz.mpg.de

Advanced technologies require the development of materials able to respond to external triggers (temperature, pH, pressure, electrical fields, light etc) by changing their physicochemical properties. Light has important advantages as source for activating processes. Light stimulus can be readily available and focused, allowing precise temporal and spatial definition of the stimulus. Light exposure can be also precisely controlled over the irradiation time and intensity and, as a consequence, the strength of the stimulus (and the response) can easily be modulated. We present a strategy to control materials properties (reactive state, polymerisation or depolymerisation) at the surface[(1)] and in the bulk of a polymer material using chromic-tunable caging groups with sensitivity to light of different wavelengths. In addition, using two-photon excitation our strategy allows 3D control over the stimulus and response.

Photoresponsive Polymer Brushes

Jiaxi Cui, A. del Campo

Max-Planck Institut für Polymerforschung. Ackermannweg 10, 55128 Mainz, Germany

e-mail: cui@mpip-mainz.mpg.de

Polymer brushes (polymer chains tethered by one end to a solid substrate), can be used to modify surface properties (wettability, biocompatibility, adhesion etc.). When stimuli-responsive polymers are selected to anchor, the physicochemical properties of the brush (extended/collapsed state) can be tuned via external triggers. As a consequence, surface properties also change. Several examples of temperature and pH sensitive brushes have been reported. Here we present a novel example of a light-responsive brush. We have used the photoremovable caging group 4,5-dimethoxy-2-nitrobenzyl to cage charged side groups (i.e. COOH, NH2…) of polyacrylates and we have prepared polymer brushes via suface-initiated ATRP. Upon irradiation, the photocleavable group can be removed and this generates charged groups in the polymer chains. Consequently, the swelling state changes and the surface becomes light and pH-sensitive.

Properties of cyanoacrylate adhesives with different alkyl chain length

Rafael Torregrosa-Coque[1], Ana María Villarreal-Gómez[2], José Miguel Martín-Martínez[1]

jm.martin@ua.es

Introduction

Cyanoacrylates polymerize in the presence of bases, such as water. Skin has a high concentration of water, so cyanoacrylate adhesives can be used for surgical practice and wound closure. However, despite producing effective joining, the cyanoacrylate adhesives show exothermic cure and the polymerised product is too stiff. One simple route to reduce the exothermic reaction and stiffness of the cyanoacrylate adhesives is to increase the length of the hydrocarbon chain backbone.

To the best of our knowledge there are a few scientific studies dealing with the physico-chemical characterization of cyanoacrylate adhesives and only four of them consider the incidence of the length of the alkyl chain [1,2]. In this study, the properties of cyanoacrylate monomer and the polymer obtained after cure will be compared, paying particular attention to the modifications produced during polymerization.

Materials and Methods

Ethyl (ECN), butyl (BCN) and octyl cyanoacrylate (R=8) were used. Cyanoacrylate monomers were cured by adding water (1:1 vol%). The monomers and polymers films were characterized by ATR-IR spectroscopy, scanning electron microscopy (SEM) and thermal gravimetric analysis (TGA). Adhesion was obtained from single lap-shear tests of aluminium/cyanoacrylate adhesive joints.

Results and Discussion

The derivative curves of the TGA thermograms (Figure 1) show the thermal decompositions of the cyanoacrylate monomers. The first decomposition was found at about 120 ºC and the weight loss decreased by increasing the length of the alkyl chain. The increase in the alkyl chain length increases the decomposition temperature of the cyanoacrylate and several decompositions are obtained.

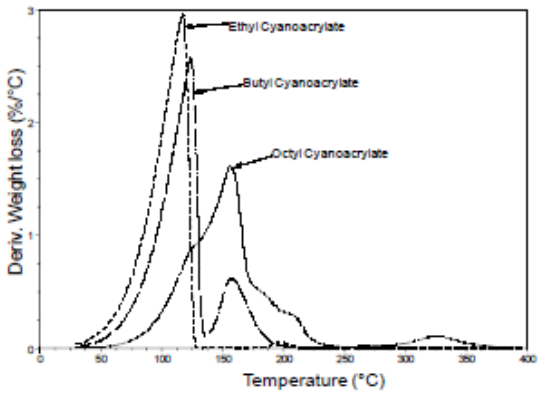

Figure 1. Derivative of the TGA thermograms of the cyanoacrylate monomers.

The thermal properties of the cyanoacrylate polymers differ from those of the corresponding monomers. The polymerization increases noticeably the temperature at which the polymer degrades (Figure 2). In general, the temperature at which decomposition is produced increases by increasing the length of the alkyl chain in the cyanoacrylate polymer. Whereas the ethyl cyanoacrylate polymer shows a unique decomposition at 199 ºC, both the n-butyl and the n-octyl cyanoacrylate polymer show two thermal decompositions corresponding to two different polymer structures.

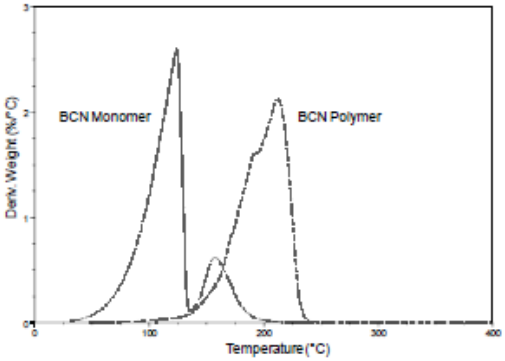

Figure 2. Derivative of the TGA thermograms of butyl cyanoacrylate monomer and polymer.

Polymerization modifies the chemical structure of the cyanoacrylate. The SEM micrograph of the ethyl cyanoacrylate polymer showed a homogeneous and smooth surface, whereas the n-butyl and, more markedly, the n-octyl cyanoacrylate polymer showed a heterogeneous topography consisting in shredded polymer chains. This is in agreement with the loss in elastic modulus and cohesion of the cyanoacrylate by increasing the length of the alkyl chain.

Conclusions

Whereas the ethyl cyanoacrylate is mainly composed of monomer, the n-butyl cyanoacrylate contains monomer and some dimmers and the n-octyl cyanoacrylate has only a minor content of monomer.

Introduction

Polyamide 6 (PA 6) is a high-performance engineering plastic used for a wide range of applications in everyday life. However, there is an increasing demand for disposable packaging applications because of environmental considerations. The biodegradability of PA 6 could be enhanced by incorporating hydrolyzable groups into the main chain.[1] If these hydrolyzable groups are randomly introduced into the PA 6 main chain during melt polymerization, the crystallization behavior of PA 6 will be negatively affected, the melting point will be reduced and the mechanical and physical properties crucial for packaging applications (such as barrier properties) will become worse.[2] An alternative method can be incorporating these groups into the amorphous part of a relatively low molar mass PA 6 by solid state modification at reduced temperature, *viz.* below the melting point of the PA 6 crystals.[3] To achieve this, a new synthetic approach can be followed: Epoxide end-capped oligoesters and carboxylic acid end capped PA 6 can be copolymerized in the solid state.

Experimental Methods, Results and Discussion

The synthetic procedure for the preparation of multi-block polyesteramide copolymers is shown in ***Scheme 1.*** The first step included the preparation of low molar mass, fully carboxyl end-capped PA 6 by the addition of 5 mol% adipic acid during the hydrolytic ε-caprolactam polymerization. According to the number of end groups determined by titration, the number average molecular weight of the PA 6 is 2400 g/mol. Diepoxy propylene adipate (DEPA) with a molecular weight of 450 g/mol was synthesized as described before[4] and both components were mixed in HFIP with the addition of DMAP as the base catalyst. After full dissolution of all components vacuum distillation was started and continued at room temperature until full removal of the solvent. Finally, solid state polymerization was done under Argon in the temperature range of 70-100°C. An increase in molecular weight was observed by SEC analysis (M_n=10 kg/mol). The molecular weight of the copolymers can be improved by using different types of catalysts in different concentrations. Further characterization will be done by FTIR, DSC and NMR.

Protein surface hydration is essential to its structural stability and flexibility and protein associated water is often an integral element in biological activities [1,2]. Protein function usually involves protein motions corresponding to transitions between conformational substates. The conformational motions imply α fluctuations that originate in the bulk solvent, and β fluctuations that originate in the hydration shell [3]. Nevertheless, a complete understanding of the underlying coupling of proteins and water motions is still lacking [4]. For a series of globular proteins, the protein dynamics were proposed to be slaved [5-7] or plasticized by water dynamics, but the mechanism remains questionable.

So it is of peculiar interest to study the temperature dependence of proteins and water dynamics. Elastin is a main protein of connective tissues such as lung, arteries and skin, and the mechanism of elasticity of this hydrophobic and insoluble protein is still subject to debate. We used Differential Scanning Calorimetry (DSC) to quantify free (freezable) water and bound (unfreezable) water [8]. Dielectric techniques - Dynamic Dielectric Spectroscopy (DDS) and Thermally Stimulated Current (TSC) -, well-suited experimental methods to characterize the system elastin-water were used to access to the dynamics of the system. The protein was studied between 123 and 313 K in the $10^{-3}/10^{6}$ Hz range, at different hydrations levels [9].

By DSC, a localized water phase is evidenced, with a maximal value of 1.2-1.3 molecules of water bound to one elastin residue. Above this value, bulk water appears in the system.
By DDS, a complex relaxation map is observed with four dipolar modes labeled β1, β2, p1 and p2. Assignments for the different modes can be proposed by the combination of DDS and TSC experiments as well as the determination of the activation parameters of the relaxation times.

The temperature dependence of the two β_1 and β_2 modes is found to be Arrhenius-like, with a direct proportionality between β_1 and β_2. The elastin dynamics are "slaved" by water dynamics.
Localized molecular mobility (at the nanometric scale), undetectable by DSC, which occur at low temperature can be observed by the combined use of DDS and TSC. In this case, the evolution of the local dipolar reorientations have been followed for different hydration contents, revealing an increasing complexity when coexist elastin, unfreezable water and freezable water. The fastest process β1 mode is attributed to reorientations of water in the hydration shell, needing the breaking of two hydrogen bonds (≈50 KJ/mol) to occur; the β1 mode drives the β2 one, associated to water/elastin local reorientations. So the dynamic nature of the localized water phase lends significant mobility to the protein, as already observed in globular proteins.

These fast processes were shown non or little cooperative when compared to the lower processes p1 and p2, which are associated with more energetic (55-80 KJ/mol) and more delocalized motions in the elastin-water system, merging at around 0°C and exhibiting a non Arrhenius-like behavior at higher temperature.

These results on hydrated elastin are a basis to help to answer the question - How the solvent influences the protein dynamics - which still remains largely unanswered. Moreover, our experimental data could be useful for the assessment of starting conditions in molecular dynamics simulations: simulation on long polypeptidic sequences of elastin could be launched with a small hydration level, typically 10°%, corresponding to detectable localized reorientations of the complex water/residues in dielectric spectroscopies.

Introduction

Biomaterials made with Poly l-Lactic Acid (PLLA) and Poly ε-Caprolactone (PCL) have been widely studied as suitable biodegradable materials for tissue implants. In a previous work, the freeze extraction technique was used to produce porous PLLA/PCL membranes and their properties were evaluated. So, the next step was to evaluate how PLLA/PCL scaffolds behave when degraded, and in this study the PLLA/PCL membranes made by freeze extraction were degraded hydrolytically in Phosphate Buffered Saline solution. After 11, 33 and 65 weeks of degradation the membranes were characterized using Gravimetric Analysis, Differential Scanning Calorimetry (DSC), Gel Permeation Chromatography (GPC) and Strength Compression by Indentation. Better resistance to degradation is associated with PCL composition meanwhile PLA does not let the scaffold keep its structure long time. This study demonstrates the capacity for PCL to make slower the degradation of PLLA/PCL scaffolds made by freeze extraction, giving better support to its suitability as graft biomaterial.

Materials and Methods

The scaffolds were prepared by freeze extraction of PLLA and PCL solutions in different weight ratios using Dioxane as solvent. The dissolution was poured into a Teflon mould and frozen in liquid nitrogen. The disks obtained were immersed in ethanol at -10ºC for two days. The disks were then removed, vacuum dried and stored in a dry environment. After being synthesized the membranes underwent a degradation process keeping them in PBS dissolution for 65 weeks; they were washed with distilled water and vacuum dried. After different degradation time, weight loss was measured by gravimetric analysis; crystallinity was determined by DSC heating from 0 to 200ºC at 10ºC/min; Molecular Weight Distribution was measured by Gel Permeation Chromatography (GPC) preparing the samples in Tetrahydro Furan (THF), with an elution volume of 1mL/min, obtaining a profile of signals associated to molecular weight; and Compression Strength was determined by Indentation with a Thermo Mechanical Analyzer (TMA)

Results and Discussion

Gravimetric analysis shows a significant weight loss in PLLA membranes compared to weight loss in PCL membranes. So it can be deduced that weight loss in PLLA/PCL membranes is associated the most to PLLA degradation.

DSC thermograms at different degradation ratios show how the melting temperature of PCL rises from 57 to 58ºC approximately when its fraction rises. It can be seen also that melting temperature of PLA diminishes in the same order, as its fraction is smaller, likely due to smaller crystal size or more imperfections. It is clear also, that for PLLA the peak width is bigger as its fraction rises, and the opposite case for PCL. A slightly peak of crystallization of PLLA appears as its fraction is smaller, which indicates that PLLA does not cold-crystallize in the membranes after freeze extraction due to crystallization of the whole crystallizable fraction during the process. After degradation, thermograms show practically no changes in PCL behavior, however PLA shows broader peaks, and even a second peak in blends with both higher amounts of PLLA and as the degradation time rises, because of the smaller crystals formation. The melting temperatures for PCL do not undergo significant changes in all degradation time; as opposed of PCL since the presence of smaller crystals, melting temperature of PLLA diminishes drastically in almost 20°C after the 33th degradation week.

The GPC results do not show distinct peaks as PLLA and PCL used have very similar molecular weights and only one peak is seen for both polymers. So, GPC peak was deconvoluted into smaller peaks that were associated whether to PCL or to PLLA molecular weight distribution, according with the expected composition at different degradation times. Besides the degradation of PCL is very light, it can be seen in PCL-rich blends that molecular weight drops slightly after 11 weeks of degradation, which is consistent with end chain degradation as often seen in very crystalline polymers. On the other hand, molecular weight of PLLA-rich blends decrease much more and new peaks appear, which is consistent with a random cleavage of the chains that produces more polymers with low crystallinity.

Changes in compressive elastic modulus for the PLLA/PCL membranes are somewhat puzzling, due the difficulty of defining the appropriate zone for calculation in Stress-Strain curves and the tendency to non-lineal behavior when indentated. However, a slightly drop in modulus is observed at 11th week, followed by modulus rising maybe due to re-crystallization phenomenon during degradation.

Conclusions

The degradation process affects primary to PLLA-rich phase in the membranes, not only because of terminal chain cleavage but also because random cleavage. PCL undergoes a slightly change during the degradation time in both its molecular weight and weight loss, but it seems not to affect significantly its properties, like crystallinity and melting temperature. The presence of PCL in the membrane makes it more resistant to degradation and enhances the mechanical properties in degraded state. These materials should thus be suitable for tissue engineering since the PCL/PLA ratio allows the design of a composite blend with a degradation rate that matches the regeneration rate of the tissue.

[*]ykwark@ssu.ac.kr

Controlling streospecificity in polymer chemistry is important because it affects properties of polymers. However it is very difficult to control stereochemistry in radical polymerization because the nature of active radical species has low energy barrier between two enantiomers. Protic solvents like fluoroalcohols or lewis acid are known to be efficient for the stereo-controlled radical polymerization of vinyl esters. Along with using protic solvents, lowering polymerization temperature is generally preferred to further improve stereoregularity of the prepared polymers, because it lowers the possibility of inter-conversion between two enantiomers.

On the other hand, controlling molecular weight (MW) and its distribution in radical polymerization can be achieved by controlled polymerization techniques, such as ATRP, NMP, and RAFT. There have been several reports of preparing polymers with controlled MW and streospecificity by controlled radical polymerizations in fluoroalcohols. However, it is not easily achievable to run the polymerization at low temperature. Since in many cases radical generation process, for example homolytic cleavage of AIBN or BPO, requires sufficient thermal energy, the polymerizations proceed at elevated temperatures, which is not favored in preparing polymers with high streospecificity. It is also the case for RAFT process. Photo-initiation can be applied to the technique to lower the reaction temperature, but thioester chain ends in RAFT process can be cleaved by UV irradiation to deteriorate the controlling characteristics of the process. This system has been known as 'photo-iniferter' system.

In this work, we used photochemically inert RAFT agent in photo-initiated polymerization of vinyl acetate (VAc) to minimize the photochemical cleavage of the chain ends. With this approach, it was possible to get polymers with better controlled MW and lower PDI. Then lower reaction temperature and fluoroalcohol solvents were applied to attain higher level of control in streospecificity.

Aside from its requisite effectiveness in controlling polymerization, the RAFT agent in a photo-initiated system must be inert under UV irradiation. Therefore, the photochemical properties of RAFT agents and photo-initiators were tested using UV-Vis spectroscopy. Among the tested compounds, bis(2,4,6-trimethyl benzoyl)phenylphosphine oxide BAPO decomposed upon the tested UV irradiation, while Methyl(ethoxy carbonothioyl)-sulfanyl acetate (MESA) was unchanged. Therefore we used BAPO as a photo-initiator and MESA as a chain transfer agent in the polymerization of VAc. Polymerization using the photo-initiation system was performed at 0 °C. The polymerization produced polymer with low PDI. It indicated that photo-initiated RAFT of VAc was well-controlled at low temperature (Figure 1).

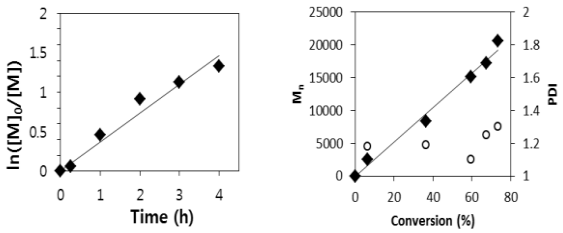

Figure 1. Kinetic plots for the photo-initiated RAFT of vinyl acetate at 0 °C.

In search of an efficient fluoroalcohol in controlling stereospecificity of the prepared polymer, $(CF_3)_2CHCOH$, $(CF_3)_3COH$, $PhC(CF_3)_2OH$, $m\text{-}C_6H_4\{C(CF_3)_2OH\}_2$ were employed as solvents in the polymerization of VAc (Figure 2). The syndiotacticity of the prepared polymer was affected by the structure of fluoroalcohol. The more acidic $(CF_3)_3COH$ yielded higher syndio- tacticity (r = 62.3) than $(CF_3)_2CHCOH$ (r = 60.1). With bulkier $m\text{-}C_6H_4\{C(CF_3)_2OH\}_2$, higher syndiotacticity (r = 61.0) could be attained, compared to the one with $PhC(CF_3)_2OH$ (r = 58.6). The fluoroalcohols also affected the control of MW. The best results was achieved with $(CF_3)_3COH$ to produce polymer with the lowest value of PDI (1.05)

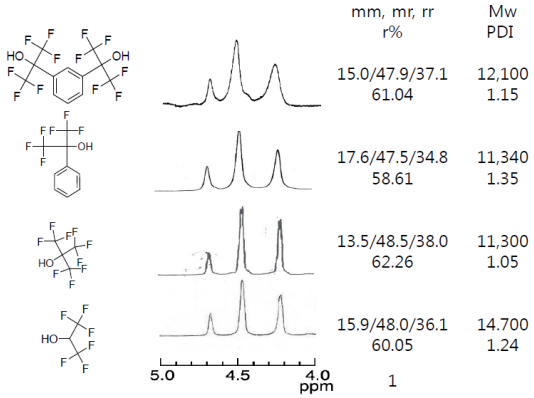

Figure 2. Effect of various fluoroalcohols on the MW and tacticity of the prepared polymers at 0 °C.

In conclusion, the simultaneous control of the molecular weight and stereospecificity of PVA has been achieved for the RAFT Polymerization in fluoroalcohol solvent. Low temperature polymerization in fluoroalcohol solvents gave polymers with higher syndiotacticity.

Towards Sustainable Polymerization of Stimuli-Responsive Polyglycerol Hydrogels

Somaieh Salehpour and Marc A. Dubé

Department of Chemical and Biological Engineering,
Centre for Catalysis Research and Innovation
University of Ottawa, Ottawa, ON Canada

Ssale050@uOttawa.ca; Marc.Dube@uOttawa.ca

Introduction: There is growing interest in the use of bio-based polymers due to their lower environmental burden as an alternative to conventional polymers made from petroleum, which is a limited natural resource. Due to a significant glut in the glycerol market because of increasing biodiesel production, interest in finding economic ways to utilize the emerging surplus has grown.[1] Currently, new opportunities for the conversion of glycerol into value-added chemicals have emerged due its functionality, properties, biocompatibility and biodegradability.[2] One approach to use this glycerol surplus is polymerization. Until now, only oligomers have been synthesized directly from glycerol. On the other hand, high molecular weight polyglycerols, have been produced from toxic monomers, which are environmentally hazardous (e.g., glycidol).[3]

In this study, the step-growth polymerization of polyglycerol to relatively high molecular weight from glycerol feedstock was investigated. One focus of our investigation was the use of different catalysts to improve polymer properties. The biocompatibility and functionality of the polymer makes polyglycerol an interesting option for pharmaceutical and medical applications, such as hydrogels. Consequently, the cross-linking of polyglycerol by multifunctional electrophilic compounds was investigated to achieve a controlled increase in polyglycerol molecular weight.

Materials and Methods: Polymerizations were carried out in a 1 L glass reactor equipped with a distillation trap, a condenser, nitrogen inlet, catalyst feeding and sampling ports, temperature probe, and a mechanical stirrer. The stirring speed (250 rpm) and the temperature were controlled separately. Polyglycerol was synthesized by glycerol etherification at 414 K in the presence of various catalysts. To shift the reaction equilibrium, a vacuum pump was attached to the reactor to carry out the condensation reaction at pressures below 200 mm Hg absolute. A Dean-stark trap topped by a condenser was attached to the reactor to continuously remove water from the reaction mixture. The reaction progress was determined by monitoring the water formation in the trap. The reactants were blanketed with nitrogen throughout the polymerization.

Polymer molecular weight and distribution were measured using gel permeation chromatography. Gel content was determined by the membrane gel partitioning method.[4] Swelling ratio measurements of the hydrogels were performed using distilled water at various temperatures and pH. Sulphuric acid, calcium carbonate and calcium hydroxide were used as catalysts. Polyethylene glycol diglycidyl ether (molecular weight: 400 g/mol) was used as a cross-linker. In order to form the gels, high molecular weight polyglycerol was added to a 2M NaOH solution. The solution was heated and stirred until all the polyglycerol was dissolved. The cross-linker was added to the solution, poured into Teflon moulds and then left to cure at 120°C for 24 h.

Results and Discussion: Conversion and polymer molecular weight were greatly influenced by the type of catalyst employed. The polymerization of glycerol proceeded fastest with sulphuric acid; conversion of functional hydroxyl groups was 71 to 77 mol%, along with molecular weights between 58000 and 114000 g. mol^{-1}. The polyglycerol obtained was a mixture of polyols with linear, branched and cyclic structures of different degree of polymerization with high functionality. The predominant species was polyglycerol with a linear structure, followed by branched structures as confirmed by ^{13}C-NMR. From a practical point of view, it was important to predict the extent of reaction at the gel point in order to stop the polymerization prior to that point and avoid gelation for straightforward removal from the reaction vessel. Using theoretical models,[5] the functionality of the monomer was found to be 2.4 and the critical extent of reaction (gel point) was calculated to be 71 mol%. Hydrogels formed from this high molecular weight polyglycerol using a cross-linker showed swelling ratios as high as 600 wt%. The swelling of the hydrogel was observed to be both pH and temperature dependent.

Conclusions: Using step-growth polymerization at 140°C, polyglycerols of relatively high molecular weights were produced. The most effective catalyst for this process at the tested conditions was sulphuric acid.

Novel temperature and pH-responsive polyglycerol-based hydrogels were successfully synthesized and characterized. Hydrophilicity and biocompatibility of this hydrogel make it suitable for applications in the pharmaceutical, biomedical and biotechnological fields as hydrogel adhesives for wound dressing and drug delivery.

arantxa.eceiza@ehu.es

Introduction

Due to the finite nature of fossil resources and their environmental impact, alternative renewable based materials are increasingly attractive. Cellulose is one of the most abundant organic materials that can be easily obtained in nature and used as precursor for chemical modification to prepare a broad variety of commercial polymers. On the other hand, cellulose nanocrystals (CNC) have focused attention as a potential reinforcement in bionanocomposites due to the combination of their high surface area, high aspect ratio, environmental benefits and low cost as well as due to the exceptional mechanical properties. However, it is well known that to obtain an improvement in the thermo-mechanical properties of polymeric nanocomposites, is essential to carry out several challenges in using cellulose reinforcements, including the efficient separation of nanocrystals from plant resources, compatibilization of the nanoreinforcements with the matrix and development of suitable methods for processing these nanocomposites. In this work, CNC have been isolated from microcrystalline cellulose (MCC) and functionalized with hexametylene diisocyanate (HDI) through covalent attachment. On the other hand, bionanocomposites with high toughness have been prepared adding different contents of CNC to segmented thermoplastic elastomeric polyurethane (STPUE) by casting method. STPUE are versatile polymeric matrices typically constituted alternating soft (SS) and hard segments (HS). The thermodynamic incompatibility between both segments leads to nano/microphase separation of the polymeric system. Thermal, morphological and mechanical properties of bionanocomposite films have been evaluated from the viewpoint of the influence of CNC content and fucntionalization on the resulting nano/microstructure.

Materials and Methods

STPUE with 18 wt% of HS was synthesized by two step polymerization procedure using a block copolymer diol as SS and HDI and 1,4-butanediol as HS.

CNC were isolated from MCC by acid hydrolysis with concentrated sulphuric acid (64 wt%) at 44 ºC during 1h and functionalized using different CNC:HDI molar ratios at 80 ºC for 24 h.

STPUE/CNC bionanocomposite films were prepared casting suspensions of STPUE and CNC in dimethylformamide (DMF) onto Teflon dishes, which were subjected to a pressure-temperature cycle.

The isolated CNC were characterized by light scattering and transmission electron microscopy (TEM). CNC functionalization was examined by elemental analysis, nuclear magnetic resonance (^{13}C-NMR) in solid state and Fourier transform infrared spectroscopy (FT-IR).

Thermal, morphological and mechanical characterization of bionanocomposites was performed by differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA), atomic force microscopy (AFM) and tensile test.

Results and Discussion

Acid hydrolysis of MCC leads to aqueous suspensions of CNC with high aspect ratio. The rod-like CNC showed an average diameter of 15 ± 5 nm and a length of about 157 ± 53 nm as estimated by TEM. The FT-IR spectra of functionalized CNC showed the $\nu_{-C=O}$ stretching vibration in the amide I region at 1710 cm^{-1} corresponding to urethane groups, the amide II band at 1560 cm^{-1} and the band assigned to amide III aliphatic urethane at 1250 cm^{-1}. Bionanocomposites showed an enhancement in storage modulus because of effective dispersion of CNC. The storage modulus plateau of nanocomposites with functionalized CNC extended to higher temperatures, showing an improvement in dimensional stability. This can be due to the preferential interactions of covalently attached HDI in functionalized CNC with polyurethane HS, in agreement with DSC results. Elastic modulus of bionanocomposites increased with CNC content.

Conclusions

CNC were extracted from MCC and functionalized with HDI. Higher functionalization efficiency was achieved with an excess of HDI. Interactions between well dispersed CNC and STPUE matrix increased the storage modulus of bionanocomposites. HDI chains attached to the stiff CNC formed a network with the surrounding STPUE matrix, leading to improved dimensional stability and mechanical properties. Functionalized CNC preferentially located in the hard domains of the STPUE matrix enhanced the HS crystallization.

Polyurethanes Derived From Renewable Resources: Effect of Polyol Structure

Ainara Saralegui, Lorena Rueda, Borja Fernández d'Arlas, Mª Dolores Martín, Iñaki Mondragon, Arantxa Eceiza, Mª Angeles Corcuera

"Materials + Technologies" Group, Department of Chemical and Environmental Engineering, Polytechnic School, University of the Basque Country, Pza Europa 1, 20018, Donostia-San Sebastián, Spain

marian.corcuera@ehu.es

Introduction

Polyols derived from vegetable oils are new materials from renewable sources (1,2). Combined with diisocyanates, these polyols produce polyurethanes that can compete in many aspects with polyurethanes derived from petrochemical polyols, reducing the environmental impact.

Segmented polyurethane elastomers (SPU) are block copolymers formed by soft segments (SS) and hard segments (HS). The SS, formed by the polyol, provides extensibility and the HS, formed by diisocyanate and chain extender, plays the role of physical crosslinker and acts as high modulus filler. The incompatibility between both segments causes phase separation determined by several factors (3).

In this work two polyols, of similar molecular mass and different structure, derived from castor oil were used as SS and a low molecular weight diol derived from corn sugar and an aliphatic diisocyanate as HS. The effect of the HS content and the structure and functionality of SS were analyzed on the final properties.

The aim of this work was the synthesis of SPU with a high content of carbon derived from renewable resources and their characterization by mean of physico-chemical, mechanical and morphology techniques.

Materials and Methods

SPU were synthesized by using commercial polyols, CO1 and CO2, derived from castor oil with a functionality of 2 and 2.7 respectively, 1,6-hexamethylenediisocyanate (HDI), kindly supplied by Bayer and 1,3-propanediol (1,3-PD) from Quimidroga as chain extender. The molecular weight of CO1 and CO2 (3505 and 3366 g/mol) was evaluated from the hydroxyl number determined by the standard procedure ASTM D4275-05 test method A. Prior to be used, the polyol and 1,3-PD were dried at 60ºC.

Polyurethanes with different HS content ranging from 16 wt% to 60 wt%, maintaining a NCO/OH molar ratio equal to 1 for all the compositions, were prepared using two-step bulk polymerization procedure. Firstly, the isocyanate-terminated prepolymers were prepared by the reaction between the polyol with the diisocyanate at 90 ºC for 5 h in nitrogen atmosphere. Then, 1,3-PD was added at the same temperature during 10 min with vigorous stirring. Finally, the viscous liquid was quickly poured between two Teflon coated metal plaques separated by 1.5 mm and left to cure under pressure for 10 h at 100 ºC.

Microdomain structure and properties of synthesized polyurethanes with different HS content were analyzed by attenuated total reflexion Fourier transform infrared spectroscopy (ATR-FTIR), differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), and performing tensile and Shore D hardness tests.

Results and Discussion

ATR-FTIR spectroscopy was used to investigate the effect of chemical structure and HS content on the microstructure of polyurethanes, based on CO1 and CO2 castor oil derived polyols as SS, by means of hydrogen bonding formation in the amide I region. In both polyurethane systems, while the band associated with H-bonded urethane carbonyl groups in disordered (amorphous) domains at 1721cm^{-1} decreases with increasing HS content, H-bonded urethane carbonyl groups in ordered (crystalline) hard domains at 1685 cm^{-1} increases with HS content and, in this way, it provokes the formation of large HS domains that contribute to the phase separated microstructure.

The results obtained from tensile test are shown in table 1. The CO1-based SPU show higher modulus (E), strength at break (σ) and percent of elongation (EL) than those based on CO2. As observed by DSC, this may be due to the crystalline nature of CO1-based SS while not crystallinity is observed in CO2-based SS. In both SPU systems HS crystallize showing similar melting temperatures and cristallinity.

The thermal stability of SPU systems has been studied by TGA. All the analyzed systems show similar weight loss profiles in the whole temperature range. Derivative TGA curves revealed three main degradation processes and higher thermal stability of CO1-based SPU.

Polyurethane	E (MPa)	σ (MPa)	EL (%)
SPU-CO1-3	178.2±6.3	24.4±1.4	740±34
SPU-CO1-5	222.9±8.0	14.7±0.2	310±25
SPU-CO1-9	284.9±7.4	16.4±0.4	50±3
SPU-CO1-13	319.1±6.0	19.6±0.4	18±3
SPU-CO2-3	6.7±2.1	1.9±0.2	254.7±34
SPU-CO2-5	36.5±7.6	5.3±0.1	194.4±8
SPU-CO2-10	73.8±34.3	7.5±0.4	161.2±36
SPU-CO2-15	223.9±91.6	8.7±0.4	64.5±17

Table 1. Mechanical properties of the synthesized SPU

Conclusions

Two SPU systems based on renewable precursors were synthesized, analyzed and characterized. The final properties of synthesized SPU were analyzed taking into account the functionality and crystallinity of polyol and the HS content.

Synthesis of polyesters from Castor Oil and their use as polymer matrix for magnetic nanocomposites

Paulo Anselmo Ziani Suarez[*], *Fabricio Machado Silva, Eduardo Ulisses Xavier Péres and Fernando Gomes de Souza Junior*[1].

University of Brasília, [1]Instituto de Macromoléculas Professora Eloisa Mano

e-mail: [*]psuarez@unb.br

Introduction

The synthesis of polymeric materials derived from renewable resource has been intensely studied in the last decades.[1] Depending on the nature of the monomeric specie, the bio-based polymeric materials can present final properties similar to those usually observed in polymer materials obtained from petrochemicals. In addition, some biopolymeric material can also present biodegradability feature and can be tailored in order to be used for controlled drug delivery applications[2].

Specifically, ricinoleic acid (RA, 12-hydroxy-9-*cis*-octadecenoic acid) has been utilized as raw material to produce aliphatic polyesters and lactones. This fatty acid presents specific characteristics, intrinsically related to its chemical structure that involves two reactive functional groups (hydroxyl, carboxyl) and a double bond, which makes easy the formation of several polymeric materials through step-growth polymerization mechanism.[3]

From this point, the use of dispersions of magnetic iron oxide nanoparticles with their surface modified by organic molecules or polymers have given rise to intensive research for biomedical applications such as magnetic drug targeting, cancer treatment (hyperthermia), enzyme immobilization, or magnetic resonance imaging[4], as well as for a bottom-up approach to build nanodevices such as high density storage systems.

The aim of this work is developing new routes to prepare composites from castor oil and magnetic iron nanoparticles.

Materials and Methods

Castor oil was purchased from Celtic (São Paulo, Brazil); chloridric acid and sodium hydroxide were obtained from VETEC (Rio de Janeiro, Brazil); chloroform was acquired from Synth (São Paulo, Brazil); nitrogen was provided by White Martins Ltda (Rio de Janeiro, Brazil). All other reagents were used as received.

Synthesis of Ricinoleic Acid

Castor oil was mixed with a 3 mol L^{-1} sodium hydroxide solution and kept at 70 °C under mechanical stirring for 3 h. To the obtained soap was added a 2 M chloridric acid solution and the mixture was mechanically stirred for 30 min at 80 °C. A two phase mixture was obtained (an aqueous phase and an organic phase rich in ricinoleic acid), which were separated by decantation. The isolated organic phase was washed three times with distilled water. Then, the ricinoleic acid was dissolved in chloroform and mixed with magnesium sulphate. The mixture was filtered and chloroform was removed by distillation under reduced pressure.

Synthesis of Magnetic Nanoparticles

Magnetite (Fe_3O_4) nanoparticles were prepared by chemical coprecipitation of aqueous Fe^{2+} and Fe^{3+} salts solution and NaOH solution. Initially, 6.1 g of $FeCl_3.6H_2O$ and 3.1 g of $FeSO_4.7H_2O$ were dissolved in distilled water (125 mL) and hydrochloric acid (5 mL) and kept at 60 ºC with bubbling of nitrogen gas. Separately, NaOH (37.5 g) was dissolved in distilled water (625 mL). The base solution was added into the iron salts solution and kept under nitrogen atmosphere and vigorous stirring at 60 ºC for 30 min. The resulting black magnetic nanoparticles were isolated by magnetic decantation and washed with distilled water until neutral pH.

Surface Modification of Nanoparticles

RA (1.12 mL) was slowly dropped into a nanoparticles (1 g) suspension under mechanical stirring in water at 85 °C.

Synthesis of Polymer

Polymerizations were carried out in a 1 L five necked round-bottom flask. The flask was equipped with a mechanical stirred, nitrogen inlet tube, adjacent partial reflux condenser and a thermocouple. The reaction vessel was heated with an electrical heating mantle connected to an automatic temperature controller. The monomer RA and modified nanoparticles were introduced into the reaction vessel and purged with nitrogen. Then the mixture was kept under stirring at the desired temperature during a determined time. The composite was characterized by FT-IR (IRPrestige-21 Shimadzu) and DSC (DSC-60 Shimadzu).

Results and Discussion

The polyesterification of RA was confirmed by FT-IR. The ester formation was confirmed by two new strong stretches at 1732 cm^{-1} and 1178.51 cm^{-1}. The RA consumption was observed by the disappearance of stretches related to the carboxyl (at 1708 cm^{-1}) and hydroxyl (at 3352 cm^{-1}) groups.

The Tg observed values for polymeric materials at 190 °C was –75.2 °C. This behavior may be understood as a result of the increasing molecular weight and also related to the crosslinking of growing polymeric chains.[5]

Conclusions

The method used here was suitable to prepare composites of biopolyester from RA and surface modified magnetic nanoparticles. Measures Magnetic force realized after further showed that the material formed has superparamagnetic behavior. At this behavior there is not histerese.

Thermosensitive Copolymers Based on Alginate and Poly(N-isopropylacrylamide) Obtained by Gamma-radiation

M. M. Soledad Lencina[1], *Noemí A. Andreucetti*[2], *Marcelo A. Villar*[1]

[1]Planta Piloto de Ingeniería Química, PLAPIQUI (UNS-CONICET), Departamento de Ingeniería Química, Universidad Nacional del Sur, Camino "La Carrindanga" Km. 7, (8000) Bahía Blanca, Argentina.
[2]Departamento de Química, Universidad Nacional del Sur, Av. Alem 1253, (8000), Bahía Blanca, Argentina

e-mail: mlencina@plapiqui.edu.ar, mvillar@plapiqui.edu.ar

Introduction: Irradiation is a valuable technique for the modification of physical and chemical properties of polymeric materials. The use of gamma-irradiation methods has advantages, such as relatively simple manipulation and the absence of any extra agents for polymerization and/or crosslinking [1].
Alginate is a linear biopolymer of 1,4-linked β-D-mannuronate (M) and α-L-guluronate (G) residues [2]. N-isopropylacrylamide (NIPAAm) could be polymerized in order to obtain poly(NIPAAm), a thermo-responsive polymer, which shows coil-globule transformation at a lower critical solution temperature (LCST) around 32 °C [3].
The aim of this work is to obtain alginate-PNIPAAm copolymers via irradiation with gamma rays from ^{60}Co with the final goal of synthesized thermoresposive hydrogels.

Materials and Methods: The irradiation was carried out in solution. First, a water solution containing 5 % NIPAAm recrystallizated from n-hexane was prepared. Then, 1 g of alginate and the necessary amount of the NIPAAm solution to achieve alginate:NIPAAm molar ratios of 0.5:1, 1:1, and 1:0.5 were introduced in 100 mL flasks. In order to have a constant alginate concentration, the volume of final solution was 50 mL for all the cases. The flasks were connected to a vacuum line, evacuated and heat sealed having alginate-NIPAAm solutions under vacuum. Water solutions were irradiated with ^{60}Co at Centro Atómico Ezeiza (Argentina). Different doses between 0.5 and 10 kGy were applied with a low dose rate (1 kGy/h).
After irradiation, the copolymers obtained were washed in a soxhlet extractor with methanol. Percentages of grafting (% G) and grafting efficiency (% EG) were calculated from mass recovered and from elemental analysis.

Results and Discussion: Values of % G and % EG, calculated according to other authors [4], for samples irradiated with 0,5 and 1 kGy, are presented in Table 1.

Table 1. % G and % EG values of irradiated solution.

Dose	ID	Alg:NIPAAm molar ratio	% G	% EG
0.5 kGy	A1	0.5:1	67.9	30.2
	A2	1:1	45.3	39.7
	A3	1:0.5	38.1	66.9
1 kGy	B1	0.5:1	152.7	67.9
	B2	1:1	38.5	33.8
	B3	1:0.5	27.7	48.7

% EG values are function of both NIPAAm concentration and dose rate used. Then further studies must be done in order to understand the influence of each variable.
Values of percentage of carbon and nitrogen content, obtained from elemental analysis, along with % G calculated from these values are shown in table 2 for copolymers irradiated with 1 kGy.
% G increases with the increase in the content of initial solution. The values obtained from elemental analysis are in good agreement with those calculated from mass measurements.

Table 2. Elemental analysis and % G calculated.

ID	% C	% N	% G
B1	48.9	7.06	154.2
B2	41.1	4.43	65.5
B3	38.7	3.16	37.0

Fourier Transform Infrared (FTIR) spectrum of samples B1, B2, and B3 are presented in Figure 1. The presence of PNIPAAm in the copolymer is reflected in the signals at 3072, 2969, and ~1550 cm^{-1} associated to stretching ν N-H, ν^{as} CH_3, and δ N-H respectively. The mains signals for alginate are at 1413 cm^{-1} (δ O-H) and ~ 1050 cm^{-1} (ν C-O; ν^{as} C-O-C). In B1 spectra the bands for PNIPAAm are deeper than in B2 and B3, according to the degree of grafting calculated from elementary analysis.

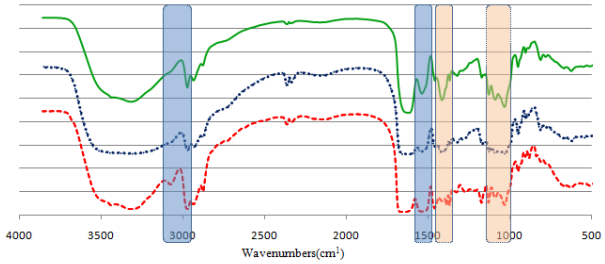

Figure 1. FTIR spectra of samples B1 (- - -), B2 (· · ·), and B3 (—).

Conclusions: Alginate-PNIPAAm copolymers were obtained by solution irradiation of alginate and NIPAAm monomer. % G is a function of NIPAAm content and % GE is a function of both NIPAAm content and irradiation dose. At higher irradiation dose a gel is produced as consequence of PNIPAAm crosslinking. For this reason, low doses with a low dose rate must be used in order to obtain soluble copolymers.

Study of Incorporation of Vegetable Waste as Filler in Flexible Polyurethane Foam

Francisco José Melero Muñoz, Mª Virtudes Navarro Bañón, José Roberto Vega Baudrit, Mª del Rosario Sibaja

Ballestero Technological Center of Furniture and Wood (CETEM), National Nanotechnology Laboratory (LANOTEC), Polymers Laboratory National University of Costa Rica (POLIUNA)

fj.melero@cetem.es

Introduction: Use of flexible polyurethane foam has been widely extended to a high range of commercial applications. Manufacturing of cushioning and sleeping devices is one of the most outstanding applications. In the foaming process, different fillers are usually added in the formulation with the aim of reduce manufacturing costs and enhance physical properties of the final product, such as increase density, strenght and mechanical resistance. Most commonly used fillers are inorganic powders, like barium sulfate, calcium carbonate, talc and inorganic fibers. The main objective of this study has consisted of characterising properties of flexible polyurethane foams in which formulation conventional fillers, that nowadays are being used, have been replaced by vegetal waste.

Materials and Methods: The raw materials employed were polyols, isocyanates and additives such as silicone, amine and tin octoate commonly used in the manufacturing of flexible polyurethane foams for its use in cushioning and sleeping devices. Calcium carbonate and rice shell previusly pulverized and sieved obtained from rice harvest were used as fillers. Optical microscopy, thermogravimetric analysis and infrared spectroscopy were used for the analysis of foams obtained. Standard test method for cellular polymeric materials were carried out to analyse their mechanical properties: hardness, static fatigue at constant deformation and tensile strenght and elongation at break.

Results and discusions: After selection and characterisation of raw materials that were used in this study, four flexible polyurethane foams were obtained and subsequently characterized, which difference between them was the kind of filler: No filler, Calcium Carbonate, Milled Rice Shell and Mix of them.

Conclusions: It has been shown that milled rice shell can be used as filler in the production of flexible polyurethane foams for it use in cushioning and sleeping devices :

- It disperses homogeneously during the foaming process.
- TGA analysis shows that flexible polyurethane foam filled with milled rice shell is thermically more stable than polyurethane foam without fillers.

Standard test methods carried out showed that flexible polyurethane foam filled with milled rice shell has a mechanical behaviour similar and even better in some aspects to polyurethane foams filled with calcium carbonate.

Lyocell Fibers Reinforced with Anisotropic Nanofiller

Ahmed Jalal Uddin, Atsushi Yamamoto, Yasuo Gotoh

Faculty of Textile Science and Technology, Shinshu University, 3-15-1 Tokida, Ueda, Nagano 386-8567, Japan

Email: jalal@shinshu-u.ac.jp

Introduction: Cellulose is one of the most abundant natural resources on earth and it is a source of biodegradable and eco-friendly regenerated fibres for both apparel and industrial applications. The cellulose fibres regenerated from NMMO solutions, known by the generic name lyocell, yield fibres with good physical properties than those produced using earlier technologies. The cellulose of lyocell is usually derived from pulp as found in hardwood tress such as eucalyptus, oak and birch. The production of pulp material from these trees is relatively costly. Conversely, bagasse, derived from the crushing of sugarcane stalks, is a much cheaper that can reduce the production cost of lyocell fibres. With our persistent efforts, we successfully prepared lyocell fiber from bagasse equivalent with the commercial lyocell. [1]

In this work, we attempted to reinforce our lyocell fiber prepared from baggase with single-walled carbon nanotubes (SWCNTs). Homogeneous suspensions of cellulose and nanotubes were extruded through the nozzle in dry-jet wet spinning method and taken up to their highest possible speed. The morphology, structure, thermal and mechanical properties of composite fibers were characterized.

Materials and Methods: The spinning solutions were prepared by taking bagasse, NMMO 0.9 hydrate (solvent), propyl gallate (antioxidant) and sodium dodecyl-sulphate (surfactant). The suspension of SWCNT with catechin, recent finding as a good dispersant of SWCNT [2], and CMC were made separately and added to the cellulose solution to become SWCNT 0.05, 0.1, 0.2 and 0.3 wt% relative to the cellulose content.

Dry jet-wet spinning was carried out with a single-hole spinneret of diameter 0.5 mm at 120°C with the injection speed of 4.0 m min^{-1}. Coagulation was taken place in water/NMMO mixture (10 wt%) at room temperature (20°C) with a 2-m coagulating bath followed by a water wash. The prepared fibers were taken up at their maximum possible speeds. The spin-draw ratio d_f/d_0 was determined by measuring the cross-sectional diameter of the solution dope at the spinneret exit (d_f) over the fiber cross-sectional diameter at the take-up point (d_0).

Results and Discussion: Table 1 shows the spin-draw ratio, and the tensile properties of neat cellulose and composite fibers. It is seen that the spin-draw ratio was drastically increased after incorporation only a small amount of SWCNTs i.e., 0.05% and the trend continued till filler loading of 0.2%. It indicates that the spinnability of cellulose is enhanced with SWCNT loadings. Tenacity and initial modulus also show the same dramatic increase with the spin-draw ratio and highest properties were obtained for 0.2% filler loading. However, the tenacity and Young's modulus of 0.2% nanotube filled fibre are 1.18 GPa and 65 GPa that are respectively 188% and 400% higher than the neat cellulose ones. Storage modulus of composite fibers increases with the loading of nanotubes in the whole temperature range. Such high-resistant fibers will hopefully be useful as tire-cord and in other industrial applications. The WAXD images, in Figure 1, support the corresponding structural development of composite fibers with the spin-draw ratio that lead to outstanding mechanical properties.

TABLE 1. Properties of neat cellulose and SWNT loaded composite fibers

Fiber	*Spin-draw ratio*	*Tenacity (GPa)*	*Young's modulus (GPa)*	*Elong. at break (%)*
Neat cellulose	*17.5*	*0.41*	*13*	*15*
SWCNTs 0.05%	*48.8*	*1.04*	*54*	*3.2*
SWCNTs 0.1%	*52.5*	*1.15*	*63*	*3.8*
SWCNTs 0.2%	*57.5*	*1.18*	*65*	*3.5*
SWCNTs 0.3%	*45*	*0.71*	*39*	*2.4*

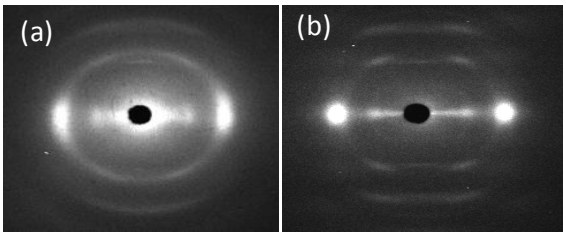

Fig 1. WAXD patterns of the neat cellulose and 0.2% loaded SWCNTs composite fibers.

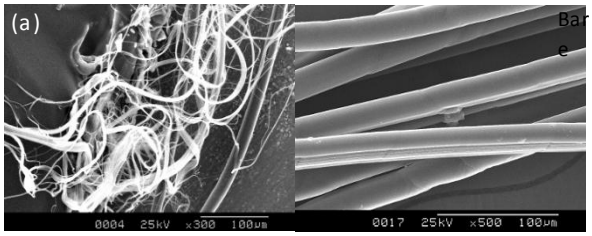

Fig 2. SEM images of the neat cellulose and 0.2% loaded SWCNTs composite fibers after pulverization in a laboratory blender.

It is well-known that lyocell fiber suffers in fibrillation against any mechanical abrasion. We checked the fibrillation property of our nanotube incorporated fibers after a harsh-beating in a laboratory blender. As shown in figure 2, it was observed that only an introduction of a small content of nanotubes resulted drastic prevention of fibrillation of our lyocell fiber.

Castor Oil based Poly(urethane-co-pyrrole)s as Novel Electroactive Anticorrosive Coatings for Steel

*Reza Gharibi, Mohammad Yousefi, Hamid Yeganeh**

Iran Polymer and Petrochemical Institute, P.O. Box: 14965/115, Tehran, Iran

E-mail: h.yeganeh@ippi.ac.ir

Introduction

The discovery of the corrosion protective properties of electrochemically deposited conducting polymers such as polythiophene, polyaniline and polypyrrole (PPy) on metallic surfaces has opened a new dimension in the field of anticorrosive organic coatings [1]. Despite their considerable merits as corrosion protective coatings, poor mechanical properties, improper processability and low environmental stability are main drawbacks of these compounds [2]. To tackle these problems, preparation of copolymers or composites of conducting polymers with some tractable insulating polymers was considered [3].

In the present work, preparation of novel block copolymers of polypyrroles and polyurethanes with high flexibility and mechanical properties similar to pure polyurethane and conductivity close to pristine PPy was considered. For the synthesis of polyurethane, castor oil was used as starting material. Because, castor oil is one of the most important renewable resources raw material, due to its low cost, low toxicity and widespread availability in most region of the world.

Experimental

At the first step, hydroxyl terminated polyurethane (HCO) was prepared via the reaction of three equivalents of butane diol with one equivalent of NCO-terminated urethane prepolymer, which itself prepared from the reaction of three equivalents of isophorone diisocyanate with one equivalent of castor oil. At the second step, for the preparation of block copolymers (HCO-PPy1-4), HCO was used as initiator for oxidative polymerization of pyrrole (Py) in the presence of cerric ammonium nitrate (CAN) as catalyst. Different formulations of copolymers are tabulated in Table 1.

Results and discussion

In contrast to polypyyrole homopolymer, the prepared copolymers were readily soluble in common organic solvents; therefore, they freed from homopolymer by simple filtration of polymerization mixture. The structure of the prepared copolymers was confirmed by examination of their FTIR and ^{1}HNMR spectra. Electrical conductivity of the obtained block copolymers were measured by four-point probe technique (Table 1). Conductivity of copolymers was depended on the molar ratio of HCO/Py/CAN. The observed trend is in accordance with Kızılcan findings [4].

The PPy-HCO2 copolymer with highest conductivity was used for the coating step. The protective coating was applied on steel 316 electrode (0.6 cm^2) by electrochemical deposition of electroactive copolymer from its solution in acetonitrile solvent containing lithium perchlorate (0.1 M) as supporting electrolyte using a cyclic voltammetry technique. The electrodepositing was performed by cycling continuously the potential between -0.8 and 1.8 V versus Ag/AgCl reference electrode at a potential scan rate of 0.03 V/Sec (Figure 1). Bare and coated steel were evaluated by examination of corrosion potential (Ecorr), polarization resistance (Rp) and corrosion current (Icorr). Aqueous solutions of NaCl (3.5wt %) were used as electrolyte. The Tafel plots (Figure 2) were obtained by scanning the potential in the range of ± 250 mV around the Ecorr, at a scan rate of 5 mV/min. The coated steel electrode showed much higher Ecorr (0.254v) and Rp (7800Ω) values and lower Icorr value than uncoated steel electrode. Therefore, HCO-PPy2 can be considered as effective anticorrosive coating for steel with 0.6 V shift of corrosion potential.

Table 1: Different formulations and conductivity of copolymers

Name	CAN (mmol)	Py (mmol)	HCO (g)	Conductivity (s/cm)
HCO-PPy1	0. 25	2.3	0.62	7×10^{-3}
HCO-PPy2	0.5	2.3	0.62	1.8×10^{-1}
HCO-PPy3	0. 8	2.3	0.62	4×10^{-3}
HCO-PPy4	0.125	4.6	0.62	5.5×10^{-2}

Synthesis of Isotactic Poly(hydroxy acrylic acid) by Radical Polymerization of Methylene Dioxolanone Prepared from Lactic Acid

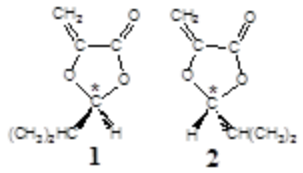
Hitoshi Tanaka, Yoshitaka Matsubara, Kazuya Okuda, and Miki Niwa

Institute of Technology and Science, University of Tokushima

tanaka@opt.tokushima-u.ac.jp

Introduction:

Control of tacticity and helicity has been known to be difficult in free radical polymerization in contrast to ionic polymerization. However, we found that the acrylates with s-cis conformation would propagate preferentially to give an isotactic helical polymer near ceiling temperature (*Tc*) in the polymerization of the acrylates including (-)-menthyl 2-acetamidoacrylate.[1] From this fact and the standpoint of sustainability, we focused on the preparation of an isotactic polymer by free radical polymerization under normal conditions, e.g. reaction temperature far from *Tc*, using a bioresource monomer. We report here the preparation of bioresource monomer and isotactic polymer as well as a conversion of the resulting polymer to a hydrophilic material according to the green chemical process for **1** and **2**.



1 **2**

Materials and Methods:

1 and **2** were synthesized by mainly two steps, i.e. cyclization using lactic acid and iso-butylaldehyde and following a vinylization of resulting cyclic compound according to the literature.[2] Cyclization was carried out by refluxing a mixture of lactic acid and iso-butyl aldehyde in the presence of *p*-toluenesufonic acid. This condensation reaction gave a mixture of cis and trans dioxolanone diastereomers, with the cis isomer always predominating. Isolation of the cis dioxolanone, (*S*)-2-*iso*-propyl-(*S*)-5-methyl-1,3- dioxolan-4-one, from trans one, (*R*)-2-*iso*-propyl-(*S*)-5-methyl-1,3-dioxolan-4-one, was performed at need by silica gel column chromatography. Resulting dioxolanones were readily transformed into the required olefins by vinylization, i.e. **1** and **2** from cis and trans dioxolanones respectively by bromination with N-bromosuccinimide (NBS) and AIBN followed by a dehydrobromination with triethylamine. After dehydrobromination, crude produc was purified by distillation under reduced pressure; bp.41°C/1.5mmHg, to give a colorless liquid.

Polymerization was carried out in a sealed ampoule with shaking at given temperature. The ampoule containing required amounts of reagents was degassed several times by a freeze-thaw method and then sealed under reduced pressure and placed in a constant temperature bath. The resulting polymer was isolated by pouring the reaction mixture into methanol.

Polymer was hydrolyzed with KOH in THF at room temperature for 1 day.

Results and Discussion:

Methylene dioxolanone (mixture of **1** and **2**) which were synthesized from ferment lactic acid (LA) and chemically synthesized DL-LA as a starting LA gave a polymer with Mn=15,000~20,000 in ca.60% yield in the polymerization with AIBN for 3 hrs at 60°C. Polymerizability of both dioxolanones synthesized from ferment LA and DL-LA is similar to each other. Tacticity of the resulting polymer, however, is much different, and

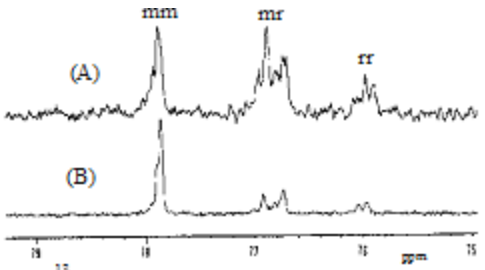


Fig.1 ^{13}C-NMR spectra of poly(hydroxy acrylate) originally obtained from the polymerization of methylene dioxolanone prepared from (A) DL- and (B)ferment lactic acid.

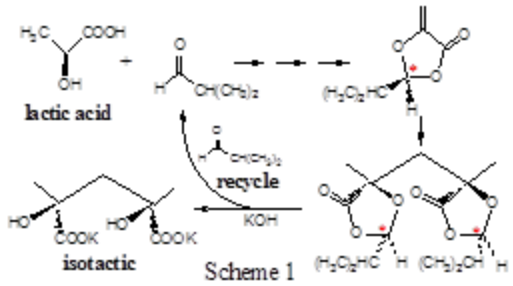
the polymer obtained from the monomer originated from ferment LA represents high isotacticity (mm) as seen in Fig.1, in which hydrolyzed polymer is used for the convenience of the NMR measurement. Moreover, much higher isotactic polymer was obtained by the polymerization of isolated **1**. For the study on the second structure of the polymer is now in progress.

Preparation of isotactic polymer from LA is summarized in Scheme 1. In this scheme, aldehyde is recovered by facile hydrolysis of methylene dioxolanone



Scheme 1

polymer. Structural comparison between the present polymer and well-known poly(LA) is shown in Fig.2.

In conclusion, the monomer synthesized from a ferment LA gives an isotactic polymer, which converts to a hydrophilic material according to the green recycle process as in Scheme 1.

Investigation of the type of the bridge on the activity of supported metallocene catalyst in ethylene polymerization.

A. Talaei

alirezatalaei@yahoo.com

ABSTRACT:

Ethylene polymerization was carried out with immobilization of rac-Ethylenebis(1-indenyl)zirconium dichloride ($Et(Ind)_2ZrCl_2$) and rac-Dimethylsilylbis(1-indenyl)zirconium dichloride ($Me_2Si(Ind)_2ZrCl_2$) on ES70W Silica support by indirect method. Effects of pre-activated catalyst concentration and calcination temperature of support on activity of supported catalyst were investigated. At [Zr]:[Si]= 0.04 wt% and 450 ^oC calcinating of silica temperature the maximum activity were observed. The ethylene bridge catalyst was more active than silyl bridge by the activity of 8142 kg PE. (mol Zr. h)$^{-1}$ and 4523 kg PE.(mol Zr. h)$^{-1}$ respectively. It was observed that the molecular weight of polyethylene that produced by ethylene bridge was higher than silyl bridge. The two type of bridge showed same trend in activity by changing of polymerization condition. It was observed that the reactor fouling was removed by supporting of catalyst.

Biopolymers from Natural Oils

Ausra Remeikyte, Jolita Ostrauskaite, Juozas Vidas Grazulevicius

Kaunas University of Technology

jolita.ostrauskaite@ktu.lt

Introduction

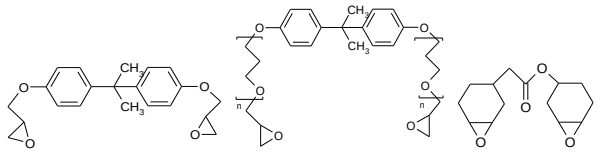
In recent years, natural oils have become the center of attraction for their potential use as starting materials for the preparation of polymers. This is an alternate route, which has the potential to augment the use of petroleum-based polymers [1].

In this study, the biopolymer films have been prepared by the cationic cross-linking in the dark or by photocross-linking of the epoxydized natural oils with or without the reactive diluents. The effect of the method of curing and of the addition of the reactive diluent on the thermal, mechanical properties, and biodegradability of the cross-linked polymers was studied.

Materials and Methods

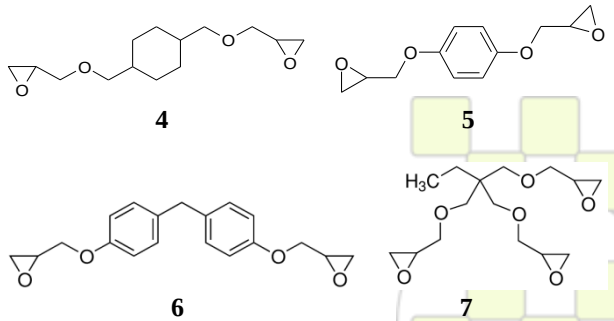
The linseed oil, rapeseed oil, and fish oil were epoxydized with 3-chloroperbenzoic acid [2] or with methyltrioxorhenium catalyst and hydrogen peroxide as oxygen source [3]. The highest conversion of carbon double bonds reached 86% and the highest number of epoxy groups per triglyceride of 5.3 was obtained.

The epoxydized natural oils were cross-linked in the dark using ytterbium trifluoromethane sulfonate as cationic initiator at 60°C with the following reactive diluents: bisphenol A diglycidyl ether (**1**), bisphenol A propoxylate diglycidyl ether (**2**), and 3,4-epoxycyclohexylmethyl-3,4-epoxycyclohexane-carboxylate (**3**).



1 **2** **3**

The photocross-linking of different natural oils was carried out using diphenyliodonium hexafluorophosphate or triarylsulfonium hexafluoroantimonate as photoinitiators at the room temperature with the reactive diluents **1**-**3** as well as with the following reactive diluents: 1,4–cyclohexane dimethanol diglycidylether (**4**), resorcinol diglycidylether (**5**), bis[4-(glycidyloxy)phenyl]methane (**6**), and trimethylolpropane triglycidyl ether (**7**).



4 **5**

6 **7**

Results and Discussion

Cross-linking of epoxydized natural oils in the absence of diepoxy compounds resulted in viscous polymers. The fastest curing was observed for the layers containing reactive diluents **3** and **4**. The yield of the insoluble fraction of the polymers was found to be 59-90%. It depended on the curing method and on the ratio of the epoxydized oil and the reactive diluent in the reaction mixture.

The Young modulus of the cross-linked polymer films ranged from 2 to 861 MPa. The cross-linked polymer obtained with the reactive diluent **3** showed the highest Young modulus. The hardness of some compositions prepared from the epoxydized linseed oil was similar to that of the commodity polymer films. The thermogravimetric analysis indicated that the cross-linked polymers were thermally stable up to 200°C in nitrogen atmosphere. The 10% weight loss temperature of the polymers ranged from 250 to 420°C. The water vapour transmission rate of the cross-linked polymer films was in the range of 6-49 g/m^2/24h. The increase of the amount of the reactive diluent used leaded to the decrease of the water vapour transmission in the polymer films. The measurements of the biochemical oxygen demand indicated that the cross-linked polymers showed higher biodegradation rate than cellulose, starch and polyvinylalcohol. The composting of the polymer films showed that the cross-linked polymers of epoxydized natural oils prepared without diepoxy reactive diluents showed higher biodegrability than those prepared with the reactive diluents.

Conclusions

The biopolymer films have been prepared by the cationic cross-linking in the dark or by photocross-linking of the epoxydized natural oils with or without the reactive diluents. The thermal, mechanical properties and biodegradability of the cross-linked biopolymers depended on the curing method and on the epoxydized oil, the reactive diluent, and their ratio in the reaction mixture.

Synthesis of Polystyrene-Rubber Waterborne Nanoparticles by Miniemulsion Polymerization

Ludmila Ronco, Roque J. Minari, Jorge R. Vega, Luis M. Gugliotta

INTEC (Universidad Nacional del Litoral - Conicet) - Güemes 3450 - (3000) Santa Fe – Argentina

rjminari@santafe-conicet.gov.ar

Introduction: Actually research on waterborne hybrid latexes has gained a lot of interest, since it is considered as the opportunity for developing new products based on the synergy effects of the adopted compounds.[1] Polystyrene/rubber waterborne hybrid systems are expected to combine positive properties to produce nanoparticles with high impact resistance. The improvement of properties is expected to be maximum with intimate contact of both materials. Unfortunately, polystyrene (PS) and polybutadiene (PB) are not compatible. Miniemulsion (mE) polymerization allows the incorporation of hydrophobic components, like PB based rubbers, into PS particles. The molecular structure of rubber, the formulation and polymerization conditions affect the phase compatibilization.

In this work, the mE polymerization is used to synthesize waterborne PS/PB based-rubber (anionic PB and styrene-butadiene random copolymer: SBR) nanocomposites; and the effect of the process variables and rubber architecture was investigated.

Experimental Work: mE of 20-30% wt solids content, with variable rubber content, 2% wbop (weight based on organic phase) of sodium lauryl sulphate as surfactant, 4% wbm (weight based on monomer) of hexadecane as costabilizer, and $NaHCO_3$ at a 0.04 M concentration in the water phase. In order to produce the mE, organic and water phases were first strongly mixed and then treated with a Sonics VC 750 ultrasonic homogenizer (100% of amplitude with cycle of 20 sec on and 5 sec off).

Polymerizations were carried out in batch at 70ºC and under constant N_2 bubbling. Along the polymerizations the following was measured: i) monomer conversion (x) by gravimetry; ii) droplet (d_d) and particle (d_p) diameters by dynamic light scattering, using a Brookhaven BI-2030 equipment; and iii) molecular properties by size exclusion chromatographic (SEC) with a Waters 1515 chromatograph. mE stability and surface tension (ST) were measured using a turbiscan TMA2000 and a Krüss tensiometer K8, respectively.

Results and Discussions: Table 1 and Fig. 1.a,b present the results of the mE polymerization when 5 % wbop of PB (M_w=445000 g/mol) was used as preformed polymer. All mE were stable; and while in experiment ME1 the solids content was 30 %, in ME2 and ME3 it was 20%. Also, 2 kinds of initiators were employed: potassium persulfate (KPS) in ME1-2 and the redox system tert-butyl hydroperoxide/ascorbic acid (TBHP/ AA) in ME3. Independently of the initiator type and the solids content, the final x was greater than 90 %. The reduction in the solids content mainly affects d_d, thus favoring the droplet nucleation (i.e., N_p/N_d is reduced). The redox initiator produces an increment of the radical availability and increases the rates of polymerization and nucleation (Fig. 1.a,b and Table 1), with a reduction of N_p/N_d. Notice that the higher the particle fraction produced by droplet nucleation, the lower the phase separation, and the lower the collected coagulum (mainly composed by PB, according to SEC analysis.)

Table 1. Experiments with 5% wbop of PB

Experiment	*ME1*	*ME2*	**ME3**
Solid content [%]	30	20	20
Initiator (%wbm)	KPS(0.8)	KPS(1.5)	TBHP/AA(1.5)
x [%]	94.2	94.3	94
d_d [nm]	340	229	160
d_p [nm]	96	108	108
N_p/N_d [a]	44.7	9.5	3.3
Coagulum [%]	1.7	0.1	> 0.1

[a] N_p: number of particles; N_d: number of droplets

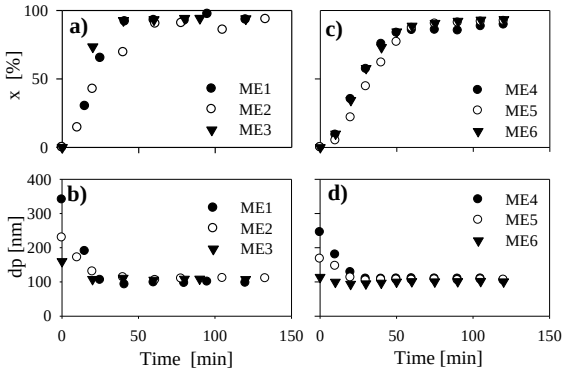

Fig. 1. mE polymerizations with PB (a, b) and SBR (c, d).

Table 2 and Fig. 1.c,d show the experimental results obtained with SBR as preformed polymer and KPS as initiator. While in ME4 and ME5 high M_w SBR (305000 g/mol) was used, low M_w SBR (65000 g/mol) was employed in ME6. Not significant effect on x of the SBR concentration and M_w was observed. As expected, the reduction of the organic phase viscosity (by decreasing the amount of SBR or its M_w) diminishes d_d, thus increasing the droplet nucleation (Table 2 and Fig. 1.d). The highest droplets nucleation efficiency ($N_p/N_d \approx 1$) was achieved in ME6 with 1 % wbop of low M_w SBR. ME6 also presents the smallest d_d and ST=49 mN/m, indicating the absence of micelles in the mE. Finally, a negligible amount of coagulum was observed in these experiments.

Table 2. Experiments with SBR and 0.75 % wbm of KPS

	ME4	*ME5*	**ME6**
SBR [% wbop]	5	1	1
x [%]	89.4	92.1	93.4
d_d [nm]	245	167	114
d_p [nm]	110	106	101
N_p/N_d	11.2	3.9	1.4

Conclusions: The effect of M_w and rubber composition was studied in order to produce compatibilized nanoparticles. The employment of low M_w SBR (a rubber more compatible with PS than PB) allows the achievement of higher droplets nucleation efficiency, with minimum phase separation.

Lithium Naphthalenide Initiators for Controlled Anionic Polymerization

Verónica A. González, Angel J. Satti, Mario D. Ninago, Enrique M. Vallés, Marcelo A. Villar, Andrés E. Ciolino

Planta Piloto de Ingeniería Química, PLAPIQUI (UNS-CONICET), Departamento de Ingeniería Química, Universidad Nacional del Sur, Camino "La Carrindanga" Km. 7, (8000) Bahía Blanca, Argentina.

e-mail: valles@plapiqui.edu.ar, mvillar@plapiqui.edu.ar, aciolino@plapiqui.edu.ar

Introduction: The use of effective initiators is the key for a successful synthesis of complex macromolecular architectures by anionic polymerization techniques. In this work we report the synthesis and polymerization performance of a soluble initiator obtained by the reaction of naphthalene (Naph) and lithium metal (Li), under mild experimental conditions. Its efficiency was tested in homopolymerization reactions by using different monomers such as styrene (S), isoprene (I) and hexamethyl(cyclotrisiloxane) (D_3).

Experimental: All manipulations were performed under high vacuum in glass reactors designed according to anionic polymerization standards [1]. The apparatus employed is shown in Figure 1.

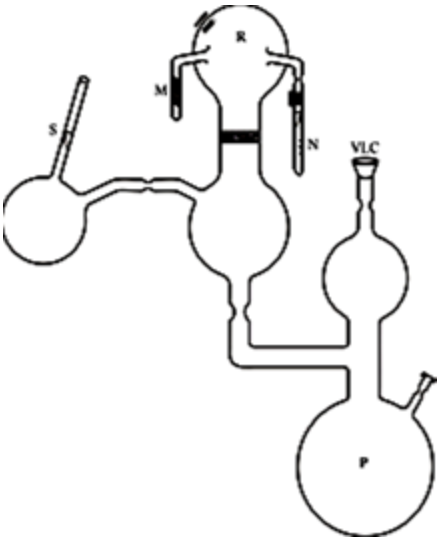

Figure 1. Apparatus used for the synthesis of lithium naphthalenide. References: **P**: Purge Section, **R**: Reactor, **VLC**: Vacuum Line Conection, **N**: Naphtalene Solution in Benzene, **M**: Lithium Metal, and **S**: Sampling Ampoule.

The synthesis was performed in a carefully cleaned apparatus by using granulated lithium and powder naphtalene as reagents and pure distilled benzene or THF/benzene mixtures as reaction solvent. Different [Li]:[Naph] molar ratios were studied. The reaction was performed during 24 h at room temperature (RT), under continuous and vigorous stirring. The crude reaction product was then filtered from the reactor to the sampling ampoule by employing a fritted glass filter between them. For each [Li]:[Naph] ratio studied, pure S monomer polymerization experiences were performed. The PS homopolymers obtained were evaluated by Size Exclusion Chromatography (SEC) in order to test the polymerization activity and the efficiency of the synthesized initiator. After testing all the experimental variables with S, similar experiences were done by using D_3 or I as monomers.

Results and Discussion: Figure 2 show the chromatograms of synthesized PS.

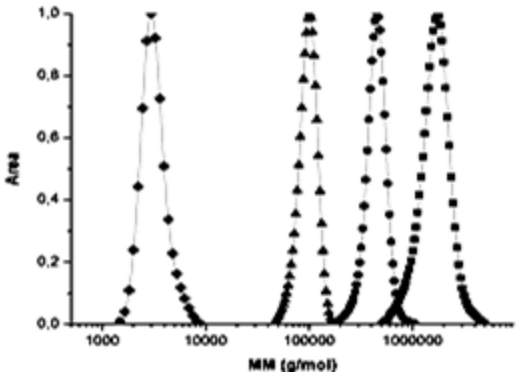

Figure 2. SEC chromatograms for model PS homopolymers synthesized in benzene (Benz.) or benzene/THF mixture. Symbols: (◆) Benz.:THF = 90:10 v/v (THF/Li = 1.5 molar), [Li: Naph] = 4:1, (■) [Li: Naph] = 4:1, (●) [Li: Naph] = 40:1, and (▲) [Li: Naph] = 400:1.

By using benzene as solvent, polymers with a monomodal distribution and high molar masses are always obtained. On the other hand, polymers with lower molar masses can be synthesized when a mixture of benzene/THF is employed,. A molar relation of THF/Li around 1 is needed to get a monomodal population. Other relations produce a bimodal signal with two polymer populations. Recent studies indicate that this result can be attributed to two different reactive species: the naphthalene radical anion and the naphthalene dianion [2], each one visually evidenced by a characteristic color: a deep purple solution (dianion) or a purple-brown solution (radical anion + dianion).

From figure 2, three facts can be clearly appreciated: **i)** all the PS synthesized show narrow molar mass distribution, without the appearance of secondary high or low molar mass peaks; **ii)** regardless the [Li:Naph] ratio, an efficient initiator is obtained; and **iii)** a broad range of molar masses (between 10^3–10^6 g/mol) can be obtained.

Conclusions: Lithium naphthalenide initiators were synthesized under mild conditions by employing different [Li:Naph] ratios, room temperature, and benzene or benzene/THF mixture as solvent. Model homopolymers such as PS, PI, or PDMS were obtained with these initiators, which clearly show the suitability of the experimental procedure employed.

A New Method for Synthesis of Photocurable Low Molecular Weight Chitosan

Laleh Solhi, Mohammad Atai, Azizollah Nodehi, Mohammad Imani

Iran Polymer and Petrochemical Institute (IPPI), P.O.Box: 14965/115, Tehran, Iran

L.solhi@ippi.ac.ir

Introduction: Light-curable polymers can undergo photopolymerization upon light exposure, which shows many advantages compared with chemical polymerization, including a high polymerization rate that overcomes the solvent effects in normal polymerization, good temporal and spatial control and resolution, ambient temperature operation and low energy consumption. Light-curable polymers may be used for in situ scaffold forming, which makes minimally invasive surgery possible. Moreover, the light-curable materials may be used for computer-aided fabrication through rapid prototyping which allows fabricating scaffolds with customized shape and reproducible microarchitecture on a large scale. Chitosan is a natural biopolymer that has been widely used in medical applications because of its biocompatibility and biodegradability [1-2]. The purpose of this study was to establish a new method for the synthesis of photocurable chitosan.

Materials and Methods: This synthetic path involves the bonding of Glycidyl Methacrylate (GM) onto the Low Molecular Weight Chitosan (LMWC) chain via glycidyl group of the monomer and the amine group of LMWC. The reaction was carried out in a way that the double bond remains intact and is then able to be polymerized. The process was carried out through a ring opening reaction of mixing the dissolved GM and Hydroquinone (HQ) in Isopropanole with an aqueous solution of LMWC with the molecular weight of about 3000. HQ was added to prevent the polymerization reaction of the double bonds of GM during the grafting reaction. After 15 hours stirring at room temperature, the product was precipitated in a large amount of Methyl Ethyl Ketone (MEK) and filtered. The precipitate was washed with MEK several times to remove the unreacted monomers and other unreacted species. MEK is a good solvent for GM, poly(GM) and HQ, but it is not able to solve the LMWC and the modified LMWC (m-LMWC). The product was then dissolved in Dimethyl Sulfoxide (DMSO) which is not able to dissolve LMWC, but is a good solvent for m-LMWC. The mixture was filtered and the clear solution of m-LMWC in DMSO was separated and freeze-dried. Figure-1 shows the scheme of the reaction. The effect of different parameters such as the temperature and the reactants concentration were investigated.

Results and Discussion: The FT-IR spectra confirmed the formation of m-LMWC. NMR spectra revealed that the reaction was performed mostly by the reaction of amine groups of LMWC and the glycidyl groups of GM. Figure-2 shows the FT-IR spectra of LMWC and m-LMWC. The appearance of the 1725 cm^{-1} peak proves the presence of carbonyl functional groups. Considering the purification process which removes the unreacted GM or Poly(GM) in the product, this peak shows the carbonyl groups of the GM-grafted-LMWC. The product was dissolved in DMSO and photo cured in the presence of 1,3-dibutanone as a photoinitiator meanwhile the solvent was evaporated. The degree of conversion, gel content, and mechanical properties of the cured polymer were also investigated.

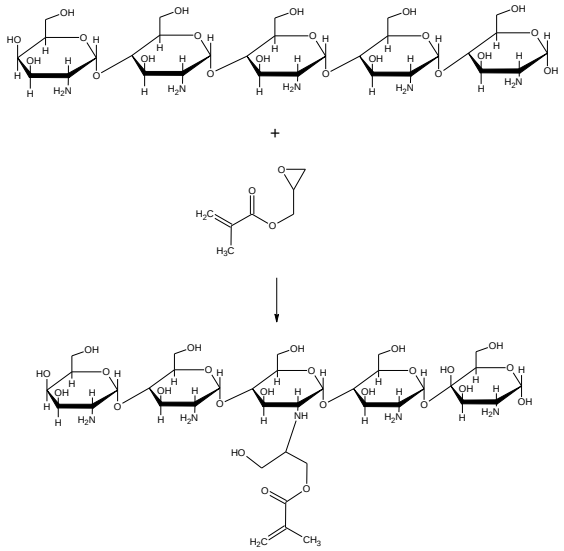

Figure-1- Scheme of the reaction of GM and LMWC

Conclusions: As a result, the synthesized photocurable chitosan seems to be a promising material for many applications. With a glance on the intrinsic wound healing properties of chitosan, this product could be applied for many biomedical and dental purposes such as in situ polymerizable scaffolds and injectable gels.

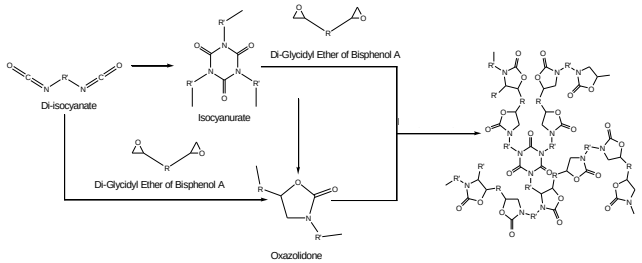
Introduction

Improving properties of epoxy resins at a lower cost is of a general great interest for certain technological applications. A good strategy is to insert heterocyclic rings in the polymer structure, increasing the distance between crosslinks while increasing the rigidity of the structure. The reaction between diepoxides and diisocyanates can lead to thermosets containing isocyanurate and oxazolidone rings in their structure. Oxazolidones act as chain extenders and isocyanurate rings play the role of crosslinking points. Although few studies report thermosets having these two kinds of heterocycles in the structure, it is accepted that these copolymers exhibit better properties, mainly higher thermal stability, than neat epoxy resins and other classical epoxy thermosets.[1-4] Usually, the curing of diepoxides/diisocyanates is catalyzed by a tertiary amine and shows short gel time and pot-life due to the formation of isocyanurate rings on the first stages of the curing. In order to offset this drawback, in the present work the amine has been substituted by a rare earth metal triflate. The aim of this work is to study the curing of mixtures of DGEBA and 4-toluene-2,4-diisocyanate (TDI) in the presence of ytterbium triflate, which is a Lewis acid, and the final properties of the materials prepared. The results obtained were compared with those obtained by using



benzyldimethylamine (BDMA) as the catalyst.

Materials and Methods

Diglycidylether of Bisphenol A (DGEBA), Epikote Resin 828 from Hexion Specialty Chemicals (epoxy equivalent = 187 g/eq) was used after drying under vacuum. Ytterbium (III) trifluoromethanesulfonate (99.99%) and BDMA from Aldrich were used without further purification. TDI from Aldrich was distilled before use. TDI and DGEBA were carefully mixed with stirring and degassed under vacuum (at 80ºC) during two hours to prevent the appearance of bubbles during curing. Samples were kept at -20ºC before use to prevent polymerization. 1 phr of catalyst was added to the corresponding DGEBA:TDI mixtures at room temperature just before curing. Kinetic parameters were determined using integral isoconversional non-isothermal kinetic analysis named Kissinger-Akahira-Sunose. Conversions of the different reactive groups, epoxide, isocyanate, isocyanurate and oxazolidone, were determined by FTIR. Gelation was studied using TMA and DSC and thermal stability was determined by TGA. The morphology was investigated by SEM and DMTA. Microhardness and modulus were determined by nanoindentation tests.

Results and discussion

The initial composition of the formulation (molar ratio of isocyanate to epoxide groups), the curing conditions and the catalyst used are the parameters that control the final structure of the network formed, the evolution of the curing and the final properties of the thermosets.

By increasing the initial proportion of isocyanate the glass transition temperature, the thermal stability and the content of isocyanurate rings increase.

The curing with the tertiary amine starts with the formation of isocyanurates, and is followed by oxazolidone ring formation, epoxy homopolymerization and isocyanurate decomposition to produce oxazolidone groups on increasing the temperature. In contrast, ytterbium triflate leads to the initial formation of oxazolidone rings and then catalyzes polyetherification, formation of isocyanurates and their reaction with epoxides to form oxazolidones. Moreover, when ytterbium triflate is used urethane formation takes place at the beginning of the cure, although they disappear at higher temperature. The differences observed in the reactivity not only affect the kinetics of curing, but also the gelation and the final properties of the materials. The most relevant differences between ytterbium triflate and tertiary amine catalyzed curing processes are the longer pot-life and higher glass transition temperature of the resulting materials obtained with the former.

Introduction

Design of new effective controlling systems for polymerization of vinyl monomers is an important sphere of modern polymer chemistry. Indicated systems allow to synthesize polymer with determined molecular-weight characteristics and stereoregularity. That is why transition metal complexes in a combination with halogen-containing compounds represent doubtless interest for synthetic polymer chemistry.

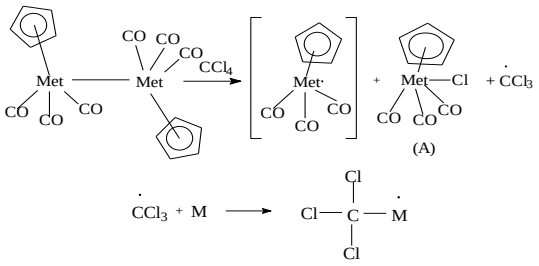
Materials and Methods

Monomers were dried over $CaCl_2$ and distilled under reduced pressure. Polymerization was carrying out in sealed glass tubes in monomer bulk at 80^0C. Obtained polymer samples were purified from monomer by dissolving in chloroform or ethyl acetate and precipitating in hexane. Conversion of monomers is determined by gravimetry method. Molecular-weight properties of obtained polymer are determined by the method of Gel-Permission Chromatography.

Results and Discussion

It was established that binary systems based on $[CpM(CO)_3]_2$ (where M = Cr, Mo, W) and carbon tetrachloride initiate homopolymerization of methyl methacrylate (MMA) and styrene (St) at 80^0C. While rate of the process increases, gelation in the system is not observed, molecular weight of synthesized polymer grows with increasing of conversion in range $(20\text{-}60)\times10^3$. However, polydispersity indexes of obtained polymer samples have quiet high values. Curves of molecular-weight distribution of polyMMA and polySt samples have unimodal character in all cases. Nature of central metal atom significantly affect rate of the process. In this respect complexes can be ranked in following line: $[CpMo(CO)_3]_2$ > $[CpW(CO)_3]_2$ > $[CpCr(CO)_3]_2$ as their efficiency goes.

On the basis of obtained data scheme of initial step was proposed:



where M = monomer.

According to this scheme, metal complex interacts with carbon tetrachloride with formation of metal-centered radical, chlorine-containing complex (A) and radical $\cdot CCl_3$ which initiates polymerization.

Indicated scheme was proved by research of model systems. Formation of metal-centered radical was established by ESR method. Complex (A) was isolated and identified by IR-spectroscopy.

Research of MMA and St copolymerization patterns shows that mechanism of process is not radical purely. Type of curves of copolymer composition (Fig.1) and values of calculated copolymerization constants ($[CpCr(CO)_3]_2$: r_{MMA} = 1.53, r_{St} = 0.67; $[CpMo(CO)_3]_2$: r_{MMA} = 1.40, r_{St} = 0.47; $[CpW(CO)_3]_2$: r_{MMA} = 1.96, r_{St} = 0.14) can be considered evidence of this fact.

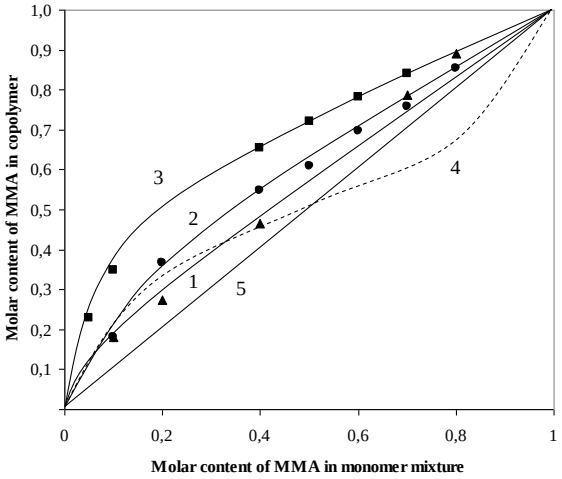


Figure 1. Curves of composition of MMA and St copolymer, synthesized in the presence of complexes $[CpM(CO)_3]_2$ (M = Cr (1), Mo (2), W (3)) and CCl_4.

Results of studying of MMA and styrene copolymerization kinetics accord to data of homopolymerization of indicated monomers. In this case proposed line of complex efficiency is also observed. In the presence of radical initiator (AIBN) studied complexes play a role of radical cages reducing molecular weight of synthesized polymer and eliminating gelation which characteristic for traditional radical polymerization of MMA and St.

According to results of researching of MMA and St copolymerization in the presence of studied complexes and AIBN, process has a radical nature (curves of copolymer composition have S-shaped character, constants of copolymerization match radical process).

Conclusion

Thus studied binuclear complexes of transition metals of VI Group $[CpM(CO)_3]_2$ (where M = Cr, Mo, W) in conjunction with either halogen-containing initiator or radical one are efficient additives in MMA and St polymerization which allow to eliminate gelation in system and reduce molecular weight of obtained polymer.

Amphiphilic Copolymers based on Sucrose Methacrylate and Acrylic Monomers

Heitor F. N. de Oliveira and Maria Isabel Felisberti

Chemical Institute - State University of Campinas (Unicamp)

heioliveira@iqm.unicamp.br, misabel@iqm.unicamp.br

Introduction

Sucrose is the most abundant of all sugars, presenting as advantages high world production and, low cost. The high versatility and reactivity of sucrose have been explored for many authors to obtain surfactants and monomers aiming polymers synthesis. For example, *Queneau et al.* reported a successful synthetic rote for sucrose 1'-*O*-methacrylate (SMA).[1] The high hydrophilicity of this molecule suggests high biocompatibility and biodegradability levels, and the carbon-carbon double bond is highly reactivity in radical reactions, which confers it a potential as a material for the preparation of amphiphilic polymers. These materials type are largely employed as degradable hydrogels, which are used in several biomedical applications, such as injectable matrices for drug delivery systems, temporary scaffolds for tissue engineering, and bioabsorbable surgical sutures. In this work, we will show the results and aspects of SMA-based copolymers synthesized in our research group.

Materials and Methods

Regioslective sucrose 1'-*O*-methacrylate (SMA) was synthesized, by enzymatic catalysis, purified and characterized by the methodology described in *Reference 1*. For the polymerization reactions, solutions 20 wt% of purified SMA and comonomer in dimethyl formamide (DMF) (10 to 15 mL) was prepared, and 0.1 % (mol/mol) of benzoyl peroxide (BPO) was added. This solution was added in an ampoule and cycles of freezing/degas were employed to eliminate oxygen, a radical inhibitor. The polymerization proceeded at 60 °C under nitrogen for 6 days. The product was precipitated in diethyl ether and dryed under vacuum at 40 °C. Non reactive monomers were eliminated by dialyze. The comonomers employed were methyl methacrylate (MMA) and N-isopropylacrylamide (NIPAAm), in molar ratios SMA/comonomer 1:1, 1:3, 1:5, 1:10 and 1:20. Homopolymers of SMA, MMA and NIPAAm were synthesized too. The polymers were characterized by ^{13}C NMR, GPC, DSC and TGA. Solubility, swelling ratio and phase behavior of aqueous solution (LCST behavior) were investigated.

Results and Discussion

The polymerization yields (Y), molar mass (Mw) and glass transition temperature (Tg) of the synthesized polymers are summarized in *Table 1*. These results show that the copolymers are synthesized in good yields, with high molar mass and polydispersity in the range from 1.5 to 2.0 and glass transition at temperatures dependent on the composition. The composition of the copolymers determined by ^{13}C NMR analysis shows a good agreement with the composition of the reactional medium, indicating that the copolymerization parameters of the studied monomers are close.

Table 1 – Polymerization yield (Y), molar mass (Mw) and glass transition temperature (Tg) of the polymers.

Sample	Y/ %	Mw[(a)]/ g mol^{-1}	Tg[(b)]/ °C
PMMA	100	334,000	117
P(SMA-*co*-MMA) 1:20	100	725,000	127
P(SMA-*co*-MMA) 1:10	100	385,000	131
P(SMA-*co*-MMA) 1:5	99	749,000	130
P(SMA-*co*-MMA) 1:3	90	788,000	132
P(SMA-*co*-MMA) 1:1	95	393,000	120
PSMA	100	802,000	113
P(SMA-*co*-NIPAAm) 1:1	93	822,000	124
P(SMA-*co*-NIPAAm) 1-3	71	478,000	125
P(SMA-*co*-NIPAAm) 1:5	78	1,330,000	118
P(SMA-*co*-NIPAAm) 1:10	64	673,000	143
P(SMA-*co*-NIPAAm) 1:20	41	957,000	145
PNIPAAm	78	278,000	122

(a) GPC; (b) DSC.

The copolymers with SMA present higher thermal stability in comparison with MMA and NIPAAm homopolymers, which increases with increasing SMA fraction. Residual mass increases as the SMA fraction in the copolymers increases, as consequence of condensation between SMA hydroxyl groups. No residual mass were observed for MMA and NIPAAm homopolymers.

Because SMA/MMA copolymers combine hydrophilic and hydrophobic segments, respectively, their solubility and swelling ratio are strongly dependent on the composition. As expected, copolymers richer in SMA are water soluble, while the copolymers richer in MMA swell in water and the amount of sorved water increases with increasing SMA contents.

SMA/NIPAAm copolymers are water soluble and the solutions present LCST behavior, as determined by turbidimetry of diluted solutions (0.1 wt%) at 300 nm. PNIPAAm presents LCST at 32.5 °C, in agreement with literature[2], P(SMA-*co*-NIPAAm) 1:5 at 37.0 °C and P(SMA-*co*-NIPAAm) 1:20 at 41.0 °C. How expected, the increase in the hydrophilic component (SMA) results in higher LCST for the copolymer. The other copolymers had not presented LCST.

Conclusions

These studies show that it is possible to obtain the desirable amphiphilic copolymers based on sucrose methacrylate, showing physical-chemical properties dependent on the copolymer composition.

Non Isocyanate Polyurethane Obtained From Different Vegetable Oils

MAZO PAULA, RIOS LUIS

UNIVERSIDAD DE ANTIOQUIA

paulamazo@yahoo.com

Introduction: The NIPU can be obtained by reaction of polycyclocarbonates with polyamines to form β hydroxy urethanes [1]. The cyclocarbonates are obtained by the reaction of ethylene oxide with CO_2 by cycloaddition. Tetrabutylammonium bromide (TBAB) is the most widely used catalyst [2]. It is proposed in this paper to obtain NIPU from renewable sources (vegetable oils) and compare the properties of polymers.

Materials and Methods: Soybean Oil (SO), dehydrated Castor Oil (DCO) and Sasha Inchi Oil. Acetic acid (AA), Sulphuric acid (AS), H_2O_2 (33% v/v), Hexamethylenediamine (HEXA), CO_2, Tetrabutylammonium bromide (TBAB).
The Fig 1 shown the synthesis processes for modified oil and NIPU.

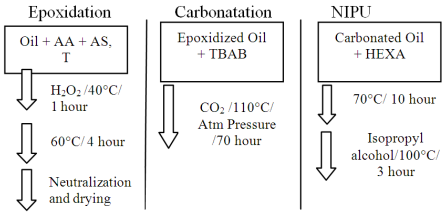

Fig. 1. Synthesis Processes for modified oil and NIPU.
Percentage of epoxy oxygen (%OO), iodo value (VI), acid value (AV), percentage of humidity (%H), viscosity, IR, Tensile Strength, Tensile module, elongation, DSC.

Results and Discussion:
The Table 1 shown the physico-chemical properties of modified oils.
TABLE I. PHYSICO-CHEMICAL PROPERTIES OF MODIFIED OILS.

		%OO (g epoxy/ 100g oil)	VI (gI/100g oil)	AV (mg KOH/g sample)	%H	Viscosity (cps)
Epox Oil	SO	5,75	1,78	0,61	0,210	450
	DCO	5,82	1,43	3,50	0,570	1530
	Sasha	7,96	2,43	1,24	0,340	425
Carb Oil	SO	2,50	0,43	0,13	0,051	13200
	DCO	3,42	0,35	2,38	0,192	19320
	Sasha	2,78	1,27	0,11	0,064	9500

Sasha Epoxidized oil has the highest content of oxirane oxygen and the lowest viscosity that is due to the increased amount of unsaturation that it has. DCO oil exhibits a similar %OO that SO Oil, but the viscosity is much higher due to ricinoleic acid remaining in it. More efficient conversion of epoxy groups to cyclocarbonates is obtained with Sasha Oil and lower conversion with DCO Oil, this is due to reduced diffusional resistance in the liquid from CO_2. Carbonated Oils have a higher viscosity than the Epoxidised Oil.
An infrared spectroscopy analysis shown that: epoxy peaks appear in 845-823 cm^{-1} for SO and DCO Oil, but Sasha Oil moving to 825-799 cm^{-1}, due to the high concentration of these. In 1803 cm^{-1} appear the signal of cyclocarbonate C=O. For the NIPU the signal are: peak 300-3400 cm^{-1} OH and NH, 1733 cm^{-1} NH-CO-O urethane group. The band 1803 cm^{-1} disappear. (See Fig 2).

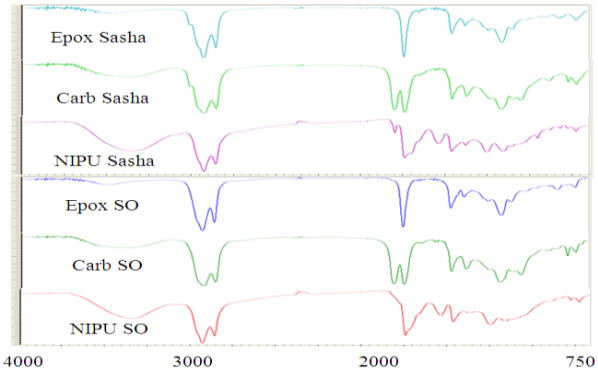

Fig. 2. Sasha and SO Oils Infrared Espectroscopy.
In the Table 2 shown NIPU properties, The Tg of NIPU Sasha is the lowest because the epoxy, amine and cyclocarbonates groups act as plasticizers decreasing the glass transition temperature and properties of polymers.
In the DCO NIPU, the ricinoleic acid can react with the cyclocarbonates, increasing the crosslinking and decreasing the elongation.
TABLE II. PROPERTIES OF NIPU

Sample	Tg (°C)	Tensil Strength MPa	% Elongation	Young Module MPa
NIPU Soja	24,5	0.35	160	0,002
NIPU DCO	12,8	0.20	50	0,003
NIPU Sasha	-10	------	------	------

The NIPU Sasha is tacky and highly viscous liquid, for this reason we could not measure their mechanical properties.

Conclusions: In this paper, polyurethane is obtained without using diisocyanates. SO oils and DCO, produce NIPU with good mechanical properties to be used as coatings and adhesives. Sasha oil is presented as a good alternative but requires a higher content of amine.

Kinetic Study of 2-Acrylamido-2-methylpropanesulfonic Acid in Free-Radical Polymerization method by Differential Scanning Calorimetry

E. Nadim, H. Bouhendi, F. Ziaee, R. Bazhrang*

Iran Polymer and petrochemical Institute, P.O.BOX 14965/115, Tehran, Iran.

*Boouhendi@yahoo.com

Introduction

A driving force for polymerization reaction is the heat of polymerization which governs the rates and kinetics of polymerization. So, accurate measurement of thermochemical data is an appropriate method for following the kinetic of polymerization. Thus, differential scanning calorimetry is a suitable technique for recording heat production of chemical process because of its advantages such as small sample size which help better temperature control, handiness of manipulation, performance rapidity and versatility [1]. In the present work, aqueous kinetic of AMPS polymerization initiated by a thermal initiator was studied by using DSC.

Material and Methods

AMPS and potassium persulfate (KPS) were purchased from Fluka and Merck, respectively, and were recrystalized from ethanol for further purification. In this study, DSC thermograms were obtained on a NETSCH DSC 200 F3 instrument. Monomer and initiator were weighted precisely and dissolved in de-ionized water. Closed pans were loaded with 22-24 mg of the solution. In order to prevent side and retarding reactions, a hole was produced in pans and all the reactions were carried out under the nitrogen atmosphere.

Results and Discussions

If E_a is representative of overall activation energy, general rate of polymerization is given by equation 1;

$$R_p = k_0 e^{-\frac{E_a}{R}\frac{1}{T}}[M]^n[I]^p$$

or

$$\ln R_p = \ln(k_0[M]^n[I]^p) - (\frac{E_a}{R})\frac{1}{T} \qquad (1)$$

DSC thermograms at isothermal conditions were done at desired amount of monomer and initiator. In order to sure complete reaction of entire monomer for all samples a non-isothermal run, from ambient temperature to 80°C at heating rate of 1°C/min, was purposed. Absence of exothermic peak for the samples demonstrated complete conversion of monomer in isothermal run. DSC thermogram of polymerization for samples 1-3 ([I] = 0.074, 0.148, 0.185 mol/lit) are illustrated in Figure 1. Monomer conversion was calculated as a fraction of exothermic heat in a specific time to total exothermic heat of polymerization Figure 2 shows a typical calculation of monomer conversion (π) at 7 minutes in which A_p and A are peak area at 7 minutes and total peak area of polymerization, respectively. In constant initial monomer concentration, slope of $-\ln R_p$ vs.-ln [I] reveals the order of reaction with respect to the initiator concentration (p=0.52). Determined n value by slope of $-\ln R_p$ vs.-ln [M] plot was 1.56. E_a and k_0 could be deliberated from slope and intercept of $-\ln R_p$ vs.1/T plot in a constant amount of monomer and initiator. E_a was 83kj/mol.K. k_0 determined by intercept of mentioned plot was 1.2×10^{13} $mol.lit^{-1}.sec^{-1}$.

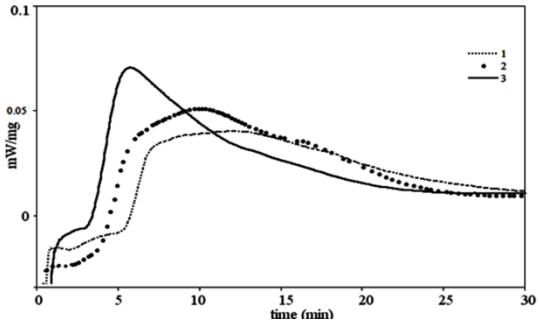

Fig1. DSC thermogram of polymerization at different initiator content.

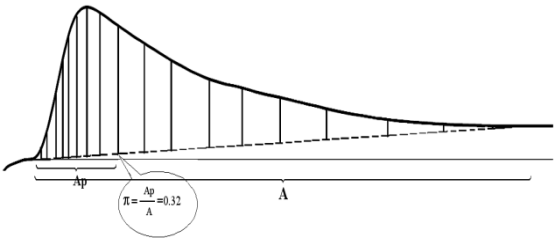

Fig2. Partial area of exothermic peak of a typical sample at 420 seconds.

Dependence of polymerization rate on monomer concentration greater than unity can be described by three theories: a) the solvent transfer theory, b) the cage effect theory, and c) the complex theory[2].

The solvent transfer theory was ignored in aqueous polymerization of AMPS because derived sulfur-containing fragment from persulfate are very reactive toward monomers. Cage effect theory is based on forming a barrier for separation of sulfur-containing fragment from the surrounding solvent molecules. In Complex theory, formation of a complex between monomer and initiator is proposed in complex theory and rate of complex decomposition is the key factor in initiation process[2]. In cage effect theory, activation energy is predicted to be smaller than that matches complex theory. Activation energy that was measured in present work was in the range of conventional activation energy of radical polymerization (80-90 kj/mol). Thus, in monomer concentration ranges from 0.966 to 2.41 mol/lit and temperature ranges 35-47 °C polymerization mechanism of AMPS in aqueous medium could be described by the cage effect theory.

Conclusion

n value and activation energy supported the assumption that polymerization kinetic was according to cage effect theory.

Synthesis and Characterization of Novel Bio-Based Polyesters Based on Curcumin as a Natural Diol Monomer and Commercially Available Aromatic Dicarboxylic Acids

Abbas Shockravi, Ali Javadi, Saeideh Hajavi

Faculty of Chemistry, Tarbiat Moallem University, No.49, Postal Code 1571914911, Tehran, Iran

Email: hajavi_saeideh@yahoo.com

Introduction

In recent years, interest in polymeric materials from renewable resources has increased and a great deal of efforts have been paid to utilize a wide variety of bio-resources instead of petroleum ones for the polymer industry. Also, there is a great demand to design and develop high-performance bio-based polymers because the use of such products leads to decrease carbon dioxide emission [1, 2].

Polyesters are a family of polymers of increasing significance because of their biodegradability [3]. They are one of the most versatile polymers. They contain widely different materials with large applications, which are produced by a variety of manufacturing techniques [4].

Curcumin is a natural yellow-orange dye extracted from turmeric (dry rhizomes of the plant *Curcuma Longa*) and has widely used as the spices and the cosmetics. Moreover, it possesses diverse pharmacological effects, such as anti-inflammatory, antioxidant, antimicrobial anticancer, and wound healing activities. Furthermore, it is nontoxic, even at relatively high doses. On the other hand, curcumin is a bis-*α,β*-unsaturated *β*-diketone (commonly called diferuloylmethane) that exhibits keto-enol tautomerism (Scheme 1 ***a***). It also has a predominant keto form in acidic and neutral solutions and a stable enol form in alkaline media. In addition, symmetric curcumin molecule has two phenolic hydroxyl groups which are available as polymerizable functional groups. Thus, curcumin can be regarded as a suitable monomer for synthesis of bio-based polymers [5-8]. In the field of polymer chemistry, there have been some reports using curcumin in producing various polymers [2, 6-8].

In this work, we aimed to synthesis novel series of bio-based polyesters through a polycondensation reaction between aromatic diacid chlorides and the phenolic groups of curcumin as a bio monomer. (Scheme 1 ***b***)

Materials and methods

All chemicals were purchased either from Merck or Fluka chemical Co. Cucumin used after recrystallization in 2-propanol. O-Dichlorobenzene was dried over molecular sieve. Acid chlorides were obtained from the condensation reaction of their corresponding dicarboxylic acids with excess of thionyl chloride, in the presence of few drops of pyridine as a catalyst. They were purified by crystallization with hexane. The polymerization was carried out by adding acid chloride to a suspension of an equimolar amount of curcumin in o-dichlorobenzene in the presence of TEA as HCl scavenger at 0°C under nitrogen atmosphere. Then, the resulting mixture was stirred for 30 min at room temperature and then slowly heated and reflux under magnetic stirring at 180°*C* overnight. The polymer suspension was precipitated in methanol.

Results and Discussion

The polyesters were obtained in high yields and possessed inherent viscosities in the range of 0.41-0.87 dLg^{-1}. Structure of polyesters was characterized using ^{1}HNMR, ^{13}CNMR and FTIR. In the ^{1}HNMR the methine proton was at 5.5 ppm. In the ^{13}CNMR the methine carbon of enol structure was at 101.5 ppm while peak due to methylene carbon of *β*-diketone was not observed. These results show that the β-diketone unit in the polyester backbone tends to be in the enol form. This fact is also verified by the presence of a broad OH peak at 3457 cm^{-1} in the FTIR spectrum.

In the FTIR spectrum the C=O peak of the ester bond was at 1741 cm^{-1}.

The Oxypropylation of Olive Stone and the Use of the Ensuing Polyols for the Synthesis of Novel Polyesters and Polyurethanes Based on Renewable Resources

Marina Matos[1,2], *Filomena Barreiro*[2], *Alessandro Gandini*[1]

1. CICECO and Chemistry Department, University of Aveiro, Campus de Santiago, 3810-193 Aveiro, Portugal
2. LSRE, Polytechnic Institute of Bragança, Campus de Santa Apolónia Ap. 1134, 5301-857 Bragança, Portugal
marina.matos@ua.pt, agandini@ua.pt, barreiro@ipb.pt

The development of polyols by the oxypropylation of abundant and renewable vegetable and animal resources constitutes an original approach to the exploitation of the biomass. Cellulose, starch, chitosan, chitin, different types of lignins, cork and more complex structures like sugar beet pulp, are among the documented examples[(1)]. All these systems displayed a similar pattern in terms of the grafting of short poly(propylene oxide) (POP) chains from the OH groups of the substrate, albeit of course each situation required a specific set of optimized experimental conditions to transform the natural solid into a viscous polyol. The transformation of these polyols into polyurethanes is the only operation which has been studied to date as a form of their exploitation into polymer materials.

In a similar vein, we have undertaken a study of the oxypropylation of olive stone, a by-product of the olive oil production, which, like many other biomass residues, is presently burnt for energy recovery. The purpose of this investigation was of course the search of a more useful and promising way to exploit this abundant and renewable Mediterranean natural material. A preliminary report on some aspects of this work has already been published[(2)], and the purpose of this communication is to provide an up-to-date account of its progress.

On the one hand, a detailed relationship was obtained between the reaction parameters applied to the oxypropylation of olive stone and the structure and physical properties of the ensuing polyols, and this for different particle sizes of the substrate. The characterization involved FTIR and NMR spectra, viscosity and OH index, as well as the proportion of POP homopolymer formed in these reactions.

On the other hand, a choice of more promising polyols was selected for chemical modifications involving first ester and urethane formations with aliphatic and aromatic monofunctional reagents. The conversion of part or all of the OH groups of the polyols into much less polar moieties brought about significant changes in the properties of the ensuing materials, which were thoroughly characterized. Thereafter, difunctional reagents were employed to transform the polyols into polyester and polyurethane networks, whose properties were again assessed as a function of the type of reaction (different modes of esterification and condensation with diisocyanates), the specific structure of the reagent (aliphatic vs. aromatic) and the extent of OH conversion (stoichiometry).

pierre.marcasuzaa@univ-pau.fr

Microwave (MW) synthesis represents a major breakthrough in synthetic chemistry versus conventional heating sometimes known to be time consuming because of its low efficiency. If the microwave energy was developed for industrial application from the middle of the 20th century, first microwave-enhanced organic chemistry was not explored until the mid 1980's. In comparison to the impressive development of the microwave technique in organic synthesis during the last decades, microwave-assisted polymer synthesis[1,2] is rather new emerging field and mainly reported from the late of 1990's. The aim of our work[3] is to study the use of MW synthesis to obtain conducting HCl-doped tetraaniline (TANI) end-capped polymers while controlling the molecular weights and polydispersity. The synthesis of block copolymers containing one block of intrinsic conducting polymer[4] has already been reported. The strategies involved fastidious syntheses as multi-step routes and drastic experimental conditions. However the synthesis of these kind of polymer are still of interest because these materials are used as models to study the conduction phenomena and interface organization[4], and may be used as conducting additives in insulating matrices[5].

Our objectives were at the same time to reduce the duration of the synthesis while keeping the process as simple as possible. Special attention was also given to the comparison with the results obtained under conventional heating in order to determine the occurrence of non-thermal microwave effects which is still a controversial topic. After a brief presentation of the MW irradiation methods *i.e.* dynamic and pulsed modes, kinetic results will be presented. This poster will present the difference between polymerization performed under microwave irradiation and by conventional heating (CH = oil bath) (Figure 52).

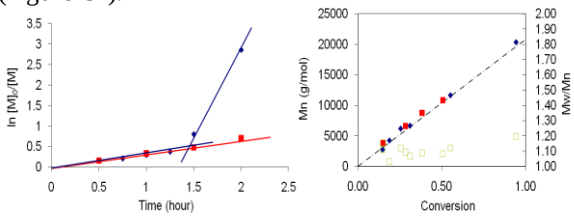

Figure 52: ATRP kinetic study of styrene/EBP/CuBr/PMDETA (200/1/1/1). (red square) CH at 98°C; (bleu rhomb) MW at 80W and 98°C; (green empty square) polydispersity of PS under MW and CH.

A sharp increase of the logarithmic conversion versus time is observed under MW while CH leads to a linear fit. This phenomenon is observed for different monomers at different powers. In spite of this acceleration of kinetic, the living/controlled nature of the polymerization is kept. Thus, the occurrence of a "microwave effect" will be discussed.

Optimized experimental conditions have been obtained from the previous kinetic study and used to perform the end-capped conducting polymer. The latter is obtain in two steps: ATRP to obtain the precursor polymer (PStyr) followed by the coupling reaction between PStyr ad TANI. A specific initiator leaded to a end-chain functionalization PSty able to react with the TANI is necessary (**Figure 53**). End-capped conducting polymers (TANI content from 2 to 7 wt%) have been obtained by both heating methods: MW and CH and fully characterized. Conductivities as high as 5 $S.cm^{-1}$ are obtained. Synthetic methods (MW and CH)are compared and MW effect has been demonstrated.

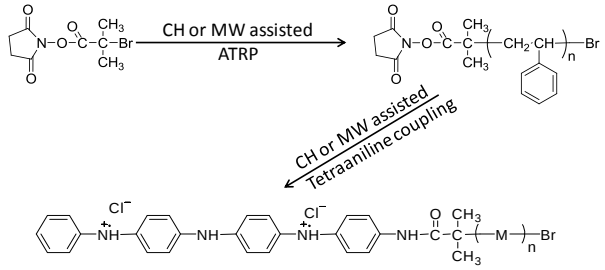

Figure 53: Synthesis routes of HCl-doped TANI end-capped polymers either by conventional heating (CH) or under microwave irradiation (MW).

Within this study, microwave assisted synthesis has been tested both in polymer synthesis and polymer functionalization. Conducting end-capped polymers with controlled architectures in terms of molecular size of both the insulating and the conducting parts as well as the chemical formulation have been obtained. The synthesis has been performed under conventional heating and microwave irradiation to highlight the effect of MW heating.

r.mallavia@umh.es

Abstract: In this work, we report the synthesis and characterization of a new copoly-2,7-(fluorene-1,4-(2,3-diamine)naphthalene using the corresponding monomer 1,4-dibromo-2,3-diaminonaphthalene. Transformation posterior of the pendant bromide group for ammonium group, which will be provide it the properties and characteristic designed. The high reactivity of the monomer involves performing work on the amino group protection in order to obtain of copolymers composition

Introduction

Conjugated polymers have received great interest for its applications, in particular as sensing platforms [1]. In general, fluorene derivatives are interesting because they contain a rigidly planar biphenyl unit and also for the facile substitution at the remote C9 site that provides the possibility of improving the solubility and processability of polymers without significant increase of the steric interactions in the polymer backbone. For induce a change in the fluorescence response of the conjugated polymer we selected a model close to 2,3-diaminebenzene high sensitive in order to introduce it on backbone, as previously obtained analogous copolymers by Yamaguchi *et al*. [2].

Results and Discussion

We prepared the corresponding monomer 1,4-dibromo-2,3-diaminonaphthalene, as previously report [3], with a noticeable difference between the assignments realised. The ^{1}H and ^{13}C NMR spectra of the monomer were corrected assigned and contrasted with literature. FTIR spectrum confirm the structural monomer and mass their composition. Then, we proceed to the polymerization by cross-coupling Suzuki with different ratio feed 1,4-dibromo-2,3-diaminonaphthalene monomer using palladium zero (Scheme 1, first reaction). In these experimental conditions, we need a low feed ratio due to the high reactivity of the monomer. In fact, we have studied some details of the effect of carbonyl groups in the monomer using different spectroscopic techniques (UV-visible and NMR). Thus, the great reactivity of monomer with carbonyl groups, even acetone, and their copolymer will be able to as sensing of this organic compound.

The polycondensation, as indicated in Scheme 1, give only **P3**, with R_2 =-$(CH_2)_6$-Br and R_1=$(CH_2)_5CH_3$ while **P2** and **P1** were not obtained. As indicated, monomer reacts with boronic group still need a protection before to used in Suzuki polycondensation. NMR data of **P3** are well resolved indicating a well-defined structure and their spectroscopic characteristic are similar to those of the other fluorene polymer derivates. Current reactions are being carried out to achieve these stoichiometries.

The structural assignment of polymer was based on their ^{1}H and ^{13}C NMR spectra by analogy with monomer spectra. **P5** was obtained by Menschutkin reaction like before neutral precursor [4]. Now, we are measuring the distribution of molecular weight by gel permeation chromatography coupled with light scattering detector and also, other characteristic parameters are currently under progress.

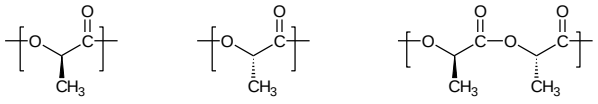
Introduction

Polylactic acid (PLA) is the most used biodegradable polymer [1]. In recent years it has been applied in medicine, packaging or agriculture. Its properties are similar to polypropylene and it is therefore an excellent alternative to oil derived polymers. Three structures are known: the isotactic polymers derived from a single enantiomer (PLLA or PDLA), the syndiotactic polymer derived from the meso form of polylactide (PLDLA) and atactic form, mixture of isomers L and D.



PLLA PDLA PDLLA

Since the homopolymers have insufficient mechanical properties (very fragile), copolymers based on one enantioner and small percentages from the other are put onto the market, yielding less rigid materials but more tough. However, this change causes a decrease in softening temperature and potential applications are limited to medium temperatures (less than 60 ºC). Moreover, PLA is very sensitive to hydrolytic degradation in processing, which leads to molded materials with lower molar mass polymers and, consequently, with poorer mechanical properties.
Some approaches are currently being studied for improvement, which include altering the structure of PLA with branching agents or chain extensors (bifunctional or polyfunctional compounds) and formulating materials with nanoparticles [2].

In this study we have prepared a collection of PLA copolymers with different candidates to extensors or chain branching agents and the resulting compounds have been characterized chemically. In some cases we have evaluated their biodegradability.

Materials and methods

The starting material is NatureWorks PLA 2002D, which has been copolymerized with compounds such as polycaprolactone, maleic anhydride, oligomeric polyfunctional extensors Joncryl from BASF, among others. The reactions were carried out in batch at 170 ºC with different percentages of modifier (0,5, 1, 2, 5, 10 %). In some cases, transesterification catalyst ($Ti(BuO)_4$) is used. The polymers obtained were analyzed spectroscopically (IR and NMR) and by viscometry and GPC. The degradation studies were conducted hydrolytically or biologically according to ISO 14851 and followed by GPC in HFIP.

Results

Copolymers obtained with bifunctional compounds, as polycaprolactone or maleic anhydride, have shown a loss of properties when high concentrations of modifier were added. This effect can be explained to promotion of degradation due to acid catalyst. Copolymers with low concentrations (2, 5 %) of maleic anhydride afford macromolecules with similar molar masses (around 100 kg/mol) than original PLA. However, inert atmosphere (N_2) was necessary to avoid degradation due to tertiary radicals promoted by O_2 [3]. ^{1}H-NMR spectra of these compounds show two doublets at 6.5 and 6.4 ppm indicating that maleic anhydride has reacted different ester bonds. In same region, a relatively broad singulet at 6.48 ppm is identified as maleate diester obtained by reaction of OH originated in hydrolysis of PLA; this signal is being analyzed in proof in order to not to be confused with others like fumarates or free diacids.

Reaction of PLA with oligomeric polyfunctional extensors (Joncryl from BASF) has given from slightly increased molecular size compounds (GPC) to crosslinked insoluble materials, not analyzed. Joncryl contains a number of epoxy groups (grade depending) and a very low dosage is imperative. Concentrations of 0.5, 1 and 2 % affords to polydispersed polymers (up to 4.5) in both sides of distribution curve. Analysis by NMR or IR is very difficult due to dispersed nature (structure and composition) of obtained compounds.

The polymers have been found to be readily degradable hydrolytically, similar to pure PLA. The results of biodegradation have also been positive, but less conclusive.

Conclusion

We have prepared various PLA copolymers by reactions with chain extensors agents or crosslinkers that have attractive features new materials to be processed successfully. These copolymers have been hydrolytically and biologically degraded.

Synthesis of photocleavable block copolymers based on *p*-methoxyphenacyl groups

Olivier Bertrand, Charles-André Fustin and Jean-François Gohy

Université chatholique de Louvain, Institut de la matière condensée et des nanoscience/Bio et Soft Matter

olivier.bertrand@uclouvain.be

Block copolymers have been the focus of much interest during the last 30 years because their constituent blocks are generally immiscible, leading to phase separated structures. Since the different blocks are linked together by covalent bonds, the phase separation process is spatially limited and results in self-assembled structures in bulk, thin films or in solution (micelles) whose characteristic sizes are in the range from ca. 10 to 100 nm [1,2]. Stimuli-responsive polymers are polymers that undergo relatively large and abrupt, physical or chemical changes in response to small external changes in the environmental conditions [3]. Among all the existing stimuli light is particularly interesting [4] since it can be localized in time and space, it can be triggered from outside of the system, and it does not require particular reagents which limit byproducts.

Here, we report on the synthesis of new light-responsive block copolymers containing *p*-methoxyphenacyl photocleavable side groups. They are particularly interesting because it generally generate harmless side product after cleavage [5]. The block copolymers are composed of a poly(p-methoxypenacyl methacrylate) block and a block composed of polystyrene (PS), poly(tert-butyl acrylate) or poly(oligoethyleneglycol methacrylate) (PMPMA-b-PS and PMPMA-b-PtBA and PMPMA-*b*-POEGMA). The synthetic strategy consists in the direct polymerization of the monomers by Atom Transfer Radical Polymerization (ATRP). These polymers are then used for light induced micellization.

Introduction

Technological applications of biodegradable polymers usually require changes in their mechanical properties or, at least, a balance between the rate of degradation and the properties of the final product, and an affordable cost [1]. In order to obtain a material with improved properties and economically acceptable, an alternative that has been widely explored is the development of new materials consisting of two or more types of polymeric materials, i.e., the formation of blends, copolymers, and polymer networks (IPNs or semi-IPNs) [2]. The specific interest in the synthesis of semi-IPNs based on poly(*N*-vinylpyrrolidone), PVP, and poly(L-lactide), PLLA, comes from the fact that these homopolymers are biodegradable and biocompatible, which allows to infer applications for the medical area such as surgical sutures, implants, matrixes for drug delivery systems, etc. [3]. The objective of this work was to prepare an amphiphilc multicomponent materials in the form of semi-interpenetrating polymer networks, based on PLLA, a hydrophobic homopolymer, and PVP, a hydrophilic component. The preparation of the semi-IPN combined the polymerization and crosslinking of *N*-vinylpyrrolidone in the presence of PLLA. The products were characterized by spectroscopic, thermal and morphological methods.

Materials and Methods

N-vinylpyrrolidone (Aldrich) was vacuum distilled prior to polymerization. Benzoyl peroxide (BPO, Sigma) was dried in vacuum at room temperature. Di(ethylene glycol)divinyl ether (DEG, Aldrich) was used as received.

The polymerization in bulk of *N*-vinylpyrrolidone occurred by radical polymerization using as initiator benzoyl peroxide; PLLA was synthesized by ring opening polymerization of L-lactide. The homopolymers were characterized by infrared spectroscopy (FT-IR), nuclear magnetic ressonance proton and carbon 13 (^{1}H NMR and ^{13}C), thermogravimetry (TG), differential scanning calorimetry (DSC) and gel permeation chromatography (GPC).

The preparation of semi-IPNs combined polymerization and crosslinking of *N*-vinylpyrrolidone in the presence of poly(L-lactide). BPO was used as initiator and DEG as crosslinker for *N*-vinylpyrrolidone (VP), mass ratios of 0.5 and 1% on the mass of VP were used, and the cure process was carried out at 70 and 90°C for different periods of time. The semi-IPNs prepared were characterized by elemental analysis (CHN), TG, DSC, dynamic mechanical analysis (DMA), scanning electron microscopy (SEM) and swelling measurements.

Results and Discussion

The applied synthesis to obtain PVP and PLLA homopolymers were effective. FT-IR, ^{1}H and ^{13}C NMR, TG and DSC analysis confirmed the formation of PLLA and PVP. PLLA presented Mn, Mw and polydispersity of 52216 Daltons, 37294 Daltons and 1.4, respectively.

The composition of the semi-IPNs was determined from the amount of nitrogen in semi-IPNs provided by elemental analysis. PVP contents in the semi-IPNs varies from 49 to 70 wt%. The thermal study of the semi-IPNs by TG showed that the semi-IPNs exhibit thermal behavior characteristics of each of the starting homopolymers, reflecting the composition in terms of PVP and PLLA components. Data obtained by DSC showed that the polymerization and the crosslinking of *N*-vinylpyrrolidone during formation of semi-IPNs hinder the crystallization of PLLA. According to the DSC results the glass transition temperature shifts to higher temperatures with increasing concentration of the stiffer component, PVP. From DMA results secondary relaxations of the polymers were detected. Scanning electron microscopy micrographs show the presence of small particles of PLLA in the form of dispersed fibers in the matrix of PVP, indicating phase separation. Swelling studies of the semi-IPNs in water showed that these materials are able to quickly absorb large amounts of solvent, proving its performance as hydrogel.

Conclusions

The synthesis of semi-interpenetrating polymers networks of PVP and PLLA was effectively carried out. The bulk polymerization and crosslinking of the VP in the presence of PLLA result in a complex mixture with phase separation. Also, it is possible to conclude that the semi-IPNs thermal properties were dependent on the homopolymer contents. Lastly, the prepared semi-IPNs presented excellent absorbing characteristics, being probably efficient hydrogel material.

Evaluation of Yam Agriculture Wastes to Obtain Fructans

M. Esquivel, A. Aguilar, M. Sibaja, J. Vega-Baudrit, S. Madrigal-Carballo

Laboratorio de Polímeros, POLIUNA, Universidad Nacional, Heredia, Costa Rica

mesquive@una.ac.cr

In Costa Rica, the agricultural sector has been modernized over years in order to increase production and become more competitive in international markets. Because of that it had become specialized not only in the cultivation of traditional products (cocoa, coffee, bananas), but also in non-traditional products, like citrus, roots and tubers. Yam is a kind of tuber with high nutritional value, and it is within the products that Costa Rica had diversified its exports in recent years; it occurs mainly in Northern and Atlantic regions of our country. Agro-industrial activities generate large quantities of waste, those that are biodegradable, are mainly leaves and rejected products. In Costa Rica, there is no exact data about the amount of wastes produced from the yam production, however, Sandi in 2008, reported that the percentage of rejected product is about 30% of total production, which corresponds to 34.486 metric tons per year. Therefore there is an interest to obtain higher added value products, extracted from yam wastes, generated by the rejected material that do not meet the export standards (defects, appearance, quality, conservation) This investigation intends to evaluate this waste to extract fructans, due to the natural wealth of yam in this compound, it was used the *Dioscorea alata* yam. The fructans have many potential uses in the food industry, mainly as a sweetener or dietary fiber. Yam belongs to the family *Dioscoreaceae*, it is characterized on the basis of a wide range of species of widely dispersed geographic origins around the world, which are vegetatively propagated through tubers.

Figure 1. Yam tuber (*Dioscorea alata*)

Yam tubers are used for human consumption, are formed internally by parenchymal tissues, high in starch and water, fiber, calcium oxalate and mucilage channels. By definition according to Bender, 2006; fructans is the general name to call the polysaccharides of fructose, this are part of the fiber and non-starch polysaccharides in plants. These compounds are also called polyfructosylfructoses. Fructans have linear, cyclic and branched structures. The fructosyl - glucose links are β-(2 ↔ 1) type, as the sucrose, but the fructosyl -fructose bonds are β-(1 → 2) or β-(6→ 2) types. For the branched fructans, the links tend to be β-(2 → 6) type. According to the type of structure, the fructans can be classified as inulin (branched), levan (linear). In dicotyledonous plants are mainly present the inulin type, but in monocots there is only a small part of this type.

Figure 2. Fructan structure, inulin type

Yam samples were obtained from San Carlos, Costa Rica; then was characterized and the fructans were extracted. In order to obtain the optimum conditions for fructans extraction, the extraction process was evaluated at three temperatures and five levels of time. The extracted fructans were separated by ultrafiltration and then were quantified. Quantification was carried out by the technique of HPLC; the samples were analyzed using a sugars determination column, using water as eluent, reading with a refractive index detector and using chicory inulin as standard. The fructans content obtained with the different method conditions were evaluated statistically, to determine the optimal conditions of extraction at a laboratory scale.

Synthesis of Low Formaldehyde Emission Urea-Formaldehyde Resins and Their Application to the Manufacturing of Particleboards

P. Estévez, S. Vallejos, H. El Kaoutit, M. Trigo-López, F. Serna, F. García, J.L. de la peña, J.M. Pérez.

Departamento de Química, Grupo de Polímeros, Facultad de Ciencias, Universidad de Burgos, 09001 Burgos

e-mail: peb0002@alu.ubu.es

1.-Introduction

Urea-formaldehyde (UF) resins are the most used polycondensation resins for the manufacturing of particleboard panels due to their high reactivity, good performance and water solubility.[1] In spite of these advantages, they have two main disadvantages that are the formaldehyde emission from the panels and the poor resistance to water.

Response surface methodology (RSM) has being used as optimization procedure for low formaldehyde emission UF resins synthesis.[2] This work describes a central composite design methodology to optimize 3 selected variables (number of urea additions, pH and temperature) in the second urea addition, following three-stage process.

2.-Materials and Methods

Resins were synthesized from a precondensed formalin-urea solution and urea, following the traditional three stage process. Synthesis conditions of alkaline-acid step reactions were optimized in previous researches.[3] Central composite rotatable design was adopted for the experimental runs for response surface methodology, in the preparation of low formaldehyde emission UF resins.

Laboratory particleboards were prepared by using a standard mix of wood particles for the core and face layers. UF resins with additives and catalyst were sprayed on the wood particles and then were formed into a mat of dimensions 400 mm x 400 mm. The mat was prepressed at room temperature and further hot-pressed at 195 ºC for 2-3 minutes.

Perforator Method (European Standard EN 120) was used for measuring the formaldehyde content of wood-based panels.

3.-Results and Discussion

All resins were analyzed by standard methods. Differences in viscosity, gel time and free formaldehyde content were found depending on the synthesis conditions, but all of them were able to be used in the particleboard manufacturing process.

All particleboards were characterized according to European standard methods. Table 1 reports the main properties shown by the particleboards manufactured using the different UF resins synthesized. The formaldehyde content of the particleboards bonded with the modified process UF resins is well below the specified level of class E1 products (≤ 8 mg/ 100 g dry board) according to EN 13986, while maintaining good levels of internal bond strength, established in 0.35 Mpa (Particleboards Type P2, EN 312).

Table 1. Particleboards Characterization

Resin	Formaldehyde content (mg / 100 g dry board)	Internal Bond Strength (MPa)
1	2.6	0.46
2	2.8	0.46
3	3.2	0.62
4	2.3	0.52
5	2.6	0.66
6	3.9	0.67
7	3.2	0.50
8	3.1	0.57
9	2.5	0.66
10	2.2	0.56
11	2.1	0.53
12	4.0	0.50
13	4.3	0.47
14	3.3	0.56
15	3.6	0.58
16	3.6	0.55
17	3.0	0.69

Figure 1 shows: (a) Optimal response plot, with a minimum level of formaldehyde at a distance of 1,5; and (b) Optimal coordinate plot for the response in codified variables. These data transformed into natural variables are: pH: 7.4; Urea additions: 2 and Temperature: 50 ºC.

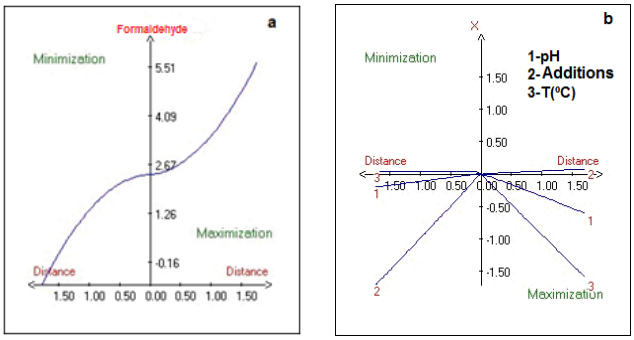

Figure 1. Ridge analysis (RSM).

4.-Conclusions

The effect of the number of second urea additions, pH and temperature was studied for the preparation of UF resins. The process was optimized on the basis of these studies. The results showed that the studied variables played a significant role in reducing the formaldehyde emission with a minor withdrawal of internal bond strength.

Controlled Free-Radical Copolymerization of 4-Vinyl Pyridine and *tert*-Butyl Acrylate via Reversible Addition-Fragmentation Chain Transfer (RAFT) Technique: Kinetics and Mechanism

Eugene Sivtsov[1], *Alexey Gostev*[1], *Elena Chernikova*[2]

[1] Saint-Petersburg State Institute of Technology, Plastics Technology Department, Saint-Petesburg, Russia
[2] Moscow State University, Department of Chemistry, Moscow, Russia

pjeka@yahoo.fr

The reversible addition-fragmentation chain transfer (RAFT) technique of free-radical polymerization was used to synthesize 4-vinyl pyridine (4VP)–tert-butyl acrylate (TBA) copolymers of gradient and block microstructure. Poly(4VP–TBA) can be easy transformed to copolymers of 4VP and acrylic acid, the self-assembling in acidic aqueous solutions of which was investigated by means of dynamic light scattering, turbidimetric and potentiometric titration. It was shown that microstructure strongly affected the size of the aggregates formed and the conditions of self-assembling.

Bulk copolymerization of 4VP and TBA was carried out in the presence of dibenzyl trithiocarbonate (BTC) as a RAFT agent and using the classic radical polymerization initiator N,N′-azobis(isobutyronitrile) (AIBN).

The gradient copolymers were obtained using monomers mixture in one-step process. Gradient structure was the result of the following:

– the monomers reactivity ratios difference (r_{4VP}=1.41 and r_{TBA}=0.04 as it was determined from NMR ^{1}H data of the monomers concentrations and the copolymer composition during the reaction);

– and a living character of the polymerization (a clear evidence of which is the copolymer molecular mass growing with the increasing of conversion, see Fig. 1).

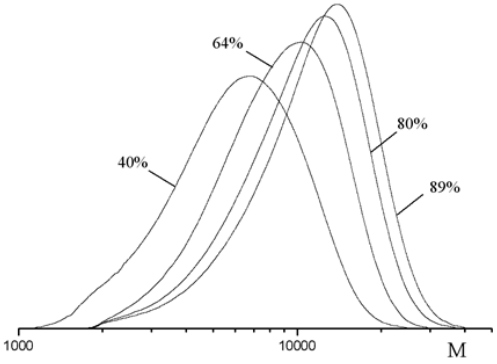

Figure 1. SEC traces of copolymers formed in bulk copolymerization of 4VP and TBA in the presence of BTC (80°C) at different conversions. [4VP]/[TBA]=58:42 mol.%.

As a result it leads to changing of the chain microstructure from both the tails of the macromolecules to their centres: the tails of the chains are enriched with 4VP units, while the middle of the chains – with TBA units. This gradient chain structure is formed due to 4VP higher reactivity and taking into account the mechanism of RAFT polymerization in the presence of trithiocarbonates (see the Table).

Table. Molecular mass and composition (concentrations of 4VP and TBA in copolymers) of the gradient poly(4VP-TBA) obtained from the monomers mixture 4VP:TBA=31:69, mol.% at different conversions C(%).

C, %	[4VP], mol.%	[4VP], units	[TBA], mol. %	[TBA], units	M_n
34	50	32	50	32	7700
56	45	38	55	46	10200
71	40	56	60	84	17000
81	36	59	64	105	20000

Kinetics and mechanism of 4VP and TBA RAFT copolymerization were studied by NMR ^{1}H spectroscopy. Thus, dynamics of benzyl protons concentration changing gives the information of comparative reactivity and effectiveness as a RAFT agent the initial BTC and polymeric trithiocarbonates formed in the course of the polymerization. The concentrations of BTC and mono substituted trithiocarbonate (polyRAFT$_1$) were registered during the polymerization. The data obtained in this study shows that polymeric radical is a better leaving group than benzyl radical. It is the reason that polyRAFT$_1$ concentration decreases slowly after its maximum, and polyRAFT$_1$ and polyRAFT$_2$ are present in the reaction mass together up to the high conversions. It is very important if the strictly definite gradient structure with composition changing from the tails to the middle of macromolecule must be synthesized.

Another useful information – concentration of 4VP units bound to the sulphur atom of trithiocarbonate fragment in polyRAFT$_1$ and polyRAFT$_2$, can be obtained from NMR ^{1}H spectra of the reaction mass. It was shown that after reaching the maximum at the early stage of reaction the concentration decreased slowly (see Fig. 2). It is a direct evidence of gradient microstructure poly(4VP-TBA) obtained.

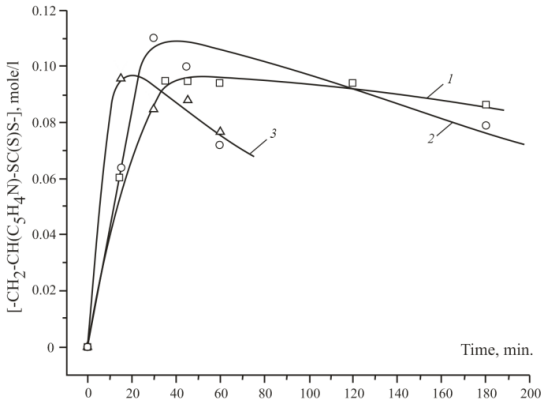

Figure 2. Time dependence of [-CH_2-CH(C_5H_4N)-SC(S)S-]. The monomers mixture composition, [4VP], mol.%: *1* – 25, *2* – 49, *3* – 75.

Conventional and RAFT Copolymerization of N-Vinyl Succinimide and 4-Vinyl Pyridine

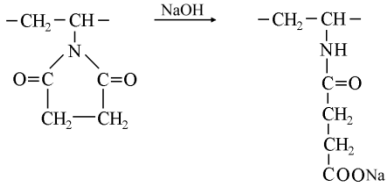
(Co)polymers based on N-vinylsuccinimide (VSI) cause intense interest due to possibility of application as hydrophilic non-toxic materials in medicine. Such copolymers can be easily modified by alkaline hydrolysis resulting in conversion of VSI units to the N-vinylsuccinimidic acid (VSA) units:



The carboxylic groups attached to the main chain via –NH–C(O)–CH_2–CH_2– spacer permit to bind low molecular compounds including medicinal products to the polymers, leading to various advantages of such polymeric drug conjugates, for instance, their prolonged action *in vivo*. However, a strong problem arises during production of VSI copolymers at high conversions: due to usual difference in reactivity ratios of VSI and other comonomers, which are most commonly used in copolymerization, the composition heterogeneous copolymers are formed that influences noticeably on the properties of the final product. Meanwhile the copolymer microstructure and composition heterogeneity are of great importance due to their influence on the reactions of addition of low molecular compounds to carboxylic groups of modified VSI copolymers and on macromolecules behavior in solutions.

Another problem arises when it is necessary to obtain soluble VSI polymers with high composition homogeneity by polymerization in bulk. This task cannot be achieved using conventional free-radical polymerization because of the chain transfer reaction to VSI cycle methylen protons leading to cross-linked unsoluble products. RAFT technique seems to be the most efficient way to solve both the problems of VSI polymerization denoted above.

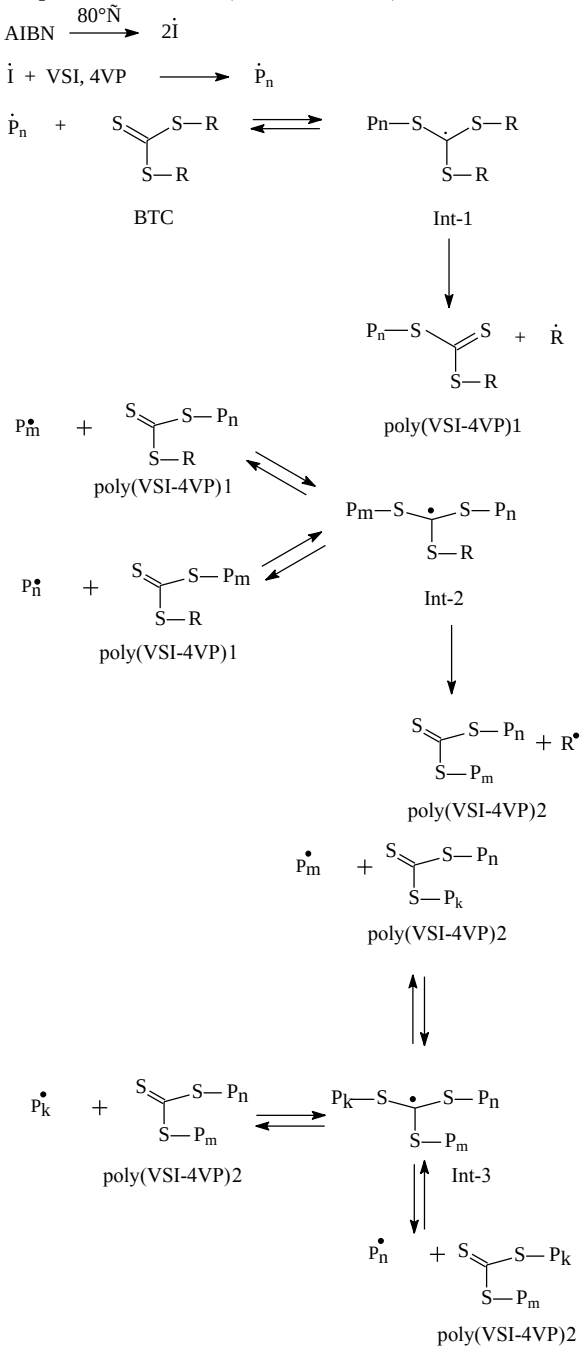
Conventional and RAFT copolymerization of VSI and 4-vinyl pyridine (4VP) was studied in bulk and in solutions. Copolymers of VSI and 4VP can be used as precursors for obtaining zwitterionic copolymers by hydrolysis of VSI units and quaternization of 4VP units.

RAFT copolymerization of VSI and 4VP was carried out using dibenzyl trithiocarbonate (BTC) as a RAFT agent. The mechanism of the polymerization is shown on the Scheme below.

Monitoring of the reaction mixture components concentrations by NMR ^{1}H spectroscopy was used to study mechanism and kinetics of copolymerization and to calculate reactivity ratios of VSI and 4VP which were not described before in literature.

It was shown that poly(VSI-4VP) with various microstructures could be obtained using RAFT technique and BTC as a RAFT agent. Growing of MM in course of reaction is an evidence of pseudo-living character of the polymerization.

Scheme. Mechanism of copolymerization of VSI and 4VP in the presence of BTC (R= – $C_6H_5CH_2$).



Copolymers synthesized according the Scheme have gradient structure in which CS_3-fragment is close to the middle of macromolecule and the composition of both the polymeric substituents P_n changes from the tails to the middle. The simplest gradient structure with the composition changing from one tail to another can be obtained by the reaction with a big excess of free radicals (e.g. AIBN, 80°C) in inert solvent.

Aromatic Copolyesters Containing Cyclic Diacetalized D-Glucitol

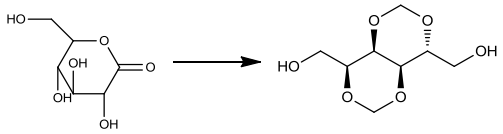
Introduction

The development of polymers based on monomers from renewable feedstocks is a steadily growing field of interest, especially from carbohydrates because of the unique structure and properties that can be generated in this case.[1] 2,4:3,5-Di-*O*-methylene-D-glucitol (Glux) is a carbohydrate-based diol suitable for the preparation of linear polycondensates.[2] The fused bicyclic dioxolane rings provide rigidity to the molecule making it an interesting candidate for replacing aromatic rings in conventional aromatic polyesters.

Materials and Methods

The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX-300 spectrometer. DSC experiments were performed at heating/cooling rates of 10 ºC·min^{-1} and TGA analysis was carried out under inert atmosphere. WAXS was performed on a Siemens diffractometer using K_{α}(Cu) radiation. Molecular weight analysis was performed by GPC using HFIP. Glux was readily prepared by acetalization of 1,5-D-gluconolactone with paraformaldehyde, followed by esterification with methanol of 2,4:3,5-di-*O*-methylidene-D-gluconic acid, and subsequent reduction.[1]



Results and Discussion

Copolyesters *co*PH$_x$Glux$_y$T (Figure 1) were synthesized by melt polycondensation from dimethyl terephthalate, 1,6-hexanediol and 2,4:3,5-di-*O*-methylene-D-glucitol using tetrabutyl titanate as catalyst. A series of copolyesters with Glux contents ranging between 5 and 32 mol-% was prepared. Synthesis results are displayed in Table 1.

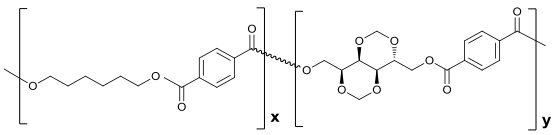


Figure 1. Structure of *co*PH$_x$Glux$_y$T copolyesters.

The ^{13}C NMR analysis showed that all the copolyesters had a random microstructure; the degree of randomness was determined from the signals of the non-protonated aromatic carbons of terephthalic units, which were split into nine peaks due to sequence distribution. The *co*PH$_x$Glux$_y$T copolyesters displayed optical activity according to what should be expected from the asymmetrical constitution of Gulx; specific optical rotations were found to span in the range from 1 to 10º.

Table 1. PH$_x$Glux$_y$T copolyesters: Synthesis results

Polyester	Reaction			Molecular size			
	Yield (%)	HD (mol %)	Glux (mol %)	M_n (g·mol^{-1})	M_w (g·mol^{-1})	PD	[η] (dL·g^{-1})
PHT	88	100	0	17 700	46 000	2.3	0.83
PH$_{95}$Glux$_5$T	80	95.4	4.6	15 500	41 000	2.4	0.72
PH$_{90}$Glux$_{10}$T	76	90.3	9.7	14 800	31 400	2.1	0.68
PH$_{80}$Glux$_{20}$T	68	81.6	18.4	13 900	33 000	2.2	0.65
PH$_{74}$Glux$_{26}$T	60	73.9	26.1	6050	16 000	2.5	0.34
PH$_{68}$Glux$_{32}$T	57	68.2	31.8	5100	12 400	2.5	0.29
PGluxT	30	-	100	3000	10 100	3.3	-

The thermal behaviour of *co*PH$_x$Glux$_y$T was evaluated by DSC and TGA and compared with that of poly(hexamethylene terephthalate) (PHT). The incorporation of Glux units in the chain of PHT decreased T_m and also T_d although the thermal stability of the copolyesters continued being satisfactory. Conversely, T_g increased significantly with the content in Glux so that a content of 5% in these units was enough to raise its value in 14 ºC.

The powder X-ray diffraction analysis of the copolyesters confirmed DSC data showing that all samples were semicrystalline. Nevertheless the cristallinity of *co*PH$_x$Glux$_y$T was lower than of PHT and decreased with increasing contents in Glux. The WAXS profiles revealed after annealing intense peaks corresponding to *d*-spacing characteristic of the β crystal form of PHT.[3]

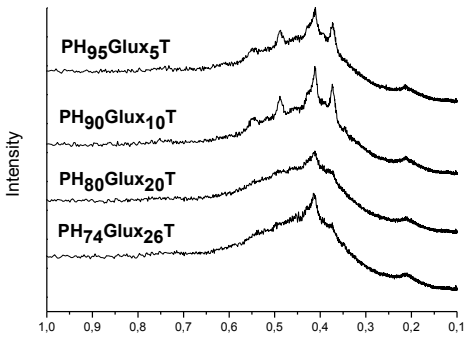

Figure 2. WAXS of annealed *co*PH$_x$Glux$_y$T.

Introduction

Aliphatic polyesters containing 1,4-cyclohexylene rings are an interesting class of materials, not yet fully investigated. They potentially have the good characteristics typical of biopolyesters (for example, polyalkylene dicarboxylates and polyhydroxy alkanoates), such as sustainability and biodegradability. Indeed, renewable biomass resources can be used as feedstock to prepare the monomers and some preliminary tests of biodegradation suggest that the aliphatic rings do not hinder the microorganism attack.[1] Moreover, the presence of cyclohexyl groups into the main chain provides rigidity to macromolecular chains, raises T_g, and imparts desirable physical-mechanical properties. In this way, the problem of the poor mechanical properties generally found in aliphatic polyesters can be solved. Finally, the 1,4-cyclohexylene unit shows the other remarkable peculiarity that it can have two possible configurations, *cis* and *trans*. In a polymer containing the 1,4-cyclohexylene rings, it will suffice to slightly modify the *cis*/*trans* isomeric ratio to obtain materials whose phase behavior changes from fully amorphous to semicrystalline.[2] Therefore, the final properties of these materials can be easily tailored according to the specific applications.
In this work diols with different chain length were tested as monomers for novel polyesters and the effects of the molecular characteristics on final properties were analyzed.

Materials

Two commercial samples of 1,4-dimethyl cyclohexanedicarboxylate (DMCD) with 22% and 100% of trans isomer, ethanediol, 1,3-propanediol, 1,4-butanediol, 1,5-pentanediol, 1,8-octanediol, and titanium tetrabutoxide (TBT) (all from Aldrich chemicals) were high purity products , used as received.

Results and Discussion

Polyesters from dimethyl 1,4-cyclohexane dicarboxylate (DMCD) and linear diols, containing from 2 to 8 $-CH_2-$ units, were synthesized (see Scheme 1). The *cis*/*trans* isomeric ratio of the aliphatic rings in the final polyesters is 90 or 50 mol%. Thermal and mechanical properties were investigated by DSC and DMTA. By comparing polymers having an odd or even number of $-CH_2-$ in the diol, to exclude odd/even effects, T_g significantly decreases with the increment of the chain length. For example, T_g, changes from 24 to -34°C by passing from ethanediol to 1,8-octanediol as monomers, when DMCD is 90 mol% *trans*. This large difference of 50°C is due to the increment of chain flexibility of the $-CH_2-$ sequences derived from the diol. Correspondently, melting temperature decreases from 146 to 94°C by passing from 1,4-butanediol to 1,8-octanediol. On the other hand, the mechanical properties are always good, independently of the diol chain length: the elastic modulus before T_g is about 10^9 Pa for all the semicrystalline samples prepared from DMCD 90% *trans*.
By decreasing the *trans* content of the DMCD monomer the materials generally lose the capability to crystallize, even if for the polymer from 1,8-octanediol the long flexible chain of the diol favours the formation of a low crystallinity level.

Conclusions

Novel polyesters have been successful prepared by using DMCD and different aliphatic diols as monomers. Significant relationships between the diol chain length, the *cis/trans* ratio of the cycloaliphatic units, and the solid-state properties were found.

Introduction

Many countries nowadays are putting effort and emphasis on recycling plastic waste and, at the same time, on developing alternative degradable materials and materials from renewable resources. Several synthetic polymers have been identified as degradable in the natural environment, and, among them, aliphatic polyesters appear very attractive and promising. Despite their utility there remains a need to design materials with more variation in, for example, crystallinity, polarity, solubility, mechanical properties, etc. This need for an expanded set of properties has driven research in the area of preparing aliphatic polyesters with tunable properties. In this study the modifications of poly(lactic acid) (PLA) by reactive blending with citronellol (CL) and cardanol (CD) are reported. CL is a natural monoterpenoid, known as bioactive molecule with disinfectant and odor properties. CD (3-pentadecenyl phenol) instead, the main component obtained by thermal treatment of cashew nut shell liquid (CNSL), is a phenol derivative mainly having the meta substituent of a C15 unsatured hydrocarbon chain with mostly 1-3 double bonds. Only a small part of CD obtained in the production of the cashew kernel is used in the industrial field, though it has various potential industrial uses. Therefore, development of new applications for CD is strongly desiderable. CL was also employed in the synthesis of novel aliphatic polyesters based on dimethyl succinate (DMS) and 1,3-propanediol (PD). The aim was the production of linear and unsatured materials, without the addition of cross-linking inhibitors, and that can be further easily modified through several reactions techniques.

Materials and Methods

DMS, PD, CL, tin octanoate ($Sn(Oct)_2$) were furnished by Aldrich. CD was a gift from Satya Cashew Chemicals and PLA was supplied by NatureWorks.

Reactive blending: 0.200 mol (14.4 g) of PLA, 0.0100 mol of CL (1.64 g) or CD (8.95 g) and 175 ppm of $Sn(Oct)_2$ as catalyst were reacted for 2 hours at 170 °C in a 250 ml round bottomed flask equipped with a mechanical stirrer and a condenser.

Polymerization: 0.0950 mol (7.22 g) of PD, 0.0730 mol (10.7 g) of DMS and $3.60 \cdot 10^{-3}$ mol (0.560 g) of CL were reacted following a standard two stages polycondensation process with $Sn(Oct)_2$ as catalyst.

Results and Discussion

In Fig. 1. it is reported the reaction scheme between PLA and CL or CD. As can be seen in Table 1 the unsatured molecules covalently attached to PLA resulted to be around 1 and 2 mol%, as measured by ^{1}H-NMR. The molecular weights of the final products and the T_g were drastically lowered respect to the starting material, probably because of transesterification reactions occurring with the functional groups in the chain.

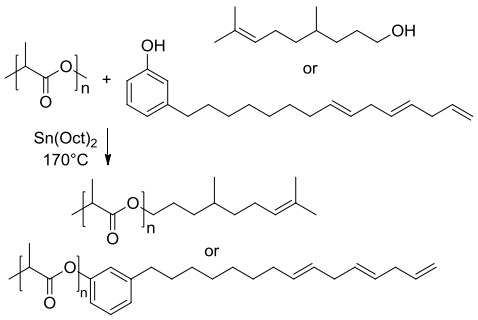

Fig. 1. Reactive blending scheme

In Fig. 2. The direct polymerization reaction scheme and conditions are reported. By ^{1}H-NMR it resulted that 2 mol% of unsaturation is present and that both molecular weights and thermal properties of the reference (poly(propylene succinate) – PPS) and telechelic unsatured material are comparable.

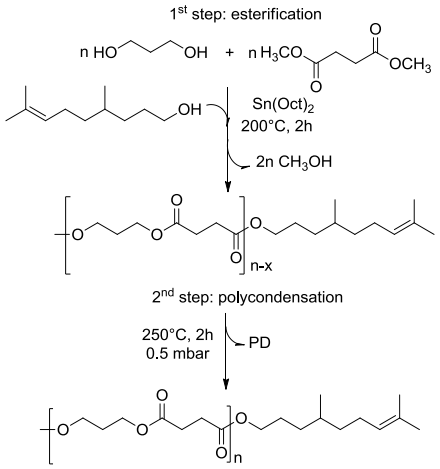

Fig. 2. PPScitronellol polymerization scheme

Tab. 1. Samples characterizations

Sample	Unsaturation[a] (mol %)	M_w[b]	T_g[c] (°C)
PLA	-	170000	62
PLA_citronellol	2	22000	49
PLA_cardanol	1	30000	45
PPSref	-	71000	-32
PPScitronellol	2	68000	-31

[a] ^{1}H-NMR analysis; [b] GPC analysis; [c] DSC 2nd heating scan

Conclusions

Telechelic unsatured aliphatic polyesters have been prepared by reactive blending and by direct polymerization. In particular direct polymerization permits to get a final material with a relatively high molecular weight. CL and CD were covalently bonded to the polymer allowing for further modifications of the polymeric structure.

Synthesis and characterization of lactide-graft-poly(vinyl alcohol) and miscibility study with poly(ethylene oxide)

Introduction. Poly(vinyl alcohol) (PVA) is a well known water-soluble polymer with widespread commercial applications. The repeating unit of PVA contains reactive hydroxyl groups that can be converted to ester groups through ring opening reactions. On the other hand Poly(ethyelene oxide) (PEO) is a highly crystalline polymer that exhibits miscibility with chemically dissimilar polymeric materials.[1] According to the Flory-Huggins model, attractive interactions between the components of a polymer blend are necessary to obtain a miscible polymer blend. The most commonly used method for establishing miscibility in polymer blends is through the determination of the glass transition temperature (T_g). A miscible polymer blend possesses a homogeneous amorphous phase and hence will exhibit a single glass transition temperature between the Tg´s of the pure components. In the case of blends in which one of the components is semicrystalline, the miscibility of the system involves a decrease in the equilibrium melting point of the crystalline polymer as a function of the blend composition. The presence of this depression is often considered to be a miscibility criterion.[2]

In this work we have selected a semicrystalline/amorphous pair to prepare blends: poly(ethylene oxide), PEO, and lactide-graft-poly(vinylalcohol),VA-g-LA. Although it is known in advance that PEO/PVA blend is immiscible and PEO/PLLA blend is partially miscible,[3,4] grafting is expected to favor miscibility in the PEO/VA-g-LA system, since it should decrease the OH self-association.

Materials and methods. PEO with weight-average molecular weight of 70,000 and PVA with weight-average molecular weight in the range of 13,000-23,000 and a degree of saponification of 98% were supplied from Sigma Aldrich. The monomer L-lactide was obtained from Purac.

The chemical characterization of the graft copolymers obtained was carried out by ^{1}H NMR, ^{13}C NMR and IR spectroscopy. The composition, the degree of substitution (DS) and the degree of polymerization (DP) were determined by means of ^{1}H NMR spectroscopy. The thermal properties of copolymers and the miscibility study were investigated by differential scanning calorimetry (DSC), IR spectroscopy (FTIR) and scanning electron microscopy (SEM).

Films of pure PEO and blends of PEO/VA-g-LA were prepared by casting the chloroform solutions of the polymers, followed by drying at room temperature.

Results and discussions. Ring-opening graft polymerization of L-lactide (LA) was carried out with poly(vinyl alcohol) in the presence of tin(II) 2-ethyl hexanoate catalyst in dimethyl sulfoxide (DMSO) in nitrogen atmosphere at 100º C. The desired graft copolymers, lactide-graft-poly(vinyl alcohol) were obtained using different feed compositions, and ^{1}H NMR shows that the length of the lactide side chain increases with the monomer feed composition.

The analysis of the PEO/VA-g-LA blends by DSC, FTIR and SEM suggests miscibility in the whole range of compositions. Due to the high crystallinity of PEO, the DSC curves for the PEO rich systems did not show a discernable glass transition temperature. However, the value obtained for polymer-polymer interaction parameter χ_{12}, was -0,22. The negative value of the interaction parameter confirms a thermodynamically miscible blend.

On the other hand, FTIR spectroscopy reveals that the hydroxyl stretching region shifts to lower wavenumbers as the content of PEO in the blend increases. This behavior is attributed to the presence of a new band, attributed to hydrogen-bonded species, indicative of the intermolecular interaction involving the PEO ether group and the VA-g-LA hydroxyl group.

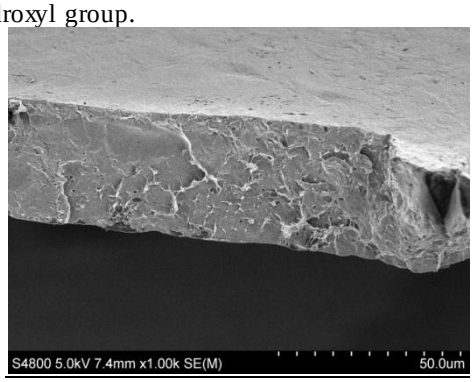

Figure1. SEM micrograph of PEO/VA-g-LA (50/50)

Figure 1 shows the SEM micrograph for the PEO/VA-g-LA 50/50 blend in which there is no observed phase separation. These micrographs support the results obtained by DSC and FTIR and indicate that the PEO/VA-g-LA blend is miscible.

Acknowledgements. The authors are thankful for funds from MICINN (BIO-2010-21542-CO2-01) and from the Basque Government, Department of Industry, Innovation and Commerce (Etortek IE10-276). A.L. thanks to the University of the Basque Country a pre-doctoral grant and SGIker (UPV/EHU) technical support for SEM measurements.

Introduction

Nature offers an abundance of opportunities for designing novel monomers and shaping structural and functional polymers in its wide variety of raw materials. Presently their relative use for monomers and polymers synthesis compared to petrochemicals is small. Natural oils, such as vegetable oils provide interesting feedstock - triglyceride fatty acids- that beyond their use in food allow additional chemistry that yields either opportunities for replacing petrochemicals or may be directly used to synthesize bio-inspired materials.[1]

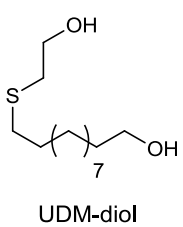
Vegetable oils are becoming extremely important as renewable resources for the preparation of polyols required for the polyurethane industry.[2]

Classically the reaction between a thiol and a double bond has received significant attention as candidate for many applications. Resurgence over the past decades has occurred in response to the many benefits that thiol-ene coupling presents for polymer synthesis: tolerance to many different reaction conditions/solvents, clearly defined reaction pathways/products, and facile synthetic strategies from a range of easily obtained starting materials.[3]

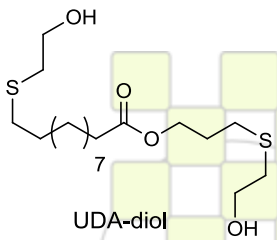
In particular, thiol-ene click chemistry of fatty acid derivatives, obtained from plant oils, is a promising route that can be used for the synthesis of novel chemical intermediates from renewable resources.[4,5,6]

Results and Discussion

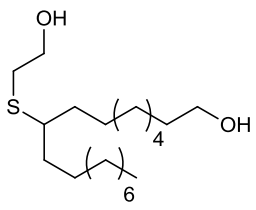
Our research applies the photoinitiated thiol-ene click chemistry of unsaturated oleic and 10-undecenoic acid methyl and allyl esters with hydroxyl-functionalized thiol (2-mercaptoethanol) for its ability to add hydroxyl functionality in lieu of double bonds. Due to terminal enes are significantly more reactive towards hydrothiolation compared to internal enes, thiol-ene addition to oleic acid derivatives required longer reaction times and higher amounts of radical photoinitiator, 2,2-dimethoxy-2-phenylacetophenone (DMPA). This methodology provides a green approach toward four novel plant-derived diols: UDM-diol, UDA-diol, OLM-diol and OLA-diol. The chemical structures of these products were confirmed by NMR and FTIR.



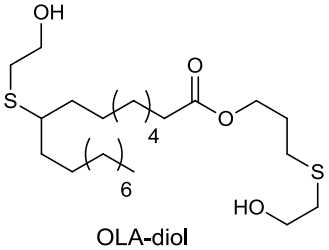
UDM-diol



UDA-diol



OLM-diol



OLA-diol

The synthesized undecylenic and oleic acids based diols were polymerized with 4,4′-methylenebis (phenylisocyanate) (MDI), in DMF solution at 50 ºC for 24 h using tin (II) 2-ethylhexanoate as catalyst, to produce the corresponding thermoplastic polyurethanes (TPUs). Also, ultrasound irradiation has been tested to improve the polyurethane synthesis. Under these conditions TPUs were obtained in high yields (80-99%) with weight-average molecular weights in the 36-83 KDa range. Polydispersity degrees oscilated between 2.2 and 1.9 with perceivable differences between those with and without ester groups in the polymer chain. In the case of polyurethanes obtained with ultrasound irradiation weight-average molecular weight was higher and polydispersity was lower.

The chemical structures of polyurethanes were assessed by FTIR and NMR spectroscopy. The thermal and mechanical properties of the synthesized TPUs have been studied and show a clear dependence on the structure of the parent diol. MTT test was carried out to asses the potential citotoxicitity of the prepared polyurethanes. All thermoplastic polyurethanes scored 0, indicating no cytotoxic response, in spite of some evidences indicating that aromatic-based polyurethanes are cytotoxic.

Preparation of new surfaces to fight against microbial contamination is a subject of major interest nowadays in different areas such as household, industry, hospital, etc. Polymer surfaces with anti-adhesive or antibacterial properties would be of great interest for example to manufacture sheets and clothes as protections against nosocomial infections.

The aim of this study is to prepare new polymers based on biomolecules with a known antibacterial activity.

These polymers were prepared by conventional and controlled radical (Atom Transfer Radical Polymerization) polymerizations.

Natural biocide molecules are numerous but we will focus on some of them: gaïacol, myrtenol and D-glucosamine (Figure 1).

Gaïacol (2-methoxyphenol) **1** is a natural biocide molecule obtained from beechwood. Gaïacol is isolated from the gaïac resin. Gaïacol and derivatives are known and used for more than a century. Their main uses are antiseptics, gastric sedatives, flavorings, deodorants, fungicides and parasiticides.

Myrtenol **2** is an essential oil obtained from the myrtle (*Myrtus communis L.*). The benefits of myrtle are various. Different parts of the plants are used in cosmetics and medicine (antibacterial and antifungal activity).

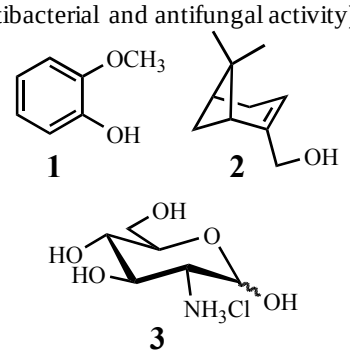

Figure 1. Gaïacol, myrtenol and D-glucosamine

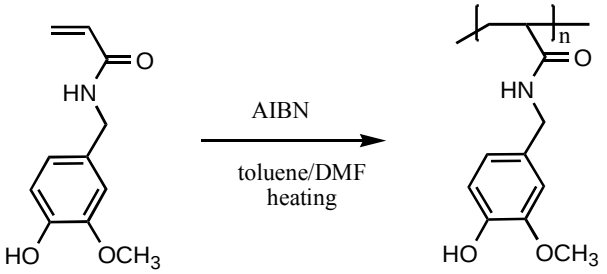
Chitosan is a linear copolymer of β-(1→4)-linked D-glucosamine and *N*-acetyl D-glucosamine units in varying proportions. Among its various bioactivities, the antimicrobial activity of chitosan has been pointed out as one of its most interesting properties. Chitosan has exhibited high antimicrobial activity against a wide variety of pathogenic and spoilage microorganisms, including fungi, Gram-positive and Gram-negative bacteria. D-glucosamine **3**, monomer unit of chitosan was used in our study.

Methacrylate and acrylamide monomers were prepared using these biomolecules and their radical polymerization was studied.

For example, *N*-(4-hydroxy-3-methoxy-benzyl)-acrylamide monomer was prepared from gaïacol by Friedel-Craft reaction and polymerized using AIBN as thermal initiator (Scheme 1).

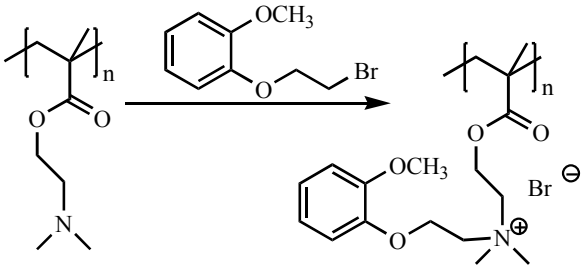


Scheme 1. Conventional radical polymerization of *N*-(4-hydroxy-3-methoxy-benzyl)-acrylamide

Anti-adhesive activity is tested after adsorption of polymer derived from gaïacol on glass slides. It is evaluated with different kind of bacteria (*H. alvei*, *S. epidermidis*, *E. coli* and *B. subtilis*).

Combination of ammonium groups and biomolecule-derivatives in the same polymer was performed to enhance the antibacterial activity.

For example, brominated compounds derived from gaïacol were prepared and used for quaternization reaction with poly((2-dimethylamino)ethyl methacrylate) (Scheme 2).



Scheme 2. Preparation of antibacterial polymer with both ammonium and gaïacol-derivatived groups.

Carbohydrate-based Polyurethanes: A Comparative Study of Polymers Made from Isosorbide and 1,4-Butanediol

R. Marín, A. Alla, A. Martínez de Ilarduya and S. Muñoz-Guerra

Dept d'Engingería Química, Universitat Politècnica de Catalunya, ETSEIB, Diagonal 647, 08028 Barcelona

sebastian.munoz@upc.edu

Introduction

Although some polyurethanes (PUR) containing isosorbide were described at the beginning of the nineties,[1] the knowledge on these compounds is very limited. Recently we have reported on segmented poly(ester-urethane)s in which 1,4-butanodiol (BD) was replaced by isosorbide (Is) as chain extender.[2] The main purpose of this work was to make a comparative study of non-segmented Is containing polyurethanes with their analogues made from BD. Hexamethylene diisocyanate (HDI) and 4,4'-methylene-bis(phenyl isocyanate) (MDI) are used for this synthesis.

Materials and Methods

Isosorbide was a gift from Roquette Freres S.A. Molecular sizes of PUR were estimated by both viscosimetry in dichloroacetic acid and GPC. NMR spectra were recorded on a Bruker AMX-300 in DMSO-d_6. DSC experiments were performed at heating/cooling rates of 10 ºC·min^{-1} and TGA analysis was carried out under inert atmosphere. Wide angle X-ray scattering (WAXS) was performed on a lab diffractometer or at the A2 beamline of the HASYLAB synchrotron (DESY, Hamburg).

Results and Discussion

The chemical structures of PUR studied in this work are depicted in Figure 1.

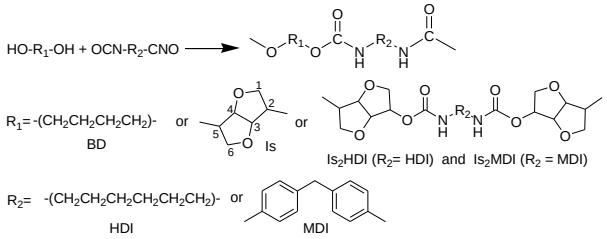

Figure 1. Chemical structures of polyurethanes studied in this work.

The selected diol or combination of diols (BD, Is, Is_2HDI or Is_2MDI) were made to react with the selected diisocyanate using dibutyltin dilaurate catalyst. The use of diol-urethane compounds as monomers ensured the incorporation of the Is units as dyads in the PUR chain and contributed to minimize the decomposition of isosorbide during polymerization. Synthesis results are compared in Table 1. The ^{1}H NMR spectra showed that PUR were enriched in BD units and all them displayed predominance of isosorbide end groups, mostly with the unreacted hydroxyl in *exo* position. This result is contrary to the relative reactivity of the hydroxyl groups observed in the synthesis of polyesters.[3]

The thermal properties and stability of PUR containing Is were evaluated and compared with those of PUR entirely made of BD. Incorporation of Is produced significant changes in T_g, T_m and T_d but no noteworthy differences were found between copolymers made from

Is or Is_2 monomers. In general the insertion of the Is units in the PUR chain increased the T_g and depressed the crystallinity.

WAXS revealed that the triclinic structure of PUR-(BD-HDI) was essentially retained in PUR-(BDIs-HDI), whereas the aromatic PUR gave profiles typical of disordered material. Annealing of PUR-(Is-HDI) induced the split of the 0.43 nm peak indicating that a new crystal structure was adopted.

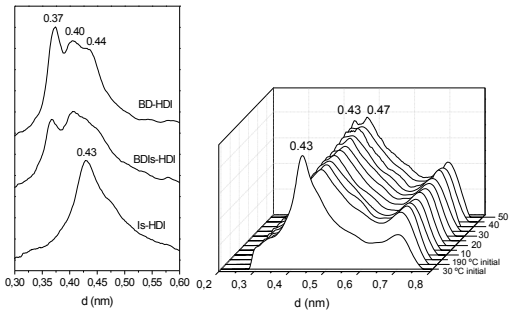

Figure 2. WAXS of PUR (left) and evolution of the PUR-(Is-HDI) profile with annealing time at 190 ºC (right).

The degradation in aqueous buffers (pH 2, 7.4 and 10, at 37 and 60 ºC for 40 days) of the pair PUR-(BD-HDI) and PUR-(Is-HDI) showed that the replacement of BD by Is weakens the resistance of PUR to water. This result is in agreement to previously reported work on polyamides and polyesters and confirm that the hydrodegradability enhancement in polycondensates made of carbohydrate-based units is a general fact.

Financial support given by MICINN with grant MAT-2009-14053-CO2-01 and HASYLAB technical support is acknowledged.

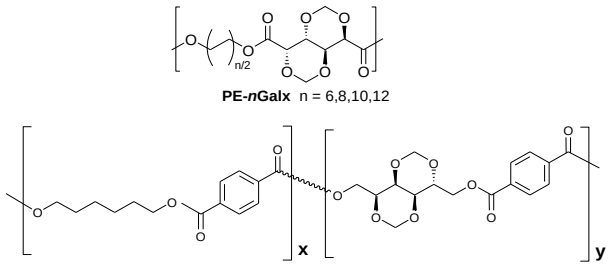
Introduction

The development of biobased polymers obtained from carbohydrates is a field of interest because of the unique structure and properties that can be generated in this case.[1] Cyclic acetalized diacids and diols, *i.e.* dimethyl 2,4:3,5-di-*O*-methylene-galactarate (Galx) and 2,4:3,5-di-*O*-methylene-D-glucitol (Glux) have been recently proven to be suitable monomers for the preparation of linear polyesters. One major problem associated to polyesters made from cyclic carbohydrate derivatives is their susceptibility to heat, which may limit the synthesis work and give rise to undesirable discoloration of the final polymer. On the other hand, it is of interest to evaluate the influence of the carbohydrate units on the hydrolytic degradability of the polyesters. In this communication, the degradability of a set of polyesters and copolyesters containing either Glux or Galx is preliminary evaluated.



Scheme 1. Chemical structure of PE-*n*Galx polyesters (top) and *co*PH$_x$Glux$_y$T copolyesters (bottom).

Materials and Methods

PE-*n*Galx polyesters of M_w in the 30,000-40,000 range were obtained by melt polycondensation of Galx with aliphatic α,ω-alkanediols. Random copolyesters *co*PH$_x$Glux$_y$T with Glux contents ranging between 5 and 32 mol-% were synthesized by melt polycondensation of dimethyl terephthalate with mixtures of Glux and 1,6-hexanediol. The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX-300 spectrometer and the TGA analysis was carried out in the 30-600 ºC range under inert atmosphere. ATR-FT-IR was performed in a Jasco 4100 instrument.

Results and Discussion

The TGA traces of PE-*n*Galx polyesters reveal that PE-*n*Galx polyesters lost 5 % of mass at temperatures higher than 320 ºC. Comparison of the TGA traces of PE-*n*Galx polyesters with their homologues PE-*n*Ad made from adipic acid revealed that the introduction of ring acetal groups improves the thermal stability. The analysis by NMR of volatile generated upon heating a sample of PE-8Galx at 300 ºC indicated the presence of aldehydic, formiate and methylol groups. The ATR-FTIR of the residue revealed that the structure of the cyclic acetals might have been modified during the thermal treatment. On the other side the replacement of the 1,6-hexanodiol by Glux give rises to a decreasing in the thermal stability of the resulting copolymers that is more accentuated with increasing contents in the sugar units.

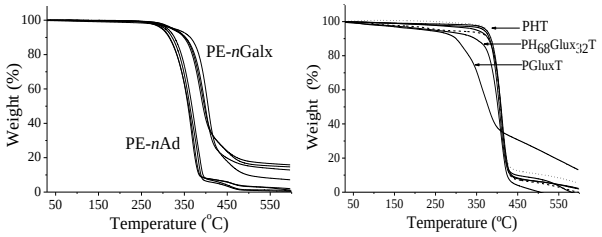


Figure 1. Compared TGA traces of polyesters.

The hydrolytic degradability of PE-8Galx and PE-8Ad was compared by incubating them in parallel in aqueous buffer under different conditions. Significant weight losses were detected for PE-8Galx, which apparently hydrolysed into low molecular water-soluble monomers and oligomers. The hydrolysis study of *co*PH$_x$Glux$_y$T was made comparing with the aromatic homopolyester PHT. In this case, it was also found that the incorporation of the Glux units slightly increased the degradability although the loss of weight only reached a few %.

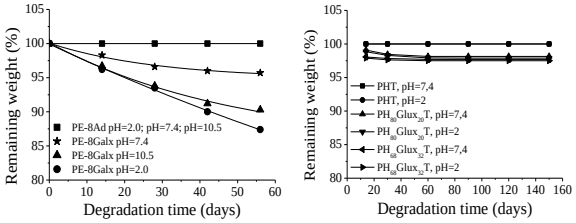

Figure 2. Evolution of the sample weight of polyesters incubated in aqueous buffer at room temperature at the indicated pH.

Conclusions

The replacement of alkylene diols by cyclic carbohydrate units, in both aliphatic and aromatic polyesters, increases slightly their susceptibility to the hydrolytic degradation. The effect of the replacement on the thermal stability seems to be opposite in each case.

Polyhydroxybutyrate Nanocomposite Microcapsules with Brazilian Smectitic Clays

Maria das Graças da Silva Valenzuela, Wang Hui Shu, Hélio Wiebeck, Francisco Rolando Valenzuela Díaz

Departamento de Engenharia Metalúrgica e de Materiais, Escola Politécnica da Universidade de São Paulo, Brazil

mdgdsval@yahoo.com

Introduction: The search for better materials has placed the polymer/clay nanocomposites in the center of attention, especially because their considerable increasing of material properties in function of the nanoscale reinforcement. Biopolymer-based nanocomposites as polyhydroxybutyrate (PHB), due to the current concern over environmental problems and biomedical use, can be a good alternative to produce microcapsules with application in drug delivery systems. Polymeric microcapsules are microparticles such as can be loaded with biological or chemical substance at the sphere surface or encapsulated within the particle and be used as a drug delivery systems. The drug delivery systems based on polymeric microcapsules has witnessed tremendous progress in recent years due to their unlimited potential to improve human health [1]. It can be used in several industrial sectors, especially medical, pharmaceuticals and cosmetics to allow the developing of better therapies. PHB has been described as a good candidate for fabricating prolonged-action drug in the form of polymeric microcapsules [2]. This biopolymer offers many advantages over traditional petrochemically derived plastics. It is a linear homopolymer biosynthesized by various strains of bacteria by condensation of D(-)-B-hydroxybutyric acid and used as an energy and carbon source. PHB can be obtained by extraction from bacteria or by chemical synthesis. It is biocompatible and biodegradable, and completely nontoxic in the environment [2]. In this work, we describe the preparation of microcapsules from two PHB nanocomposite systems: a) PHB/OMMT (Cloisite 20A), (PHB1) and b) PHB/montmorilonite (MMT), natural Brazilian green policationic clay, (PHB2).

Materials and Methods: The PHB used for the nanocapsule preparation was obtained from PHB Industrial S.A. (São Paulo, Brazil). The organophilic clay (Cloisite 20A) with positively charged quaternary ammonium (dimethyl hydrogenated tallow 2-ethylhexyl quaternary ammonium chloride) was obtained from Southern Clay. The MMT clay, Brazilian green clay, a natural clay, was obtained from Bentonisa do Nordeste S.A. (Paraíba, Brazil). Firstly, the polymer PHB was dissolved in chloroform (25/1) at 40°C for 10 min, while the Cloisite 20A and Brazilian green clay were dispersed in chloroform (250/1) at room temperature, for 10 min. The organoclay and the polycationic clay dispersions were added separately to two PHB solutions and then mixed by stirring for 1 hour. After this time, 2 mL of each mixture were placed in glass dishes and leaved in a hood, overnight. After the solvent was evaporated, the two samples were dried in a vacuum oven for 1 day at 25°C. The microcapsules PHB/OMMT and PHB/MMT nanocomposite (NCN) were prepared by solvent evaporation technique from the resulting organic solutions.

Results: The XRD of films and microcapsules do not show $d_{(001)}$ peak, evidencing an exfoliated structure in the nanocomposites. The films have shown by SEM a homogeneous distribution of the claymineral particles spread uniformly in the PHB film matrix, Figure 1

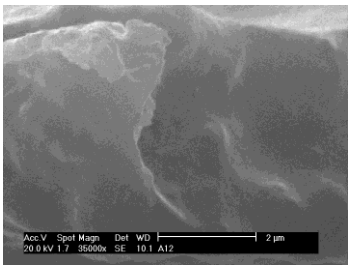

Figure 1. SEM, PHB film with green clay.

The nanocomposite microcapsules when analyzed by SEM revealed spheric particles with a porous surface structure very similar to a “hydrangea”, Figure 2.

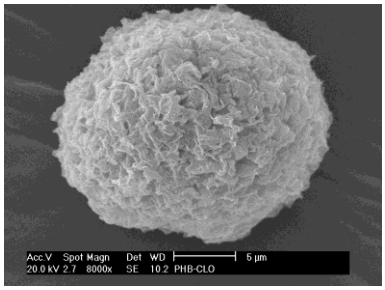

Figure 2. SEM PHB microcapsule with Cloisite clay.

Conclusions: PHB has been described as a good candidate for the manufacture of medicines with prolonged action in the form of polymeric microspheres. This biodegradable polymer, member of the polyhydrixyalkanoates family, offers many advantages over traditional plastics derived from petrochemicals. The properties of PHB can be improved by adding clay to form a compound. In this work were obtained nanocomposite microcapsules PHB / clay, using both hydrophilic and organophilic smectitic clays.

Introduction

The search of new polymeric materials from renewable resources is of great technological, scientific and environmental importance, since they can replace petroleum based polymers, and contribute to reducing greenhouse gases and the accumulation of plastic waste. Vegetable oils are renewable resources that mainly consist of triglycerides, whose structural features provide a wide range of synthetic possibilities to obtain several polymers that have shown similar properties to those of conventional polymers from petroleum, as well as the interesting properties such as mechanical damping and shape memory[1, 2]. The rubber seed oil (RSO) is a vegetable oil produced in large quantities in some countries like Brazil and Nigeria, and it does not compete with the food industry. Therefore, this vegetable oil is a very valuable alternative to produce new polymers with significant economic and environmental benefits. In this work we synthesized a series of copolymers of styrene (St) and vinyl macromers of RSO (monomers of high molecular weight).

Material and Methods

Macromers were obtained by synthetic route in two steps: glycerolysis oil followed by maleinization[3, 4]. This route affords macromers with functionality ranging from 2 to 4, which can generate crosslinked polymers useful to design biocomposites[5]. Macromers were characterized by thin layer chromatography (TLC), ^{1}H and ^{13}C NMR, infrared spectroscopy (FT-IR) and Raman Spectroscopy. Copolymers with different compositions were obtained by radical polymerization and characterized by swelling measurements and extraction in toluene, ^{1}H NMR and GPC of soluble fraction, dynamic mechanical analysis (DMA) of the whole materials and thermogravimetric analysis (TG/DTG) (before and after extraction of soluble fraction).

Results and Discussion

The macromers are mainly constituted by monoglyceride bis-maleate half-esters, as determined by spectroscopic characterizations.

Swelling and extraction of soluble fraction experiments of the copolymers show that the increase in St amount in the copolymers favors the incorporation of both monomers in the polymeric network, reducing the soluble fraction. However, the soluble fraction of the copolymer containing 90 % of St increases dramatically.

DMA analysis indicate that this copolymer is heterogeneous and presents at least two phases: one richer in St segments presenting Tg at 70°C and another poor in St at 48°C (Figure 1a).

Moreover, the width of peaks in the tan δ x T curves indicates that these copolymers are capable of absorbing a wide range of frequencies and thus are potentially applicable for soundproofing.

TG/DTG analyses of the copolymers allow concluding that both soluble and insoluble fractions of copolymers have macromers and St units, however a soluble fraction of copolymers with low content of St is richer in macromers.

The global composition of the soluble fraction approaches the structure of polystyrene as St content increases, as determined by ^{1}H NMR (Figure 1b) and GPC. The drastic increase in the soluble fraction of the copolymer containing 90 % St can be explain by the solubilization of the phase riche in St.

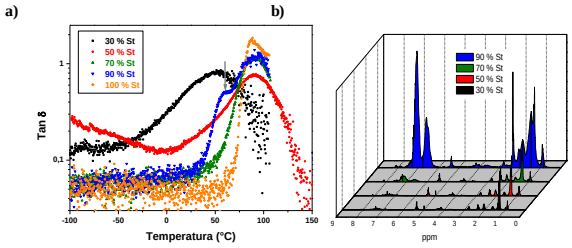

Figure 1. a) Tan δ as a function of temperature for RSO-macromers/styrene copolymers of different compositions. b) ^{1}H NMR spectra for soluble fraction of RSO-macromers/styrene copolymers of different compositions.

Copolymers with St content up to 50 % hydrolytically degrade easily, and copolymers with higher amounts are resistant to hydrolytic degradation. For this reason, the latter polymers are suitable for long term applications such as construction.

Conclusions

The synthesized copolymers possess a complex structure dependent on the composition characterized by a three-dimensional network with oligomers and/or polymers inside it. Phase segregation was observed for copolymers with high content of St. Copolymers have significant differences in their capacity to hydrolytic degradation.

Introduction. Poly(L-lactide) (PLLA) is one of the most intensively studied biodegradable polymers[1]. However, its high stiffness and rather low deformability limits its potential for numerous clinical uses where elastomeric and shape memory biodegradable materials may be required. This unsuitability might be overcome by blending or copolymerization of PLLA with lower glass-transition temperature polymers such as poly(ε-caprolactone) (PCL). Hence, the synthesis of diblock, triblock, multiblock or random poly(L-lactide-co-ε-caprolactone) (PLCL) copolymers is of great interest.

In this work, random PLCL copolymers at variable temperatures are synthesized by ring-opening polymerization with tin (II) octoate as catalyst/initiator. The reaction by simultaneous addition of the L-LA and ε-CL at different comonomer ratio appears to be a suitable method for the preparation of copolymers with mechanical properties ranging from rigid to elastomeric[2].

Materials and methods. L-lactide monomer (assay > 99,5%) was obtained from Purac (The Netherlands). ε-CL monomer (99% assay) and stannous octoate were supplied by Sigma Aldrich.

The polymerization was carried out in a 50mL flask with magnetic stirring immersed in a controlled temperature oil bath. In each synthesis, predetermined amounts of L-La and ε-CL were simultaneously added and melted. The flask was purged for 30 minutes with a nitrogen stream under the surface of the melt. Then, the stannous octoate was added using a 2000:1 comonomers/catalyst molar ratio. After 24 hours, the product was dissolved in chloroform, precipitated pouring the polymer solution into excess of methanol and then dried under vacuum.

The average molecular weights and polydispersity were determined by Gel Permeation chromatography (GPC). Thermal properties were analysed by differential scanning calorimetry (DSC) at heating rate of 20ºC/min from -90ºC to 210ºC. The composition and microstructure of the copolymers were determined by means of Nuclear Magnetic Resonance spectroscopy[3] (^{1}H –NMR and ^{13}C NMR).

Tensile tests were performed with an Instron testing machine at a crosshead displacement rate of 5mm/min. The specimens for tensile tests were obtained from films of the synthesized PLCL. 250µm films were obtained by casting the chloroform solutions of the polymers followed by pressure melting at 175ºC and water quenching in order to achieve an amorphous state.

Results and discussions. Stannous octoate catalyst in cyclic esters polymerization is considered more effective at 120-150ºC. Therefore, ring-opening polymerization was carried out at 120ºC, 130ºC, 140ºC and 150ºC. On the other hand, feed monomer composition of the synthesized copolymers was 90:10, 80:20, 75:25 and 70:30 (mass:mass ratio of LA to CL) on several mixtures.

From the experiences developed varying the added catalyst it can be concluded that the highest conversions and molecular weights were obtained for a 2000:1 comonomers/catalyst molar ratio. As observed, the synthesis of random PLCL using stannous octoate follows the mechanism proposed by Kowalski et al[4].

Increasing the LA content in the feed, the glass transition temperature (T_g) and the melting temperature (T_m) approached to that of PLLA homopolymer. The crystallinity degree was also increased. The mechanical properties evolved in the same way towards the PLLA character, observing an increase in elastic modulus increase and a decrease in deformation at break.

Higher molecular weights were obtained at 130ºC and 140ºC. Furthermore, both the number and weight average molecular weights of synthesized PLCL copolymers increased at higher LA:CL ratio, probably due to the higher reactivity of LA units during copolymerization.

At lower temperatures a predominant formation of copolymers with moderate block character (multiblock character) was found; the number average sequence lengths were longer and the randomless character was closer to 0, the value corresponding to a pure block copolymer.

Thermosets from methyldiphenolic acid-based benzoxazine and diphenolic acid mixtures

Zuñiga, C.; Lligadas, G.; Ronda, J.C.; Galià, M.; Cádiz, V.

Department of Analytical Chemistry and Organic Chemistry, Rovira i Virgili University, Marcel.li Domingo s/n, 43007 Tarragona (Spain)

virginia.cadiz@urv.cat

Introduction

Over the last decade, an interesting addition cure phenolic resin, namely benzoxazine, has attracted much attention of the research community because of its unique advantages over most of the known polymers.

The chemistry of benzoxazines is responsible for a number of inherent processing advantages, including low melt viscosity, no harsh catalyst required, no volatile release during cure and minimal cure shrinkage. They also have a good thermal stability that is demonstrated by their high glass transition temperatures, degradation temperatures, and char yields. A unique combination of intramolecular and intermolecular hydrogen bonding also contributes to the properties of polybenzoxazines.

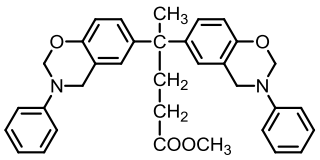
Although, polybenzoxazines offer a variety of advantages, pure polybenzoxazine-based polymers also suffer number of disadvantages too. The disadvantages of the typical polybenzoxazines are the high temperature needed for complete curing and the brittleness of the cured materials that can sometimes limit their potential applications. To properly address these issues and overcome the associated disadvantages, one of the most succesful strategies is the preparation of monomers with one additional functionality.[1] The crosslinking densities of polybenzoxazine homopolymers are believed to be considerably lower than those of ordinary thermosetting resins. The tightening of the network structure has been achieved by introducing additional crosslinkable sites.

Until now, benzoxazine monomers are synthesized either in solution or by a melt-state reaction using a combination of petroleum-based phenolic derivatives, formaldehyde and primary amines. The scarcity of nonrenewable resources encouraged the scientific community to develop and commercialize new biobased products that can alleviate the wide-spread dependence on fossil fuels and, enhance security, the environment and the economy.[2]

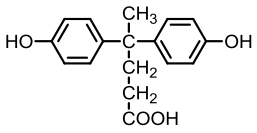
In this work, we studied the thermal behaviour of mixtures of renewable diphenolic acid (DPA) and its methylesterbenzoxazine derivative (MDP-Bz). The presence of a carboxylic group in DPA monomer should lower the high temperature needed to complete curing of these benzoxazines and serve as additional crosslinking site.

Results and Discussion

Recently, we have synthesized the ester derivative based benzoxazine, MDP-Bz, from renewable DPA, with a similar structure to bisphenol A (BPA), by traditional approaches.[3] Polybenzoxazines from MDP-Bz showed higher Tg 270 ºC, and higher crosslinking density compared to BPA-Bz, due to the transesterification that extensively takes place during the curing reaction.



MDP-Bz



DPA

The curing behaviour of mixtures of MDP-Bz and 0, 1, 5, 10 y 25% (w/w) of DPA has been studied by DSC. A decrease of up to 80 ºC was observed for the mixture with higher DPA content. This catalytic effect can be related to the presence of free carboxylic acid groups, as using the methyl ester of DPA instead of DPA the decrease in the curing temperature is much lower.

To evaluate the thermal and mechanical properties of the resulting materials, rectangular samples with dimensions of 30 x 7 x 0.5 mm^3 were prepared by compression molding using either the free resin mixture or a glass fiber embeded mixture. The curing cycle was fixed according to DSC data. The resulting materials were orange rigid solids. In the case of free resin mixtures brittle materials were obtained but not in the glass fiber reinforced composites.

The dynamic mechanical and thermogravimetric properties of the polybenzoxazines were investigated.

The dynamic mechanical behaviour of the cured benzoxazine resins was obtained as a function of the temperature beginning in the glassy state of each composition to the rubbery plateau of each material. The crosslinking density of the polybenzoxazines can be estimated from the plateau of the elastic modulus in the rubbery state. The results indicate a similar crosslinking density and Tg's above 270ºC.

To determine the thermal stability and the decomposition behaviour, thermogravimetric analysis were carried out under nitrogen and air atmosphere. Materials showed thermal stability below 300 ºC and the degradation takes place in one main step. Samples have char yields, at 800 ºC, under nitrogen of ca. 30%.

Polybenzoxazine foams from renewable diphenolic acid

Zúñiga, C.; Lligadas, G.; Ronda, J.C.; Galià, M.; Cádiz, V.

Department of Analytical Chemistry and Organic Chemistry, Rovira i Virgili University, Marcel.li Domingo s/n, 43007 Tarragona (Spain)

camilojavier.zuniga@urv.cat

Introduction

Polymeric foam is a two-phase material consisting of gas dispersed in a continuous polymer matrix. This material is important and useful due to its strength-to-weight ratio. Furthermore the chemical resistance, cushioning performance, shock absorption, and thermal insulation are also prominent characteristics of this type of material.[1]

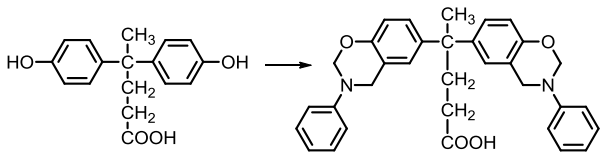
In many specific applications the fire resistance properties have to be considered. Although polyurethane, polyethylene and polystyrene foams have good mechanical and thermal properties they are not appropriate as they are easily burned. Among the inexpensive commercial polymeric foams, phenolic foam is the preferred material when fire resistance is critical. Phenolic foam also has low flammability, a low peak heat release rate, no dripping during combustion, and low smoke density, so they are suitable in these applications.

Polybenzoxazine is a newly developed class of phenolic resins derived from ring opening polymerization. Polybenzoxazine can overcome the drawbacks of conventional phenolic resin synthesis by eliminating the release of any byproducts during the curing reactions, the need of strong acid as catalyst and for toxic materials. Furthermore, polybenzoxazine has many advantageous characteristics compared with the traditional phenolic resin, such as high thermal stability, an excellent mechanical properties, easy processibility, low water absorption and near zero shrinkage after polymerization.[2]

This study deals with a new type of phenolic foams derived from a polybenzoxazine obtained from the non-toxic renewable diphenolic acid (DPA).

Results and Discussion

Recently, we have synthesized the benzoxazine monomer DPA-Bz, from renewable DPA by the traditional approach.[3]



DPA DPA-Bz

Curing studies of this DPA-Bz showed the existence of esterification reaction between the carboxylic groups and the phenolic OHs, formed during the ring opening of oxazines. Thus, a highly crosslinked system with Tg of 208 ºC was obtained. These studies also showed that when curing was carried out without pressure a extensive foaming process occurred, probably due to the partial decarboxylation of the sample.

According to this behaviour, in a first step DPA-Bz was partially polymerized under pressure 6 h at 140 ºC and 2 h at 160 ºC, and further heated up to 220 ºC in air atmosphere to obtain a rigid foam. The sample incompletely cured showed by DSC a Tg at 145 ºC followed by an endothermic peak at 211 ºC that could be attributed to a decarboxylation reaction that promotes the foaming. Both thermal processes were also detected by DMTA as two different slopes in the loss of storage modulus plot versus temperature. This can be also observed in the Tan δ plot which showed two maxima at 178 ºC corresponding to the Tg, and at 206 ºC corresponding to the foaming process.

The Tg's of the completely cured polybenzoxazines were similar, with values of 207 ° C for the unfoamed polybenzoxazine and 200 ºC for the foam polybenzoxazine respectively, indicating a similar final crosslinking degree. However the density of the completely cured material was 1221 ± 0.6 Kg/m^3 whereas the density of the foam material was 48.6 ± 0.9 Kg/m^3. The decrease of the density corresponds to the resulting gases developed during the foaming process which increase the volume of the original sample around 25 times under the studied conditions.

The visual examination of a cross-section of the foam was carried out using ESEM. An examination of the foam revealed well-foamed structure. The foam showed a fine heterogeneous structure of relatively cell roundness with interconnected pores. The image analysis showed the cell size distribution of the foam which reveals that the most of the cells have a size between 20 and 100 μm. These results indicate that the obtained benzoxazine foam is much lighter than those obtained from similar benzoxazines where a foaming agent was added.[4]

It was observed that temperature and heating rate are significant parameters to control the foam morphology. As the higher these parameters the lower foam density.

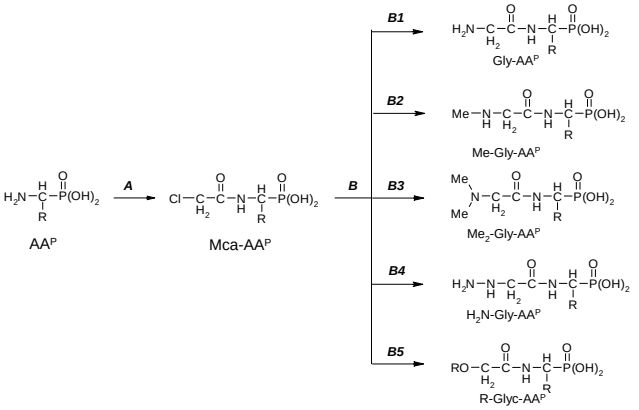
Introduction

Aminoalkylphosphonic acids (AA^P) belong to the class of phosphoroorganic compounds of multidisciplinar importance due to their biological activity and chelating ability [1].

Materials and Methods

Recently we have published on the *N*-acylation [2] and chloroacetylation [3] of 1-aminoalkylphosphonic acids AA^P ($AA^P \rightarrow$ Mca-AA^P) and conversion of Mca-AA^P into glycylo-phosphonic peptides (Scheme 1: routes ***B1-B4***) [4].



In this communication we would like to present our results on the biological properties of representative phosphonopeptides depicted on the Scheme 1.

Conclusions

Since compounds Mca-AA^P react also with alcohols (Scheme 1, route ***B5***), they can be consider as reagents for cotton modification.

Amphiphilic Poly(4-vinylpyrine) (P4VP) Block Copolymer Micelles for Metal Binding

Nurulsaidah Abdul Rahim, Fabrice Audoin, Johannes G.Vos, Andreas Heise

Dublin City University, School of Chemical Sciences, Polymer Chemistry Group, Glasnevin, Ireland

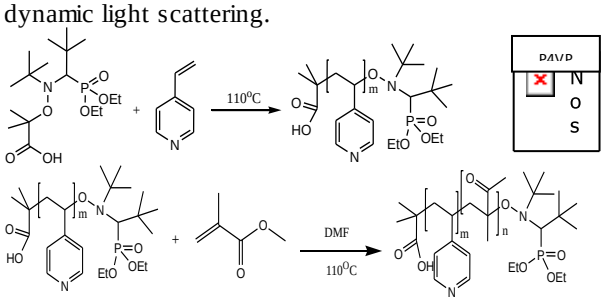
nurulsaidah.abdulrahim2@mail.dcu.ie

INTRODUCTION

Block copolymers (BC) with metal binding capability have a great potential as template for nanoparticles and catalytic process. Due to their potential to control molecular weight (Mn) and polydispersity index (PDI) controlled radical polymerisation is often applied in synthesis block copolymer.[1] For example, nitroxide mediated polymerisation (NMP) is effective method in controlled radical polymerisation of amine-containing vinyl monomers such as 4-vinylpyridine.[2] Here, we used SG1-alkoxyamine as unimolecular initiator in the synthesis of poly(4-vinylpyridine) (P4VP) and further chain extension with methyl methacrylate (MMA).

EXPERIMENTAL METHODS

P4VP was synthesised in DMF solution at 110°C with BlocBuilder (MAMA-SG1). Then, P4VP was used as macroinitiator for polymerization of MMA to produce block copolymer (P4VP-*b*-PMMA) at 90°C (Scheme1). Polymers were characterized by NMR, GPC in DMF and IR. For micelle formation, P4VP-b-PMMA was dissolve in THF solution and the size particles was analysed by dynamic light scattering.



Scheme 1: Polymerisation of P4VP (*top*). Polymerisation of P4VP-*b*-PMMA (*bottom*).

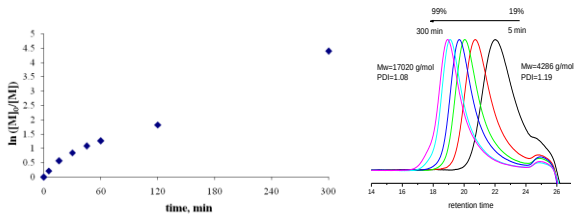


Figure 1. Evolution of ln ($[M]_0/[M]$) vs time of P4VP (*left*). SEC chromatograms of P4VP (*right*).

RESULTS AND DISCUSSION

P4VP was synthesised successfully by MAMA-SG1 as initiator with high monomer conversion to controlled molecular weight (17000 g/mol) and narrow polydispersity index (1.08). The kinetic plot ln ($[M]_0/[M]$) vs. reaction time shows a linear increase. (see Figure 1). Block copolymer were synthesised from the P4VP macroinitiators by chain extension with PMMA with and without addition of 10 % styrene (Table 1). The latter improved the monomer conversion.[3]

$P4VP_{200}$-$PMMA_{95}$ spontaneously associates into spherical inverse micelles in THF consisting of soluble PMMA shell and insoluble P4VP core at critical micelle concentration (CMC) of 0.1mg/mL with average diameter, 70 nm (Figure 2).

Table 1. Molecular weight, Mn and Polydispersity index (PDI) of P4VP-b-PMMA

Sample	Mn NMR g/mol	Mn GPC[a], g/mol	PDI[a]
P4VP-b-PMMA	26000	33000	1.14
P4VP-b-PMMA + 10% styrene	22000	28000	1.10

[a] measured by DMF GPC with Multy angle light scattering detection.

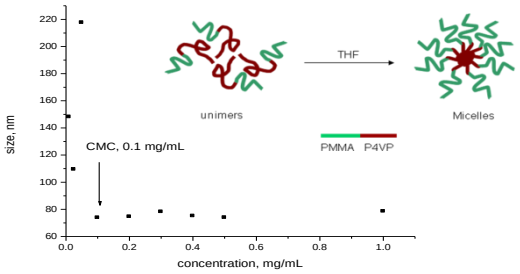

Figure 2. Plot of hydrodynamic diameter versus the concentration of $P4VP_{200}$-$PMMA_{95}$measured by dynamic light scattering at 90°C

CONCLUSION

In this work we successfully synthesised P4VP in high conversion with controlled Mn and narrow PDI by NMP. These macroinitiators were extended by PMMA to yield amphiphilic block copolymers capable of micelle formation in THF. Future work will emphasise on metal binding of the micelles.

Sunflower Oil-modified Polyester Synthesis by Ring Opening Polymerization and Its Use in Organic Coatings

Çiğdem Taşdelen-Yücedağ, *A. Tuncer Erciyes*[*]

Istanbul Technical University, Faculty of Chemical and Metallurgical Engineering, Chemical Engineering Department, 34469, Maslak, Istanbul / Turkey

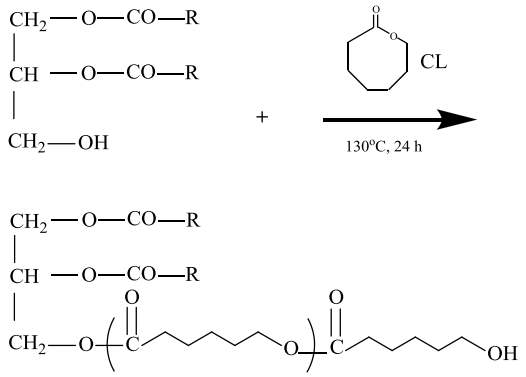
e-mail: erciyes@itu.edu.tr

Introduction

Triglyceride oils are the most important class of renewable sources since they have been used in the production of biodegradable polymer products[1]. In this study a sunflower oil-modified polyester (SOMPE) was prepared by the ring opening polymerization of ε-caprolactone in the presence of partial glyceride which is used as an initiator. Thus the obtained polyester was combined with benzoxazine monomer and the resulting product was examined in view of film properties.

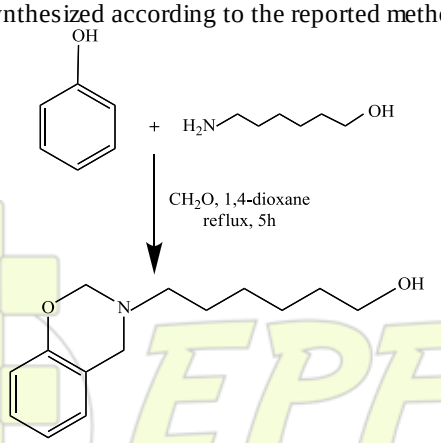
Materials and Methods

SOMPE was synthesized by ring opening polymerization of ε-caprolactone (ε-CL) (Aldrich, 97%) initiated with partial glycerides of sunflower oil in the presence of tin (II) 2-ethylhexanoate (Aldrich, 95%) as catalyst (Scheme 1). The reaction was carried out at 130°C and then stopped after 24 h, by cooling. The product was isolated by precipitation of the reaction mixture from methanol and dried under vacuum at 30°C for 24 h.



Scheme 1. The ring opening polymerization of ε-caprolactone initiated by partial glyceride.

The hydroxy-functional 1,3-benzoxazine (HFB-a) (Scheme 2) was synthesized according to the reported method[2].



Scheme 2. Synthesis of hydroxy-functional 1,3-benzoxazine.

Results and Discussion

In the applied approach for the oil modification, the polyester chains were combined with the oil moieties through the hydroxyl groups of the partial glycerides. In order to confirm that partial glycerides were linked to the polyester segments, a reference homopolyester sample was prepared by water initiated ring opening polymerization of ε-caprolactone. The structure of SOMPE was well evidenced by comparing its ^{1}H-NMR spectrum with that of reference homopolyester sample. In the characterization studies together with ^{1}H-NMR measurements, FT-IR and GPC analysis were carried out. Since the film of SOMPE was found to be soft, SOMPE and HFB-a were combined with 2,4-toluene diisocyanate (TDI) through their hydroxyl groups (SOMPE/HFB-a). SOMPE/HFB-a was mixed with HFB-a in various weight ratios and cured. The cured film properties were investigated in order to find the optimum SOMPE/HFB-a ratio.

Conclusions

In the present study, a polyester modified with triglyceride oil was obtained by the ring opening polymerization of ε-caprolactone. The advantage of this process is the combining of oil and polyester segments during the ring opening polymerization without any additional application. It was understood that SOMPE could be used in order to improve the film properties of benzoxazine which can be used as a organic coating material.

Introduction

Conjugated polymers bearing reactive functional groups have been attracting interest and significant attention as promising components in luminescent optoelectronic devices and optical sensor (1-3). The great synthetic versatility of organic polymers makes them excellent candidates for studying the effects of structural modifications in the material properties. For example, π-conjugated polymers having a sulfo group, carboxylic group or hydroxy group have been reported. However, π-conjugated polymer having a $-NH_2$ side group has received less attention (4, 5), in spite of the presence of a tremendous number of reports about polyanilines. In this work, aniline units were introduced into polyfluorene backbone; by adjusting the monomer feed ratios (**Scheme 1**).

Results and Discussion

Synthesis and polymer characterization of **P1-P6** was done by conventional techniques, previously used in our lab (6). Stoichiometric copolymers poly[9,9-bis(hexyl-fluoren-2,7-diyl)-alt-co-(2/3-aminobenzen-1,4-diyl)] were synthesized via Suzuki coupling with air stable palladium (II) catalyst. All data were collected according to the typical co-polyfluorene structures and the results obtained in the polymer composition have been compared and contrasted by NMR and FTIR. Molecular weights were obtained by GPC calibration based on polyfluorene following the procedure described above (6). Special attention has been performed in the optical and electrochemical characterization of these polymers, in solution and solid films. Significant changes have been noted in the physicochemical parameters (wavelength absorption and emission, quantum yields and, also, redox potential) due to the presence of acceptor groups. It has been established electrochemical behavior acceptor ring in terms of its content in the final polymer. Stabilized cyclic voltammograms of **P1-P6** polymers deposited onto ITO glasses were obtained for cathodic (p-doping) and anodic branches (n-doping).

All the polymers present reversible p and n doping processes, except for polymer **P1**, where we observe only p-doping. Devices were fabricated using the following configuration: ITO/ PEDOT: PSS (50 nm)/ active polymer (~100 nm)/ Ca (20 nm)/ Al. Electroluminescence (EL) and current−voltage (I−V) characteristics of the synthesized polymers **P3** and **P5** into luminescent devices are encouraging. Thus, **P5** present maxima efficiency of 0.084 Cd/A (600 μA, 5,2 V), brightness of 6.38 Cd/m^2, and CIE coordinates (0.1758;0.1059) , without degradation colour while **P3** present change in CIES coordinates, low colour stability (0.2003;0.2011)→(0.1915;0.1725), as show in **figure 1**.

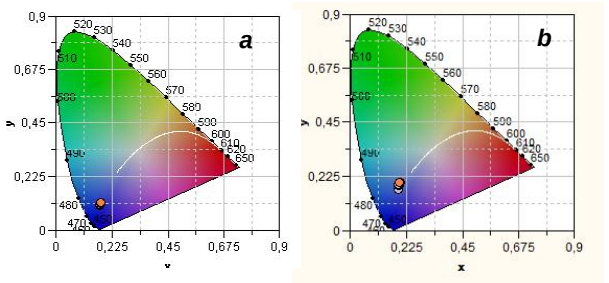

Figure 1. Colour evolution of two copolymer devices a) **P5** (1%-NH_2) and **P3** (10%-NH_2).

Metathesis degradation of natural rubber in the presence of avocado and mandarin oils using ruthenium alkylidene catalysts

Araceli Martínez[1], *Mikhail A. Tlenkopatchev*[1]

[1] Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México, Apartado postal 70-360, CU, Coyoacán, México D.F. 04510, México

tma@servidor.unam.mx

Introduction

In recent years, bio-based products have attracted much attention since these resources are renewable and can be used for energy, chemicals and other important materials production [1]. Thus, bio-based products such as *D*-limonene from citrus peel, soybean and avocado oils, can undergo metathesis reactions due to they contain carbon-carbon double bonds in their structures.

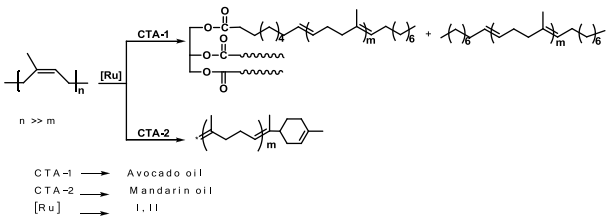
It has been reported that D-limonene and β-pinene have been used as chain transfer agents (CTAs) in order to obtain telechelics via ring opening metathesis polymerization (ROMP) of cycloolefins as well as cross metathesis degradation of natural rubber (NR) using ruthenium alkylidene catalysts[2-4].

The main aim of this research is focused on the metathesis degradation of natural rubber in the presence of avocado and mandarin oils as CTAs and using well-defined alkylidene ruthenium catalysts $(PCy_3)_2(CI)_2Ru{=}CHPh$ (**I**) and (1,3-dimesityl-4,5-dihydroimidazol-2-ylidene) $(PCy_3)CI_2Ru{=}CHPh$ (**II**).

Materials and Methods

NR was obtained from fresh field latex of AGROS (Guatemala) and used without further purification (M_n = 1.7x10^6, *MWD* = 1.5). Avocado and mandarin oils (NATURAL OILS & CHEMICAL) and alkylidene ruthenium catalysts **I** and **II** were used as received. 1,2-dichloroethane (Baker > 97%) was distilled over CaH_2 prior to use.

Metathesis degradations of NR (3.0 g) using avocado and mandarin oils as CTAs (***Scheme 1***) were carried out under a dry nitrogen atmosphere, in a reactor stirred magnetically, at 45°C. Avocado and mandarin oils (CTAs) were used in molar ratios of NR/CTA = 3:1 and 1:1 respectively. The catalyst **I** or **II** was added in molar ratios ranging from NR/catalyst = 250 to 1,000. Adding ethyl vinyl ether (0.3 mL, 3 mmol) under a nitrogen atmosphere terminated the reactions. The products were dried under a vacuum and characterized by ^{1}H-NMR and GPC.



***Scheme 1*. Metathesis degradation of NR using avocado and mandarin oils as CTAs.**

Results and Discussion

Isolated oligomers were obtained in yields ranging from 50 to 80% when catalyst **I** was used whereas catalyst **II** produced oligomers in high yields (80-95%). Molecular weights were controlled primarily by the NR/CTA molar ratios giving values around M_n x 10^3 when molar ratios of 3:1 and 1:1 were used for avocado and mandarin oils, respectively.

Conclusions

Both, avocado and mandarin natural oils were successfully used as chain transfer agents in the metathesis degradation of natural rubber leading to the formation of oligomers with molecular weight distributions close to two. Catalyst **II** was able to depolymerized NR completely in comparison with catalyst **I** when the reactions were conducted in the same period of time.

Introduction

Plant oils and thereof derived fatty acids are important renewable raw materials for polymer chemistry.[1] Especially, castor oil is a very versatile renewable feedstock for all kinds of polymeric materials. One of the commercially available castor oil derived platform chemicals, undecylenic acid, was recently used to prepare a great variety of polymers, thus demonstrating its broad range of application possibilities. [2]

Whilst alkenic fatty acids occur abundantly in nature, alkynic fatty acids are rare. However, alkynic fatty acids are accessible in good yield by bromine addition and dehydrobromination from alkenic fatty acids. Alkynic fatty acids are furthermore prepared and used as intermediates in fatty acid synthesis, because the acetylene unit allows the easy assembly of building blocks and the stereospecific hydrogenation to *cis*- or *trans*-double bonds. The triple bond in alkynes allows C-C bond formations and functional group interconversions that supplement those at the double bond. [3]

In recent years, the radical mediated thiol-yne coupling procedure was introduced. The beauty of this thiol-yne coupling procedure is that it combines the readily available building blocks of the copper (I) azide-alkyne click reaction and the thiol-ene chemistry to create multifunctional materials under mild reaction conditions: two thiols are coupled to one alkyne using either a chemical radical source, UV irradiation, or sunlight at ambient temperature. The radical mechanism of the thiol-yne reaction makes it very robust and versatile method that tolerates a variety of functional groups. [4,5]

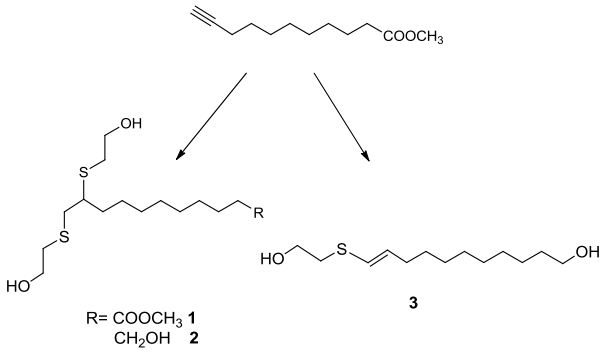
In this work, we take advantage of this reactivity to synthesize 10-undecinoic acid based diols as polyurethane precursors.

Results and Discussion

10-methyl undecynoate was obtained in moderate yield from the corresponding fatty acid by bromination, dehydrobromination, and esterification using well established procedures.

Our research applies the photoinitiated thiol-yne click chemistry to this alkine using mercaptoethanol and 2,2-dimethoxy-2-phenylacetophenone (DMPA) as initiator to obtain the ester-containing diol **1**. Moreover, the reduction of ester group yields a triol **2**. The chemical structures of these products were confirmed by NMR and FTIR.

To prepare a reactive vinylsulfide-containing diol **3**, we studied the mono thiol-yne addition. Thus, 1- hexyne, 1-octyne thiol and benzene thiol were used as model compounds. It was observed that an excess of alkyne is necessary to obtain the vinylsulfide in high yields.



Functionalized linear polyurethanes have been obtained from **1** and **3** and thermosetting polyurethanes have been obtained from **2**. Linear polymers were characterized by NMR spectroscopy and molecular weights could be determined by SEC**.** The thermal and mechanical properties of linear and thermosetting polymers have been investigated. Preliminary studies on the functionalization of vinylsulfide containing linear polymers are also reported.

Phosphorus-containing high oleic sunflower oil flame retardant thermosets

Moreno, M., Lligadas, G, Ronda, J.C.; Galià, M.; Cádiz, V.

Departament de Química Analítica i Química Orgànica, Universitat Rovira i Virgili, Carrer Marcel·lí Domingo s/n, Campus Sescelades, 43007 Tarragona, Spain

e-mail: maryluz.moreno@urv.cat

Introduction

Recently, the use of plant oils as renewable feedstock for the development of designed polymeric materials has received particular attention due to environmental and economic concerns.[1] Synthetic polymeric materials are used in many areas and thus the fire hazards associated with the use of these materials are of great concern for both users and manufacturers. Plant oil based materials, just than many other currently used polymeric materials, are flammable, being this flammability a shortcoming in some applications. According to the sustainability issues, the design of a flame retardant material must preserve the efficacy of function while reducing risk and toxicity to human health and environment. Phosphorus based polymers are a well established class of flame retardant material which are preferred to the widely applied halogenated flame retardants due to health and environment reasons.[2]

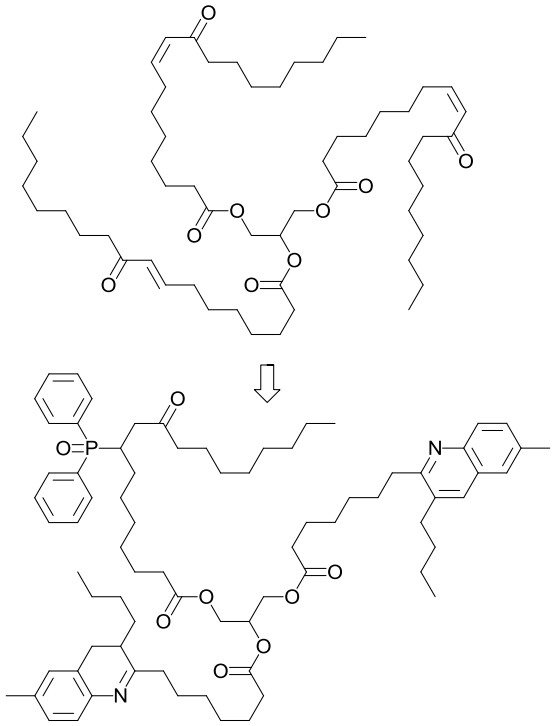
The main component of the triglyceride vegetable oils are saturated and unsaturated fatty acids. The reactivity of the internal double bonds is limited and much work has been done on the functionalization of triglycerides to obtain useful monomers.[3] We described a new environmentally friendly route to obtain a enone-containing triglyceride from high oleic sunflower oil. [4] This derivative can react with aromatic primary amines via aza-Michael addition. We reported the formation of quinoline-containing triglyceride-based thermosets when this reaction is carried out at high temperatures. [5]

The aim of this work is to synthesize new phosphorus-containing plant oil derived thermosets with flame retardant properties. The previously mentioned enone-containing high oleic sunflower oil derivative has been partially modified via phospha-Michael addition and crosslinked through aza-Michael amine addition to the remaining double bonds.

Results and Discussion

The phospha-Michael addition has been studied by using diphenylphosphine oxide and the enone derivative of methyl oleate as model compounds. ^{1}H NMR kinetic experiments allow to establish the best reaction conditions and BF_3 as the most effective catalyst.

High oleic sunflower oil has been modified by applying these reaction conditions. The reaction has been done taking into account the average number of double bonds in the starting materials and designing a final thermoset with a phosphorus content of 2,5% weight. The chemical structure of the phosphine oxide containing triglyceride was assessed by FTIR and NMR spectroscopy, supporting the complete addition of the phosphine oxide. In a further step, the remaining double bonds have been reacted with 4,4'diaminodiphenylmethane to obtain crosslinked thermosets. The materials were also obtained in a one pot procedure by carring out the phospha-Michael and the aza-Michael addition in one step.



The thermal, mechanical and flame retardant properties of the synthesized polymers were evaluated, showing that the incorporation of phosphorus improves the flame retardant behaviour of these materials.

Amphiphilic triblock copolymers of poly(ethylene glycol) and l-lactide: a possible mechanism of polymerization for coordination/insertion catalysts.

Rafael Bergamo Trinca[1], *Heitor Fernando Nunes de Oliveira*[2], *Maria Isabel Felisberti*[3]

Chemistry Institute, University of Campinas (UNICAMP), P.O. Box 6121, Zip Code 13083-970, Campinas - SP, Brazil

[1]rafaeltrinca@gmail.com, heioliveira@iqm.unicamp.br, [3]misabel@iqm.unicamp.br

Introduction

Amphiphilic polymers are macromolecules which simultaneously presents hydrophilic and lipophilic segments. This property may be reached by the synthesis of block copolymers, and in this case the choice of the blocks will lead to the final properties of the materials.

The synthesized copolymers, PLLA-*b*-PEG-*b*-PLLA, combine the characteristics of PLLA, such as biodegradability and lipophilicity, with the PEG biocompatibility and hydrophilicity. In other words, this triblock copolymer is a suitable candidate to use in pharmaceuticals, medical and biomedical engineering field.

There are many proposals to the catalytic mechanism of coordination/insertion ROP used to produce these copolymers. In order to study the mechanism of catalysis of tin 2-ethylhexanoate, two reactions conditions were proposed.

Materials and Methods

General synthesis of PLLA-b-PEG-b-PLLA copolymers

The copolymers were synthesized by Ring Opening Polymerization in toluene solution using 2-ethyl-hexanoate Sn(II) as catalyst. The macro initiator PEG is pre added to the reaction media with the catalyst to pre activation and then the monomer is added.

Catalyst Study

In order to study the catalyst action, two different ratios of the catalyst where used:

Method A: an equimolar ratio of catalyst and PEG hydroxyls groups was used.

Method B: the amount of catalyst used was related to the monomer LLA. The average LLA/ $Sn(oct)_2$ molar ratio was $n_{LLA}/n_{Sn(oct2)}$= 5000 This method is the most common on literature. [1,2,3,4]

Five different molar ratios of LLA and EG were used (n_{LLA}/n_{EG} = 0.3; 0.5; 1.0; 1.5 and 2.0).

Results and Discussion

The synthesized copolymers were characterized by ^1H NMR, DSC, TGA and GPC techniques. *Figure 1a* and *1b)* show the molar fraction of LLA in the copolymers obtained by using *Method A* and *Method B*, respectively. While copolymers obtained by using *Method A* kept the molar ratio of the reactants, in a very close agreement, the products from the *Method B* were richer with PEG in comparison with the reaction medium, an indicative of poor LLA monomer conversion.

DSC results showed a depression of the melting point of PEG crystalline phases, which were more pronounced in the *Method A* copolymers.

GPC analysis showed that the *Method A* materials present only a molar mass distribution while the *Method B* materials present a bimodal molar mass distribution, which means that side reactions are took place, like such as homopolymerization.

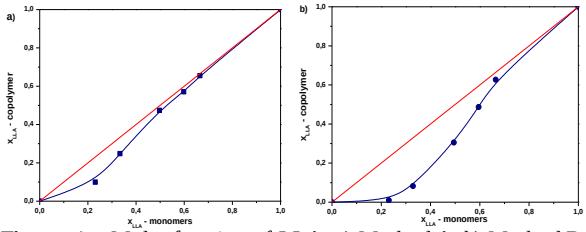

Figure 1 – Molar fraction of LLA: a) Method A, b) Method B;

The table bellow show the M_n molar mass obtained by GPC technique for these copolymers.

Method A	M_n (kDa)	Method B	M_n (kDa)
LP-8A-0.3	6.6	LP-8B-0.3	6.0
LP-8A-0.5	9.3	LP-8B-0.5	6.0
LP-8A-1.0	14.8	LP-8B-1.0	8.7
LP-8A-1.5	15.7	LP-8B-1.5	11.6
LP-8A-2.0	14.9	LP-8B-2.0	16.6

The molar mass M_n of PEG used as macro initiator was 5,8 kDa. Therefore, the molar mass of the *Method B* copolymers monomer molar ratios from 0.3 to 1.0 corresponds to a insertion of around 3 to 10 LLA units in the PEG macro initiator; this means these copolymers contain small PLLA block, which does not affect the PEG blocks crystallization.

Moreover, the *Method A* materials showed a noticeable growth of PLLA blocks, leading to the desired copolymers with best monomer conversion and reaction control.

Conclusion

The results presented in this work allow us to conclude that the hypothesis assumed in *Method A* is true. The coordination of each reactive PEG hydroxyl group leads to better results; in other words, the growing chains keep the coordination with the catalyst until a chain termination agent is added. *Method B* conditions, which use a small amount of catalyst, leave an excess of unreacted PEG and LLA monomer. This is due to absence of uncoordination of growing chains, as well as PEG chains, leading to a low conversion of monomer.

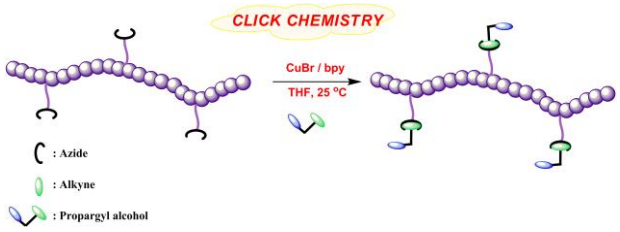
Introduction

Numerous methods have been explored for the modification of existing materials or synthesis of new types of organic materials containing triglyceride oil. These materials play important role in industrial applications in the production of coating materials, lubricants, printing inks, soap, and surface active materials. Without any advancing modification as a coating material, film characteristics of a coating material reflected by triglyceride oils can not provide the desired properties such as drying time, flexibility, adhesion, hardness, resistances to water, alkali and acid. For the chemical modification various types of vinyl monomers are used. Among these monomers, styrene is the most widely used to improve the film properties [1].

In our laboratory, several studies from our laboratory were reported for the modification of oils in order to obtain oil-based binders [1-5]. As a continuation of these studies, in the present study, "click" chemistry strategy was applied as a new route for the preparation of styrenated oil. In the modification, polystyrene (PS) samples with controlled molecular weight and narrow polydispersity index, which were prepared by nitroxide mediated radical polymerization (NMRP) technique, were used [2, 3].

"Click" chemistry strategy provides quantitative yields, high tolerance of functional groups, insensitivity of the reaction to solvents, moderate reaction temperatures, possibility of working under both homogeneous and heterogeneous systems, short reaction times and high selectivity [6]. These mentioned benefits will be valid in this new styrenated oil production by "click" chemistry approach.



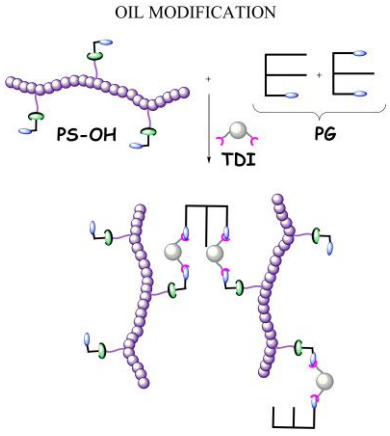
Scheme-1: Hydroxyl functionalized P(S-*co*-CMS) by "Click" chemistry.

Materials and Methods

The copper (I) catalyzed azide-alkyne cycloaddition (CuAAC) between terminal alkynes and azide were performed in the styrenated oil preparation. Copolymers of styrene and 4-chloromethyl styrene (P(S-*co*-CMS)) were prepared by NMRP technique and the chloromethyl groups were converted to azido groups by using NaN_3 and these azido groups were coupled with propargyl alcohol to result in hydroxyl groups on the PS chain by "click" chemistry (Scheme-1). In the next step these alcohol groups (PS-OH) were combined with the partial glyceride (PG) hydroxyls by the reaction of 2,4-toluene diisocyanate (TDI) (Scheme-2). The structures of the products were confirmed by FTIR and H^1-NMR. Thermal properties were determined by DSC and TGA analyses. In the end the sample was investigated in view of the film properties.

Results and Discussion

In this study, main goal is to modify triglyceride oils by using "Click" chemistry approach. For this purpose hydroxyl functionalized PS was prepared by "click" reaction and then PG's were incorporated to the PS chain. The usual benefits of the "click" reaction were also noted in the styrenated oil process. The obtained styrenated oil samples showed good film properties.



Scheme-2: Oil modification step.

Conclusion

The results showed that the "click" chemistry could be applied successfully for the modification of triglyceride oil through styrenation. It should be noted that the advantages of the "click" reaction was reverberated to this new process.

Abstract: Polymer layered silicate nanocomposites have been studied for nearly 50 years, but many papers focus only on the importance of the chemistry used to modify the surface of the filler, without including considerations about the role of processing conditions. Nanocomposites synthesis by conventional polymer processing operations requires strong interfacial interaction between the polymer matrix and the clay to generate shear forces of sufficient strength in order to improve clay exfoliation[1]. Nylon 6 (N6) /clay nanocomposites have gained particular attention since the earliest researches, but studies have been concentrated mainly on preparation methods involving in situ polymerization[2]. Although the increase in barrier properties is claimed for this type of materials, there are very few papers about the improvement of barrier performances. Starting from these considerations the aim of this work was to show that the degree of clay delamination and dispersion depends on a combination of effective chemical treatment and optimized processing conditions. In this study the clay has been intercalated with organic species such as hexadecyltrimethyl ammonium chloride according Valenzuela et al.[3] (MMTAO2) and ε-caprolactam in HCl medium[4] (MMTA2). Polymer/clay nanocomposites were then prepared by two techniques. . The first was a melt intercalation process in a mixer chamber at 240°C for 10 min and 60 rpm with a 3% fill factor obtained from intercalated clays and commercial Nylon 6 (Nylodur) called N6/MMTA2 and N6/ MMTAO2.The other was an in situ polymerization process from intercalated material using the Kojima et al. techniques[4] for mixture of MMTAr2 and MMTAO2 with ε-caprolactam and 6-aminocaproic acid, as accelerator. A polymerized nylon "in situ" has been obtained, called MMTA3 and MMTAO3. Films for characterization were manufactured by compression molding in a Carver press, heating at 240°C and cooling the film in a cold press at room temperature. Barrier properties of N6/clay nanocomposites were studied by cyclohexane pervaporation. The influence of exfoliation and/or intercalation of clay platelets on barrier properties were then examined. In addition, the morphologies of N6/modified clay nanocomposites were studied by X-ray diffraction (XRD), scanning electron and transmission electron microscopy (SEM and TEM) and thermal gravimetric analysis (TGA). In figure 1 and figure 2 it can be observed that intercalation occurs for MMTA3 and N6/MMTA2, but a substantial reduction in the intensity of the diffraction peak derived from the interlayer spacing of the clay, evident in the MMTAO3 and N6/MMTAO2 composites, indicates that almost complete exfoliation of the silicate layers took place and the nanocomposite structure was obtained.

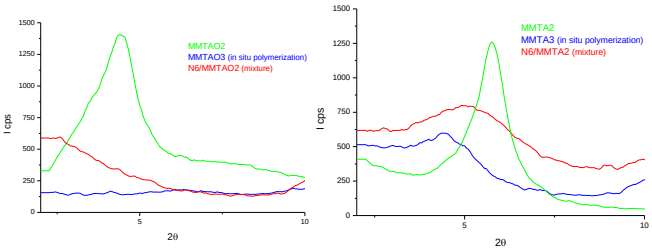

Figure 1 and Figure 2: XRD patterns for modified clays and the composites for two types of processing, mixture and "in situ" polymerization.

Results of TEM show that the addition of modified clay changes the material morphology and that the obtained materials present an intercalated and/or exfoliated nanocomposite structure (Figure 3 and 4).

Figure 3 and Figure 4: TEM images of a) N6/MMTA2 and b) MMTA3

All thermal degradation profiles were obtained from TG and DTG curves, with the course of the decomposition has that has been affected by the structure of the organoclay.
The decrease in the pervaporation values of nanocomposites, considering pure nylon 6 as reference, is associated with a reduction of free volume and mobility of polymer chains resulting in lower permeated flows. Hence it has been concluded that chemical modification of the montmorillonite clay and an adequate processing of polymer clay composites are necessary to generate polyamides with enhanced barrier properties without losing the properties of pure polymer.

Thermoplastic Polyurethanes with Undecylenic Acid-based Soft Segments: Synthesis and Properties

Lluch, C.; Lligadas, G.; Ronda, J.C.; Galià, M.; Cádiz, V.

Department of Analytical Chemistry and Organic Chemistry, Rovira i Virgili University, Marcel.li Domingo s/n, 43007 Tarragona (Spain)

marina.galia@urv.cat

Introduction

The popularity of polyurethanes (PUs) for biomedical applications stems from their excellent physical properties and good biocompatibility. Plant oils incorporation into PUs is known to provide flexibility, low melting temperature, hydrophobicity and pliability. Most importantly, it's degradation into naturally occurring compounds expands its utility in various medical applications like drug delivery and temporary implantable devices. Nowadays, the design of novel biobased polyols derived from plant oils is an active area of research.[1] By taking advantage of the wide variety of possibilities for chemical modification of plant oils, there is a broad palette of strategies to functionalize its structure with hydroxyl groups. Here, we report the preparation of novel thermoplastic PUs based on undecylenic acid, a major product of castor oil pyrolysis. The materials were characterized for properties relevant to biomaterial applications.

Materials and Methods

Soft segments used in this study were prepared from potentially 100% biomass-derived monomer, allyl ester of 10-undecenoic acid (UDA) via two one-pot thiol-ene click reactions.[2] The general chemical structure of these telechelic diols is shown in Figure 1a. PUs with 0, 40, and 60% hard segment content were synthesized in two-steps from UDA-based diols with M_n of 1000, 2000, and 3000 Da, diphenylmethane diisocyanate, and 1,4-butanediol in DMF solution at 70ºC. Polymers were analyzed by DSC, FTIR, SEC, DMTA, TGA and tensile tester. In addition, given the potential use of these materials for biomedical applications, hydrolytic degradation, biocompatibility, and performance as drug carriers have been evaluated.

Results and Discussion

As mentioned above, three series of PUs based on renewable oligomeric diols of different molecular weight as soft segment, and 1,4-butanediol, as chain extenders, in the hard segment structure have been synthesized via two-step polymerization to produce materials with distinct microstructures and properties. DSC and DMTA analysis showed several transitions associated with soft and hard segments in the low and high temperature range, respectively. Segmented PUs posses a nearly constant soft segment Tg values with the increase of hard segment content, as a result of the chain extension occurring during the first step of polymerization. However, when UDA-based diol with M_n of 1000 Da was used small amount of hard segment mixed in the soft domains. FTIR analysis confirmed the formation of disordered hard segment domains at high hard segment contents which were imaged by using tapping mode AFM. The thermal degradation follows the same trend in all synthesized PUs showing three main degradation steps, whereas mechanical properties were found to be governed by hard segment content.

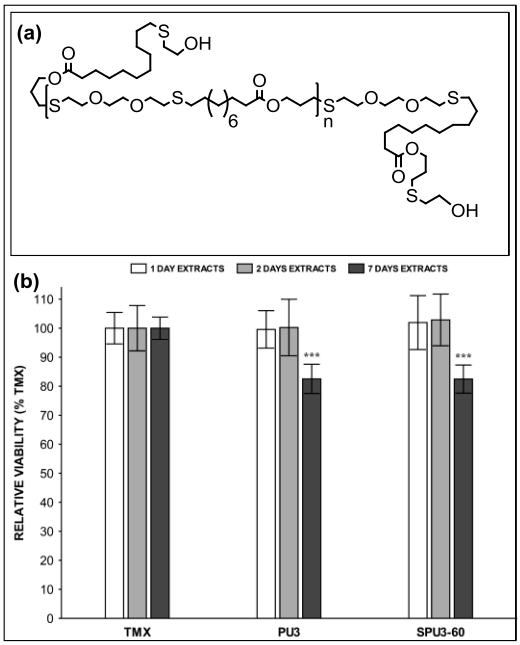

Figure 1. (a) Chemical strucucture of undecylenic acid-based soft segment. (b) MTT cytotoxicity results for control TMX, PU3, and SPU3-60.

Hydrolytic degradation of these materials was studied by placing individual samples in a phosphate buffer solution at 37 and 60ºC. Over a period of 3 months no significant mass loss of the polymer was detected. The biocompatibility of PUs and their parent diols was tested using a standard MTT cytotoxicity assay. The data in Figure 1b indicates that PUs extracts are not statistically toxic to human fibroblasts. Finally, drug-delivery experiments using rhodamine B showed that synthesized PUs provide a prolonged diffuse-controlled release and therefore could be suitable in applications where prolonged drug action over some days is required.

Conclusions

The suitability of the UDA-based telechelic diols as components for the synthesis segmented PUs with promising applicability as biomaterials has been demonstrated.

Polybenzoxazine Prepolymers from Renewable Fatty Acid Derivatives

Tüzün A.; Lligadas, G.; Ronda. J.C.; Galià, M.; Cádiz, V.

Department of Analytical Chemistry and Organic Chemistry, Rovira i Virgili University, Marcel.li Domingo s/n, 43007 Tarragona (Spain)

Introduction

Polybenzoxazines are a new class of phenolic resins that can be prepared easily from phenols, primary amines and formaldehyde. The wide variation of raw materials allows considerable molecular-design flexibility for these monomers. The properties of polybenzoxazines are comparable or even superior to traditional phenolic resins, but polybenzoxazines also overcome many of the problems associated with phenolic resins. Benzoxazine polymerization exhibits negligible volumetric shrinkage, does not require any harsh acid catalyst, and has no reaction byproduct. Furthermore, polybenzoxazines posses excellent mechanical properties as well as thermal stability.[1]

However, there are some shortcomings for polybenzoxazines. The cured materials are brittle and relatively high temperature is needed for the ring-opening polymerization. Also, processing into thin film from the typical monomers is difficult because most monomers are powder and the polymers are brittle due to the short molecular weight of the network structure. In this way, extensive research has been done to address these specific drawbacks.

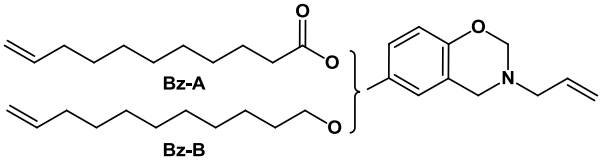
Traditionally, only low molecular weight benzoxazine monomers have been used as precursors of polybenzoxazines but in the last years linear polymeric benzoxazines have been developed by replacing the monofuncional amines and phenols by difunctional compounds. The resulting polymers contain benzoxazine units in the main chain and behave as a conventional thermoplastic which has good solubility, processability and film formation. This thermoplastic polymer can be crosslinked upon thermal treatment at elevated temperatures. Until now,[2,3] the approaches to prepare these useful low viscosity thermosetting polybenzoxazine precursors are based on the reaction of diamines of variable length and diphenols, thus producing polymers with uncontrolled molecular weight and high polydispersity.

We have recently demonstrated that thiol-ene click addition of difunctional thiols to α,ω-dienes is a straightforward methodology to prepare well-defined telechelics with controlled molecular weight.[4] Thus, in this work we have applied this methodology to two dienic benzoxazine monomer obtained from renewable unsaturated fatty acid derivatives.

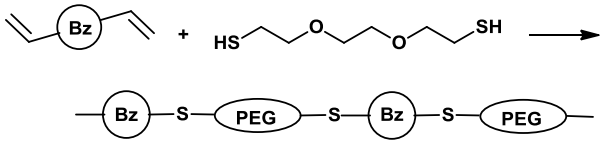
Results and Discussion

Two α,ω-dienic benzoxazine monomers were prepared following conventional synthetic approach using formaldehyde, allylamine and two p-substituted phenols derived from 10-undecenoic acid, a pyrolysis derivative of castor oil. The parent phenols were synthesized from 4-benzyloxyphenol by reaction with 10-undecenyl bromide or 10-undecenoyl chloride and further hydrogenolytic deprotection of the benzyl groups. In this way the 3-allyl-6-(10-undecenoyl)-3,4-dihydro-2H-benzoxazine (Bz-A)

and the 3-allyl-6-(10-undecenyl)-3,4-dihydro-2H-benzoxazine (Bz-b) were obtained in good yield and purity as colourless oils.



NMR structural characterization confirmed the formation of the benzoxazine ring and the absence of phenolic by-products. The thermal curing behaviour of these benzoxazines was studied by DSC showing the polymerization activating effect of the N-allyl group described by some authors. Bz-A or Bz-B and 3,6-dioxa-1,8-octanedithiol (DODT) were "clicked" to prepare benzoxazine-containing linear polymers with variable molecular weight by thiol-ene step–growth polymerization. The obtained low to medium molecular weight polymers were characterized by NMR, SEC and MALDI-TOF-MS which confirmed the high efficiency of this methodology.



Kinetic studies by NMR allowed establishing the different reactivity of both ene groups, which leads to polymers predominantly ended by the less reactive allyl groups. Finally the curing behaviour of these low viscosity benzoxazine prepolymers was studied by DSC and the thermal and mechanical properties evaluated by TGA and DMTA.

gituchia@gmail.com

Molecular imprinting is an approach to study and/or mimic nature. In this technique a target molecule acts as a template around which monomers and cross-linking agents are arranged and copolymerized. After the template removal, binding sites complementary to the template are left in the resulting polymer. These binding sites are stabilized by the cross-linked structure and, like binding sites of biological receptors, are able to rebind the template selectively. [1]

In this contribution we present a preparation of molecularly imprinted polymer nanoparticles (NP) via polymerization in oil-in-oil emulsion [2, 3]. The biggest advantage of the presented method is the absence of water which can hamper the stability of monomer-template assembly during non-covalent imprinting thus decreasing the efficiency of the imprinting process. This problem is avoided here since polymerization occurs in droplets of acetonitrile (ACN) or dimethylformamide (DMF) dispersed in an immiscible non-polar phase such as cyclohexane or *n*-hexane. In this way, it is possible to prepare monodisperse molecularly imprinted polymer nanospheres of around 100 nm in size.

Imprinted (MIP) as well as non-imprinted nanoparticles (NIP) were synthesized using methacrylic acid (MAA) and ethylene glycol dimethacrylate (EDMA) as a functional monomer and cross-linker, respectively. Molecularly imprinted nanoparticles were prepared using different MAA:template ratio to study the effect of template present during the polymerization on rebinding properties of nanoparticles. All NP were characterized using dynamic light scattering and scanning electron microscopy (SEM) (Fig.1).

The efficiency of template removal and the rebinding properties of NP were studied by UV-Vis spectroscopy. Interactions between the template and the polymer were studied using Isothermal Titration Calorimetry (ITC).

Successful molecular imprinting of these nanoparticles was proved, and the resulting imprinting efficiency was indeed found to be superior to that obtained through related emulsion polymerization approaches using water.

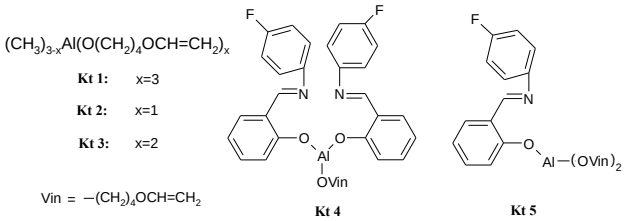
vasilenkoi@bsu.by

Introduction. Polyesters like poly-ε-caprolactone, polylactide and its copolymers have a great importance because of their biodegradability, biocompatibility and good compatibility with many other polymers. They are widely used in medicine, pharmacology, in the production of environment friendly polymer materials etc. Recently, considerable attention has been paid to the synthesis of functionalized polylactones due to the possibility to use them as building blocks, macromonomers or macroinitiators. This work is devoted to the investigation of ε-caprolactone polymerization initiated by simple functional aluminum alkoxides (**kt1**–**kt3**, Scheme 1) as well as new Al complexes with phenoxy-imine ligands (**kt4**, **kt 5**, Scheme 1).



Scheme 1. Structures of catalyst used in this work

Results and Discussion. The main results of ring-opening polymerization of ε-caprolactone in the presence of aluminum alkoxides as catalysts are summarized in Table 1.

Table 1. Polymerization of ε-caprolactone in bulk initiated by functional aluminum-based catalysts

kt	T (°C)	time (min)	conv (%)	M_n[a]	PDI	F_n[b]	N[c]
1	40	40	69	16800	1.28	90	1.0
2		180	45	18870	1.36	100	1.0
3		545	55	21320	1.22	105	0.9
2	80	120	99	35600	1.62	95	1.0
3		120	97	20400	1.57	112	1.7
4		20[d]	15	4660	1.81	37	1.0
5		20[d]	60	14820	1.16	70	1.3
4	130	60	94	19380	1.45	65	1.4
5		60	93	24000	1.63	75	1.2

Conditions: [Al]=31.5 mM; [M]/[Al]=300. [a] Calculated according to following equation: M_n=0.52×M_n(SEC). [b] Calculated from ^{1}H NMR spectra as follows: F_n=2I(-O-C<u>H</u>=CH$_2$)/I(-C<u>H$_2$</u>-OH)×100. [c] N-number of chains per catalyst molecule, calculated as N=M_n(theor)/M_n(exp), where M_n(theor)=[M]/[kt]×114×Conv. [d] Time in hours.

As shown in Table 1, all aluminum alkoxides (**kt1**–**kt3**) studied in this work exhibited low activity at 40 ºC, although polyesters with high molecular weight (M_n up to 20,000 g mol^{-1}) and narrow molecular weight distribution (M_w/M_n≤1.36) could be obtained under these conditions (see Table 1). Among aluminum alkoxides studied, the highest activity showed **kt1**. Importantly, all polymers synthesized at 40 ºC are characterized by excellent functionality at the ω-end. The number of vinyl group per Al atom (N) equals 1.0 for all investigated catalysts at 40 °C despite the fact that di- and trialkoxyaluminum have two and three reactive groups, respectively. This is likely due to the aggregation of catalysts at low polymerization temperature, that is in agreement with data obtained earlier in ε-caprolactone polymerization with Al(O^{i}Pr)$_3$ as catalyst by Duda and Penczek [1].

The increase of the polymerization temperature up to 80 ºC led to increase of the catalyst activity of functional aluminum alkoxides (full monomer conversion less than for 2 h) keeping a high functionality of synthesized poly-ε-caprolactones (F_n~100%). However, some broadening of MWD was observed (see Table 1). The Al complexes with phenoxy-imine ligands (**kt4**, **kt 5**) exhibited low activity in comparison with aluminum alkoxides, although **kt5** afforded polymers with low polydispersity (M_w/M_n=1.16) and acceptable functionality (F_n=70). These complexes showed a good activity only at 130 ºC affording polymers with relatively broad MWD (M_w/M_n=1.45–1.63) and acceptable functionality in the case of **kt5** (Table 1).

Conclusions. In this work, we demonstrated that simple functional aluminum alkoxides are very effective catalyst for the synthesis of perfectly functionalized polyesters (F_n~100%) with M_n up to 20,000 g mol^{-1} and relatively narrow MWD (M_w/M_n<1.6) at elevated temperatures (40–80 ºC). The Al complexes with phenoxy-imine ligands exhibited high activity only at 130 ºC affording polyesters with acceptable functionality (F_n~75%) and MWD (M_w/M_n<1.6).

Introduction

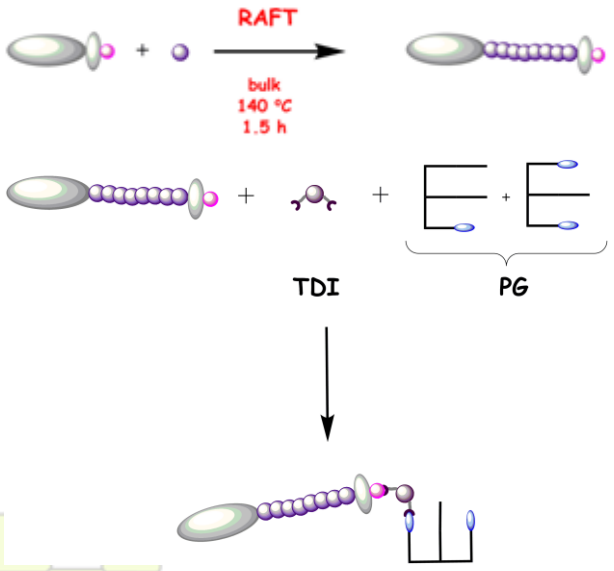
Triglyceride oils as natural sources are widely used in organic coating materials. In order to improve the film properties, modification processes are applied. For this purpose, styrenation is the well known modification method. In classical styrenation due to the homopolymer formation, the film properties of resulting product are not at the desired level. In order to eliminate the homopolymer formation, previously several studies were carried out in our laboratory [1-6]. Very recently the styrenation of triglyceride was carried out by the living/radical polymerization techniques [1, 3]. In a continuation of these studies, in the present study styrenated oil was prepared by RAFT technique using carboxylic acid functionalized RAFT agent (S-1-Dodecyl-S'-(α,α'-dimethyl-α"-acetic acid)-trithiocarbo-nate) [7].

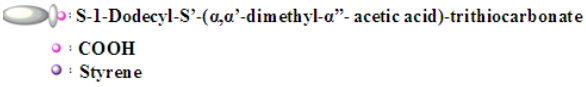
Materials and Methods

Styrene (St) and 2,4-toluene diisocyanate (TDI) were purchased from Aldrich chemicals. As mentioned before, styrenated oil was prepared by the RAFT method. For this purpose polystyrene (PS) was prepared by the acid functionalized raft agent. The obtained PS chains were combined with partial glyceride (PG) by the reaction of TDI.

Results and Discussion

The applied styrenation process was explained in Scheme 1.





Scheme 1: The production of styrenated oil

In order to obtain a styrenated oil sample with good film properties, the PS/PG ratio and the molecular weight of PS were determined. Optimum PS/PG molar ratio and the molecular weight of PS were found to be 1/0.125 and 6589 Daltons, respectively. The obtained product showed good film properties.

Conclusion

In the present study, the styrenated oil was prepared by RAFT technique using acid functional RAFT agent. This new route provided the styrenated oil with good film properties.

Starch containing polyurethanes: structure and biodegradability

Travinskaya T., Mishchuk E., Savelyev Yu.

Institute of macromolecular chemistry, NAS of Ukraine, Kharkovskoe shosse, 48, o2160, Kiev, Ukraine

travinskaya-tamara@rambler.ru

Introduction. The increasing problem of accumulative plastic wastes and exhaustion of mineral oil have stipulated for the creation of biodegradable polymer materials on the basis of renewable recourses. Natural compounds based biodegradable waterborne polyurethanes are of increasing interests due to combination of their pollution free status and high performance properties.

Materials and Methods. In this work starch (1,5-35 wt%) containing aqueous polyurethane dispersions (IPU/St) with tailorable susceptibility for acid and alkaline hydrolysis, microorganisms' attack (*Bacillus subtilis*), temperature, UF radiation, and soil microflora have been obtained by dispersing of anionic oligourethane (based on hexamethylene diisocyanate and polyoxytetramethylene glycol) with starch water solution on the stage of chain extension. Supramolecular structure and degree of phase separation of the based film materials were evaluated by infrared spectroscopy (FTIR) and small X-ray scattering (SAXS). Relaxation behavior of IPU/St was studied by dynamic mechanical analysis; thermal-physic and viscoelastic properties were studied by DSC. Thermodestructive processes were evaluated by pyrolytic mass-spectroscopy.

Results and discussion. Obtained materials combine high physic-mechanical characteristics (tensile strength 8-13 MPa, elongation at the break point 875-2000%) and susceptibility to biodegradation: the adhesion of microorganisms (*B. sub*). to the film surface is one order higher in comparison with initial IPU. Besides, IPU/St samples are more exposed to acid and alkaline hydrolysis compared to IPU. Thermostability of the hydrolyzed films decreases drastically. Introduction of the St essentially changes the viscoelastic behavior of IPU material: the height of α-transition has been changed at low St content due to decrease of the part of flexible component and it localization during the hydrogen bonds formation. The further increase of St content leads to the formation of more ordered periodic structure. The IR-spectroscopy and dynamic thermal mechanical analysis data testify to the formation of intermolecular hydrogen bonds between urethane linkages of IPU and hydroxyl groups of St, and the analysis of pyrolysis mass spectra (after storage the samples in the soil during 6 month) allows to conclude the existence of chemical interaction between NCO groups of IPU precursor and hydroxyl groups of St. In accordance with pyrolysis data it should be noted that among native St destruction products', only a few have been observed among the pyrolysis products of starch-containing polyurethane dispersions. The formation of polymer-polymer amorphous micro areas in the composites' volume as the result of strong intermolecular interaction between components has been shown. All studied IPU/St systems are structurally heterogeneous. The higher the St content, the lower the
degree of microphase separation between the soft and hard blocks. Correspondingly, the degree of ordering of the hard blocks in domains as well as the domains in composites' volume becomes lower.

Conclusions. Thus, the novel biodegradable polyurethane-starch containing materials have been developed. The structural organization of the obtained IPU/St systems, and therefore their properties and ability to biodegradation are determined by their composition.

Preparation of Ordered Au/PEO-*b*-PFOMA Hybrid Films Through Phase Transition of Micellar Thin Films

Introduction

Gold nanoparticles (NPs) have attracted much interest for applications as catalysts, chemical sensing and as well as building blocks for electronic devices that operate at the single-electron level. Semifluorinated block copolymers (BCPs) are amphiphilic materials that combine the unique self-assembly characteristics of block copolymers and the unparalleled properties of fluorinated polymers. Fluorinated blocks have attracted much attention due to their unique properties such as low surface energy, excellent chemical and thermal stability, low refractive index and dielectric constant, which cannot be achieved by the corresponding non-fluorinated materials. This paper reports a simple *in situ* synthesis of gold NPs in semifluorinated BCP thin films and size change of the NPs through a phase transition of the BCP thin films. Three different annealing modes of $LiAuCl_4$-load block copolymeric thin films were employed: in solvent vapor annealing at 70 ^{0}C, in supercritical CO_2 at 70 ^{0}C and in a vacuum oven at 100 ^{0}C. $LiAuCl_4$, gold precursor complexed with BCP consisting of semifluorinated and PEO blocks were reduced to Au nanoparticles that were well dispersed in the PEO phase of the disordered BCPs micellar thin films. The same sample after annealing, the formation of larger single gold particle per PEO domain with a small variation in size was observed.

Experimental

The semifluorinated BCPs, poly(ethylene oxide)-block-poly(1H,1H-perfluoro octyl methacrylate) (PEO-*b*-PFOMA) were synthesized by ATRP of FOMA using PEO-Br as the macroinitiator in the mixed solvent of TFT and benzene as described previously. For this study, 10k was utilized to make PEO_{10k}-*b*-$PFOMA_{12k}$.

PEO_{10k}-*b*-$PFOMA_{12k}$ was dissolved in $CHCl_3$ to yield 0.5 wt% solutions. $LiAuCl_4$ loaded micellar solutions were prepared by adding 0.1 wt% of $LiAuCl_4$ (99.995%, Aldrich) into the pre-prepared copolymeric micellar solutions. The thin films were prepared on mica substrates by spin-coating of the BCPs micellar solutions and $LiAuCl_4$ treated micellar solutions. Such the thin film was annealed in a vacuum oven at 100 ^{0}C for 24 h, $scCO_2$ annealing and PF-5080 vapor annealing at 70 ^{0}C.

Results and Discussion

Amphiphilic BCPs self-assemble into micelle-like objects when dissolved in solvents that are selective good solvents for one of the blocks. When the soluble block is much shorter than the insoluble block, the aggregates form a crew-cut morphology. $LiAuCl_4$ loaded micellar solutions were prepared by adding 0.1 wt % of $LiAuCl_4$ into the pre-prepared copolymeric micellar solutions. In TEM image, the gray regions are the PFOMA phase in accordance with the higher electron density of the fluorinated blocks, the bright color of the PEO phase is marked by dark dots, which are gold nanoparticles resulting from the reduction of tetrachloroaurate ions due to an interaction with PEO chains. It is clear that gold nanoparticles are well dispersed in the PEO phase and were not located in the entire PFOMA phase; and it showed a denser array of NPs. In the thin films, the average diameter of the gold nanoparticles was 6 nm. For phase transition, the thin films were annealed under saturated PF-5080 at 70 ^{0}C, in a supercritical fluid ($scCO_2$) environment at 70 ^{0}C, or thermally at 100 ^{0}C in a vacuum oven. Each treatment imparts mobility to the BCP thin films, allowing them to reach the equilibrium morphology. During phase transition, the nanoparticles were moved together with the PEO blocks, leading to the formation of a larger single particle in each domain. The particle size distribution of the gold nanoparticles from annealing at 100 ^{0}C was smaller than that from annealing in $scCO_2$ at 70 ^{0}C but broader than that from annealing in PF-5080 vapor at 70 ^{0}C. But in the case of $scCO_2$ annealing, many gold nanoparticles were observed. It is most likely that all nanoparticles locating in the PEO phase were constrained to follow the morphological change more easily than in the case of thermal and solvent treatment.

Conclusions

This study demonstrated the formation of larger single gold NPs in each phase PEO domain from a number of well dispersed smaller gold NPs within the self-assembled copolymeric thin films after annealing. PEO_{10k}-*b*-$PFOMA_{12k}$ diblock copolymers provide an excellent means of producing well dispersed gold NPs in the PEO phase with an average particle diameter of 6 nm. While the phase transitions that enable control of the size and location of the nanoparticles within a bulk BCP can be accomplished by exposing a BCP to any selective solvent, the use of supercritical fluids offers the possibility of tuning the morphology of the polymer in a very controlled manner. Sintering of NPs using phase transition of semifluorinated BCP is a simple and versatile method that can be extended to other particles.

Department of Imaging System Engineering, Pukyong National University, Busan 608-739. Korea

E-mail: ktlim@pknu.ac.kr

Introduction

Poly(acrylic acid) is typical hydrophilic polymer and known as a weak polyelectrolyte. It can form complexes with some metal ions or organic compounds.[1] Block copolymers containing polyelectrolyte segment have structural features of polyelectrolytes, block copolymers and surfactants. The self-assembled nanostructures lack stability and tend to spontaneously dissociate into unimers under various factors such as temperature, high dilution or changes in ionic strength, which results in decreasing their efficiency in role as vehicles for drug and gene delivery. A variety of strategies have been explored to enhance the structural integrity of polymeric micelles of block copolymers. The cross-linking reaction performed within core domain[2] or through shell layer[3] was often employed for this purpose. Here, we reported the preparation of stable micelles by core-surface crosslinking.

Two types of amphiphillic PAA-b-PS diblock copolymers of different lengths of PS segment were prepared by reversible addition fragmentation chain transfer (RAFT) radical polymerization. Subsequently, the micelles of the block copolymers were subjected to *in situ* inter-block crosslinking by RAFT of divinyl benzene.

Experimental

Two types of amphiphilic diblock copolymer poly(acrylic acid)-*b*-polystyrene (PAA-*b*-PS) were synthesized by (RAFT) polymerization in dioxane by using trithiocarbonate-terminated PAA as a macroinitiator. The aggregates, star-like micelles and crew-cut aggregates, consisting of PS cores and PAA coronas, were prepared by direct dissolution of the copolymer in a selective solvent, ethanol. Subsequently, core-shell interface cross-link was governed by RAFT polymerization using divinylbenzene as a crosslinking agent.

Results and Discussion

The chemical structures, compositions of block copolymers, morphology and the size of the core-cross-linked micelles were characterized by NMR, FTIR, GPC, TEM, SEM. TEM images of the block copolymeric micelles before and after crosslinking reaction indicated that most of structures of star-like micelles were found to be globular aggregates with diameter ranging from 30 nm to 50 nm. Unlike the star-like micelles which is existing in solution as discrete spherical micelles, a large number of compound crew-cut micelles with diameter range from 50 nm to 120 nm were observed for larger PS block copolymers. Cross-linked micelles were found to have diameters much larger than those of initial micelles. There was a remarkable change in the structure of micelles after crosslinking reaction. The necklace-like compound nanoparticles were obtained after crosslinking crew-cut aggregates. The decrease of the cross-linking agent led to the formation of discrete cross-linked star-like micelles with average diameter of 80 nm.

Conclusions

Cross-linked spherical micelles from two types of PAA-*b*-PS diblock copolymers with the same PAA block length but different length of PS segment were prepared by RAFT technique. The self-assembly of the block copolymers in ethanol, followed by the inter-block crosslinking reaction with divinyl benzene which was occured *in situ*, provided an efficient method for the preparation of stable nanosized micelles.

Ethylene/1-Octene Copolymerization with Supported Salen-Type Complexes. Effect of Metal Type

Anna Pietruszka, Marzena Białek, Krystyna Czaja

Opole University, Faculty of Chemistry, Oleska 48, 45-052 Opole, Poland

krystyna.czaja@uni.opole.pl

Introduction

Linear low-density polyethylene (LLDPE) synthesized by copolymerization of ethylene with 1-olefins is among the polymers with highest production capacity. The structure and properties of such copolymer, for example its molecular weight, microstructure, density, melting point, and crystallinity depends on polymerization conditions, especially comonomer concentration, and are also influenced by catalytic system composition [1,2]. The subject of this work is the study of ethylene copolymerization with 1-octene over salen type complexes of titanium, zirconium and vanadium (Fig.1) supported on $MgCl_2(THF)_2$ modified by Et_2AlCl. The studies included the effect of transition metal type in catalyst as well as the effect of 1-octene concentration in the feed on catalyst productivity, comonomer reactivity and on copolymer composition and other properties of ethylene/1-octene copolymers produced. Moreover, the obtained results were compared with those obtained for appropriate salen complexes not immobilized on the carrier.

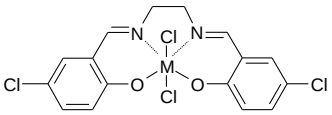

Fig. 1. Structure of salen complexes (M=Ti, V, Zr)

Materials and Methods

Materials. Ethylene (3.0 grade, Linde Gas) was purified by passing it over a column of sodium metal supported on Al_2O_3. Hexane was distilled from sodium/benzophenone. 1-Octene (Aldrich) was dried over molecular sieves. MAO (Witco, 10.0 wt %), Me_3Al (Witco, 2 M), argon (5.0 grade, Linde Gas) were used as received.

Catalyst synthesis. The supported precatalysts were synthesized according to the procedure described in ref. [3]. The carrier material (2.19g) obtained by the reaction of $MgCl_2(THF)_2$ with the Et_2AlCl (Mg/Al = 1/2 mol/mol) was co-milled with appropriate salen complex (0.2309mmol) in hexane/toluene at room temperature overnight. The resulting solid was separated, washed several times with toluene and hexane and dried.

Ethylene/1-octene copolymerization. The reactor was filled with hexane (0.15L), the required amounts of cocatalyst and 1-octene and then the catalyst precursor was added. The copolymerization was initiated by the introduction of ethylene. The monomer pressure was kept constant during polymerization (0.5 MPa). The reaction was stopped after 0.5 hr by the addition of acidic methanol solution. The polymer was subsequently filtered off, washed with methanol and dried.

Characterization. Molecular weight and molecular weight distribution were determined by gel permeation chromatography (using the Alliance 135 GPCV 2000 apparatus from Waters) at 135°C. Trichlorobenzene was used as a solvent, at the flow rate of 0.6 mL/min. DSC analyses were carried out using the 2010 DSC calorimeter from TA Instruments. The heat of fusion (ΔH_f) and the melting temperature (T_m) were measured for samples which had been previously melted and re-crystallized at the heating rate of 10°K/min. The comonomer content in copolymer was determined by FT-IR with the use of the Nicole Nexus 2002 FT-IR spectrometer.

Results and Discussion

Salen type complexes, both supported and unsupported, proved to be active in ethylene/1-octene copolymerization. However, it was found that supported complexes are more active then their unsupported counterparts. Activity of all investigated catalysts, independently on their composition, decreases with the increase of the concentration of the comonomer in the feed.

The compositions of the copolymers were determined by the IR method. It was found that the 1-octene incorporation rises with the increase of the comonomer concentration in the feed for all studied catalysts. Nevertheless, the amount of comonomer incorporated meaningly depends on the type of catalytic system used. First of all, immobilization of salen complexes on a magnesium carrier reduced their copolymerisation ability. This mean that the high steric hindrance brought about by the presence of the support. Secondly, the type of transition metal also determined 1-octene incorporation. Copolymers with clearly higher comonomer content were obtained over vanadium complex then over its titanium counterpart.

As it was observed for ethylene/1-olefin copolymers obtained with different catalysts, melting point and crystallinity of obtained products decrease with an increase of comonomer content in the copolymer.

Conclusions

It has been demonstrated that postmetallocene catalysts containing salen type complexes of early transition metals can effectively copolymerize ethylene with 1-octene and that their copolymerisation behaviour is significantly influenced by presence of the support and type of transition metal.

beatriz.paredes@urjc.es

Copolymers of ethylene and α-olefin such as 1-hexene ($C_6^=$) are very important commercial products classified as linear low density polyethylene (LLDPE). Because of the short chain branches that 1-hexene introduces onto the polymer backbone, the copolymers have lower melting point, crystallinity and density than the corresponding homopolymers; therefore, they can find applications in packaging, shrink films and cable coatings.[1] In the case of the characterization of copolymers, it is very important to measure the chemical composition distribution (CCD) in order to get a more complete understanding of the catalysts active sites and polymer properties.[2] Typically, temperature rising elution fractionation (TREF) or crystallization analysis fractionation (Crystaf) are used to determine CCD.

Ethylene-1-hexene copolymers synthesized with several comonomer contents were analyzed by GPC, DSC, ^{13}C-NMR, Crystaf and TREF. The catalytic system $(nBuCp)_2ZrCl_2$/MAO was supported on SBA-15 mesoporous materials with different pore sizes (8.8, 11.3 and 22.7 nm). Crystaf and TREF profiles show a bimodal chemical composition distribution, suggesting two different contributions in the same copolymer in spite of using a single site metallocene catalyst.

In order to study the influence of this bimodal character on the copolymer properties, fractionation techniques were used with the purpose of obtaining fractions to be analyzed off-line and correlate their properties with the characterization of the overall copolymer. These fractionation techniques are based on crystallinity differences and they are performed by precipitation or dissolution through temperature changes. In this context, the aim of this work was the analysis of support pore size on ethylene-1-hexene copolymers properties at different comonomer contents.

Figure 1 shows TREF results. An increment on support pore diameter increases the comonomer incorporation, perhaps due to the lower steric hindrance for the 1-hexene molecules in supports with larger pores. Bimodality can be attributed to the parallel channels' structure of SBA-15 materials; there must be sites located deep inside the pores while other sites may be placed outer and exposed to higher comonomer concentrations. TREF profiles of the obtained fractions demonstrate that separation by preparative TREF was done properly and their characterization reveals that the two copolymers fractions have distinct 1-hexene contents, which determines their properties. Chemical composition distribution of F2 is wider than F1 as a there is more heterogeneity for external sites leading to a copolymer with wider CCD. So, each copolymer has two populations of polyethylene chains related with the textural properties of the support and both influencing in the final properties of the copolymer.

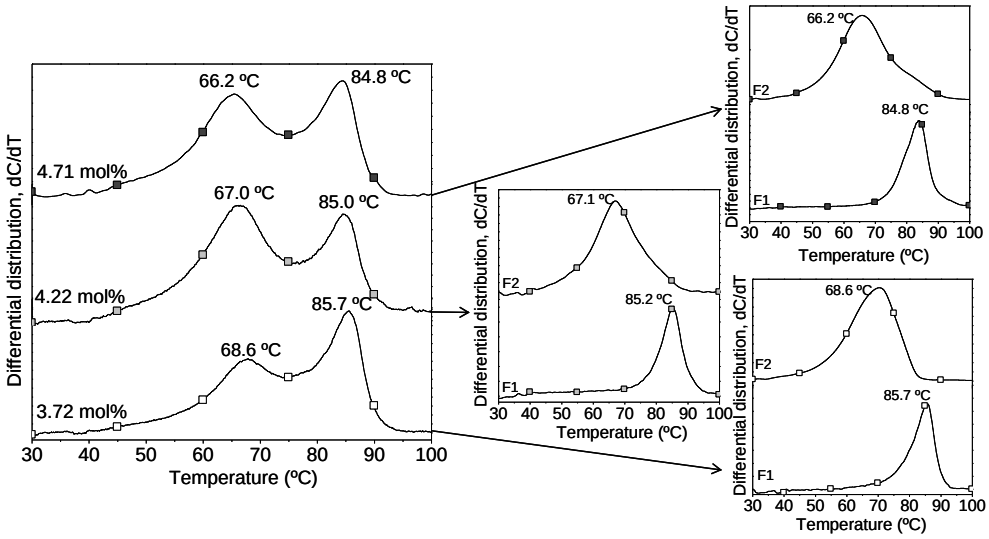

Figure 1. TREF profiles of ethylene-1-hexene copolymers and its fractions. Copolymers synthesized with MAO/$(nBuCp)_2ZrCl_2$ supported over SBA-15 materials with pore sizes 8.8 nm (□),11.3 nm (▣) and 22.7 nm (■).

e-mail: chabyfer@yahoo.es

Introduction

Curing shrinkage is an important issue in the processing of thermosets because of the generation of internal stresses, microcracks and microvoids that reduce the durability of the material. There are several methods described in the literature for the measurement of shrinkage, among which rheometric,[1,2] gravimetric[1,3,4] and laser dilatometry[3] methods seem to be the most reliable and meaningful in comparison with indirect estimation using densities measured at room temperature.[4] However, these methods have some disadvantages, such as that they can only measure shrinkage above gelation,[2] a fairly high amount of sample is necessary[4] and temperature overshoots can take place in the sample,[1,3] thus limiting the method to somewhat slow processes.

We propose a novel method for the in-situ determination of degree of curing and curing shrinkage using FTIR/ATR and refractive index measurements at the curing temperature that overcomes some of the aforementioned drawbacks.

Materials and Methods

The dimethacrylates BisGMA and TEGDMA (Aldrich) were cured with Luperox AFR40 (Aldrich). DGEBA (Epikote 828, Hexion) was cured with ethylenediamine (Aldrich), ytterbium triflate (Aldrich) and 1-methylimidazole (Aldrich). DGEBA (Araldite CY 228-1, Huntsman) and anhydride (Aradur HY 918, Huntsman) were cured with a tertiary amine (DY 062, Huntsman).

Density measurements are based on the Lambert-Beer law. Considering that the path length in ATR devices is related to the penetration depth which, in turn, depends on the refractive index of the polymers, the degree of shrinkage can be calculated as

$$\frac{\Delta V_t}{V_0} = \frac{A_0}{A_t} \cdot C - 1$$

Where the absorbance *A* corresponds to that of a reference species that should not change during the curing process, C is a factor that depends on the refractive index change of the reference wavelength during curing and the subindexes *t* and *0* indicate the reaction time and the beginning of reaction. The degree of curing *x* can be calculated as

$$x = 1 - \frac{\left(A_{spec}/A_{ref}\right)_t}{\left(A_{spec}/A_{ref}\right)_0} \cdot B$$

Where the subindexes spec and ref correspond to the reactive and the reference species respectively and the factor B depends on the refractive index change of both species during curing. In order to simplify the determination, the refractive index changes can be directly related to the degree of curing[5] and the factor *B* can be approximately made equal to 1.

An FTIR Bruker Vertex 70 equipped with an attenuated total reflection accessory with thermal control and a diamond crystal (Golden Gate Heated Single Reflection Diamond ATR, Specac-Teknokroma) was used to determine the FTIR spectra. Refractive indexes of cured samples were measured with a Metricon device using 632 nm wavelength laser. Refractive indexes of uncured formulations were analyzed with an Abbé refractometer. An ARG2 rheometer with an EHP temperature device was used to determine gelation and monitor the shrinkage after gelation. A Mettler DSC822e was used to determine conversion at the gel point.

Results and Discussion

Preliminary results show a good linear relationship between degree of curing and the degree of shrinkage calculated with the FTIR/ATR and refractive index technique for all the systems, with similar results at the different curing temperatures. The results are comparable to those obtained with the rheometer, thus validating the proposed technique, which can be used to assess the real curing shrinkage of existing and novel systems.

nikolaeva@kapella.gpi.ru

The region of the stretching vibrations of CH_2 and CH_3 groups is very interesting for structural analysis of polymers due to the very strong dependence of the corresponding Raman spectra on the material structure. For many polymers, Raman lines in this region are significantly more intense as compared with the lines in other spectral regions. This can be advantageous in examining substances in a small amount and/or in the presence of intense background. However, the analysis of Raman spectra in the region of the stretching vibrations of CH_2 and CH_3 groups usually faces the problem of the overlapping of a large number of unresolved lines. The deconvolution of the spectra cannot be unequivocally proven from the mathematical point of view. As a consequence, spectral characteristics of individual lines cannot be accurately determined.

In this work we discuss different procedures for the analysis of polarized Raman spectra of a number of materials including liquid n-alkanes, polyethylene (PE), isotactic polypropylene (PP), random ethylene/olefin and propylene/olefin copolymers, PE/clay and PP/clay nanocomposites, and PE/PP blends. These materials have common spectral features: The comparison of their Raman spectra allows us to develop new approaches for structural analysis of olefins and their derivatives.

As an example, we have considered neat PP and nanocomposites of PP with modified clay (Fig. 1). The presence of the clay leads to the appearance of intense luminescence background in the Raman spectra and to low signal-to-noise ratio which is especially lower in the spectra measured with crossed polarizations of the laser and scattered radiations. Therefore, the standard approach of the evaluation of molecular orientation, based on the measurements of depolarization ratios of certain Raman lines, is not feasible. Noteworthy, the qualitative analysis of the degree of macromolecular orientation in the nanocomposites can also be based on the intensity ratio of the lines peaking at 2963 and 2885 cm^{-1}. These lines are assigned to the asymmetric and symmetric vibrations of the CH_3 groups, respectively.

Fig. 2 shows the ratio of the peak intensities of the 2963 and 2885 cm^{-1} lines as a function of the draw ratio for PP/clay nanocomposites with different filler content. The spectra were measured with parallel polarizations of the laser and scattered radiations. The intensity ratio sharply increases with the draw ratio "λ" until $\lambda \approx 5$, corresponding to the formation of the neck region. Then it exhibits substantially slower variations. Interestingly, the rate of increase in the intensity ratio, and therefore the orientational ability of the PP macromolecules, decreases with the growth of the filler content.

Both lines with peaks at 2963 and 2885 cm^{-1} correspond to PP isotactic chains localized in the crystalline and noncrystalline phases. Our X-ray data indicate that the presence of the filler does not affect the orientational ability of the macromolecules localized within PP crystallites. Therefore, the decrease in the degree of molecular orientation in the PP/clay nanocomposites is due to the decrease in the orientational ability of the isotactic chains localized in the noncrystalline regions of the polymer matrix.

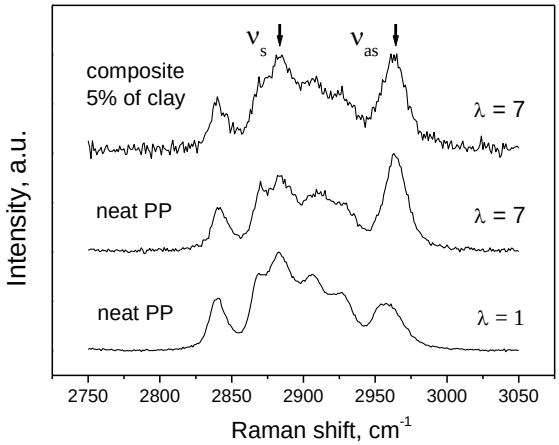

Fig. 1. Raman spectra of the neat PP and PP/clay nanocomposite with 5% of clay (λ is the PP draw ratio).

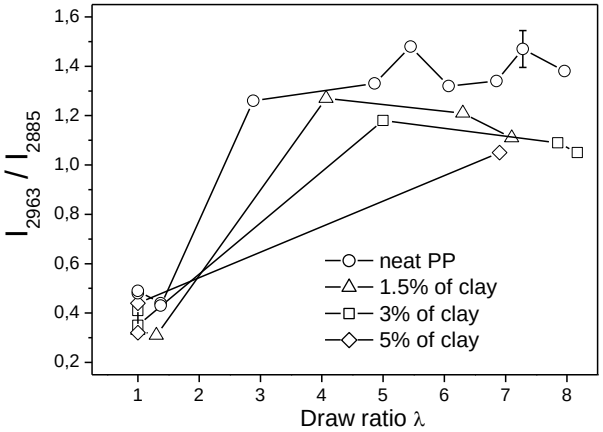

Fig. 2. Ratio of the peak intensities of the asymmetric and symmetric stretching vibrations of CH_3 groups as a function of the draw ratio for PP/clay nanocomposites.

Introduction: Polymer films play a substantial role in the packaging of many consumer goods including perishable and non-perishable food items, medical instruments and supplies, and electrical components (1).
Among polyolefins, Polypropylene (PP) is a thermoplastic with a number of desirable properties such as high melting temperature, low density and high chemical inertness. In addition, its low cost places PP in an advantageous position with respect to most other plastic materials. Also, adequate properties are achieved commercially through a biorientation process that enhance toughness and gas barrier of films. So, the biaxially oriented PP (BOPP) is one of the most used film for packaging applications (2).
The complex technologies involved in the production of these films of thickness about 15-20 µm, justify the application of sophisticated analytical tools to solve processing troubles that could arise in some of the different manufacturing steps.
The present work focuses on the study of the structural characteristics of defects of about 50 µm on commercial BOPP films by Optical Microscopy (OM), Infrared Micro-Spectroscopy (IMS) and Scanning Electron Microscopy with Energy-Dispersive X-ray Spectroscopy (SEM/EDX).

Materials and Methods: Samples of about 2 µm thickness containing the imperfection were microtomed with a LEICA UCT at - 40 °C. They were observed under polarized light using an Optical Microscope Zeiss Phomi III POL and a video camera. Then samples were observed in the microscope while they were heated to 280 °C in a Mettler FP5 hot stage. Images were recorded and processed with the software AnalySIS 3.
IMS analysis was performed on microtomed samples of about ≅ 5 µm thickness using a Nicolet Nexus FTIR spectrometer with a Continuum Microscope. The number of scans was 200 and the digital spectral resolution was 4 cm^{-1} for each sample. The analyzed area was about 20 x 20 µm.
The morphological aspects and elemental composition of the microtomed surfaces containing the defects were studied by SEM/EDX using a JEOL 35 CF microscope equipped with a secondary electron detector and x-ray dispersive system EDAX DX-4. The samples were gold coated and the incident beam was perpendicular to the surfaces (voltage used was 10 kV).

Results and Discussion: Figure 1a shows an optical micrograph of the microtomed sample showing a defect in the central region. The defect appeared dark due to a lower light transmission in this region and remained without morphological modification after being heated to 280 °C. Figure 1b shows a SEM micrograph of the defect which was easily detected because a clear topographic contrast with the surroundings was obtained.

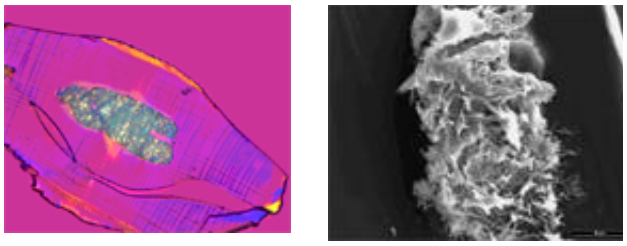

Figure 1: a) MO (x 400), b) SEM (x 1100)

Figure 2a shows an EDX spectrum obtained in the defect region where C, O and Na peaks appeared. In the rest of the film only the C peak was observed. The infrared spectrum of the defect region is shown in figure 2b. It was observed the presence of an aromatic compound. Additionally, absorption in the 1550-1610 cm^{-1} and 1300-1420 cm^{-1} region could be detected which are characteristics of stretching asymmetric and symmetric vibrations of CO_2^- groups present in salts of carboxylic acid (3).

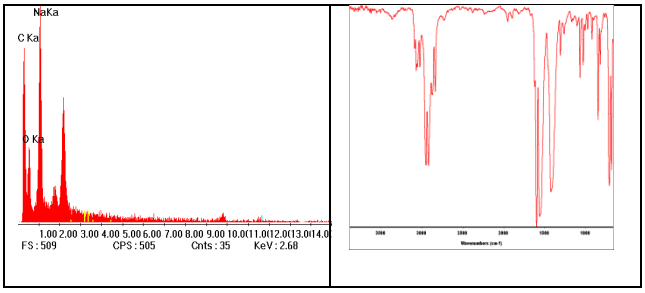

Figure 2: (a) X Ray, (b) IMS

Conclusions: The results showed that the defects on BOPP film were due to the presence of sodium benzoate.

Interplay between Raman Scattering and Atomic Force Microscopy in Characterization of Polymer Blends

P.Dorozhkin[1], A. Shelaev[2] and S. Magonov[3]

[1,2] NT-MDT, Zelenograd, Russia, [3]NT-MDT Development Inc., Tempe AZ 85284 USA

Atomic force microscopy (AFM) is routinely applied to compositional mapping of heterogeneous polymer materials. Recognition of the individual components in these materials is usually based on their specific morphology and differences of their local mechanical and electric properties. Nowadays a deficit of local chemical or spectral information in AFM can be overcome by combining it with confocal Raman microscopy. Such applications to polymer blends are fast developing and can be substantially enhanced with the use of multi-frequency AFM techniques which allow the simultaneous recording of surface morphology, local mechanical, dielectric and chemical (Raman spectra) response from the same sample area. Initial efforts in this direction will be presented in our work, which was focused on studies of films of immiscible blend of polystyrene (PS) and polyvinyl acetate (PVAC). The constituents of this blend have different local electric properties (surface potential, dielectric permittivity) that is well documented in single-pass Kelvin force microscopy and dC/dZ studies. The Raman spectra of PS and PVAC are characterized by specific individual bands of these components that provide their direct recognition in confocal Raman maps obtained on the surface of the blend films. A comparison of the KFM and dC/dZ images with Raman maps recorded at the same locations offers useful information about sensitivity as well as spatial and in-depth resolution of such characterization.

Characterization of Different Polymer Systems via Asymmetric Flow Field-Flow Fractionation (AF4)

Introduction

The field of polymer science advances continuously due to the new emerged polymerization techniques and a need for new materials. In this context it is highly important to characterize different types of polymers to analyze their chemical structure and morphology. Therefore, there is a need for different separation methods to characterize various polymeric materials. The field flow fractionation (FFF)[1] technique is a fast emerging technique that can provide good separation for many different polymers, proteins, and particles using a single channel without any packing material inside. Recent progresses in the development of asymmetric flow field-flow fractionation (AF4) open new opportunities for the characterization of various polymers.

Materials and Methods

Asymmetric flow field-flow fractionation (AF4) system (AF2000 MT from Postnova) has been used to characterize different polymer systems. A mixture of poly(styrene sulfonate)s with different molar masses has been used as a model system with a broad molar mass distribution. A complete polymer separation and analysis was performed. A range of poly(2-ethyl-2-oxazoline)s and poly(ethyleneimine)s have been synthesized to measure with this system.

Results and Discussion

In this contribution, asymmetric flow field-flow fractionation (AF4) is used as an analytical separation technique for the characterization of different polymer systems such as poly(styrene sulfonate)s, poly(2-ethyl-2-oxazoline)s, and poly(ethyleneimine)s. Detailed information on the polymers is available on radii of gyration, polymer contour lengths, molar masses and coil conformation. This method is expected to be applicable for a wide range of water soluble synthetic and natural polymers.

Introduction

Known that the molecular properties, such as, chemical composition, stereochemical, molecular weight and molecular weight distribution are directly related with polymer properties and which in turn, are a reflection of the kinetic history of the reaction occurred during its formation. For this reason, when we think about the design of homopolymers, a blend of polymers or copolymers, glass transition temperature (Tg) is a very important parameter to consider as it defines in a way its flexibility, which influence on final properties of the material[1].

In this work is present the thermogravimetric analysis (TGA) for different composition of poly(diisopropil fumarate -co- p-nitrobenzyl acrylate) [P(DIPF-NBA)] and degradation activation energies were calculated for each composition.

Materials and Methods

The copolymers were synthesized under microwave energy using different amounts of both monomers. The mole fractions of the monomers in the copolymers were determinate by ^{1}H-RMN (see table).

To assess the transformation as well as the thermal stability of the resulting copolymers, thermogravimetry analysis was carried out using a 51 Shimadzu thermogravimetric Analyzer under nitrogen flow (25 mL / min) between 25 to 700 °C and heating rate 10 °C / min. The analysis of the glass transition temperature (Tg) was carried out in a differential scanning calorimeter Shimadzu-TA60. To that end, 5 mgr samples were introduced in sealed aluminum pans and analyzed with a flow of N_2 of 30 ml / min. To erase the thermal history were made heating / cooling ramps: 150 °C to 30 °C / min -100 °C to -30 °C / min to 250 °C to 10 °C / min. The degradation activation energies (E) of the sample were calculated from non-isothermal TG curves using Freeman and Carroll equation[2], assuming a first order reaction kinetic.

Results and Discussion

All copolymers appear to decompose in two-stage process and show higher initial decomposition temperatures (IDT) than corresponding homopolymers. PDIPF is degraded in single-step, starting to 250 °C, according to previously reported[3]. Although the maximum rate of degradation is similar for all polymers (320-330 °C), the degradation activation energy (E) was different. The Figure and Table shows that PNBA decompose more easily than the other polymers. An increase in thermal stability of copolymers, when the NBA content increases up to 0.66, was observed. Can not establish an order of stability only based on the composition copolymer, probably due to different average molecular weights of samples. In fact, the last two polymers exhibit M_w which are an order of magnitude lower than the others M_w.

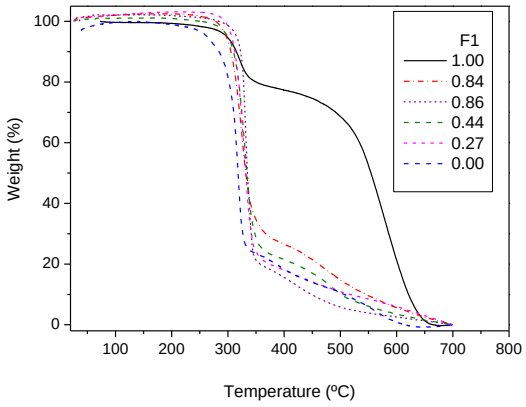

Figure: TGA curves of DIPF-pNBA copolymers under nitrogen at heating rate of 10 °C/min. F_1 is the mole fraction of pNBA in the copolymer.

Polymer	F_1	T_g (°K)	IDT	T_{max1}	T_{max2}	E (kJ/mol)	r^2
PDIPF	0.00	348	250	318(53.9)	-	228.6	0.94
(DIPF-NBA)	0.27	337	280	332(51.3)	616(95)	226.8	0.97
	0.44	331	272	332(46.5)	490(88.5)	254.6	0.99
	0.66	324	290	331(35.9)	452(90.3)	362	0.95
	0.84	321	290	327(41.7)	475(81.9)	189.6	0.97
PNBA	1.00	316	220	320(14.7)	580(67.3)	142.3	0.94

F_1 is the mole fraction of NBA in the copolymer
IDT is the initial decomposition temperature
T_{max} temperature at which the degradation rate reached a maximum (from DTG curves). Value in parentheses indicates the total weight loss (%) up to the temperature stated.

Conclusions

Since no melting peaks observed in DSC curves, these copolymers do not have crystalline regions.

The presence of ANB increases the thermal stability of the material.

kusai@JEOL.fr

[Introduction]

Recently, a tandem time-of-flight mass spectrometer (TOF-TOF) is used for structural analysis of synthetic polymer. A high-energy collision-induced dissociation (HE-CID) is mostly used method to make a fragmentation. There are two factors which make interpretation of a HE-CID product ion spectrum difficult: i) overlap of fragment pathways of HE-CID and post-source decay (PSD) on a product ion spectrum, ii) insufficient separation of fragment peaks caused by low precursor ion selectivity and low mass resolution.

The MALDI TOF-TOF combined a SpiralTOF [1] and an offset parabolic reflectron [2] for first and second TOFMS, respectively has been developed. The SpiralTOF, which has 17 m flight path, can select a monoisotopic ion so that each fragment pathway is observed as single peak on product ion spectrum. Furthermore, PSD ions are eliminated by electrostatic sectors inside the SpiralTOF. As a result, fragment pathways of HE-CID are preferentially observed on product ion spectrum.

In this study, some synthetic polymers were investigated for structural analysis using HE-CID spectrum acquired by the MALDI SpiralTOF-TOF.

[Experimental]

Poly(propylene glycol) average Mn ca. 1000 (Sigma-Aldrich), α-cyano-4-hydroxycinnamic acid (HCCA) (Wako) and sodium iodide were used as an anlayte, a matrix and a cationic compound, respectively. HCCA was dissolved in acetonitrile/deionized water solution (1:1) at a concentration of 10 mg/mL. PPG and sodium iodide were prepared by diluting in deionized water solution at concentrations 10 mg/μL and 1 mg/μL, respectively. PPG, HCCA and sodium iodide solutions were mixed in the ratio of 1:2:1, and 1 μL of the mixture was deposited on a MALDI target plate made of stainless steel by the dried-droplet method. JMS-S3000 with TOF-TOF option (JEOL Ltd., Japan) was used for data acquisition.

[Results and discussion]

Figure 1(a) shows the product ion spectrum of $[M+Na]^+$ whose m/z value was 1085. Repeat structure of propylene glycol monomer (58 u) was clearly observed of only selected precursor ion. There were no PSD ions on the product ion spectrum. Figure 1(b) shows enlarged spectrum of m/z < 190. In this region, fragment pathways related to near end-group were observed as single peaks.

[Conclusion]

The precursor ion was selected as a monoisotopic ion using the SpiralTOF. Also, a product ion spectrum was obtained by HE-CID using the SpiralTOF-TOF without any PSD ions. The expected fragmentation pathways were clearly observed.

INTRODUCTION

Vickers microhardness (MH) is a well established experimental technique for the mechanical characterization of polymeric materials. Depth Sensing Indentation (DSI) is a method closely related to MH determination that yields a more detailed information about the indentation process because the load-penetration curve is continuously monitored. However, DSI has been scarcely applied to the mechanical characterization of polymers.

The aim of this paper is to present some preliminary results about characterization of polyethylene, PE, samples using DSI

MATERIALS AND METHODS

A linear polyethylene was used for this study. The melt flow index of this polymer is 0.6 g/min, its nominal density is 0.958 g/cm^3 and its viscosity average molecular weight is 1.25x10^5. The samples were molten and then pressed between the plates a hydraulic Collin press. Two different cooling rates were used, either slow cooling between the press plates (~ 1ºC/min) or quenching in ice-water (~ 100ºC/min). Former sample was labeled as S and later, as Q.

Table 1: degree of crystallinity, f_c^d, elastic modulus, E, and Vickers microhardness, MH, of the samples (these values were reported previously)

Sample	f_c^d	E (MPa)	MH (MPa)
Q	0.66	625	47
S	0.78	795	66

A Berkovich indentor attached to a Shimadzu Dynamic Hardness Tester DUH-211S was used for DSI measurements at 20ºC. A 20 mN maximum load, P_0, was applied with a loading speed of 13.3 mN/s, this load was hold for 5 s. before unloading (Figure 1).

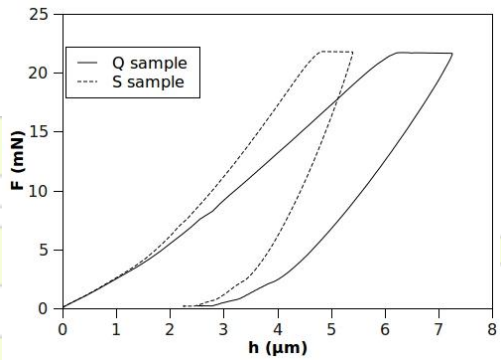

Figure 1: load (F) – penetration (h) depth curves

RESULTS AND DISCUSSION

The different hardness values that can be obtained from DSI experiments have been evaluated according to the standard methods (EN-ISO 14577-1). These methods has also been used for calculating the elastic moduli, E^*, from the initial part of the unloading curve.

The creep deformation under the indentor has been explained satisfactorily by using a four elements Maxwell-Voigt model and the correspondence principle to modify contact Hertz equation [1].

The delayed elastic-recovery has been analyzed by using the same equation that has been reported after studying Vickers indentation recovery by means of a Michelson-Morley interferometer[2].

Table 2: values for creep reduced modulus, E^*_1 (MPa), unloading modulus, E^* (MPa), Martens hardness, HT115 (MPa), indentation hardness, Hit (MPa), and retardation time for delayed elastic recovery, τ (s).

Sample	E^*_1	E^*	HT115	Hit	τ
Q	410	217	56	27	0.48
S	673	420	65.5	42.5	0.46

The comparison of the results in Table 2 with those obtained by using other experimental techniques (Table 1) shows a reasonable agreement between hardness values obtained from residual impressions, HT115 and MH, and between the different types of moduli.

Even more, it has been found that the short-term retardation time for delayed elastic-recovery under zero load does not depend on the degree of cristallinity. The same behaviour has been previously reported for the long-term delayed elastic recovery of Vickers indentations in PE [2].

CONCLUSIONS

These results show that DSI measurement can be an adequate and straightforward technique for the characterization of some aspects of the mechanical behaviour of polymeric materials

Characterization of different varieties of cassava flour by solid state NMR spectroscopy

Gisele C. V. Iulianelli, *Maria Inês B. Tavares*

Instituto de Macromoléculas - Universidade Federal do Rio de Janeiro / Brazil

gisele@ima.ufrj.br

Introduction

Cassava (*Manihot esculenta Crantz*), known in Brazil as "mandioca", "macaxeira" or "aipim", is the main crop cultivated in several farming in Brazil and, also, in other areas in tropical América [1]. Cassava flour is mainly constitutes by starch, fiber, proteins, lipids and minerals [2,3]. However, it is known that the percentage of these components may differ substantially between the varieties, resulting in differences in their nutritional aspect. The focus of this paper was to investigate six varieties of cassava with respect to chemical composition and molecular dynamic behavior, employing nuclear magnetic resonance spectroscopy (NMR).

Materials and Methods

The samples were characterized by different solid-state NMR techniques, such as cross polarization magic-angle spinning (CPMAS), variable contact time (VCT), and proton spin-lattice relaxation time in the rotating frame ($T_1\rho H$). The ^{13}C NMR spectra were obtained on a Varian INOVA 300 spectrometer operating at 75.4 MHz for ^{13}C. For the VCT experiment, a range of contact time was established from 200 to 8,000 μs, and $T_1\rho$ values were determined from the intensity decay of ^{13}C peaks with increasing contact times.

Results and Discussion

^{13}C CPMAS NMR spectra (Fig. 1) showed three NMR signal located in a particular region that is assigned as polysaccharides, indicating that these samples consist mainly of starch. Comparing the ^{13}C CPMAS spectra of M1, M2 and M3 cassava samples they present a different structural organization in relation to the other samples, since NMR signals are located at lower chemical shifts, suggesting that those samples are more amorphous, probably due to the higher quantity of amylose ratio in starch composition.

From VCT experiment (Fig 2), it was observed a simple decay for all resolved ^{13}C signals. This molecular behavior shows that these samples have molecular rigidity. The best contact-time for the polarization transfer between ^{1}H and ^{13}C was 800 μs for all cassava flour samples, excluding M1 in which 400 μs was detected as a best contact-time. This result shows that M1 sample is more rigid than the others, due to its stronger intermolecular interactions, indicating that M1 sample probably has differences in its chemical composition.

The VCT experiment permits us to determine the $T_1\rho H$ relaxation time (Table 1). It can be seen that M2, M3, M4 and M6 samples are more homogeneous, since $T_1\rho H$ values are more uniform, while M1 and M5 samples show some heterogeneity in their composition and/or molecular organization. It was also observed, that M4 sample present a slightly lower molecular mobility. The $T_1\rho H$ behavior is related to chains interaction/proximity, which may be understood as indicating that M4 sample have higher amylopectin proportion, since this component is responsible for the crystallinity in starch granules [4].

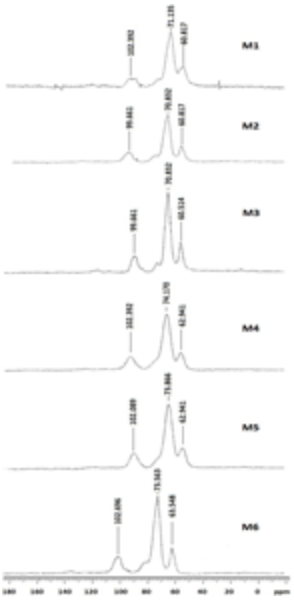

Figure 1- 13C CPMAS spectra for

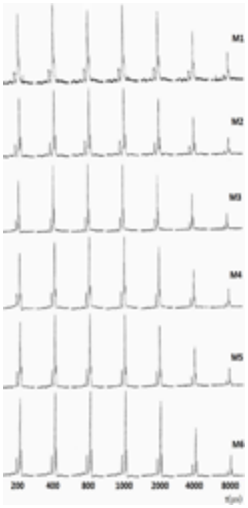

Figure2- VCT experiment

Table 1 - Proton spin-lattice relaxation parameter from cassava samples, determined during the VCT experiment

	Cassava Samples					
	M1	M2	M3	M4	M5	M6
δ(ppm)	102	99	100	102	102	103
	71	71	71	74	74	74
	60	61	61	63	63	64
$T_1\rho H$ (ms)	4	4	6	3	4	5
	11	6	5	3	6	5
	13	6	7	3	11	6

Conclusions

Solid state NMR techniques provided important information on chemical and structural characteristics of different cassava varieties. From the NMR data obtained in this study, it appears that the cassava samples studied showed variations on nutritional aspects based on their molecular structure and chemical composition, serving as markers for specific diets.

Kinetic investigation of thermal degradation for low molecular weight 1,2-polybutadiene

Mohamad Ronagh Baghbani[1], *Farshid Ziaee*[1], *Hosein Bouhendi*[1], *Farhood Ziaie*[2]

1: Iran Polymer and Petrochemical Institute. Postal Code: 1497713115
2: Nuclear Science and Technology Research Institute.

E-mail: Mb_ronaghi777@yahoo.com

Introduction

Degradation of polybutadiene has been studied in recent years. These studies were investigation of environmental condition effects and undesired situation on degradation of polybutadiene. The main degradation mechanisms are cyclization, crosslinking and chain scission [1, 2]. In this study, thermal degradation of low molecular weight 1,2-polybutadiene (1,2-PBD) with different contents of 1,2-vinyl isomers by Nuclear magnetic resonance (^{13}C-NMR) method was investigated. Also, kinetic parameters of degradation reaction have been calculated.

Experimental

Low molecular weight (1,2-PBD) with 12%, 25%, 85% of 1, 2-vinyl isomers (A, B, C respectively) were purchased from Aldrich. About 2 g of (1,2-PBD) were placed into glass tubes (Diameter= 20mm) and nitrogen gas was purged. After that, tube was vacuumed and placed in oil bath during different times and temperatures. Finally, degraded (1,2-PBD) was solved in $CDCl_3$ and ^{13}C-NMR Spectrum was obtained.

Result and discussion

NMR Spectra of degraded samples at different temperature (235, 250 and 265° C) and times are shown in Figure1. Results show that crosslinking was occurred with two different mechanism, the first is reaction between 1,2-vinyl isomers of two different chains, and the other is reaction between 1,2-vinyl isomer from one chain and cis or trans isomers of another chain. Chain scission is also occurred in two mechanisms. One of them is chain scission at two adjacent 1,2-vinyl isomers and another one is chain scission at adjacent 1,2-vinyl with cis or trans isomers. Furthermore, kinetic of first mechanism of crosslinking and chain scission have been studied. Kinetic parameters such as degree of reaction, activation energy and K_0 (kinetic rate constant at ambient temp.) at first stages of reaction were obtained from integration of NMR Spectra. Rate of first crosslinking and chain scission mechanism against of 1,2-vinyl contents at different 1,2-PBD samples shows in Figure2. The kinetic equations of degradation mechanisms are presented in equation 1 and equation 2.

Equation1:

$$R_{Crosslinking1} = k_{01} \times e^{-E_{a1}/RT}[1,2-vinyl]^{\propto}$$

Equation2:

$$R_{Chain\ scission1} = k_{02} \times e^{-E_{a2}/RT}[1,2-vinyl]^{\beta}$$

We calculated α = 2.13, E_{a1} = 166.01 kJ/mol k and K_{01} = 1.44×10^{15} $lit^{1.134}/mol^{1.134}$k for first crosslinking mechanism. Also calculated β = 1.67, E_{a2} = 195.5 kJ/mol k and K_{02} = 4.59×10^{17} $lit^{0.67}/mol^{0.67}$k.

Conclusion

^{13}C-NMR Spectra of low molecular weight (1,2-PBD) showed that crosslinking and chain scission occurred in two different mechanisms, individually. Kinetic parameters of crosslinking and chain scission mechanisms were obtained.

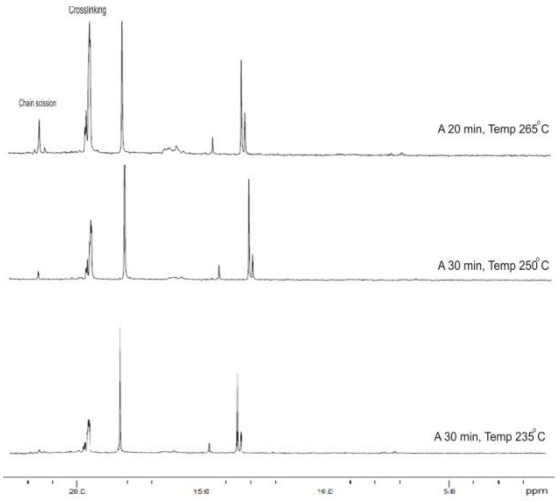

Figure1: ^{13}C-NMR spectra of degraded 1,2-PBD (sample A) in different time and temperatures

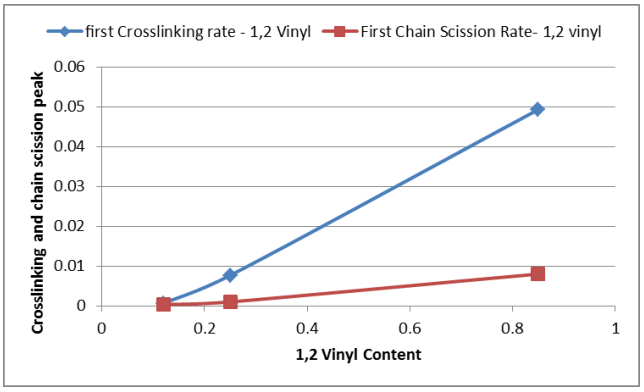

Figure 2: Rate of First Crosslinking and chain scission mechanism against of 1,2-vinyl contents at different 1,2-PBD samples

Three-dimensional modeling of mold filling process in injection process using OpenFOAM

Narjes Jafari Esfad, Bahareh Azinfar, Ahmad Ramazani S.A.

Chemical and Petroleum Engineering Department, Sharif University of Technology, Tehran, Iran

narges_jafariesfad@yahoo.com

Introduction

Process of filling in the procedure of injection forming process is so important. Our goal in this research is to model the process of filling the mold in the injection molding process with using OpenFOAM.

Material and Methods

In this research Two-phase model concerning two-phase fluid including Viscoelastic and Newtonian (Air) was applied. Giesekus model was used for Viscoelastic phase which the studied phase was considered as a combination of the polymer and solvent. The viscosity of polymer fluid was assumed 1.2 Pa.s which is about 1000 times greater than water viscosity. The applied pressure difference was considered 8000 Pa. To improve the pressure distribution in the mold, two symmetrical vents on either side of mold were designed.

The dimensions of applied mold and its entry are designed100cm×100cm×1cm and 250cm×10cm×1cm consequently.

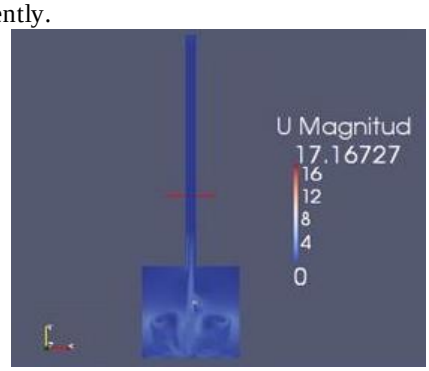

Figure 1: Velocity variation during filling process at t=1.5 for Viscoelastic fluid without vent.

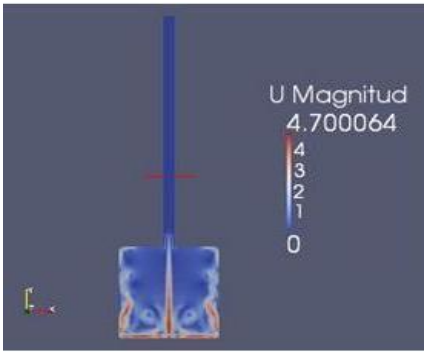

Figure 2: Velocity variation during filling process at t=1.0 for Newtonian fluid with vent.

Results and Discussion

Maximum observed flow rate for Newtonian fluid without vent is -0.0037 m/s while the applied velocity to the fluid in the program was -0.06 m/s that the velocity reduction can be considered by raising the cavity pressure during filling the mold because the upward force of air into the fluid reduces the fluid velocity. With applying a vent to the model, the problem of pressure built up in the cavity was solved and, the maximum flow rate obtained about-0.06 m/s. For viscoelastic fluid as can be observed in figure 3, when the vent not applied, the maximum flow rate is equal to -0.022 m/s which is due to the pressure rising into the cavity and therefore the upward force to the fluid decreases the velocity dramatically.

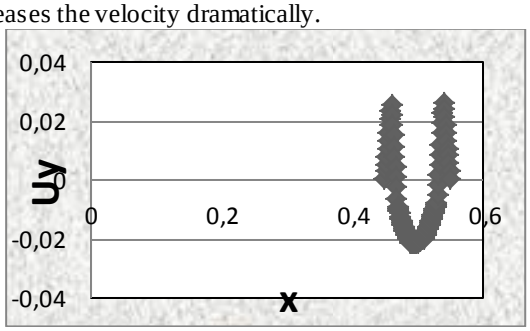

Figure 3: Velocity variation as a function of distance for viscoelastic Fluid without vent at entry point.

Two parts near the beginning and the end wall, encountered the upward velocity. To justify this phenomenon can be said, viscoelastic fluid on the walls due to non-slip condition, is trapped, while the upward air force raises the fluid near the wall which has less velocity. Thus, the attached fluid to the wall is not moving and the fluid resides in the center, finds the maximum velocity to the down direction.

Conclusions

A logical velocity gradient and pressure has been obtained. Die-swell phenomenon in viscoelastic fluid flow was observed well. When vent was not embedded, due to increase of pressure in the cavity, an upward force would be applied to the fluid which reduces the fluid velocity. When the vent is fitted, there is no upward force and the inputted fluid will be gain a greater velocity.

Derivatives of Coumarin as Fluorescent Probes for Monitoring Photopolymerization Processes by Fluorescence Probe Technology

J. Ortyl, R. Popielarz

Cracow University of Technology, Faculty of Chemical Engineering and Technology,
Institute of Organic Chemistry and Technology, Warszawska 24, 31-155 Krakow , Poland.

jortyl@chemia.pk.edu.pl

Introduction.

Fluorescence Probe Technology (FPT) is a new method, applicable for monitoring of polymerization processes. The FPT method relies on measurement of changes in fluorescence characteristics of specially designed fluorescent molecular probes upon changes occurring in the probe environment.[1] Most of known fluorescent probes suitable for monitoring free radical polymerization, usually do not perform well in cationic polymerization systems. Only a few fluorescent probes suitable for cationic polymerization have been reported so far [2]. In this communication, we report the performance of the following coumarin derivatives (Fig. 1) in cationic photopolymerization of a monomer, in comparison to commercial Coumarin-1 probe, which is used for monitoring free radical polymerization:

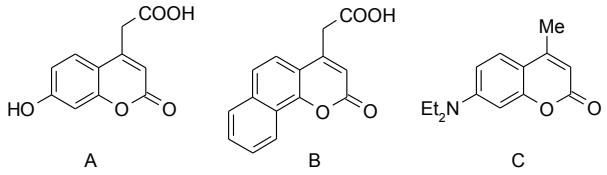

Fig.1. The fluorescent probes studied.

Materials and Methods

The compositions contained triethylene glycol divinyl ether (TEGDVE monomer, Aldrich), diphenyliodonium hexafluorophosphate (photoinitiator, $2.3 \cdot 10^{-2}$ mol dm^{-3}, Alfa Aesar) and a probe ($6.1 \cdot 10^{-3}$ mol dm^{-3}). (7-Hydroxycoumarin-4-yl)acetic acid (A) and (benzo[*h*]-coumarin-4-yl)acetic acid (B) were synthesized from 2-ketoglutaric acid and resorcinol or α-naphtol respectively, in sulfuric acid (95%). The cure monitoring system used in this study was described previously.[3]

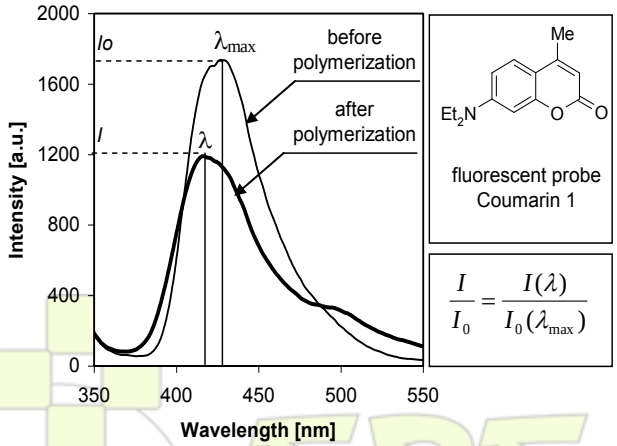

Fig.2. Fluorescence spectra of probe **C**.

Results and Discussion

The normalized fluorescence intensity (I/I_o) was applied as an indicator of the polymerization progress. The (I/I_o) was defined as the ratio of maximum fluorescence intensity at any given polymerization time to the maximum intensity at the beginning of polymerization (Fig. 2). Figure 3 shows the kinetic profiles of the photopolymerization process, obtained using (I/I_o) as the polymerization progress indicator. The coumarins A-B exhibit increase of the I/I_o upon monomer polymerization. While the I/I_o of Coumarin 1 probe, used as a reference, first decreased and then slightly increased during the polymerization of monomer. This indicates that Coumarin 1 response is strongly affected by protonation with hexafluorophosphoric acid generated in the system, while the response of the probes A-B is not sensitive to the acidic environment. Hence, the coumarins A-B are suitable for monitoring cationic polymerization processes by FPT, while Coumarin 1 is not.

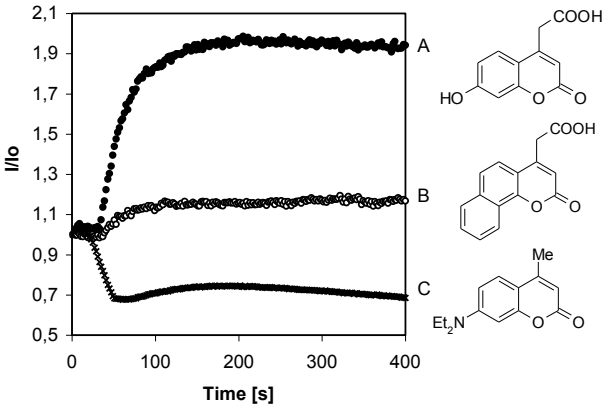

Fig.3. Kinetic profiles of cationic polymerization of TEGDVE, obtained by FPT method using the probes studied.

Conclusions

The coumarins (A-B) are applicable for use as new fluorescent probes for cure monitoring of cationic polymerization processes by FPT, using I/I_o as the polymerization progress indicator. The response of probe A is more sensitive to changes occurring in its environment than that of probe B. Regular kinetic profiles of cationic polymerization of a monomer are obtained with these probes. On the other hand, the I/I_o response of Coumarin 1 is strongly affected by the acidic polymerization catalyst, which makes it not good fore the cationic polymerization systems.

Introduction: Multiple processing by means of successive injection cycles was used to simulate the thermo-mechanical degradation effects on the oligomeric distribution of PLA under mechanical recycling. Likewise, an accelerated thermal ageing over PLA glass transition was performed in order to simulate its service life. MALDI-TOF MS was used for the analysis. The difficulty of performing good-quality and reliable MALDI measurements depends on many factors[1-2] such as the molar mass of the polymer, the choice of solvent, the choice of matrix, the ratio analyte/matrix, the use of cationization agent, the laser energy or the mode of detection (linear or reflector), among others . The sample preparation procedure was thus assessed by means of a statistical Design of Experiments (DoE).

Materials and Methods: Polylactide (PLA) 2002D from Natureworks LLC (Minnetonka, MN), was analyzed. MALDI matrixes, namely 1,8,9-anthracenetriol (dithranol), 2-(4-hydroxyphenylazo) benzoic acid (HABA), 2,5-dihydroxybenzoic acid (s-DHB) were tested as matrixes, as well as sodium trifluoroacetate (NaTFA) was used as cationization agent. Preparations were carried out in tetrahydrofurane (THF). Successive 5 processing steps (RPLA-i, with i: 1-5) by injection moulding employing an Arburg 420 C 1000-350 injector were applied. Temperature gradient set from hopper to die was 160, 170, 190, 200 and 190ºC. Moulds were set at 15 ºC. Cooling time residence was 40 s and total residence time ca. 60 s. After injection, a fraction of the samples was kept as test specimen and the rest was ground by means of a cutting mill Retsch SM2000, which provided pellets of size $\Phi < 20$ mm to be fed back into the recirculation process. Thermo-oxidative aging was performed on dehumidified virgin PLA by means of a Heraeus UT 6060 forced-ventilation oven under air atmosphere at 60 ºC. Samples were removed for analysis after the exposure times of 1, 3, 6, 10 and 12 weeks. MALDI-TOF/MS experiments were conducted in the 200-6000 Da *m/z* range by means of a Bruker UltraFlex MALDI-TOF mass spectrometer with a SCOUT-MTP ion source, in the reflector positive mode.

Results and Discussion / Conclusions: The application of DoE for the improvement of the MALDI analysis of PLA, on the basis of main effects plots, interaction effects plots and analysis of variance, stated that the best resolution was obtained with mixtures prepared with s-DHB as matrix, in a proportion analyte/matrix (V/V 1/5), without cationization agent.

Sample plate of samples for MALDI analysis

Degradation primarily affected the initially predominant cyclic $[LA_C]_n$ and linear H-$[LA_L]_n$-OH species. Intramolecular and intermolecular transesterifications as well as hydrolytic reactions occurred during the formation and disappearance of oligomeric species. In both degradation mechanisms induced by thermo-oxidative and thermo-mechanical degradation, the formation of H-$[LA_L]_n$-O-CH_3 is highlighted, although a different behavior was observed. Thermo-oxidative ageing presents a two-stage performance, governed by intramolecular transesterifications during the first stage and scission reactions during the second stage, when over-exposure to temperature conditions triggered the depolymerization of cyclic species. On the other hand, thermo-mechanical degradation seems to occur mainly via hydrolytic reactions and intermolecular transesterifications, giving rise to a noticeable major abundance of H-$[LA_L]_n$-O-CH_3 groups, especially after the third recyclate.

Diffusion during Radical Bulk Polymerization of Styrene and Metyl Methacrylate

Stempfle, B. K.; Dorfschmid, M.; Wöll, D.

Universität Konstanz, 78457 Konstanz, Germany

Beate.Stempfle@uni-konstanz.de

Diffusional changes during radical bulk polymerizations play a significant role for polymerization kinetics and the properties of the synthesized polymers. We investigated molecular diffusion of fluorescent perylene diimide molecules during the polymerization of methyl methacrylate (MMA) and styrene using fluorescence correlation spectroscopy (FCS) and single molecule widefield fluorescence microscopy (WFM). The combination of both methods allows for a detection of the diffusion of single fluorescent probe molecules from the initiation of polymerization up to high conversions.

In FCS, the detection range for the translational diffusion coefficient D reaches from 10^{-9} to 10^{-13} m^2s^{-1}, whereas WFM covers a range between 10^{-12} and 10^{-18} m^2s^{-1}. In contrast to ensemble methods, single molecule observation in WFM allows for the detection of heterogeneities of translational diffusion.[1] The fluorescent molecule acts as probe for the local microviscosity within the polymerization mixture. This microviscosity is determined by the local structure of the polymer-monomer mixture and its dynamics. With increasing conversion this structure changes and, due to a increasing polymer content, diffusion becomes more restricted.[2]

Our measurements show that translational diffusion becomes more restricted during the polymerization of MMA compared to the polymerization of styrene. Additionally, during the polymerization of MMA, an increased amount of immobile molecules was detected at conversions higher than 0.25. In styrene polymerization, this phenomenon can be also observed, but appears at much higher conversion and less pronounced. We assume that this is due to a more heterogeneous network with areas of higher density evolving during the polymerization of MMA. The size of the meshes is determined by entanglements of the polymer chains.

The conversion from monomer to polymer was monitored using RAMAN spectroscopy.[3] Compared to our earlier studies, our new set-up provides the possibility to measure RAMAN spectra and single molecule widefield movies in quick succession. Thus, even periods of rapidly changing converison, e.g. during the self-acceleration period, can be measured with high temporal accuracy.

PVT Analysis of Chemical Reactions: Polymerization, Transesterification, Crosslinking

Jürgen Pionteck

Leibniz Institute of Polymer Research Dresden, Dept. Polymer Reactions and blends
Hohe Str. 6, 01069 Dresden Germany

pionteck@ipfdd.de

Introduction: Each material changes its specific volume (V_{sp}), the inverse of the density, in dependence on outer conditions like pressure (P), temperature (T) and others, i.e. V_{sp} = f (P, T, atmosphere, etc.).
However, not only these factors determine the material density but also chemical reactions which occur within the material. So, the analysis of changes in the specific volume over time can give valuable information about degree and kinetics of polymerisation, crosslinking, degradation, transesterification and other chemical and physical processes, for which typical examples will be presented.

Method: Changes in the specific volume were measured by means of a fully automated GNOMIX high pressure mercury dilatometer, which works in the temperature range between RT and 400°C and at pressures between 10 and 200 MPa. Below 200°C the absolute accuracy of the instrument is 0.002 cm^3/g, above 200 °C 0.004 cm^3/g. In practice, changes in specific volume as small as 0.0002 cm^3/g can be resolved reliably. Typically, ca. 1.5 mL of the material are loaded into the measuring cell which then becomes completely filled with mercury ensuring permanent hydrodynamic pressure to the sample. To hinder sticking of the sample to the cell wall the samples were embedded in a nickel foil cup. Depending on the tasks, different modes for the measurement are possible: isothermal pressurization, isobaric heating and cooling, following V_{sp} at constant P and T, or mixed modes. In the standard isothermal (ITS) mode at constant temperature the sample was pressurised from 10 MPa to 200 MPa and the data were collected in steps of 10 MPa. The values for ambient pressure (0.1 MPa) were obtained by extrapolating the V_{sp} values between 30 MPa and 10 MPa in steps of 1 MPa according to the Tait equation by means of the internal PVT software. A detailed description of the instrument is given in [1].

Example: When curing epoxy resins shrinkage of > 10 % may occur limiting the applicability of the resins due to stress formation. The shrinkage can be reduced by the addition of fillers or reactive components. Figure 1 shows as example the influence of the reactive rubber poly(butadiene-co-acrylonitrile) with two terminal carboxyl units (CTBN) and of its non-reactive di-n-butyl ester (CTBN-ester) on the shrinkage of an catalysed and non-catalysed epoxy systems consisting of diglycidylether of bisphenol A (DEGBA) and diaminodiphenylsulfone (DDS). The curing was done in-situ at 10 MPa and 157°C (details see [2]). In the catalysed reactive rubber-containing system the shrinkage is reduced to less than 1 %, while the pure resin shrinks by 6.1 %. While the CTBN-ester is inert and acts just like a diluting filler, the CTBN becomes incorporated within the formed epoxy network reducing its network density. Furthermore, the catalyst (di-n-butyl benzyl amine) causes increased ether formation resulting in linear polymer structures. Both effects are responsible for the reduced shrinkage.

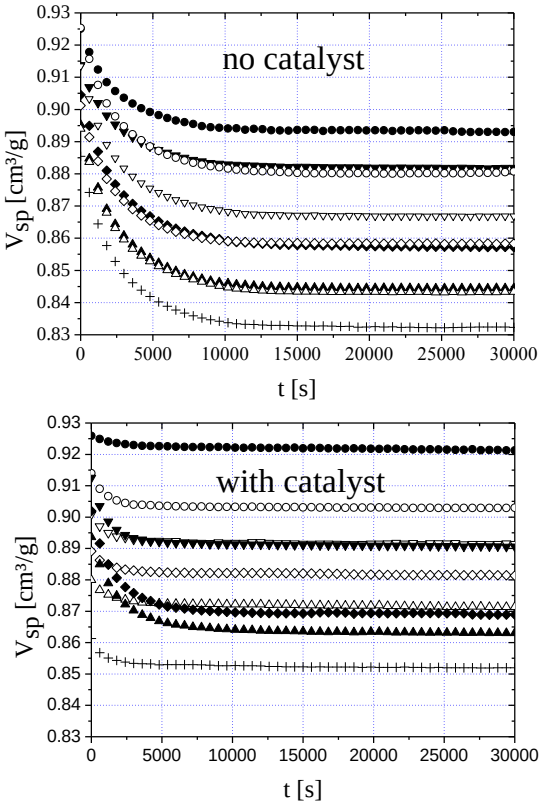

Figure 1. Influence of the rubber content and rubber reactivity on the shrinkage during curing of DGEBA/DDS. Rubber content: 0 (+), 5 (△), 10 (◇), 15 (▽), and 20 wt.% (○); full symbols CTBN, open symbols: CTBN-ester.

Further examples of PVT studies for the analysis of phase transitions, transesterification reactions, polymerisation, and physical swelling will be presented.

natalia.hernandez@ehu.es

Introduction: Polylactides are gaining interest as biodegradable plastics for ecological packaging and biomedical applications. Poly(L-lactide/ε-carpolactone) (PLCL) and poly(ethylene glycol) (PEG) are both considered medical plastics. PLCL is an elastomer thermoplastic used in tissue engineering.[1] PEG is a semicrystalline polymer suitable for clinical applications such as chemical coating and vehicles for drug delivery[2].The aim of this work is to study the phase structure and PEG crystalline development in PLCL/PEG blends by using a hot-stage atomic force microscopy (AFM).

Materials and Methods: PEG was purchased from Sigma-Aldrich, Spain (Mn=35,000 g/mol) and PLCL (70/30 %mol) was supplied from Purac Biochem, the Netherlands (Mn=, 121,433 g/mol, PI=1,6). Blends of PLCL/PEG of different weight ratios, 50/50, 20/80 were prepared for AFM by spin-coating some drops of the blend solution (60 mg/mL) onto a mica substrate. AFM measurements were carried out with a Nanoscope III Multimode scanning probe microscope (Veeco). In order to analyse the phase structure and PEG crystalline morphology, isothermal crystallization experiments were performed by heating the samples in the AFM apparatus to approximately 80ºC for 5 min in order to erase the prior state and quenched to a crystallization temperature at 45ºC. After completion of PEG crystallization, the re-melting process of PEG crystallites in the blends was programmed and monitored by AFM.

Results and Discussions Polarized Light Optical Microscopy (PLOM) measurements were initially performed to study the crystallization kinetics and spherulitic morphology of PEG in PLCL/PEG blends. Larger and more perfect spherulites were found in blends containing higher amounts of PEG. PLCL is observed within the inter-lamellar amorphous regions of spherulites intimately mixing with PEG, suggesting a good miscibility (Figure 1).

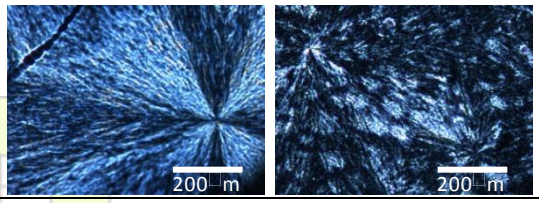

Figure 3. PLOM images of PLCL/PEG 20/80 with r_{esp}= 500µm (left) and PLCL/PEG 50/50 with r_{esp}= 277 µm (right).

For a more detailed analysis AFM was conducted. Figure 2 shows the on time phase structure and crystalline morphology of PLCL/PEG 50/50 and 20/80 blends during their isothermal crystallizations at 45 ºC. As can be observed in due course of crystallization of PLCL/PEG 50/50, PEG lamellae grow randomly from an amorphous darker phase. The arrows in the figures point to locations where amophous material, rich in PLCL, is located.

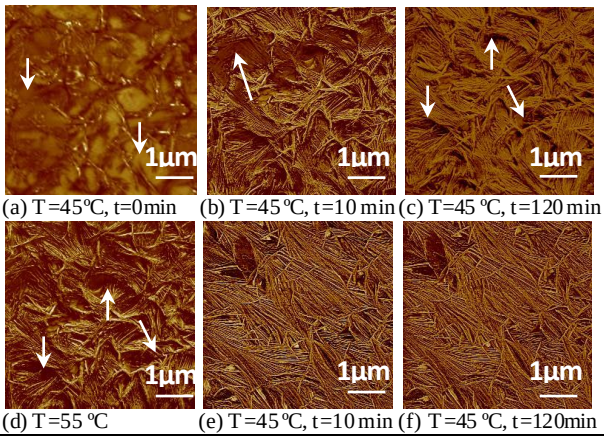

Figure 4. AFM phase images of PLCL/PEG 50/50 (a, b, c, d) and PLCL/PEG 20/80 (f,g).

With regard to PLCL/PEG 20/80 growth kinetics of PEG crystallites is much faster than in its 50/50 counterpart. PEG crystalline morphology is characterized by tightly packed well oriented stacks of lamellae of thickness within a 20-40 nm range. In addition the measured mean roughness parameter (Ra) is 11 nm after completion of the crystallization process whereas in PLCL/PEG 50/50 increases during crystallization from 6,5 nm to 20 nm.

Conclusions: PLCL content plays a key role in the organization of PEG lamellae in PLCL/PEG blends. High contents of amorphous PLCL (50/50) placed between PEG lamella stacks break the uniformity and linear growth of them. This phenomenon could be indicative of a good miscibility of both polymers.

SEC-DAD as a Powerful Tool for Characterization of Conjugated Polymers

Olga Trhlíková, Dmitrij Bondarev, Jan Sedláček, Jiří Vohlídal

Department of Physical and Macromolecular Chemistry, Faculty of Science, Charles University in Prague, Hlavova 2030, Prague 2, 128 43, Czech Republic

OlgaTrhlikova@seznam.cz

Nowadays conjugated polymers are materials of permanent interest because of large spectrum of potential applications such as construction of polymeric electroluminescence diodes, polymeric or composite photovoltaic solar cells, as sensors for ions, organic molecules as well as biomolecules. Conjugated polymers could be also used as an active component in the gas-separation and storage.

Substituted polyacetylenes as the fundamental conjugated polymers belong to the most studied materials of this class. Nevertheless, these polymers undergo oxidative degradation when exposed to atmosphere and in some cases the degradation is followed by cis-to-trans isomerisation. These processes affect the covalent and electronic characteristics of polyacetylenes and detailed study of changes during the ageing is important due to the fact that above mentioned properties are key features for potential functional applications in optoelectronic devices. Size exclusion chromatography (SEC) is very efficient method for study of molecular-weight characteristics and their changes during ageing. When equipped with diode array detector (DAD) it allows to obtain UV-vis spectra in selected retention times which correspond to apparent molecular weights according to the calibration. The differences in spectra allowed us to determine the cis-to-trans isomerisation proceeding during the ageing and also to propose detailed mechanism of the ageing processes (ref. 1).

Polyparaphenylenevinylene (PPV) and its various derivatives are promising materials for construction of light emitting diodes and polymer based solar cells. Also for this class of materials the stability is crucial. There are numerous studies dealing with the stability of PPVs in the solid state. We showed that the degradation of MEH-PPV proceeds also in the solution and the degradation processes depend on the solvent used and illumination conditions. Differences in UV-vis spectra for selected SEC retention times (molecular weights) in dependence on the conditions of ageing allow us to compare the extent of two processes accompanying the ageing, the degradation manifested by decrease in molecular weight and additions on the main-chain double bonds causing the decrease of conjugation without the decrease of molecular weight. In combination with other spectroscopic methods it is probable that we could be able to propose the mechanism of degradation and compare with the mechanisms proposed for degradation in the solid state.

SEC-DAD was also exploited in the study of preparation of composites MEH-PPV with gold nanoparticles (ref. 2). It was revealed that two methods used for preparation of nanocomposites affect MEH-PPV differently. The extent of degradation and additions on the double bonds were investigated. It was also showed that SEC-DAD technique is possible to use for monitoring of formation of nanocomposite aggregates during its preparation. The character of the spectra at different retention times allow us to distinguish between the polymer not participating in the interaction with nanoparticles and the formed nanocomposite.

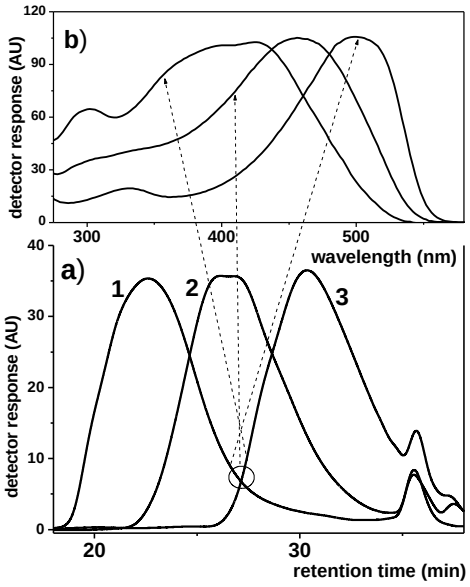

Fig. 1: Chromatograms obtained in the course of degradation of MEH-PPV in THF solution (a) and UV-vis spectra belonging to the macromolecules with apparent molecular weight 40000 which are present in all depicted stages of the degradation (b).

[*]Email: dominik.woell@uni-konstanz.de

Controlled radical polymerization has become an essential technique to produce polymers combining the advantages of free radical polymerization (inexpensive and tolerant to impurities) with those of ionic polymerization: it offers control over many key properties such as molecular weight, polydispersity and end groups. Even network properties such as network densities and homogeneity can be adjusted. These properties have great influence on the diffusion processes of particles during polymerization and in the synthesized networks. For example, many applications such as highly selective membranes demand a minimization of heterogeneities.

In our investigations on heterogeneities in polymer networks we go beyond the bulk measurements commonly performed using techniques such as Dynamic Light Scattering (DLS), Nuclear Magnetic Resonance Spectroscopy (NMR), and Positron Annihilation Lifetime Spectroscopy (PALS). Our project focuses on the observation of single molecule dynamics. Using Widefield Fluorescence Microscopy (WFM), the diffusion of single perylene diimide dye molecules which are introduced as probes for translational motion is detected and analyzed[1-2]. Recent results on local heterogeneity formation of linear and crosslinked polystyrene during the Nitroxide Mediated Polymerization (NMP) will be presented and compared with the behavior during free radical polymerization.
To follow the conversion during the polymerization process, Raman spectroscopy, a very powerful, fast and non-invasive tool was used. Combining Raman spectroscopy with widefield fluorescence microscopy on one setup offers the possibility to determine conversion and single molecule mobility almost simultaneously. This is of special interest in rapidly developing systems such as fast polymerizations or radical polymerizations at the gel point.

e-mail: mantic@agrif.bg.ac.rs

Introduction: In contrast to the very intensive study of low molecular weight organic pollutants occurring in waste waters and river waters, the pollution with high molecular weight synthetic polymers has received by far less attention. Poly(vinylpyrrolidone) (PVP) is a widely used water soluble polymer whose occurrence in waste waters is likely. PVP is intensively used in the pharmaceutical industry as a binder in many tablets and in the production of one of the most important disinfectants, PVP-iodine. PVP also has application in adhesives, paper manufacturing, the food industry, detergents (as a dye transfer inhibitor) and in personal care products such as shampoos and hair gels [1]. The PVP is presumed to be detected in the polluted water samples as a result of its very frequent usage and suggested environmental stability [2]. However, an appropriate method for its identification and quantification in environmental samples is still lacking. The aim of this work was to develop an efficient analytical method for detecting trace levels of PVP in waste waters and surface waters by applying continuous-flow off-line pyrolysis-GC/MS.

Materials and Methods: Pyrolysis of commercial PVP, of some personal care products, of spiked water samples as well as of waste water samples and river water samples was performed in a tube furnace at 500°C under a continuous nitrogen flow. Two waste water samples were derived from the outlets of the municipal waste water treatment plants of Aachen and Düren, Germany. One sample was obtained from the industrial waste water canal in Pančevo, Serbia. Surface water samples from the Rur River were taken in November 2008 in the vicinity of the effluent from the waster water treatment plant of Düren. One sample was taken upstream of the effluents and two further samples downstream, at distances of 10 m and 50 m, respectively. Degradation products were trapped in dichloromethane and identified by GC/MS. The concentration of PVP was calculated on the basis of the main pyrolytic product, *N*-vinyl-2-pyrrolidone (NVP). The amount of NVP in pyrolyzates was determined by GC-FID analysis, based on calibration curve which was constructed using commercial NVP and corrected by an internal standard, 4-*tert*-butylcyclohexanone. Very good linear correlation between initial amounts of PVP and released amounts of NVP was obtained and used as external calibration.

Results and Discussion: Specific fragments of pyrolyzed polymers can reflect its original structure and, therefore, be used for polymer identification. In this work, commercial PVP was pyrolyzed at seven different quantification levels (20-1000 µg). When higher initial amounts of PVP were degraded (250-1000 µg), only NVP was identified as a degradation product. However, in experiments with lower initial amounts of PVP (20-125 µg), a second pyrolytic product, identified as pyrrolidone, 2-Py, appeared. Fig. 1 gives the molecular structure of PVP as well as of the main degradation products, NVP and 2-Py. Both products can unambiguously be related to the former polymeric structure; however, in our study only NVP was used for quantitative determination of PVP.

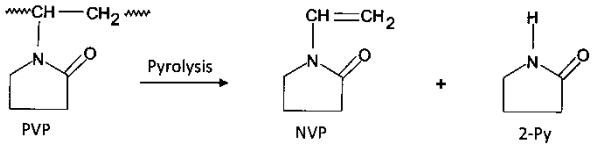

Fig. 1. Pyrolytic products of PVP

Two standard curves were used for calibration – the first which correlated the weight of NVP with the ratios of the areas of NVP peak and internal standard peak, and the second, "pyrolytic curve", which correlated amount of produced NVP with initial amount of PVP. The described pyrolytic method was applied to personal care products which contained PVP. The detected level of PVP was 6.4 (hair gel), 0.8 (laundry detergent) and 1.4 wt.% (tablets for throat disinfection). Spiked water samples, waste water samples and river water samples were pre-extracted with hexane and diethyl ether prior to pyrolysis. It was found that the recovery of spiked samples was 94.6±1.6 %, which indicated that pre-extraction did not provoke significant loss of polymer. These results also showed that "pre-extraction" can be used for environmental samples, in order to decrease the amount of organic substances which are also capable to be pyrolyzed, without significant loss of PVP. Finally, application of the developed method on real environmental samples revealed that PVP was present in effluents from waste water treatment plants in concentrations between 0.9 and 7 mg/L, as well as in river water affected by municipal sewage emissions with concentrations around 0.1 mg/L.

Conclusions: Continuous-flow off-line pyrolysis-GC/MS allowed very reliable quantification of PVP in complex environmental samples, even at trace levels. Furthermore, off-line method is very suitable for polymer detection in environmental samples because the optimal size of the sample can be easily adjusted prior to GC analysis, and the internal standards can be used in order to improve accuracy of quantitative determination of pyrolytic products.

Investigation of the Miscibility (Solubility) of Molten Polypropylene-Polyethylene Blends by means of Rheometry

Matthias Mihalic, Alois Schausberger

Institute of Polymer Science, Johannes Kepler University Linz,
Altenberger Straße 69, A-4040 Linz

E-mail: matthias.mihalic@jku.at

Rheometry is a powerful tool for the detection of phase separation in molten polymers and thus for the investigation of solubility of the components of a mixture.
An experimental set-up was designed in such a way that blends of polypropylene and polyethylene are produced in a small-scale laboratory extruder and the melt is subsequently injected directly into the measuring cell of a rheometer, where the dynamic moduli are determined. The reason for this procedure is that crystallisation, as it occurs during conventional sample preparation, always induces phase separation in a blend. This may negatively affect the measurement results, because neither will this separation be balanced out by diffusion in the melt, nor is the rheometer suitable to be used as a compounder.
The viscoelastic behaviour of soluble polymer blends is dominated by the main fraction which acts as a solvent, but it is modified by the properties of the dissolved component. In the case of solubility, the relaxation time spectrum of a blend can be gained from a simple weighted addition of the spectra of the pure components. Otherwise, phase separation will be reflected in the spectrum of the mixture obtained from dynamic mechanical data. This allows the calculation of the degree of solubility using the model of Gramespacher and Meissner.

INTRODUCTION

In 2008, almost 30% of the world plastics production was dedicated to the polyethylene (70 million tons). So, polyethylene is a consumer polymer material because of its moderate cost of manufacturing and its physical and mechanical properties which are compatible with various applications of everyday life. Indeed, this polymer allows generally speaking an easy processing (extrusion, injection), it has an excellent electric insulation and shock resistance and presents a great chemical and biological inertia (food contact). To each application corresponds a grade, that is to say a polyethylene with different rheological properties. It is then essential to know how to differentiate these products by adapted methods of characterization.

EXPERIMENTAL

The knowledge of characteristic temperatures of the polyethylene such as the melting point, the recrystallization point or the glass transition temperature gives indications onto the viscosity and thus on the grade of the polymer. Raman spectroscopy is a technique of polymer analysis which is nowadays is growing fast given its advantages. It is a non-destructive technique and it gives deepened information about the morphology of the polymer, the viscosity and its cristallinity. Moreover, this technique can be perfectly used in the industry by means of adapted sensors and of more and more miniaturized devices.

Spectroscopic study was realized with a Raman spectroscope Aramis® from Horiba Jobin-Yvon fit with a laser in 785 nm and a network in 1200 lines/mm. An extract of the studied spectral range is presented in figure 1 with in blue a flowing Low Density PolyEthylene (LDPE) grade and in red a viscous LDPE grade.

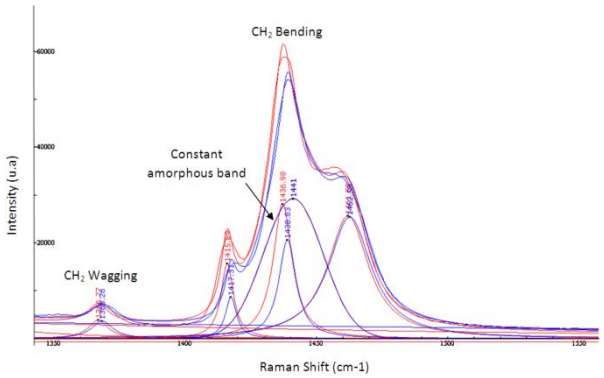

Figure 1: Raman spectroscopy of two LDPE grades

The Differential Scanning Calorimetry (DSC) and X-Ray Diffraction (XRD) will also be helpful to correlate our results. The calorimetric tests were made with DSC 200 F3 Maia® from Netzsch. It is a heat flux apparatus allowing working down to -170°C thanks to a supply in liquid nitrogen at the level of the thermostated chamber swept by nitrogen and regulated with an Intracooler at the rate of 10 K/min. Some DSC results are presented in an original shape on the radar graph of figure 2.

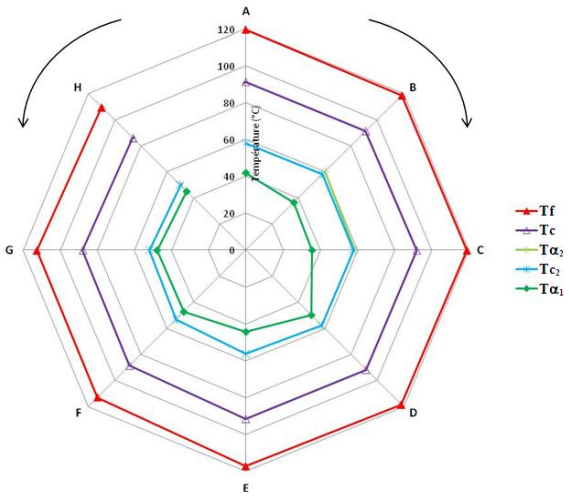

Figure 2: DSC results of 8 PE grades.

CONCLUSIONS

The object of this paper is not only to obtain the typical temperatures of polyethylene by Raman spectroscopy and to differentiate grades of polyethylene but also to get information on the structure of the polymer and of its cristallinity. In fact, with a detailed attribution of the bands, we are able to know to which bond each band corresponds[1,2] and its position in the crystalline structure. The final goal is to establish the possibilities of on-line analysis for quality control at the industrial scale. The determination of the polymer structure represents a major challenge in the industrial world of polymers.

Introduction: The morphology of a polymer has a great bearing on its mechanical strength and stability and hence is of a great interest. For semicrystalline polymers, the ratio of crystalline and amorphous phases, and molecular orientation in these phases are essential to understand this relationship and to optimise physical properties and production conditions of the materials.

Methods: Since the discovery of Raman scattering effect in the late 1920s, several research articles, review papers, books and industrial patents have been published on the application of Raman spectroscopy for polymers. Typically, the technique is used to determine the polymer type and content, polymerization reaction kinetics, amount of pigment additives, amount of degradation. The change of morphology of the polymer such as crystallinity, and molecular orientation can also be characterized by Raman spectroscopy. A typical Raman spectrum has a few peaks of interest that describe orientation and crystallinity quantitatively and qualitatively.

Polarized Raman spectroscopy is a vibrational spectroscopic technique used to determine the molecular orientation[1]. This characterisation method has a few advantages compared to other analytical techniques: quantitative and precise measurement of molecular orientation distributions, and study of these distributions on both the crystalline and amorphous phases.

Materials: The crystallinity and orientation of pressure induced polypropylene (PP) and of films of uniaxial oriented poly(ethylene terephthalate) PET were characterized via confocal and polarised Raman spectroscopy. The samples were produced in similar conditions and they differ only in the induced pressure (in case of PP) and film thickness (in case of PET). The preparation of the samples simulates the production conditions.

Results and Discussion: In case of PP the ratio of the peaks at 841 and 809 cm^{-1} is sensitive to the molecular anisotropy. The crystallinity values of PP are calculated by dividing the integrated intensity of the 809 cm^{-1} peak (helical chain conformation) by the total integrated intensity under the 809 cm^{-1} to 841 cm^{-1} band (Nielsen method[2]). The frequency bands due to longitudinal acoustic vibrations which are not observed by infrared spectra but occur in Raman spectra, are related to chain length and lamella thickness.[3,4] The longitudinal acoustic vibration is dependent on the force constant (dependent on the chain's Young modulus), the interlamellar forces, structure of the chain folding sequence, the proportions of the amorphous and crystalline components and the density of the polymer.

PET gives strong, well-defined Raman spectra with sharp intense peak at 1616 cm^{-1}, which has been assigned to the symmetric stretching vibrational mode of the phenylene ring. The polarisability tensor for this vibrational mode is treated with cylindrical symmetry, and the ratios of the diagonal components are estimated. The spectrum also contains a band due to the carbonyl group near 1740 cm^{-1} and two strong bands, typical of aromatic esters, near 1260 cm^{-1} and 1130 cm^{-1}, due to the asymmetric and symmetric stretching vibrations of the C-O-C functional group. PET has a very strong band due to the aromatic component near 1000 cm^{-1}. In addition, bands due to the aliphatic and aromatic portions of the polymer are present in the spectrum, most which are in their normal positions. The strong band due to the aromatic ring out-of-plane deformation is not in ist normal position for para-substtituted aromatics, instead it is found at slightly higher wavenumbers, 730 cm^{-1}. This shift is attributed to an interaction of the ester group with the aromatic ring. The OH and COOH groups absorb near 3450 cm^{-1} and 3260 cm^{-1} respectively.

Conclusions: As seen in crystalline and amorphous materials, the degree of molecular orientation can be regarded as one of the most crucial parameters defining the macroscopic properties of the material. The vibrational spectra of the PP and PET are greatly influenced by both the crystallinity and molecular orientation of the polymer. Confocal and polarised Raman spectroscopy is a useful method to obtain exact information about crystallinity and orientation of polymers.

A Thermoset-Thermoplastic Blend: Spectroscopy Characterization

F.A. Mesa-Rueda[a], , A. Cuellar-Burgos[a], C. Vargas-Hernandez[b], J.E. Perilla[c]

famesar@unal.edu.co

Upon processing of thermoset-thermoplastic blends, a cure-induced phase separation can take place. Although the developed morphologies can be easily observed and have been much studied, only limited information on the phase characteristics, like their composition and the degree of crosslinking, was reported in the literature. This study aimed at using micro-Raman spectroscopy for a direct and local characterization of the thermoplastic content and of the epoxide conversion within phase separated epoxy resins - polystyrene (PS) blends.

The performance of thermoplastic/thermoplastic blends is reasonably well studied and a number of their properties can be obtained as a function of their composition and of the processing conditions. In thermoset/thermoplastic blends, challenging issues remain, however, to be addressed. These include developing an understanding of the complexity of the combined curing and phase separation phenomena and the resulting blend properties. However, fewer studies have been reported concerning the chemical characteristics of the phases, such as the thermoplastic content and the epoxide conversion. Up to now, only indirect measurements of these properties have been carried out on thermoplastic-modified epoxy networks. Phase composition and partial miscibility of the components have been qualitatively assessed in cured blends on the basis of the number and values of the glass transition temperatures (T_g). Macroscopic determinations of the T_{gs} were performed by differential scanning calorimetry (DSC), temperature modulated DSC or dynamic mechanical analysis (*DMA*). In phase separated blends, most authors concluded that, at the end of cure, the epoxy-rich phase contained a low concentration of thermoplastic whilst a larger proportion of epoxy-curing agent species was dissolved in the thermoplastic-rich phase.

In brief, the above mentioned experiments did not allow the quantitative determination of the chemical characteristics of the phases. Moreover, it seems that no method has been reported to provide direct local measurements of the phase features. With the aim of filling this gap, this paper describes the use of micro-Raman spectroscopy as a direct method for characterising locally the phase chemical features in thermoplastic-modified epoxy systems. The combination of Raman spectroscopy and confocal microscopy is increasingly used for spatially resolved investigation of heterogeneous materials. In thermoplastic-thermoplastic blends, local qualitative or quantitative determination of phase composition has been performed (Overbeke et al. 2001). However, micro-Raman spectroscopy has not yet been significantly used for the characterisation of epoxy-thermoplastic blends.

In this study, one type of blend was mainly examined, composed of *trimethylene glycol di-p-aminobenzoate (TMAB)*, *diglycidyl ether of bisphenol-A* (*DGEBA*) and *polystyrene* (*PS*) identifying the most representative vibrational normal modes.

The technique is of both academic and industrial interest to study epoxy/amine systems in the production of thermosetting polymers and is demonstrated by practical applications in this paper including a study and identification of vibrational normal modes in the epoxy oligomer Diglycidyl ether of bisphenol-A (DGEBA) and trimethylene glycol di-p-aminobenzoate (TMAB) system. By micro-Raman spectroscopy, the principal vibration modes around 1626, 3333 y 3436 cm^{-1} were determined for amine groups of TMAB, and 915, 933, 1131, 1249-1252, 1407, 2713, 2760 y 3006 cm^{-1} for epoxy rings of DGEBA.

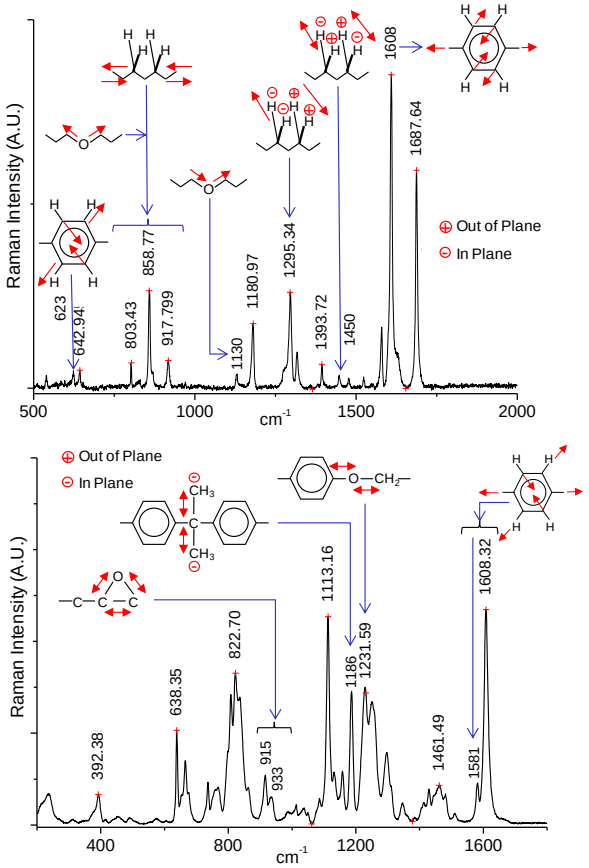

Figure 1. Some vibrational normal modes using micro-Raman spectroscopy of trimethylene glycol di-p-aminobenzoate-TMAB (up) and diglycidyl ether of bisphenol-A DGEBA (down).

Characterization of the Mechanical Properties of EVA Foams by TMA

M.I. Beltrán[1], A. Marcilla[1], I. Pelaez[1], A. Otero[2]

[1]Chemical Engineering Department, Alicante University, Spain
[2]Cauchos Karey, Alicante, Spain

e-mail:maribel.beltran@ua.es

Introduction: Crosslinked EVA foams have been increasingly used in a great variety of applications. As a shock absorber, they are commonly present in footwear and sport floorings. The mechanical properties and, especially, the softness, resilience and compression set, together with the light weight (low density) are the key feature in these materials (1). Compression test to measure the permanent deformation of foam is normally carried out according the corresponding ASTM, compressing the foam by 50% for a relatively short period of time (by 6 hours) and then allowing the foam to recover for 30 min. It is known that these test may not be representative of the recovery and resilience performance of materials under intermittent forces or at longer terms, for example as those suffered by floorings or footwear (2).
In this work, EVA crosslinked foams with different type and concentration of filler have been prepared and characterized by termomechanical analyses (TMA) in order to obtained their permanent deformation under intermittent forces. Moreover, the density, hardness and morphology of the cellular structure have been measured.

Materials and Methods: A commercial EVA copolymer with 18% of VA provided by Trithene was employed. Formulations include calcium carbonate (Rocio-3), silica (Ebrosil), stearic acid (Croda), zinc oxide (Asturiana de Zinc), azodicarbonamide (Cellcom H919) as a foaming agent and peroxide (Luperox F40) as a crosslinking agent. The composition of the blends with different silica and calcium carbonate content are shown in Table 1.
To obtain the foams, all the components were blended in a Banbury plasticorder Guix-2P at 90º C for 8 minutes, and roll milled in a two roll mill Guix-2403. The obtained sheets were compression moulded in a hot press Mecamaq DE-200 at 160º C for 20 minutes. The final thickness of the sheets was roughly 2 cm. Foams characterization included density measurement in a Metler Toledo XS205 balance. Hardness was obtained by the ShoreA method using a Baxlo durometer. TMA was carried out in a Q400 model of TA Instruments performing 8 cycles of stress (at 1N and 40º C for 30 minutes)-relaxation (at 0.01 N and 40º C for 30 minutes). The bubbles distribution was obtained from SEM photographs (JEOL JSM-840).

Results and Discussion: The presence of calcium carbonate in the blends involves higher densities whereas the hardness increases with the higher amount of silica (Table 1). Moreover, the bubble size distribution of the foams is lower and more homogeneous in the blends that contain greater amounts of filler, especially silica.

Table 1. Foams composition and results.

	Content (phr)		Results	
Blend Name	Silica	Calcium carbonate	Density (g/cm^3)	Hardness (ShA)
R	25	15	0,122	30
S	40	0	0,103	27
C	0	40	0,143	20
N-F	0	0	0,151	15

From the TMA analysis, a time-stain curve for repeated cycles was obtained for each blend, as it can be seen in the Figure 1 for the R sample. The repeated cycles carried out in TMA may represent more adequately the forces applied to these materials in their daily uses than those applied in continuous compression tests, while the permanent deformation values obtained form TMA are in the order of those found in the bibliography. The previous study carried out showed than no further deformation occurs from the eighth cycle on.

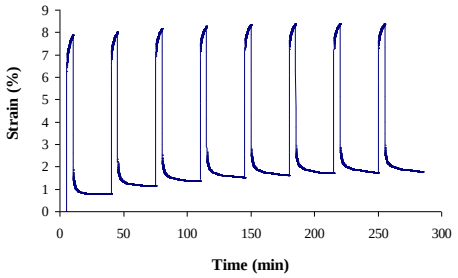

Figure 1. Strain curve of the R blend obtained in TMA.

The highest strain (last cycle) and the remaining strain of each curve have been obtained, and are shown in Table 2.

Table 2. Highest and remaining strain results.

	R	S	C	N-F
Highest strain (%)	8,09	9,34	12,14	20,64
Remaining strain (%)	1,55	1,71	2,63	4,71

Foams C and, specially, N-F, present higher values of strain than foams R and S, which present similar and low values of both parameters, showing the suitability of silica to improve resilience.

Conclusions: TMA has been employed to measure the mechanical properties of different foams, and a reasonably value of the permanent deformation has been obtained. The higher concentration of silica in the EVA foams reduces the permanent deformation of foams subjected to intermittent forces.

Molecular Weight Distribution Changes in Irradiated Films of Vinyl Ketone Copolymers

S. Sánchez-Ballester[1], *J.D. Badia*[2], *A. Martinez-Felipe*[2], *A. Ribes-Greus*[2] *V. Soria*[1,*] *Institut de Ciència dels Materials* (ICMUV), Universitat de València[2] Institut de Tecnología de Materials (ITM), Universitat Politècnica de València (UPV)

corresponding author: V. Soria (vicente.soria@uv.es)

Introduction

The characterization of polymer degradation through the chain scission mechanisms is difficult in polydisperse samples because it needs to account for the diversity of chain sizes. The sequence of chain fragmentation can be detailed in the gradual changes in the form of the molecular weight distribution functions (MWD). Progressive changes in the MWD functions could only be determined by inspecting a set of SEC chromatograms obtained from the initial or zero degradation to final molecular chain scission. The molecular interpretation of the lateral shift pattern in the evolved MWD curve sequences is critical for gaining insight into the decay trajectory. The above is clearly confirmed by the gradual temporal movement from high MW to low MW zone on the left-hand side of the chromatogram. However, the chromatograms only provide data in terms of discrete average values, e.g. degree of polymerization and various statistical moments or average molecular weights, including polydispersity index. The differences in characteristic lateral movements of SEC traces or changes in their MWD shapes were analysed and assessed in terms of a distribution function model. Complementary FTIR measurements of virgin and degraded films served to confirm the extent of degradation.

Materials and methods

Preparation and characterization details for poly(methyl methacrylate-co-methyl isopropenyl ketone), PMIK films,were reported in a previous paper [1]. Samples of all copolymers were irradiated with a Ultravitalux (Osram) sunlamp in our lab. The IR spectra were recorded by NEXUS Spectrometer, ThermoNicolet Corp. (Madison WI, USA) in all cases at least 64 scans with an accuracy of 2 cm^{-1} were signal-averaged. The frequency scale was internally calibrated with a He-Ne reference to accuracy of 0.2 cm^{-1} and externally with polystyrene. The PMIK samples were placed on a horizontal holder for beam exposure, according to the ATR (alternative total reflection) spectroscopy technique, and data processed data with OMNIC software.

Results and Discussion/Conclusions

The Average Molar Masses of neat and degraded samples, extracted from SEC-RI traces, are shown below. The degradation observed over a 2-year period in the buried specimens (9 cm soil depth) was negligible. However photo-degradation effects, as expected, increased with the copolymer MIK content. . In the more extreme deterioration step, changes from 2.4 $\times 10^5$ to 6.5 $\times 10^3$ (g/mol) in M_n and from 1.8 to 2.2 in the polydispersity index were observed. Nevertheless, in all cases, the shapes of experimental SEC traces were unimodal, revealing the absence of recombination or cross-linking reactions during the chain scission process. A mathematical model was applied to assess the time-evolution of the MWD functions of sunlight

Study of the Thermal Behavior of Syndiotactic and Atactic Polystyrene By Raman Spectroscopy

Nadège Brun[1,2], Patrice Bourson[1], Samuel Margueron[1], Michel Duc[3]

[1] Laboratoire Matériaux Optiques Photonique et Systèmes, SUPELEC, 2 rue Edouard Belin, 57070 Metz, France.
[2] Total Petrochemicals France, Usine de Carling, BP 90290, 57508 St Avold.France.
[3] Total Petrochemiclas France, Zone Industrielle Feluy , B-7181 Seneffe Belgium.

A lot of properties electrical, chemical, optical or physical can be explained by the chemical structure of polymer. For example, atactic polystyrene and syndiotactic polystyrene present differences about the regularity of their hydrocarbon chain. If the first has phenyl groups randomly distributed on both sides of the chain, the second has got a regular arrangement which the group has alternate positions along the chain. The amorphous or semi-crystalline character depends on reaction of polymerization. Actually, if reaction of polymerization is a radical polymerization, polymer will be amorphous. Whereas, polystyrene made by Ziegler-Natta polymerization is semi crystalline.

In the study of polymer, it is more important to measure of the glass transition temperature, Tg, and melting temperature Tm. Also, between the glass transition and the melting point, part of the hydrocarbon chain has enough energy to fall into crystalline arrangements. The temperature allowing this crystallisation phenomen is noted Tc. The polymer behaviour is fonction of the temperature of treatment.

Futhermore, the litterature of syndiotactic polystyrene index four polymorphs, α, β, γ et δ, can be grouped by pairs, according to the backbone conformation , the (α, β) has a planar all-trans "zigzag" conformation whereas the other pair (γ, δ) have a helical trans-trans, gauche-gauche conformation 1, illustrate the two types of conformation that literature gives. Using Raman spectroscopy, Kobayashi et al 2 observed that the ν1 vibration is very sensitive to the local backbone conformation resulting in the presence of two distinct peaks at 770-773 and 796-802 cm-1 corresponding to all-ltrans conformations and mixed trans/gauche conformations, respectively.

A preliminary work consist in comparison of Raman spectra of atactic polystyrene and syndiotactic polystyrene were investigated, in order to determine signature of crystallinity. The Raman spectrum of atactic polystyrene shows peaks which are different compared to Raman spectrum of syndiotactic polystyrene, as shows in figure 1:

The second study is function on the temperature and tries to correlate Raman spectroscopy with DSC. In figure 2, we focus on the spectra part from 700 to 800 cm-1. The peak observed at 770 cm-1, which is relating all-trans conformation, increases with temperature. Whereas the peak at 797 cm-1, which is associated trans-gauche conformation, reduces with temperature:

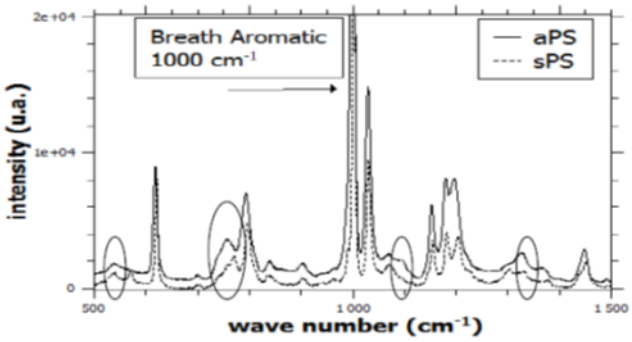

Figure 1: Raman spectrum of aPS (black) and sPS (dash line). Circles show the main differences between aPS and sPS spectra

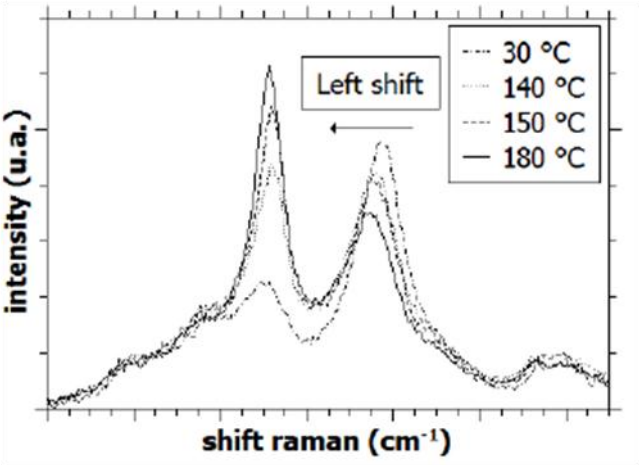

Figure 2: Raman spectrum of sPS at 30 °C, 140 °C.

As a polymer is characterized by phase transitions, observable by X-ray diffraction by DSC, XRD and vibrational spectroscopy. We propose to use Raman spectroscopy to characterize the crystallinity of polystyrene, in particular, amorphous and semi-crystalline phase, in order to correlate this method with DSC and XRD.

bourson@univ-metz.fr

Introduction During the forming process, by plastic deformation, of semi-crystalline polymers, the mechanisms of macromolecular chain orientation have an important role. It is the same during the relaxation after plastic deformations, which have a direct influence on the final product. The knowledge of these mechanisms is essential for good process control.

Therefore it conducted a study of the chains orientation of isotactic polypropylene during the elastic recovery.

Today the techniques used to study the chains orientation are heavy and long : X-ray and other light methods. In our experience using a Raman spectrometer to determine the chains orientation, the measurement takes a few seconds, which is much faster, and could allow in line measurements.

Material The semicrystalline isotactic polypropylene (noted IPP) investigated in this work was produced by ATOCHEM (Reference 3050 MN1).The density, determined by hydrostatic weighing is $\rho = 0.946$ g.cm^{-3}.

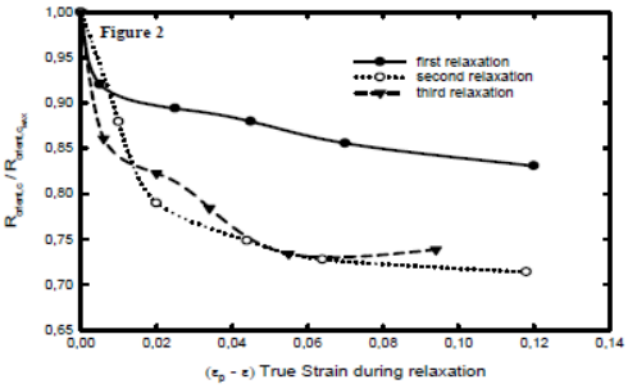
The crystallinity in weight is Xc = 0.67. The glass transition temperatures, Tg, and the melting temperature, Tm, determined by differential scanning calorimetry are respectively -5°C and 165°C [1-2].

Analyses by X-ray diffraction revealed the exclusive presence of the α-monoclinic crystal of isotactic polypropylene.

Mechanical Tests The experimental setup consists of a system VidéoTraction™[3] coupled to a Raman spectrometer. The traction machine is equipped with a camera that closely follows the movement of dots markers placed on the surface of the specimen. A computer calculates the strain from video images and control the traction machine accordingly to ensure a constant strain rate. The Raman scattering spectra are performed in a backscattering configuration. The laser has a wavelength of 785 nm. A polarizer is placed in the spectrometer; its polarization axis is parallel to the axis of the tensile test. The acquisition time is set to 5seconds. In this work, the mechanical tests were run at the strain rates $d\varepsilon/dt = 5.10^{-4}$ s^{-1}. We applied on the specimens a constant cycling deformation with increasing strain until $\varepsilon = 0.3$ (Figure 1). Then unloading it to the stress $\sigma = 0$. And a new round of tension began following up the deformation $\varepsilon = 0.6$. The strain step is $\Delta\varepsilon = 0.3$.

Spectral Signature Ponçot et al, [4] and J.Martin and al [5] have developed spectral signature to study the chain orientation of IPP during the uniaxial stain test. It uses two Raman bands located at 973 and 998cm-1. The first one is principally assigned to the asymmetric stretching mode of the C-C skeletal backbones while the second is referred to the rocking mode of the CH3 lateral alkyl groups. The CC bonds and alkyl groups which they are attached are in orthogonal positions. So when using a Raman polarized in the direction of CC bonds, must have observed an increase in the band at 973 cm^{-1} and a decrease of the band at 998cm^{-1}. Based on this observation, a simple criterion was developed, for measuring the orientation of carbon chains of the crystalline. The measure consists of calculating the intensity ratio between the 973cm^{-1} band intensity and the 998cm^{-1} band intensity. This Raman criterion correlated by X-ray diffraction, allows the measurement of orientation during the deformation. We call $R_{orient,c}$ the ratio of two bands of intensity. $R_{orient,c}$ = J(973cm^{-1}) / J(998cm^{-1}).

RESULTS AND DISCUSSION



And it is interesting to link it to the reorientation of the chains of the crystalline phase. It is found that initially the reorientation is small, then to larger deformations, the reorientation decreases consistently Figure 2, we can compare the three relaxations. For the first at small strain, reorientation is low, and takes place from the beginning. For the two others relaxations reorientation is taller and has also held mainly at the beginning of relaxation. Experience shows that in the elastic phase and the early of plastic deformation, the phenomenon of crystalline chain orientation is not predominant. But once the amorphous phase disentangled, the chains orientation becomes a dominant mechanism. And during the elastic recovery the reorientation becomes increasingly large.

CONCLUSIONS

The technique coupling a spectrometer Raman with the VideoTraction™ allows in situ measurements during tensile tests. It was able to follow the macromolecular chains orientation during load and unload. Thus the microstructure evolution during relaxation could be studied. Dahoun [8] showed the evolution of the viscoelastic coefficient w/w0 load after load. The convergence of behavior at large strains has showed. In our experience the evolution of reorientation of the macromolecular chains follow the behavior of w. This knowledge of chains orientation is important in the drawing process; the mechanical properties depend on the preferred orientation of the chains. And others share the Raman Spectra can provide other information such as crystallinity and volume damage. It is therefore an inexpensive and rapid technique with a promising future.

Chromatographic characterization of PS-block-PEO

Monika Grabowsky, Muhammad I. Malik, Pritish Sinha, Harald Pasch

Fax: +27218084967, e-mail: monikag@sun.ac.za, imran@sun.ac.za

Block copolymers are a promising group of materials used for many different applications such as surfactants, compatibilizers, detergents among many others. Block copolymers of polystyrene (hydrophobic in nature) and polyethylene oxide (hydrophilic) make them amphiphilic materials. The amphiphilic property of these block copolymers is exploited for above mentioned applications of these materials.

Block copolymers are complex materials with distributions in many properties like chemical composition distribution, molar mass distributions etc. Along with the block copolymers, the presence of homopolymers of both types in the sample is very difficult if not impossible to avoid. Specifically block copolymers of PS-b-PEO have not been investigated for above raised questions. Baran et. al.[1] used critical conditions for PS to get information about the PEO block but they have used only very lower molar mass products without facing big problems in solubility. In contrary to their study, we are investigating PS-b-PEO block copolymers with a wide range of molar masses of both blocks from several thousands to hundred thousands.

Liquid chromatography at critical conditions is used in this study to separate homopolymer fractions from the block copolymers. At critical conditions the block copolymer is separated according to the molar mass of the non-critical block which is excluded from the pores of the stationary phase.

The selection of a suitable solvent system was a real challenge for this study as both blocks are exceedingly incompatible with each other as well as with good solvents of the other block.

The block copolymer and homopolymer fractions are collected from LCCC and subjected to FTIR for further qualitative as well as quantitative analysis.

The increasing interest and new developments in the fields of nanomaterials, medicine and biology have highlighted the extraordinary properties and the potential of nanoparticles (such as carbon nanotubes, quantum nanodots, gold and silver nanoparticles and micelles but to name only a few).

The analysis and quantification of these particles are therefore becoming of increasing importance and a range of separation techniques are therefore required.

Field-flow fractionation will play an essential role in the separation and analysis of these compounds as it is a powerful separation technique and has the advantage of overcoming most of the limitations associated with traditional chromatographic techniques such as size exclusion chromatography, gradient elution chromatography, Liquid chromatography at critical conditions etc.(1).

In this study we will investigate the characterisation and separation of various nanoparticles by two Field-Flow Fractionation sub-techniques.

The first being Asymmetrical Flow Field-Flow Fractionation (AF4) in which the separation is governed by an cross-flow that is perpendicularly applied to the main flow and results in a separation according to the diffusion coefficient of the particles and therefore the hydrodynamic size of the particles.

The second sub-technique is Centrifugal Field-Flow Fractionation (CF3). In this technique the separation field is generated by rotating a ring-type centrifugal channel. This rotation (spinning) generates a differential acceleration force on different particles resulting in a separation according to the size and mass (2).

We aim to compare both AF4 and CF3 and show the capability of both sub-techniques to address the analytical challenges posed by nanoparticles.

High density polyethylene (HDPE) is the most commonly used material for the transportation and distribution of water and natural gas from nearly 40 years ago. For this application the resin has to fulfil certain mechanical properties, being one of the most critical the resistance to the Slow Crack Growth (SCG) process. This failure mechanism involves the formation of a craze at a point of stress concentration (fittings, welds, defect within the surface wall, surface flaws) and the subsequent growth and final fracture of the material in a brittle way [1].

SCG resistance is generally measured using the PENT test (Pennsylvania Notched Tensile test - ASTM F1473) in North America, whereas in Europe the FNCT (Full Nochted Creep Test – ISO 16770) is more usual. Another alternative test, currently under investigation, is the CDNT (Circumferentially Deep Notched Tensile test), which permits high degree of triaxial stress on ligament, which favours the brittle failure by SCG[2]. For any of these methods, the main problem is the long time that the new polyethylene grades need for being tested. For instance, PE100 or higher grades require hundreds (even thousands) of hours to finish the SCG test.

From mid-nineties to nowadays different groups have studied quicker methods for estimating the SCG resistance using a tensile test (mode I), drawing a polyethylene specimen to its natural draw ratio or further away to the strain hardening region. In this last method, the slope of the strain-hardening part (called strain hardening modulus $<G_p>$) in the true stress-true strain curve at elevated temperatures (~80ºC) correlates well with the data obtained by a classical accelerated ESCR test [3], being this method quite sensitive to subtle molecular differences between different polyethylene samples.

Another method for estimating the SCG resistance is based on the fact that the tie molecules density is the most important parameter which controls the SCG resistance of the resin [4]. The tie molecules density could be estimated from the molecular weight and short chain branching distributions experimentally obtained by GPC-FTIR, using a primary structural parameter (PSP2) [5]. This parameter is calculated using densities estimated from GPC-FTIR data and probability equations for tie molecules formation developed by Huang and Brown [6], showing a good correlation with the SCG resistance when a broad range of materials of different structure are analysed [7].
In the present work the SCG results obtained from different tests for evaluating the SCG resistance in polyethylene pipes have been compared with the PSP2 value and strain hardening modulus $<G_p>$ at 80ºC. With regard to the PSP2 value, the correlation is reasonably good when materials with a broad range of PSP2 values are analysed. However materials with very similar molecular and structural characteristics present lower sensitivity to the method. On the other hand, the SCG results showed in Figure 1, exhibit a good correlation with $<G_p>$, which open the possibility of using this method for a quick estimation of the resin SCG resistance, or at least, to discriminate materials with inadequate properties.

Introduction:

The research of new polymer materials with improved properties has been received considerable attention in both the academic and industrial points of view. In this way, the polymer blending is an attractive approach to obtain new polymeric materials with large scale proprieties. It has been demonstrated to be an effective alternative in achieving enhanced material properties such as better processability, lowered cost, etc. Thermodynamically, the miscibility of polymer blends is mainly dependent on the value of mixing enthalpy because the contribution of mixing entropy is negligible [1].

In the present contribution, we report in the first part the results of an investigation of the effect of introducing increasing amounts of specific group 4-vinylpyridine by copolymerization within the polystyrene (PS4VPy) matrix on Poly(4-vinylphenol-co-methyl methacrylate) (P4VPhMMA). The miscibility and phase behaviour in blends of poly(4-vinylphenol-co-methy methacrylate) (P4VPhMMA50) containing 50 % of methy methacrylate with random copolymers of poly(styrene-co-4-vinylpyridine) (PS4VPy) containing various amount of 4-vinylpyridine were investigated by differential scanning calorimetry (DSC), Fourier transform infrared spectroscopy (FTIR) and scanning electron microscope (SEM).

Results and discussion

2.1. DSC Study

The miscibility of the polymer blend can be studied by many techniques. Among them, thermal analysis is mainly used in this area. In general, the DSC is the most convenient method to elucidate the miscibility of polymer blends [2]. It well known that the binary polymeric system of poly(4 vinylphenol) (P4VPh), poly (methy methacrylate) (PMMA) and their copolymers with polystyrene (PS) have been found to be immiscible over the whole range of compositions and accessible temperatures [3].

As displayed in Figure 1, the inclusion of 5 mol % of vinylpyridine into the homopolymer PS is not sufficient to obtain the miscibility between PS and P4PhMMA50. The thermograms corresponding to blends of PS4VP05, P4VPhMMA50 and their blends reveal two Tg´s for each composition. As can be seen, these glass transition temperatures are similar to those of the pure constituents, respectively. This result indicates that the enhancing, respectively, of the repulsive interactions between comonomers styrene and 4-vinylpyridine and attractive interactions between 4-vinylphenol and 4-vinylpyridine are not sufficient to provide the miscibility between the blends of PS4VP05 and P4VPhMMA50.

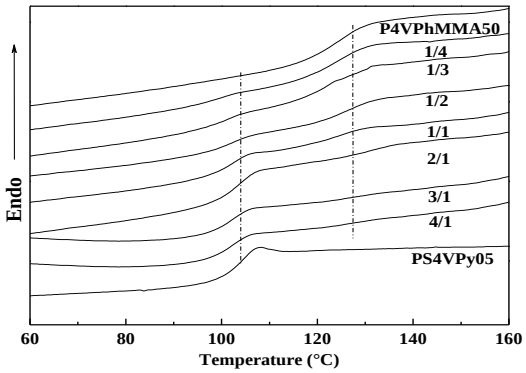

Figure 1: DSC thermograms of PS4VPy05, P4VPhMMA50 and their blends with different ratios.

2.2. SEM Study

The morphology of blends of PS4VPy05, PS4VPy15 and PS4VPy30 with P4VPhMMA50 in ratio 50/50 was also examined by SEM. In agreement with the DSC results presented earlier, the scanning electron micrographs of the fractured surfaces shown in figure 2 confirmed the immiscibility of these blends

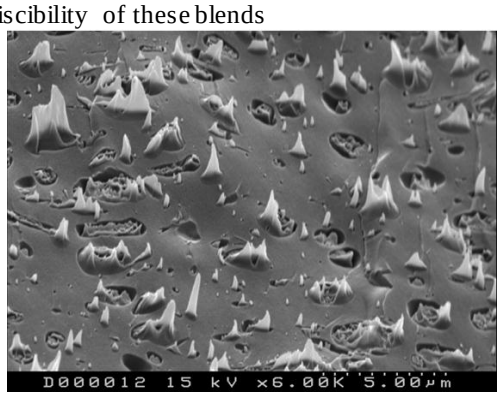

Figure 2: SEM photomicrograph of PS4VPy15/P4VPhMMA with ratio 50/50

However, above 20 % mol 4VP in PS4VP, blends of PVPhMMA50 and the random copolymers of PS4VP were found to be miscible. A single Tg intermediate between these constitutions is observed for each composition. When the amount of vinylpyridine exceeds to 40 % in PS4VPy, the obtained Tg's of P4VPhMMA50/PS4VPy blends were found to be significantly higher than those observed for each individual component of the mixture indicating that these blends are able to form interpolymer complexes. FTIR analysis reveals the existence of preferential specific interactions via hydrogen bonding between the hydroxyl and pyridine groups and intensifies when the amount of 4VPy is increased in PS4VP copolymers.

Introduction

Titanium and its alloys are widely used implant materials in orthopaedic and dental field due to their excellent corrosion resistance and mechanical properties.[1] However, titanium can not directly bond to bone, and osseointegration via the natural oxide (TiO_2) is a long-term process. Moreover, titanium is not completely inert so it could release titanium particles that could finally result in the removal of the implant.[2] One way to avoid these effects is to protect the metallic implant with a biocompatible and bioactive coating.[3] Furthermore, these coatings can be used as drug delivery system for the prevention of infections.

The sol-gel process, one of the fastest growing field in materials chemistry is a technique suitable for coating the surface of a metal. This process consists in a creation of an oxide network by progressive condensation reactions of molecular precursors in a liquid medium.[4]

In the present work, an organic-inorganic hybrid coating from methyltrimethoxysilane (MTMOS) and 3-glycidoxypropyl trimethoxysilane (GPTMS) has been produced via the sol-gel route that could be recognized by biomolecules and also allow the development of a novel process on drug delivery systems. Materials with different ratios of MTMOS and GPTMS have been synthesized to study the effect of the precursors on the final material. Different curing processes have been used in order to obtain coatings with different condensation grades.

This paper is focused on the chemical characterization of the hybrid coating. The knowledge of the chemical structure of the formed network will facilitate the understanding of the material as an osseoinductor coating and as a drug delivery system.

Materials and Methods

Synthesis of the sols

The MTMOS/GPTMS sol was prepared by acid catalysis method, using MTMOS and GPTMS as silica precursors, isopropanol as solvent and 0.1M nitric acid (HNO_3) in order to obtain an acidic pH. Water was incorporated with the nitric acid solution in stoichiometric ratio. The molar ratios of MTMOS/GPTMS were 4:1; 1:1; and 1:4. The sol solutions were stirred for about 1h and kept for another hour at room temperature before use.

Curing process of the sol

Two different curing processes have been applied to the sols: (a) 15 min. 50ºC, 15 min. 100ºC, 90 min. 140ºC and (b) 15 min. 50ºC, 15 min. 100ºC, 45 min. 140ºC.

Characterization of the coatings

The chemical composition of the coating was investigated by Fourier Transformed Infrared spectrometry (FT-IR) and ^{29}Si nuclear magnetic resonance (^{29}Si-NMR) in liquid and solid state.

Results and Discussions

The ^{29}Si-NMR study of the sols was carried on for 5 hours, with sample analyzing every hour. It was, therefore possible to identify and follow the species forming during the hydrolysis and condensation reactions. In all the cases, the intensity of T_1 species decreases while T_2 and T_3 increase.

The characteristic peaks that indicates the formation of an inorganic network are found in FT-IR spectra: ν_{as} Si-O-Si at 1115 and 1090 cm^{-1}, ν Si-OH at 900 cm^{-1} and ν_s Si-O-Si at 780 cm^{-1}. Besides these bands characteristic of the inorganic network the presence of the organic groups was registered in all spectra. In the case of the MTMOS, the band at 1275 cm^{-1} confirms the presence of Si-CH_3, whereas for the GPTMS the band at 1730 cm^{-1} is assigned to C-O vibration of the γ-glycidoxypropyl group.

The identification of the final chemical structure of coatings with different curing processes was performed via ^{29}Si MAS-NMR. The presence of condensed species confirms the formation of a well-structured Si-O-Si network.

Conclusions

This study demonstrates that the sol-gel technology is an appropriate method to obtain hybrid organic-inorganic coatings. It was possible to follow the formation of the Si-O-Si network and to identify the final structure. Further studies that provide an insight on the influence of this structure on the material properties are underway.

Introduction

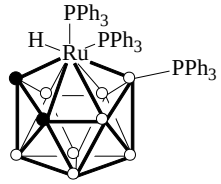
Nowadays Controlled Radical Polymerization **(CRP)** is one of the most developing areas in the modern polymer chemistry as it is very promising tool for obtaining polymer materials with necessary properties. The development of new systems for CRP is a very challenging task. Using organometallic compounds for conducting CRP is a very effective way due to the unique properties of these systems, namely the possibility of its fine tuning by changing ligand environment of a transition metal atom. In this work we report about the use ruthenium carborane complex based on C_2B_8 ligand for CRP.

Materials and Methods

Complex **1** was synthesized according the literature[1]. Monomers were dried over CaH_2 and distilled under reduced pressure prior to use. The polymerization was conducted at 80°C in sealed glass tubes under reduced pressure in monomer bulk. The obtained polymer samples were purificated from monomer and catalyst by dissolving in chloroform and precipitating in petroleum ether. The molecular-weight distributions of the polymers were analyzed by size-exclusion chromatography.

Results and Discussion

In this work the system based on ruthenium carborane complex **1** containing C_2B_8-dicarbollide ligand was used for providing CRP:



1

This is the first attempt to use *iso-nido*-metallocarboranes (0.125% mol.) for controlled synthesis of polymers. The carbon tetrachloride was used as an initiator (0.25% mol.).

The results of our experiments show that system based on **1** and carbon tetrachloride is capable to initiate polymerization of methyl methacrylate (MMA) even at 25°C. The polymerization proceeds up to high conversion of the monomer. The molecular weight of the obtained samples linearly increases with the conversion growth, what is typical for CRP. At the same time the curves of molecular weight distribution are not unimodal and have shoulders into the area of high molecular weights (fig.1.). The obtained polymer samples have rather broad molecular-weight distribution (M_w/M_n>1.5).

The polymerization can be resumed after addition of new portion of a monomer. The obtained post-polymer has a higher molecular weight indicating the living nature of the process.

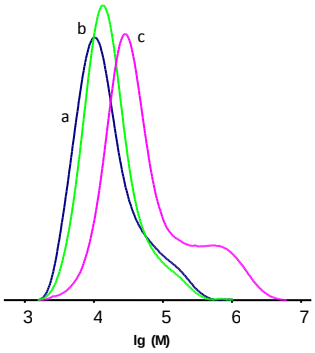


Fig 1. The curves of molecular-weight distribution of polyMMA obtained in the presence of **1** and CCl_4 at 25°C. Conversion, %: a – 20%, b – 30%, c – 95%.

The increase of temperature up to 40°C slightly improves a control over process allowing to obtain polyMMA samples with M_w/M_n=1.2-1.4. The molecular weight increases with conversion (fig. 2). The isolated polymer may be used as an initiator for post-polymerization.

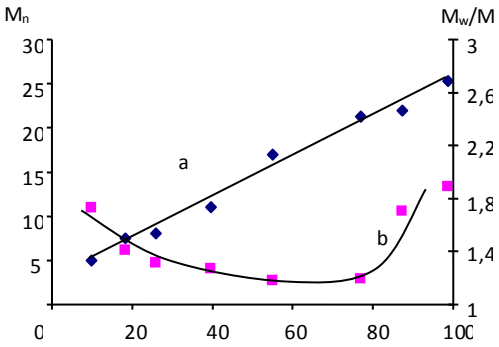

Fig 2. The dependences of molecular weight (a) and M_w/M_n (b) on conversion for MMA polymerization in the presence of **1** and CCl_4 at 40°C

It was established that the tested systems based on **1** and CCl_4 are capable to initiate polymerization of styrene and acrylates at 25°C. Unfortunately polymerization of buthyl acrylate is not controlled.

Conclusions

So, the ruthenium carborane complex **1** is a promising catalyst for CRP. Systems based on it capable to conduct polymerization of MMA even at room temperature and above, indicating it high activity.

INTRODUCTION.

Modification on conventional injection molding process of foaming thermoplastic polymers has raised much interest recent years because of its numerous advantages over conventional injection molding. However, compared to extrusion and other processes, the control of the injection foaming process appears more challenging because it deals with many additional controlling parameters such as injection speed, shot size and back pressure (1). In addition, good melt strength is fundamental to produce a foamed plastic, using either a physical or chemical blowing agent. Semicrystalline polymers like polypropylene (PP), have low melt strength, because they have linear structures with low content of branching. While resins like high melt strength polypropylene have been re-designed to improve melt strength, others may use additives or chemical modification that improve melt strength and thus enhance foaming (2-3). In this study, the feasibility of using two types of PP by different injection molding processes with a chemical blowing agent was evaluated.

MATERIALS AND METHODS.

Rheological and thermal behavior of a PP and a reinforced PP were analyzed by capillary rheology, DSC and SSA. Two ways of injection molding were used; conventional and core back injection molding. First of all, the cell structure and properties of foamed PP injected in both processes with different condition such as chemical foaming agent concentration, injection speed, as well as melt temperature were analyzed by microscopic techniques, flexural and impact properties.

RESULTS AND DISCCUSION.

The foamability of the reinforced PP was intrinsically good due to its rheological properties and material morphology, that was evaluated from SSA results and viscosity curves from Capillary rheology. Cell structure of these polymers may depend on the type of the foaming process and crystal structure, as well as the injection process used, which is clearly observed on the cell size and distribution found on the microscopy test (Figure 1). In the other hand, the skin layer of the pieces obtained on the both process could be an important factor for the flexural behavior. Although impact strength behavior is dominated by the relative density of the foam.

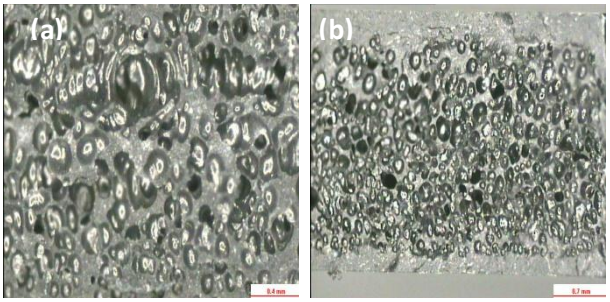

Figure 1. Optical Microscopy micrographs of (a) reinforced PP and (b) neat PP, foamed by core back injection molding

The objective of this project is present a glass fiber reinforced PVC composite, that can be used in technical application due to better mechanical properties than unreinforced rigid PVC compound. This project presents a method to produce fiber glass reinforced PVC composite.

The concept is developing a fiber glass with a new sizing compatible with PVC matrix and a process to incorporate the long fibers in the PVC compound.

The method is through incorporating continuous glass fibers with vinyl matrix prepared by wire coating process and pelletizing the coated roving (by cutting in the range 13 to 14 µm in length). The pellets are mixed with granulated rigid PVC and this blend is fed directly into the injection-molding process machine. The direct injection molding is an excellent option because it reduces the number of processing, reduces the deterioration of the glass fibers length and reduces the possibility of PVC resins degradation.

In summary, long glass fiber reinforced PVC compound through incorporating by wire coating process is possible and it created an innovating process of reinforcement into the vinyl area, in addition to the better mechanical properties achieved that allow PVC can be used in a unrecognized high-performance applications that was not possible before.

New Copolymer of Tautomerizable Monomer

Introduction.

Although there are a lot of papers published on tautomeric studies of different organic compounds [1], no much works are related with tautomerics equilibria in polymers. For example, Czech studied metal chelate zirconium acetylacetonate (ZrACA) added into acrylic polymers with self-adhesive properties [2]. These acrylic polymers, known as acrylic pressure-sensitive adhesives (PSA), were crosslinked with ZrACA to obtain acrylic self-adhesives and to study the crosslinking reaction between carboxylic groups of the polymer chain and metal chelate crosslinking agent. The tautomeric equilibrium in this reaction is very important because these reactions occur through tautomeric forms.

We consider that tautomerics equilibria in polymers could be responsible for important properties and applications. That is why the aim of our work was the study of tautomerics equilibria in styrenic copolymer including a comonomer with tautomeric β-ketonitriles form.

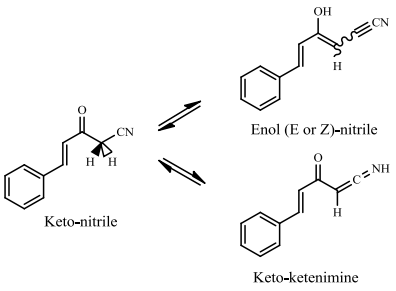
Materials and Methods.

5-phenyl-3-oxo-4-pentenonitrile (CM_3) was obtained through an adaptation of a literature method [3]. The tautomerics equilibria in this monomer was study by mass spectra-gas chromatography (GC-MS) in gas phase, Nuclear Magnetic Resonance (NMR) in solution and Infrared (IR) spectroscopy in solid state. These experimental results were compared with DFT calculations[4].

CM_3 was copolymerized with styrene in thermal conditions at 60°C using azobisisobutyronitrile (AIBN) as initiator. The polymerization reactions were carried out in closed reaction tubes in vacuum. The reactions was quenching by precipitation with cold methanol. The polymer isolated was purified by dissolving in chloroform and precipitation on methanol. We repeated this procedure until only the peak of the polymer was seen in the size-exclusion chromatography (SEC). The weight average molecular weight (M_w) and the polydispersity index ($PI=M_w/M_n$) were determined by SEC using a series of four Waters columns and Cl_3CH as eluent. Polystyrene standard was used as calibrant.

Results and Discussion.

The tautomeric form of CM_3 is shown in the figure below. The tautomerisms nitrile-ketenimine monomer only was seen by GC-MS, while the tautomerism keto-enol was seen by NMR and IR spectra only [4].



We expected that this type of behavior can be observed in the corresponding copolymers.

The table below shows the experimental condition and results obtained for copolymerization reactions.

Name	Time (hs)	Concentration AIBN*	f_{CM3}	Conversion (%)	Mw	Ip
$CoStCM_3^1$	14	0.50	0.67	14.5	34660	1.65
$CoStCM_3^2$	23	0.25	0.67	16.5	32580	1.80
$CoStCM_3^3$	24	0.25	0.2	34.3	82395	1.99
$CoStCM_3^4$	24	0.25	0.5	22.1	52520	1.88
$CoStCM_3^5$	24	0.25	0.75	14.5	33175	2.07
$CoStCM_3^6$	24	0.25	0.9	18.7	-	-

* (% p/p)

$CoStCM_3^6$ and $CoStCM_3^7$ were not determinate yet.

The polymers were characterized by IR spectroscopy. We could asignated picks for both monomers and also for tautomeric forms. Nitrile band at 2230 cm-1 and carbonyl band at 1685 cm-1. We assigned a band at 1620 cm -1 for double bound C=C for enolics forms in the polymers obtained. There is an increase of the reaction conversion when the content of CM_3 decrease, which suggest a lower reactivity of this monomer. Accordingly, an increase in the M_w was observed. Actually, we are carrying out determinations by NMR spectroscopy in order to determinate the copolymer composition (F) and then the reactivity ratio.

Conclusions.

New copolymers styrene-5-phenyl-3-oxo-4-penteno-nitrile was synthetized and characterized whose tautomeric equilibria study is been conducted.

"Smart Pellet" Additives for Reinforcement in Polypropylene Composite

Yuxin Wang, *David A. Schiraldi*

Department of Macromolecular Science and Engineering, Case Western Reserve University, Cleveland, OH-44106, United States.

Das44@case.edu

Introduction

The "smart pellet" method is based on production of an alternating, micro-scale multilayer film comprised of a matrix polymer and a fiber-filled polymer, followed by cutting this film into pellet size masterbatch particles. These multilayered pellets with the corresponding polymer matrix form a smart pellet system. Two such approaches described in the present work are: (1) use of polypropylene/inorganic fiber platelets as a means of delivering spatially-aligned inorganic fibers to polypropylene; (2) use of polysulfone /inorganic fiber platelets as both reinforcing agent and spatially-aligned inorganic fiber carrier for polypropylene.

Materials and Methods

Domolen 2300K polypropylene copolymer (PP) and a masterbatch of the same PP reinforced by 30 wt% magnesium-based inorganic whisker (Hyperform® HPR-803, Milliken Chemical) referred to as Fiber-PP (FP) were coextruded at 195°C,employing layer-multiplying technology. Basell Profax 8623 polypropylene copolymer (PP*) was also chosen as a matrix polymer. A masterbatch of PSF (Udel-3703) was reinforced by 30 wt% HPR-803; this masterbatch was referred to Fiber-PSF (FPSF). The multilayer strand of alternating PP and FPSF was melt extruded at 320°C for FPSF and at 275°C for PP while the thickness of individual PP and FP layer was targeted at 1.2 µm. The individual PP and FPSF layer thickness was designed at 4 µm. These two multilayer products were cut into pellet size by a flexible plastic blade.

These smart pellets were molded with corresponding polymer resins respectively on a Boy 22-S injection molding machine. The SEM/EDX experiments were performed on a Philips XL scanning electron microscope, operating at 15 or 20 kV. Tensile tests were conducted using an Instron 5566 Universal testing machine at a crosshead speed of 40 mm/min. Izod impact tests were conducted on specimens using a QC-63 universal impact testing machine on the half length flex bars with a V notch in the middle.

Results and Discussion

The fibers within FPP/PP "smart pellet" in the FP layers appear to be well oriented (Figure 1) in the melt flow direction. Injection molded FP/PP-PP composite exhibited greater improvement in the flexural modulus of PP than injection molded FP-PP which could be attributed to the fiber continuous dispersion in FP/PP-PP composite; though they shared similar morphology that fibers were aligned in flow direction, as well as final fiber length, which supports that no obvious difference was found in tensile and Izod strength tests.

The fibers were found to be located only in the PSF layers in FPSF/PP* smart pellet which was identified using element mapping (Figure 2).The mechanical tests of FPSF/PP*-PP* composite demonstrated that FPSF/PP* smart pellets improved the total mechanical properties more than PSF/PP* smart pellet with fiber as one more reinforcing agents. Higher flexural modulus and tensile properties of FPSF/PP*-PP* were achieved over PSF/PP*-PP*, indicating that fiber could work as an effective reinforcing agent incorporation with PSF.

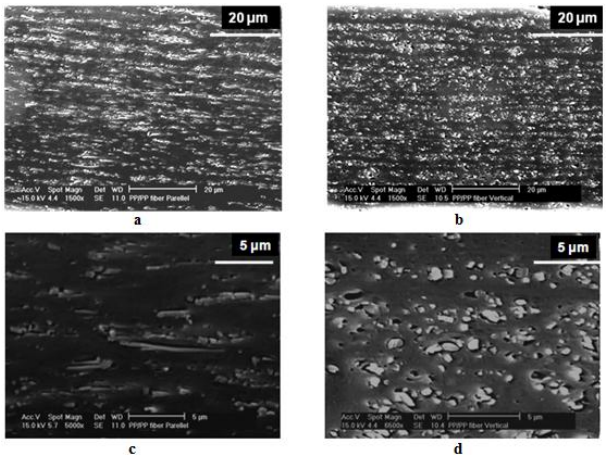

Figure 1. SEM images of the cross-section of FP/PP multilayer film. a/c: flow direction; b/d: transverse direction.

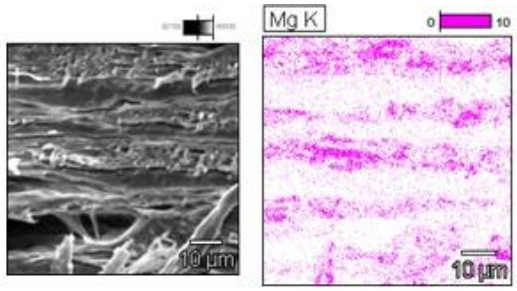

Figure 2. Element mapping graphs of the cross-section of FPSF/PP* multilayer strand in flow direction

Conclusions

"Smart pellet" method provides an effective way to improve the mechanical properties by introducing alternating polymer/fiber-filled polymer layered additives. Both a second polymer and fibers can work as reinforcing agents in the polymer system described in the paper.

Carbon Nanotube Imprinting Technique Using Brownian Motion in Polymer Melt

Masayuki Yamaguchi, *HoWon Yoon*

Japan Advanced Institute of Science and Technology

m_yama@jaist.ac.jp

ABSTRACT Localization method of multi-walled carbon nanotubes (CNTs) on the surface of a polymer sheet was demonstrated using interphase CNT transfer from one polymer to another. It was found that CNTs move from the polypropylene (PP)/CNT composite to polycarbonate (PC) during annealing procedure in the molten state of both polymers. The sheets of PP/CNT and PC were easily separated because of the large interfacial tension between PP and PC. The formation of a thin CNT-rich layer on the surface of the separated PC sheet produces electrical conductivity. Consequently, a conductive sheet is obtained with significantly small amounts of CNTs. Since the CNT transfer is attributed to Brownian motion, the annealing conditions such as temperature and time are responsible for the diffusion.

Introduction

As increasing the demand for electronic application of polymeric materials, a polymer with good electrical conductivity has been desired and investigated intensively these days. Carbon nanotubes (CNTs) are widely used as one of the high-performance modifiers because of the unique properties such as high stability, high electric and thermal conductivity, and large aspect ratio. Therefore, the properties of polymer composites containing CNTs have been studied intensively over the last decade for applications in electrostatic dissipation, electromagnetic interference shielding, and radio frequency interference shielding.

It was demonstrated by our previous work that CNT shows Brownian motion in a molten polymer. Hence, reorganization of CNT dispersion state in a molten polymer occurs at high temperature, leading to the formation of a conductive path [1].

In this paper, a new method of imprinting CNT by means of Brownian motion is demonstrated.

Experimental

Polycarbonate (PC) and polypropylene (PP) were used as polymer matrices. The composite of 20 wt% multi-walled carbon nanotubes (CNT) in a PP matrix was obtained from Hodogaya Chemical (Japan) as a pellet form. Typical diameters of employed CNT are from 40 to 80 nm, while the lengths are between 10 and 20 μm. The density is approximately 2.3 g/cm^3.

PP/CNT and PC were compressed into flat sheets using a compression-molding machine. Using them, the thermally activated transfer process of CNTs between surfaces of immiscible polymer pairs is investigated by the procedure illustrated in Figure 1. The laminated sheets were prepared by placing the pure PC sheet on the PP/CNT sheet. Then, annealing operation was performed in the compression-molding machine at various conditions [2].

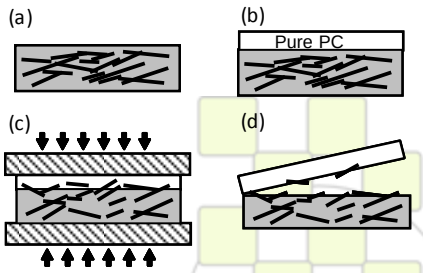

Figure 1.
Experimental procedure of CNT transfer; (a) a CNT-filled PP sheet, (b) place a pure PC sheet on the CNT-filled PP sheet, (c) anneal the laminated sheet in various conditions, and (d) separate the sheets after cooling.

Results and Discussion

Since PP is immiscible with PC, the piled sheets were separated without any difficulty after annealing operations. Then, the separated surface of the PC sheet was examined in detail.

As seen in the SEM picture of the cross-section of the PC sheet after annealing at 300 °C for 5 min, CNT-rich region is generated in the surface of PC. These CNTs were immigrated from PP/CNT during the annealing operation. Because of the concentrated layer, the surface resistivity decreases greatly to 10^3 [ohm/sq.]. This is significantly lower than the surface resistivity of a conventional polymer (> 10^{15} [ohm/sq.]).

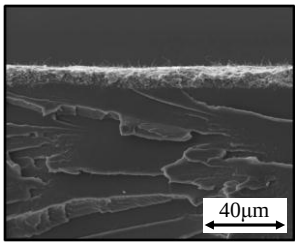

Figure 2. SEM picture of the cross-section of the PC sheet after annealing procedure at 300 ºC for 5 min with the PP/CNT sheet.

Since CNT transfer is attributed to Brownian motion, heating conditions such as temperature and duration time are responsible for the amount of transferred CNTs. For example, the thickness of CNT layers, as exemplified in Figure 2, is proportional to the square of the applied annealing time [2]. Moreover, the transfer phenomenon is influenced by the dispersion state of CNTs in the composite, the size of CNTs and their compatibility, and the chemical structure of the second polymer [2]. Finally, this method can be used to improve surface properties while minimizing CNT content in the bulk of the polymer composite and could be a feasible process to integrate CNTs into various devices.

Conclusions

Localization of CNT at the surface of a PC sheet is attained using the CNT transfer phenomenon from a PP/CNT sheet during annealing procedure at 300 °C. This result suggests that CNT prefers PC to PP. Since the technique gives a conductive polymer sheet with a small amount of CNT, it will be applicable in the industry.

Polymerisation of Pyrrole with Phenyliodine bis(trifluoroacetate)

Esin Ateş and Nilgün Kızılcan

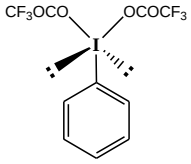
Istanbul Technical University, Department of Chemistry, Istanbul 34469, Turkey

esinatess@gmail.com

Various types of inorganic or organic catalysts are used for chemical synthesis of polypyrroles. In the case of conducting polypyrroles halogens and salts of transition metals (eg. Ag^{+}, Cu^{2+}, Fe^{3+}, Ce^{4+}) are common catalysts that are able to serve both as an oxidizing agent for monomer and a doping agent for polymer chains.

Structure, size and concentration of oxidizing agent effect solubility, morphology, processibility and conductivity of resulting polymer. Large organic molecules or ions (eg. surfactants such as aryl sulfonates and their acids) are prefered to keep polypyrrole chains in a distance and interact with solvent. Thus the solubility of polypyrrole increases in organic solvents. Regulating concentration of the oxidant gives control over crosslinking and number of defects of π-conjugation located on polypyrrole chains. High overoxidation of pyrrole rigns lead to lower conductivity of resulting polymer.

Hypervalent iodine reagents provide an alternative synthetic route to classic reagents including heavy metals such as Hg^{2+}, Tl^{3+}, Cd^{4+} and Pb^{4+}. Low toxicity, good stability, easy handling and good reactivity are attractive properties of these reagents. Most known trivalent and pentavalent iodine reagents are phenyliodine (III) bis(trifluoroacetate) (PIFA), phenyliodine (III) diacetate (PIDA), [hydroxy(tosyloxy)iodo]benzene (Koser's reagent), iodosyl benzoic acid (IBA) and 2-iodoxybenzoic acid (IBX).



(PIFA)

PIFA is a tool to generate radicals from alohols, amines and azides[1]. Besides it is used in applications to generate radical cation from aryl compounds via single-electron-transfer(SET) mechanism. The latter provides further reactions with nucleophiles. When nucleophile is an aromatic ring then biaryl compounds are synthesized[2,3]. PIFA is able to assist oxidative coupling of phenolic compounds [4-6] and reactions of heteroaromatic compounds, eg. synthesis of pyrrole derivatives[7] and thiophene oligomers[8,9], however PIFA is not a usual catalyst for polymerisation process of these species.

In present study PIFA mediated synthesis of polypyrrole was performed. Experimental parameters such as oxidant/monomer molar ratio, concentration of PIFA, temperature and solvent were investigated. Although molar ratio of PIFA/pyrrole was 1/7, vigorous exothermic reaction occured. Effect of the reaction conditions on yield, solubility, thermal properties and conductivity of resulting polymer was determined. Polypyrrole synthesized in acetonitrile at 0°C has conductivity of 0.16 S/cm.

Performance improvement of silicone rubber/carbon fiber composites

Eung Soo Kim, Young Ho Jeon, Mi Yeong Jo, Jin San Yoon

Department of Polymer Science and Engineering, Inha University, Incheon, Korea

jsyoon@inha.ac.kr

Introduction

Silicone rubber is one of the most important inorganic polymers. However, most applications require that PDMS be reinforced by solid fillers.[1] The most widely used fillers for reinforcing PDMS are silica, carbon black and fibrous fillers.[2]

Carbon fiber (CF) is an attractive reinforcing material due to its superior specific strength, specific modulus and low linear coefficient of thermal expansion.[3] Usually the interfacial interaction between CF and the polymer matrix is not strong enough to cause easy failure.[4] Therefore, surface-treatment of CF is required to raise the interfacial interaction enhancement.

In this study, silicone rubber composites were prepared with a room temperature vulcanized (RTV) type silicone rubber, carbon black, and CF. CF was modified by treating with nitric acid followed by grafting of the silane compound containing isocyanato group to the CF surface. The effects of the surface modification of CF on the mechanical and thermal properties were explored for the RTV/CF composites.

Results and Discussion

CF containing hydroxyl and carboxyl groups (Acid-CF) was prepared by treating neat CF with nitric acid under nitrogen flow. The surface of Acid-CF was then grafted with IPTS by having the isocyanate group of the IPTS residue on the surface of Acid-CF reacted with the hydroxyl and carboxyl groups of Acid-CF. The IPTS grafted CF was named as I-CF.

Condensation reaction between the alkoxy groups of I-CF and the silanol groups of RTV is feasible so that the RTV molecules grafted to I-CF should increase the interaction between the RTV silicone rubber and I-CF.

Chopped CF is usually supplied in bundles through the surface coating with organic matters because uncoated CF provokes dust scattering problems. Therefore, the coating agent needs to be removed from the CF surface in order to well disperse the chopped fiber in the rubber matrix.

The cross section morphologies of the RTV/CF composites are displayed in Fig. 1. The CF fibers in the RTV/CF composite exhibit a comparatively clean surface. On the other hand, I-CF in the RTV/I-CF composite is blotted with RTV debris, indicating that the wettability of I-CF to the RTV matrix was greatly enhanced.

The degree of cross-linking of RTV/CF and RTV/I-CF composites was estimated from the swelling properties of the composites in toluene. The swelling ratio (S_R) of the composites was determined by using Eq. (1).[5]

$$S_R = \frac{[m_s - (\alpha_{filler} m_d)]}{(\alpha_{pol} m_d)} \quad (1)$$

The RTV/carbon black/I-CF composites exhibited the lowest equilibrium swelling ratio, confirming the occurrence of the extra curing of RTV by I-CF.

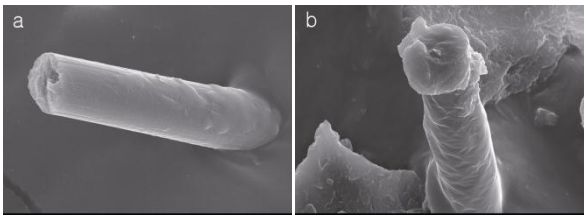

Fig. 1: SEM image of the fractured surface of (a) RTV/N774/CF (b) RTV/N774/I-CF

The tensile properties of the RTV composites are summarized in Table 1. The addition of CF to RTV/N774 did not raise the tensile strength, and the tensile strength of RTV/MA100/CF was marginally higher than that of RTV/MA100. In contrast, incorporation of I-CF to RTV/N774 and RTV/MA100 enhanced considerably the tensile strength of the respective composites. Moreover, the decrease in elongation at break of the composites was more significant when I-CF was incorporated into the composites instead of CF. These results confirm again the occurrence of the extra curing of RTV due to I-CF and the enhanced interfacial interaction.

Table 1: Tensile properties of the RTV/CF composites

	Tensile Strength (MPa)	Elongation (%)
RTV/N774	1.6	245
RTV/N774/CF	1.6	63
RTV/N774/I-CF	4.1	18
RTV/MA100	1.4	118
RTV/MA100/CF	1.7	41
RTV/MA100/I-CF	4.3	15

Novel mechanochemistry reactor and its use for rubber degradation studies in presence of stabilizers under controlled reactive gas atmosphere

Daniele Dondi, Armando Buttafava, M.Bianchi, Alberto Zeffiro, Antonio Faucitano

[1] Dipartimento di Chimica, Universita' di Pavia, V.le Taramelli 12, 27100 Pavia (Italy)

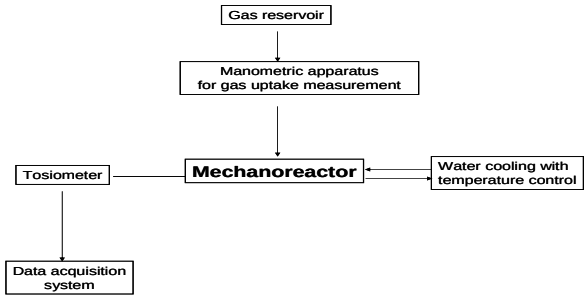
antonio.faucitano@unipv.it

Introduction

A lab reactor has been developed suited for investigating the mechanical degradation of polymeric materials in controlled gas atmosphere and with the possibility of on line monitoring of key chemical and viscosity parameter. The apparatus was then used to study the mechanical degradation of SBR rubber under inert and oxygen atmosphere and the effect of antioxidant and stabilizers belonging to the class of tetralkyl piperidine (HALS), guanidine and aromatic amines.

Materials and Methods

Fig 1 *Scheme of the lab reactor used for the mechanochemical degradation experiments.*



The tritor was made of two disks bearing interpenetrating blades one of which was kept rotating. The fixed disk was connected to a dynamometer for torque measurement. The reactor chamber was double jacket for thermostated water circulation and connected to a reservoir and a manometric apparatus for gas feed and uptake measurement . EPR and reduced viscosity measurements during the reaction were made by time to time sampling the material after stopping the apparatus.

SBR copolymer (23.5% styrene) was used as received. 2,2,6,6-tetramethyl piperidinyl sebacate (Tinuvin 770), Diphenyl guanidine (DPG) and di-tolyl paraphenylene ammine (DTPD) were used as antioxidant and stabilizers. The yield of mechanoradicals $R^{\bullet}$ was determined by carrying the reaction in presence of a known concentration of 2,2,6,6-tetramethyl piperidine-N-Oxyl stable radicals (TEMPO) and measuring its concentration decrease induced by the spin trapping reaction: $R^{\bullet} + >N\text{-}O^{\bullet} \rightarrow >N\text{-}O\text{-}R$

The reduced viscosity measurements were made with an Ubbelhode apparatus using tetraydrofurane as solvent.

Results and Conclusions

The kinetics of SBR degradation under nitrogen atmosphere is characterized by an initial stage where the viscosity decreases as a consequence of the prevalence of chain scission ; this trend is reversed in the later stages of the reaction because of the progressive taking over of the crosslinking mechanism.

.

The overall yield of mechanoradicals increases steadily with the machination time attaining magnitudes greater than 1.5×10^{-2} moles/kg after 4 h. The tendency of the radicals buil up curve to level off with the reaction time (fig 2) is to be reckoned with the decrease of mechanical stress due to the chain scission.

Under oxygen atmosphere a chain oxidation of the SBR matrix takes place which is characterized by an average oxygen uptake of 2×10^{-2} mole/h and a kinetic chain length λ ranging from 3.1 to 6.1 (moles of oxygen absorbed)/(moles of mechanoradicals) (Fig 3)

Oxygen acts as inhibitor of the crosslinking reactions so that a continuous decrease of the torque and the viscosity are observed in the whole reaction range. Similar effects are obtained when the reactions are performed under nitrogen atmosphere in presence of DTPD and DPG injbitors. The HALS T 770 acts as inhibitor of both the oxidation and the crosslinking process through the formation of the intermediate nitroxyl radicals, as a consequence, despite the difference in the reaction mechanisms, the kinetics of the SBR viscosity changes under O_2 and O_2 + HALS are similar .Reaction mechanisms are proposed for the rationalization of the observed results

Fig 2 *Mechanochemical degradation of SBR under N_2 atmosphere: Kinetics of build up of the overall yield of mechanoradicals as a function of the machination time*

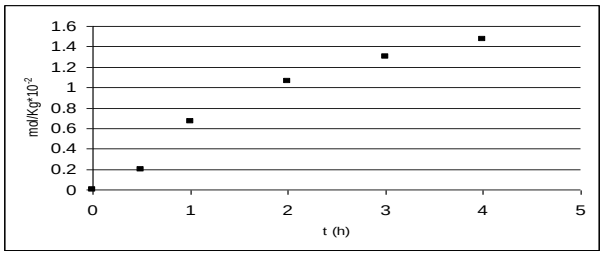


Fig 3 *Mechanochemical degradation of SBR under O_2 atmosphere: kinetics of the O_2 uptake and effect of HALS*

e-mail: mbarczak@umcs.pl

Introduction: Typical molecular imprinting approach involves arranging monomer molecules during polymerization around a template moieties, usually accompanying by complex formation between the monomer and template [1,2]. Extraction of the template molecules leads to final material with predetermined arrangement of ligands.

Apart the adsorption sites, also pore structure can be controlled by employing surfactants with different chain lengths, e.g. quaternary ammonium compounds or block-copolymers [3-6]. If, these two template approaches are applied in one-pot synthesis the resulting materials have two different imprint arrangements on different-length scales; each with a specific function [7]. This approach is known as double impregnation method [8].

Here we describe the synthesis and characterization of copper ion-imprinted silsesquioxane polymers with fine porous structure obtained by aforementioned double impregnation method. Several different silica-monomers were used to investigate type and relative content of these monomers on final porous structure of the materials studied.

Materials and Methods: The following reagents have been purchased and used as received: tetraethoxysilane, TEOS (Aldrich), bis(triethosysilyl)ethane, BTSE (ABCR), bis(triethosysilyl)benzene, BTSB (ABCR), aminopropyltriethoxysilane, APES (ABCR), cetyltri-methylammonium bromide, CTAB (Aldrich), sodium hydroxide, NaOH (POCH), hydrochloric acid (37%, POCH), ethanol (99.8%, POCH).

The typical synthesis scheme was as follows. TEOS/BTSE/BTSB, APES, CTAB, NaOH, $CuCl_2$ and H_2O have been mixed in different molar ratios. The mixture was stirred for 24h and the solid blue product was recovered by filtration and extracted three times with acidic solution of ethanol to remove surfactant template and after was washed with HCl to strip copper ions

Obtained materials were characterized by several instrumental techniques to obtain detailed description of the structure, porosity and chemical composition. Powder X-ray diffraction (XRD) patterns were recorded using a Seifert RTG DRON-3 diffractometer (CuKα radiation) with 0.02º step size and 10s step time over a range 0.5º<2θ<5.0º at room temperature. Nitrogen adsorption isotherms were measured at -196ºC by using an ASAP 2405N adsorption analyzer (Micromeritics). Contents of the amine groups in the obtained samples were determined quantitatively by elemental analysis using Perkin-Elmer CHN 2400 analyzer. AFM images were received using MultiMode Scanning Probe Microscope "Nanoscope III" (Digital Instruments). The imaging technique was TappingMode and the scan size was 500nm×500nm. FT-IR/PAS spectra were recorded by means of a Bio-Rad Excalibur 3000MX spectrometer with photoacoustic detector MTEC300 over the 4000-400 cm^{-1} range at the resolution of 4 cm^{-1}.

Results and Discussion: The obtained materials are uniformly porous systems with specific surface areas in range of 140-750 m^2/g. The porous structure depends on the types of monomers used in synthesis and their molar ratios. XRD data testify about the good degree of ordering of the porous structure created after removal of the CTAB micelles.

FT-IR/PAS spectroscopy confirms successful co-condensation between functional groups carrier (APES) and structure forming agents (TEOS, BTSE, BTSB); thus the preferentially oriented $–NH_2$ groups are present in final materials (what is also supported by elemental analysis data).

Conclusions: Copper ion-imprinted silsesquioxane polymers have been synthesized using double impregnation method. Obtained materials have well developed specific surface areas, accessible pore sizes and can be potentially used as effective and selective sorbents or solid-phase extraction agents

denis.belekian@orange.fr

The more convenient route for a chemical modification of polyethylene in an internal mixer is to use free radical initiators such as peroxides [1,2]. The "grafting from" reaction starts with hydrogen abstraction on the polyethylene by alkoxyl radical generated from thermal decomposition of the peroxide. Then, the active species generated onto the hydrocarbon backbone may react with unsaturated monomers like maleic anhydride in order to form the graft copolymer (Figure 1).

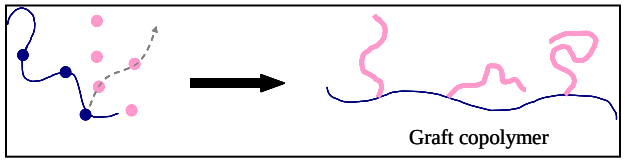

Figure 1: *Graft copolymer synthesis by using the "grafting from" process*

However, the main drawback of the free radical grafting is the low selectivity of the radical center leading to side reactions such as coupling for PE backbone, chain scission for PP backbone and homopolymer formation when using unsaturated monomers in the reaction media. This phenomenon is intensified at elevated temperature in the melt.
The main objective of our work (ANR MODEM/Arkema) is to chemically modify molten polyolefins (PH) by using nitroxide radicals ($NO^{\bullet}$) as hydrogen abstractors instead of peroxide-based radicals (Figure 2).

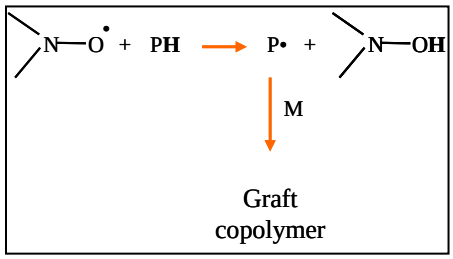

Figure 2: *Reactive pathway of free radical grafting by using nitroxyde radicals as hydrogen abstractor*

An extruder and/or a Haake rheomix can be used as internal mixer. Aspects of reactions, coupling/crosslinking and scission are determined by rheological measurements in a parallel plate geometry rheometer and discussed both in terms of the mechanism under different experimental conditions. Spectroscopy techniques (IR and UV spectroscopy) and gas chromatography-mass spectroscopy (GC-MS) allow us to highlight the grafting reaction.
However, we do not observe any polyethylene crosslinking in presence of nitroxyde radicals suggesting that these latter radicals are not efficient hydrogen abstractors. Thus, to ensure the grafting reaction, nitroxide radicals have been used in presence of peroxides (RO-OR) (Figure 3).

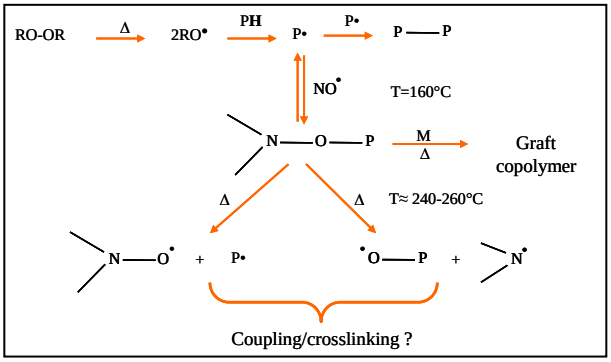

Figure 3: *Reactive pathway of free radical grafting by using a blend of the nitroxyde radical with a peroxide*

By controlling experimental conditions (peroxide/nitroxyde radical molar ratio, mixing efficiency and temperature), it allows us to prevent the polyethylene crosslinking and to form the graft copolymer.
Future work will consist in the use of a model compounds approach in order to predict the polyethylene grafting reaction. This approach will be based on a radical grafting reaction between peroxide-derived alkoxyl radicals, nitroxide radicals and a low molecular-weight alkane and/or polyethylene oligomers.

pavlovskaya@ichem.unn.ru

Introduction

Polyvinylchloride (PVC) is a thermoplastic synthetic material which scales of production rank second place after polyolefin's. PVC - universal polymer which depending on method of producing, compounding and technologies of processing gives the big assortment of materials with various physical and chemical properties: rigid, soft, transparent and opaque, maintained in the range of temperatures from -80 to +90÷110˚C. In consequence controlled radical polymerization of vinylchloride has not only scientific interest, but also a practical one.

Materials and Methods

All monomers - vinyl acetate (VA), acrylonitrile (AN), methylmethacrylate (MMA) and styrene (St) were dried and distilled before application. In a typical example monomer, initiator, iron complex were added to a reaction tube. Three freeze–pump–thaw cycles to remove oxygen were carrying out; the reaction tube was sealed under vacuum and then immersed in an oil bath thermostated. Polymer yields were determined by gravimetry. The number-average molecular weight (M_n) and molecular weight distribution (MWDs) of the (co)polymer were determined by gel permeation chromatography. Temperature of glass transition ($\mathbf{T_g}$) of synthesized polymers was measured by Differential Scanning Calorimetry.

Results and Discussion

As the initiating system in VC polymerization was offered iron carbonyl complex $[CpFe(CO)_2]_2$ in combination with organohalide compounds of the various nature (CCl_4, ethyl-α-bromoisobutyrate, *iso*-amyl iodide) at different temperatures (50-70˚C). It was shown that the initiating systems allow to spend polymerization VC without self-excited acceleration before high conversion (fig. 1).

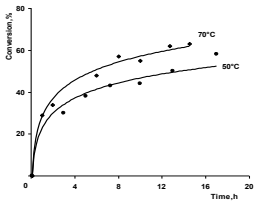

Fig. 1 Time-conversion curves for the polymerization of VC with $CCl_4/[CpFe(CO)_2]_2$ (0.25/0.125 mol.%) at various temperature

The M_n synthesized PVC increase in direct proportion to monomer conversion and also gave relatively narrow MWDs (~2.0). It was established that in the presence of the bromide initiator PVC samples are characterized by M_n=5100-6000, as well as PVC synthesized in the presence CCl_4. All polymer samples obtained have unimodal molecular weight distributions. Moreover, maximum VC conversion doesn't exceed 40% in case of injection of PPh_3 (0.125 mol. %) into initiating system and MWDs greatly increase (PDI~2.8).

The synthesized PVC used as the macroinitiator leads to formation of post-polymer and block-copolymers with monomers of various activity – MMA, St, AN, VA was investigated (fig.2). The temperatures of glass transition of the obtained block-copolymers were characterized.

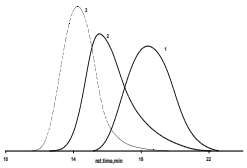

Fig. 2 Gel permeation chromatography traces of 1- initial PVC, $\mathbf{T_g}$= 78˚C , 2- PVC-b-PVA, $\mathbf{T_g}$= 43˚C, 3-PVA obtained at 70˚C, $\mathbf{T_g}$= 29˚C.

It was shown that depending on the substance content of PVC as an initiating component of system on the based iron carbonyl complexes and temperature synthesis at regulation composition and structure of obtained copolymer is possible.

By the method of the free-radical grafting in the presence of benzoyl peroxide (0.1 mol %) in butyl acetate as solvent the synthesis of the graft-copolymers on the based of obtained PVC was carrying out. The efficiency of a grafting depending on the nature of initial polymer (PVC/PVA) was estimated. Using PVC as initial polymer of it makes 36 % while for PVA - 7-10 % and not depending on temperature of synthesis. It is established that with increasing time of synthesis of copolymer PVC-PVA on the basis of PVA there is a change of structure of obtained copolymer that is reflected in change of temperature of glass transition copolymer samples (table).

Table Temperature of glass transition of synthesized copolymers

T, °C	Time, h	Tg, °C
50	10.5	40.5
	12.5	39.8; 82.5
70	12.5	50.0
	36.0	39.4; 60.9

Besides, using bromide functional polystyrene (PSt-Br) as organohalide initiator in the presence of 0.125 mol % $[CpFe(CO)_2]_2$ allows to receive copolymers with VC, AN, VA and MMA onto polystyrene.

Conclusions

Thus the system based on dicarbonylcyclopentadienyliron dimer and organohalide compounds allows to synthesize PVC in soft temperature conditions and to modify its properties. It was shown that the way of synthesis of copolymers VC influences on its physical-mechanical properties, in particular on temperature of glass transition.

Introduction.

Polyethylene and copolymer films are materials that persist in the environment for a long time. The problems with the disposal of agricultural plastic wastes become more and more severe. Nowadays, *plasticulture* (use of plastics in agriculture) results in increased yields: Agricultural films, mainly based on polyethylenes and copolymers of polyethylene-vinyl acetate, are used as coverings of greenhouses or tunnels over crop rows, as silage covers, as bale-wrap films, and as mulching films to cover soil. In this work we have compared the biodegradation of highly photodegraded polyethylene-vinyl acetate (EVA) copolymers and containing calcium and iron stearates as pro-oxidant additives in their formulations.

Materials and Methods.

In this work EVA films of 25 microns of thickness were prepared by Repsol containing iron and calcium stearates as pro-oxidant additives (at 0.2 % w/w).

The artificially simulated weathering (432 hours) was carried out in an ATLAS/ SUNTEST XLS-2500W Xenon lamp using a solar filter of borosilicate and fixing the incident energy at 550 W/m^2 in the interval 300-800 nm. EVA films degradation [1,2,3] was studied by FTIR to analyze structural changes in carbonyl region[4] (peak at 1738cm^{-1}/1715cm^{1}), and Chemiluminescence to follow the formation of hydroperoxides as oxidative species. Also, biodegradation was evaluated by measurement of the carbon dioxide produced in the bacterial metabolism using a Bac-Trac 4300 (SY-LAB Geräte GmbH, Neupurkerdorf, Austria). Biodegrading bacteria were a mixture *Bacillus* strains (MIX) isolated and identified[3] from samples exposed to agricultural soils in Murcia, Spain and a strain of *Brevibacillus borstelensis* as reference[5]. Biodegradation tests were carried out with controlled inoculums of the bacteria at 45ºC during 90 days. This temperature was selected since previous results[3] confirmed a more efficient biodegradation on the bioassays carried out at higher temperature.

Results and Discussion.

- *Photodegradation*

The analysis of non-isothermal chemiluminescence under nitrogen atmosphere provides a useful tool to evaluate the activity of stearates as pro-oxidants. The CL-temperature curves for EVA films showed the increase of intensity above ~100ºC with the degradation time and peaks at 110ºC in materials with pro-oxidant additives were observed. The activity of pro-oxidants on thermal oxidation of EVA films was also observed on CL intensity-time runs under oxygen.

Several changes in infrared absorption peaks can be seen in EVA films with irradiation time, decrease of the band at 1735 cm^{-1} (C=O of ester) and the growth at the absorption shoulder at 1715 cm^{-1} (Ketone carbonyl). After accelerated photodegradation of EVA films the effect of pro-oxidant additives was studied by different carbonyl index determinations.

- *Biodegradation.*

After biodegradation, the onset of the CL emission shifted towards lower temperature on the biodegraded samples and in general the intensity of the low temperature peaks increase. CL emission allows the evaluation of the metabolic activity of microorganisms on the polymer surface though the oxidation induced by reactive oxygen species (ROS) generated, such us peroxide radical, hydroperoxides, hydrogen superoxide and radical anion.

Incubation of the photo-oxidized polyethylene with *B. borstelensis* and *MIX* for 90 days showed a marked reduction in the amount of carbonyl peaks and estimated in terms of carbonyl index. Mineralization of the photodegraded EVA films was study by determination of the carbon dioxide produced in the metabolic action of the bacteria, using indirect impedance technique. The percentage of biodegradation reached was higher in the photodegraded materials containing Ca and Fe stearates (25-30%) that in the pure EVA films (15%)

Conclusions.

Biodegradation at 45ºC of photodegraded EVA films by bacteria: *Brevibacillus borstelensis* and the mixture of *Bacillus MIX (B.cereus, B.megaterium* and *B.subtilis*.) was efficient after 90 days of incubation and in particular when Ca and Fe stearates are present in the formulation. Photodegradation increases the rate of biodegradation of the EVA films by the bacteria studied in this work and the use of pro-oxidant in the formulations could be an interesting way to prepare more efficient biodegradable materials.

Abstract

Polyethylene films, in general, are used by a short time and often only once, with further discard [1,2]. Its saturated chain without functional groups make it resistant to oxidation processes by light and heat action and, consequently, to biodegradation processes. Polymer oxidation processes can be accelerated by the use of pro-degradant agents, whose function is to promote the fragmentation. In this work we analyzed polyethylene films with different pro- degradant agent concentrations, after exposure to UVB radiation chamber (λ_{max} =313nm) for a period of up to 480 h. Polyethylene films extruded from the mixture of high density polyethylene (HDPE) and linear low density polyethylene (LLDPE) (60/40), were supplied by METALLYN Co., Brazil, ($PEOX_1$ e $PEOX_2$) and without pro-degradant agent (PE), both with 5 µm of thickness. Carbonyl and vinyl index were evaluated by FTIR Spectroscopy; crystallinity degree, by DSC. The evidence of photodegradation of the polyethylene film was evaluated by the increase in the CI (85 – 100%), in the VI (4 – 5%) and in the crystallinity degree (60 – 68%). From PE, $PEOX_1$ and $PEOX_2$ spectrum, performed before and after the UV irradiation exposure process (Fig. 1).

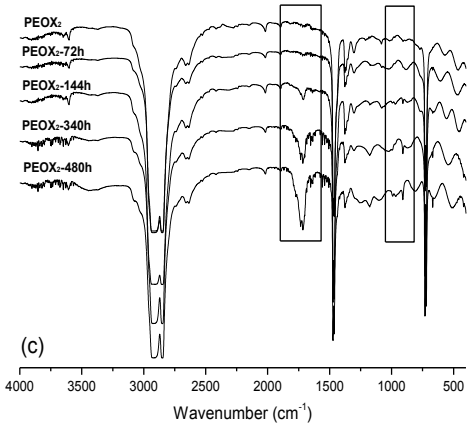

Figure 1 – FTIR spectrum showing the differences in the carbonyl and vinyl absorption peaks from samples before and after exposure to irradiation for a period of 480h.

The Figure 2 presents the vinyl index (VI) based on the absorption band at 908 cm^{-1}, measured during different exposure times[3].

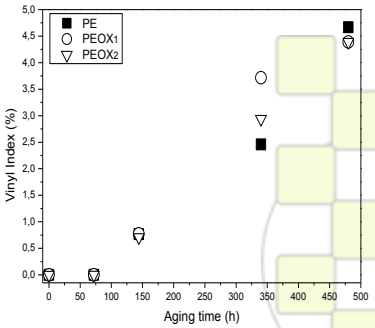

Figure 2 – Vinyl index of the samples PE, $PEOX_1$ and $PEOX_2$ as a function of UV irradiation exposure time.

The crystallization time as a function of the UV irradiation exposure time can be seen in Fig. 3.

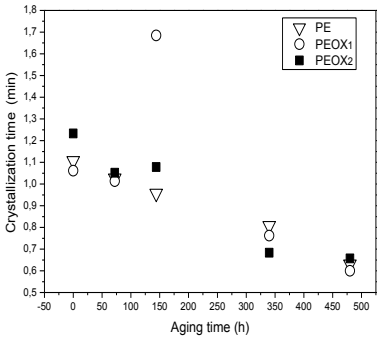

Figure 3 – Crystallization time for the samples PE, $PEOX_1$ and $PEOX_2$, before and after exposure to UV irradiation, for a period of 480h.

The photodegradation by UV irradiation of polyethylene films, with and without pro-degradant agent, was evidenced: by the increase in carbonyl index resulted from *Norrish* I reaction mechanism; and by the increase in vinyl index , resulted from *Norrish* II reaction mechanism. The chain scission reaction due to polyethylene irradiation promoted an increase in the crystallinity degree of the samples. The structure stabilization is evidenced by the crystallinity degree of samples with agent, after 480 h of exposure, and it is possible to states that the chain scission was the predominant mechanism. May be during the process of photodegradation occurred crosslinking reactions, according to *Norrish* III mechanism[4,5].

Introduction

Low-density polyethylene (LDPE), ethylene-vinyl acetate copolymers (EVA) and ethylene-butyl acrylate copolymers (EBA) are the most common plastic materials used for greenhouse cover films. The lifetimes required for these films vary from one agricultural season to several years, depending on the geographical area where they will be used, the type of greenhouse, the crop, the use of pesticides, etc. To increase efficiency in long-term applications the polymeric HALS are the most efficient structures reaching a high price. The term `reactive processing of polymers´ has emerged in the polymer science and engineering community, and intense activity both in academia and in industry largely testifies to its ever-increasing importance. This work investigates the transesterification reaction of molten EBA copolymer in presence of low molecular weight HALS and organometallic catalyst.

Materials and Methods

A poly(ethylene-co-butyl acrylate) (EBA) containing 8% w/w of butyl acrylate (PA-805) from Repsol was used in this work. Two HALS with hydroxyl groups, 1,2,2,6,6-pentamethylpiperidin-4-ol, (HALS-NMe) and 1-methoxy-2,2,6,6-tetramethylpiperidin-4-ol (HALS-NOMe) were used as reactive structures. Also, HALS-NOR-371 from BASF was used as reference. Dimethyl tin oxide (DBTO) was used as catalyst in the reactions of EBA in the molten state[1]. Reactions were carried out in an internal mixer Haake Rheocord 9000 at 190 °C and the mixing speed of 64 rpm. In all cases, concentrations were fixed at 1% w/w of HALS, and 0.05 % w/w of catalyst (DBTO). The time for the reactions was 5,10,15,30 min and as reference, the reactions were also made in the absence of catalyst. All reaction products were cooled at room temperature and then carefully treated to eliminate unreacted HALS. Films of 100µm were prepared by compression molding using a Collin P-200-P press. In the present work, X-ray photoelectron spectroscopy (XPS) has been used to study the degree of modification for the transesterification reaction. The XPS was VG Escalab 200R spectrometer. Photostability was studied by FTIR from the formation of oxidized species formed during the accelerated aging in a climate chamber (Atlas Weather-OMeter Ci4000 (WOM)) under standard ISO 4892-2:1994 cycle at 0.47 W/m2 (340nm) and applying pesticides (*metam-sodium and cypermethrin*, 1:3) each 525h.

Results and Discussion

The N1s core-level spectra for films prepared at different reaction times showed a peak at ca. 400eV associated with the HALS incorporated in the material. The modification reached in the reaction was monitored by calculating the N/C atomic ratio. There is no clear correlation between reaction time and degrees of modification obtained (0.17-0.63%). For the reaction performed in absence catalyst, no nitrogen peak was detected. This indicates that unreacted low molecular weight HALS was removed in the extraction step. To assess the photostabilization efficiency of the samples the study was focused on the infrared band at 908 cm^{-1} due to acid groups formed during the accelerated aging. Modified EBA with HALS-NMe was better photostabilized with increasing reaction time. Also, the photostabilization behavior was excellent for EBA modified with HALS-NOMe remaining carbonyl formation in stationary phase until 3200 h (see Fig 1), this may be due to increased pesticide resistance of the HALS-NOMe.

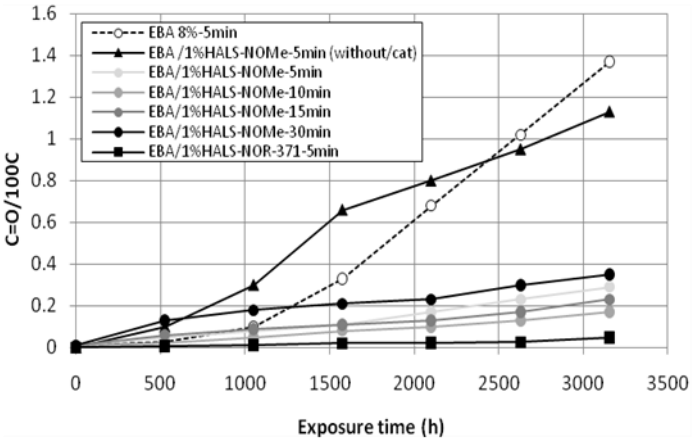

Figure 1 C=O/100C versus exposure time for the EBA, EBA/HALS-NOR-371, EBA/HALS-NMe, EBA/HALS-NMe/DBTO, EBA/HALS-NOMe, EBA/HALS-NOMe/DBTO.

Conclusions

EBA copolymer contained 8% w/w of butyl acrylate, has been modified in the molten state with HALS-NOR functionalities resulting in a very efficient polymeric light stabilizers with a large industrial interest.[2]

e-mail: peb0002@alu.ubu.es

1.-Introduction

Urea-formaldehyde (UF) resins are the most used polycondensation resins for the manufacturing of particleboard panels due to their high reactivity, good performance and water solubility.[1] In spite of these advantages, they have two main disadvantages that are the formaldehyde emission from the panels and the poor resistance to water.

Response surface methodology (RSM) has being used as optimization procedure for low formaldehyde emission UF resins synthesis.[2] This work describes a central composite design methodology to optimize 3 selected variables (number of urea additions, pH and temperature) in the second urea addition, following three-stage process.

2.-Materials and Methods

Resins were synthesized from a precondensed formalin-urea solution and urea, following the traditional three stage process. Synthesis conditions of alkaline-acid step reactions were optimized in previous researches.[3] Central composite rotatable design was adopted for the experimental runs for response surface methodology, in the preparation of low formaldehyde emission UF resins.

Laboratory particleboards were prepared by using a standard mix of wood particles for the core and face layers. UF resins with additives and catalyst were sprayed on the wood particles and then were formed into a mat of dimensions 400 mm x 400 mm. The mat was prepressed at room temperature and further hot-pressed at 195 ºC for 2-3 minutes.

Perforator Method (European Standard EN 120) was used for measuring the formaldehyde content of wood-based panels.

3.-Results and Discussion

All resins were analyzed by standard methods. Differences in viscosity, gel time and free formaldehyde content were found depending on the synthesis conditions, but all of them were able to be used in the particleboard manufacturing process.

All particleboards were characterized according to European standard methods. Table 1 reports the main properties shown by the particleboards manufactured using the different UF resins synthesized. The formaldehyde content of the particleboards bonded with the modified process UF resins is well below the specified level of class E1 products (≤ 8 mg/ 100 g dry board) according to EN 13986, while maintaining good levels of internal bond strength, established in 0.35 Mpa (Particleboards Type P2, EN 312).

Table 1. Particleboards Characterization

Resin	Formaldehyde content (mg / 100 g dry board)	Internal Bond Strength (MPa)
1	2.6	0.46
2	2.8	0.46
3	3.2	0.62
4	2.3	0.52
5	2.6	0.66
6	3.9	0.67
7	3.2	0.50
8	3.1	0.57
9	2.5	0.66
10	2.2	0.56
11	2.1	0.53
12	4.0	0.50
13	4.3	0.47
14	3.3	0.56
15	3.6	0.58
16	3.6	0.55
17	3.0	0.69

Figure 1 shows: (a) Optimal response plot, with a minimum level of formaldehyde at a distance of 1,5; and (b) Optimal coordinate plot for the response in codified variables. These data transformed into natural variables are: pH: 7.4; Urea additions: 2 and Temperature: 50 ºC.

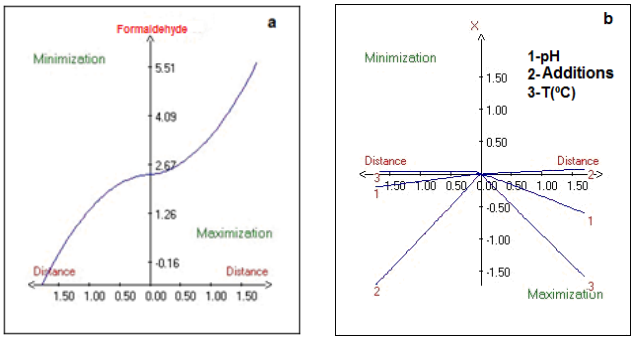

Figure 1. Ridge analysis (RSM).

4.-Conclusions

The effect of the number of second urea additions, pH and temperature was studied for the preparation of UF resins. The process was optimized on the basis of these studies. The results showed that the studied variables played a significant role in reducing the formaldehyde emission with a minor withdrawal of internal bond strength.

Modeling of butadiene polymerization using neodymium catalyst complex

Gumerov A.M., Davletbaeva I.M.

Kazan State Technological University, Kazan, Russia

gumerov_a@mail.ru

The problems of obtaining and using neodymium polybutadiene are connected with structural features of the neodymium catalyst system. First of all, it is polycentricity of a catalyst, which contains several points of anionic coordination polymerization differing by their activity. Therefore, to investigate the possibility of rubber properties regulation by controlling the molecular structure is an important scientific and practical issue.

In recent years, many researchers believe that most of the Ziegler-Natta catalysts have active centers of polymerization differing from one another by their kinetic parameters. In this study the mechanism of polymerization kinetics of 1,4-butadiene initiated by neodymium metal-complex system was identified.

The paper presents the kinetic scheme of the polymerization process. When developing the mathematical model the following assumptions were adopted. The rate constants of elementary stages do not change their values during the process and the active centers are formed simultaneously and instantaneously at the beginning of polymerization.

The consumption of monomer in chain transfer reactions is negligible compared with the monomer consumption in the reactions of chain growth.

The model polymerization kinetics is represented by differential equations of material balance of reagents involved in the process and shows the changes in their concentrations over time. The system of equations of the model can essentially be solved for known kinetic constants for polymers of length r = 1, 2, 3. . . n. It is obvious that for the considered set of polymers the investigated system has large dimensionality.

At the same time, there are efficient algorithms for solving systems of differential equations, which can reduce the order of the system. For the compact representation of the system of equations of polymerization kinetics, the method of moments is used. When the method of moments is used the system of differential equations is transformed into a closed form.

As a results of modeling the kinetic constants were found and the distribution curves of mean and average molecular weight were obtained. The solving of the direct problem describes satisfactorily the values of monomer conversion (Fig. 1), but there is a considerable discrepancy between the values of mean and average MW.

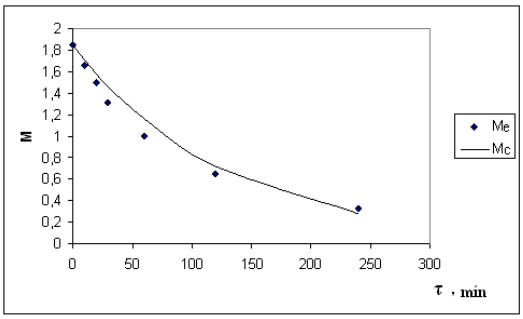

Fig. 1. The temperature dependence of monomer consumption; points - experimental data, solid line - calculation results

It was found that under the selected conditions the existence of three different activity centers for polymerization in the catalytic system is most likely.

Table 1. Kinetic parameters of polymerization of butadiene (l·min/mol) for the catalyst system, calculated with a three-center model of the active center. T_p=25 ° C; C_{but}=1,85 mol/l; $C_{Nd}=0{,}6\cdot10^{-4}$ mol/l; [Cl/Nd]=2,5

Constants	Value	Constants	Value	Constants	Value
k_{i1}	9.9132	k_{i2}	10.1016	k_{i3}	10.0116
k_{p1}	196.725	k_{p2}	21.1617	k_{p3}	98.1054
k_{m1}	0.0606	k_{m2}	0.1238	k_{m3}	0.0578
k_{Al1}	12.9915	k_{Al2}	13.1491	k_{Al3}	12.9854
k_{d1}	0.00040	k_{d2}	0.00040	k_{d3}	0.00039

where C_d is an deactivated center, k_i, k_m, k_{Al} and k_d are the rate constants of reactions of initiation, chain growth, transfer of kinetic chain onto hydrogen, the monomer, the organoaluminum compound and deactivation of the active center.

The presence of different types of active centers in the considered system, established by mathematical modeling, is confirmed by the presence of three unshared peaks at the curve of molecular weight distribution (MWD) of polybutadiene obtained at the initial stage of polymerization.

With increasing degree of monomer conversion the proportion of low molecular weight fractions decreases, while an increase of the undivided peak at the MWD curve in the region of high molecular masses is observed. Apparently, this is associated with the lower kinetic activity of the polymerization center, responsible for the formation of low molecular weight polymer.

Effects of incorporating waste rigid polyurethane foam in polymer compounds based on Polypropylene

Federal University of São Carlos

Simone Fontana Pereira; Elias Hage Junior

Introduction: The refrigeration industry widely uses the rigid polyurethane foam (PUR) as insulation in the cabinets and refrigerator's doors. Due to the large volume of industrial waste generated by this material (process, quality control and waste from end-users), it's needed to take environmental measures to avoid improper disposal of this material, what represents an environmental problem. Some alternatives to re-use this material has been studied over the past few years aimed to find an alternative for recycling rigid polyurethane foam and, if possible, with economic advantage. Materials and Methods: rigid polyurethane foam, polypropylene,PP-*g*-MA. The objective of this project is present a composite based on mixture of PP/PUR residues that can be used in a technical application showing not only a recycling alternative for the solid waste as well as improvements in mechanical properties. The method consists in incorporating residues of PUR in a matrix of PP by using PP-g-MA as a coupling agent and extrude the material. The pallets are then fed into an injection molding machine and the specimens are obtained.

Results and Discussions: Preliminary analysis shows that the incorporation of PUR residues in a thermoplastic material (PP) is feasible and the formed composite material shows good mechanical properties.

Conclusion: Automotive market is a potential end-user of this material once this industry has been gradually replacing traditional materials by plastics and composite materials over the years and mainly because both materials (PUR and PP) have a very low density what refers economy to the automotive market because a lighter car leads to lower fuel consumption.

Parallel versus perpendicular lamellar-within-lamellar self-assembly of A-b-(B-b-A)$_n$-b-C and (B-b-A)$_n$-b-C ternary multiblock copolymer melts: SSL theory, DPD, SCFT investigation.

V.A. Markov[1], Y.A. Kriksin[3], A.V. Subbotin[1,2] and G. ten Brinke[1]

[1]Department of Polymer Chemistry and Zernike Institute for Advanced Materials, University of Groningen, Nijenborgh 4, 9747 AG Groningen, The Netherlands
[2]Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, 119991,
[3]Institute for Mathematical Modeling, RAS, Moscow 125047, Russia
v.a.markov@rug.nl

One of the specific features of multiblock copolymers is the possibility of self-assembling in the form of periodical hierarchical structures involving different length scales. Such structures were first observed for comb-shaped supramolecules consisting of polystyrene-block-poly(4-vinylpyridine) (PS-*b*-P4VP) diblock copolymers and hydrogen-bonded pentadecylphenol (PDP) side chains attached to the P4VP blocks.[1] Subsequently it was found that undecablock copolymers PS-*b*-(PI-*b*-PS)$_4$-*b*-PI-*b*-PS and P2VP-*b*-(PI-*b*-PS)$_4$-*b*-PI-*b*-P2VP also formed double periodic lamellar-*within*-lamellar structures.[2] Here P2VP, PI and PS denote poly(2-vinylpyridine), polyisoprene and polystyrene, respectively. In contrast to the supramolecules systems, here the different lamellae are parallel In both cases the hierarchical structure formation results from the molecular architecture involving two different intrinsic length scales. Recently Fleury and Bates demonstrated[3] that a terpolymer C-E-C-E-C-P, consisting of cyclohexylethylene (C), ethylene (E) and propylene (P) blocks, self-assembled in the form of a perpendicular lamellar-*within*-lamellar structure when the copolymer chain length exceeded some critical value. Self consistent field theory investigations [?] showed that a transition from parallel lamellar-*within*-lamellar to perpendicular lamellar-*within*-lamellar structure will occur when the Flory-Huggins interaction parameter χ_{AB} is sufficiently large. A theoretical approach in the strong segregation limit further showed that the perpendicular lamellar-within-lamellar state becomes stable when the interaction parameters satisfy the relation

$0 < \chi_{EP} < 0.22\chi_{CP}$.[5]

For a next step the self consistent field theory approach was implemented and it was shown that the stable perpendicular lamellar-*within*-lamellar structure involved secondary structure layers that are shifted with respect to each other over half a period (see Figure 1). It can be easily understood by considering the C tail contributions. It was also found that the known methods to solve the SCFT equations suffer from unnecessary restrictions in case of ternary systems. For the existing methodology the system of equations can be only solved when the χ parameter values are beyond the Hildebrandt approximation surface. A new method was developed to solve the SCFT equations near and on the Hildebrandt approximation surface.

In order to cover all phase space dissipative particle dynamics was used. Transition from ternary to binary systemwas investigated by changing $N\chi_{BC}$ from 0 to 100.

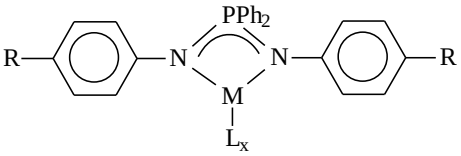
E-mail: kelena@ichem.unn.ru

Introduction. Metal-catalyzed polymerization is one of the most rapidly developing areas of organometallic chemistry and polymer science. This technique allows the synthesis of polymers with well-defined compositions, architectures, functionalities and nanomaterials. In these few decades, new classes of molecular catalysts were found for the olefin and vinyl polymerization. Especially, half-metallocenes and non-metallocenes, complexes of transition metals promote formation of polymers in high efficiency and unique selectivity.

Materials and Methods. Vinyl monomers were washed with aqueous alkaline solution and water, dried over calcium chloride and then distilled. Initiators and solvents were purified by recrystallization and distillation. Reagents were placed in an ampoule. After degassing the content, the ampoule was sealed in vacuum. The polymerization was carried out at 50-70°C. Molecular weights were determined by SEC calibrated with polystyrene and polymethyl methacrylate standards. Topography of a polymer film was studied by AFM.

Results and Discussion. The influence of platinum and palladium complexes of various structures (see scheme) on the polymerization of a wide range of monomers (methyl methacrylate - MMA, butyl methacrylate - BMA, methyl acrylate – MA, butyl acrylate – BA, styrene – St) at temperatures 25-90°C was investigated.



(M – Pd or Pt; x=1: L - allyl or aminoiminophosphoranate, x = 2: L_1 – Cl and L_2 - ethylene or PPh_3; R – ^{i}Pr, MeO, EtO_2C).

Scheme

It was shown, that these metal complexes are capable of initiating the vinyl polymerization in the presence of CCl_4. The influence of the central atom of a metal and ligands on the rate of polymerization and molecular-weight characteristics of polymers was established. For instance, the addition of the palladium complexes causes polymerization of vinyl monomers that proceeds to high conversions for 20-30 hours. The rate of polymerization in the presence of platinum complexes was essentially less than that of palladium complexes, and in some cases only small quantities of polymers were isolated. The obtained polymers with participation of the catalytic systems on the basis of the given complexes and CCl_4 are characterized by high molecular weights (MW) and index of polydispersity (2.0 - 2.5). It is necessary to note, that these metal complexes practically do not influence the process of the polymerization of MMA and St in the absence of CCl_4. In the most cases the rate of polymerization was comparable with the rate of autopolymerization.

The influence of ligand environment on the vinyl monomer polymerizations was revealed on the example of the palladium complexes. It was established, that the most effective catalysts are the complexes containing chlorine atom in the structure. The rate of polymerization of some studied monomers considerably rises when the electron donated groups (^{i}Pr, MeO) in the structure of the aminoiminophosphoranate ligand are presented in comparison with the complexes containing the electron accepting group EtO_2C. The MW of the samples synthesized in the presence of the studied catalytic systems depends on the rate of polymerization, similarly to that in the presence of traditional initiators.

The offered catalytic systems for polymerization can be used as an elegant way to incorporate nanodimensional particles of Pd to the polymeric matrix. The given complexes are thermally unstable at high temperatures and decay with formation of Pd particles *in situ*. In this case the macromolecules formed in the presence of the given systems play a role of the stabilizing ligand. Particles having size of 65 nanometers and less in the synthesized polymers are found out by atomic-force microscopy. These particles are fixed both on surface and in volume of the polymer film (figure).

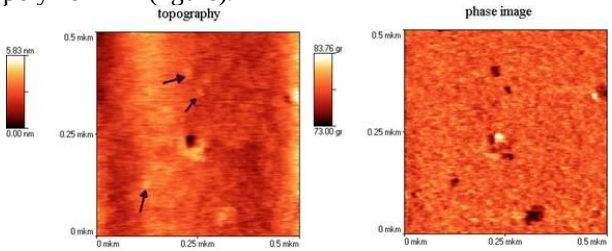


Figure. AFM images of film of polySt prepared in the presence of CCl_4 and Pd complexes.

Conclusions. It was established, that aminoiminophosphoranate platinum and palladium complexes show different properties. These complexes can simultaneously act as catalysts for polymerization of wide range of monomers and also serve as sources of nanoparticles.

E-mail: kelena@ichem.unn.ru

Introduction. The controlled/living radical polymerization technique has become a very powerful tool in the field of modern polymer science and engineering. Atom transfer radical polymerization (**ATRP**) is now one of the most rapidly developing areas in the past several years. Many novel polymers have been synthesized by the ATRP method. Through ATRP, it became possible to control over the molecular weight (**MW**), and to prepare polymers with the chain end reactivity. Traditionally ATRP is based on the catalysis of transition-metal halide/ligand complexes, which is the key point in ATRP. Up to now, various catalytic systems based on Cu, Fe, Ni, Ru, Mo and so forth, have been employed in ATRP. However, it is still challenge to develop new ATRP catalytic systems, especially cheap ones. Only few examples were reported using cobalt complexes as catalysts, which reduced initiator and were oxidized from Co(II) to Co(III) to initiate the controlled radical polymerization [1-4].

Materials and Methods. Methyl methacrylate (**MMA**) was extracted with 5% sodium hydroxide to remove the stabilizing agents, washed with water, dried over calcium hydride and distilled under reduced pressure before use. Initiators and solvents were purified by distillation. Reagents were placed in an ampoule. Oxygen was removed using three freeze-pump-thaw cycles. After degassing the content, the ampoule was sealed in vacuum. The polymerization was carried out at 50-90°C. MW were determined by SEC calibrated with polystyrene and polymethyl methacrylate standards.

Results and Discussion. The polymerization of MMA was conducted with bis-[4,6-di-*tert*-butyl-*N*-(2,6-dimethylphenyl)-*o*-iminobenzosemiquinonato]cobalt(II) (**Co(ISQ-Me)$_2$**)/amines (t-BuNH$_2$ or pyridine) as catalyst and with ethyl-2-bromoisobutyrate - **(EiB)Br** and CCl_4 as the initiators in bulk at 50-90°C. The results of experiments in **Table** show that the cobalt–mediated polymerization proceeds rapidly.

Table. The results of the polymerization catalyzed by Co(ISQ-Me)$_2$- 0.025 mol.%/t-BuNH$_2$ – 0.05 mol.%

Initiator	T,°C	*t*, (h)	Conv., %	$M_n \times 10^{-3}$	M_w/M_n
CCl_4	50	80	73	40	1.76
	70	30	94	46	1.50
	90	20	97	47	1.55
(EiB)Br	50	36	91	62	1.56
	70	24	95	51	1.48
	90	12	98	47	1.57

When the cobalt complex did not coordinate by amines no high conversion was observed, which indicate that the complex was an effective catalyst for ATRP and amines have a strong affinity to Co(ISQ-Me)$_2$. Dependence of MW of polyMMA on conversion is linear at 70°C (**Figure**).

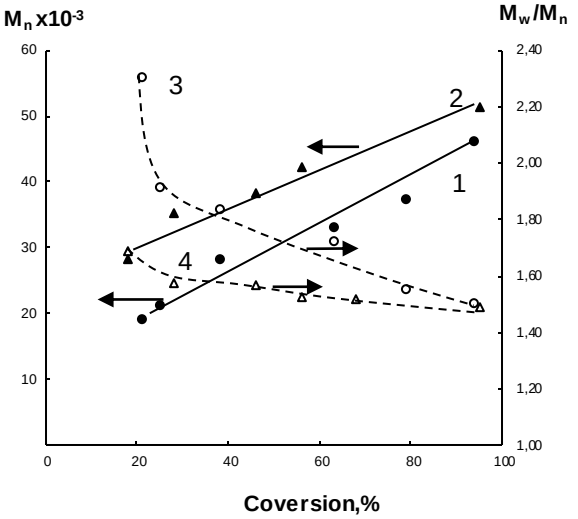

Figure. Evolution of M_n and M_w/M_n with conversion of poly MMA. *1*, *3*- CCl_4; *2*, *4* - (EiB)Br

However, the control over the polymerization was not ideal, the molecular weight distribution of the resulting polymer was relatively broad (M_w/M_n= 1.48-1.76).

In order to confirm the realization of ATRP mechanism of MMA polymerization in the presence of the cobalt catalyst system, the synthesis of block copolymers of MMA with St was performed on the basis of the macroinitiators obtained with participation of the studied complex. These results indicate the possibility of re-initiation of polymerization and the direct functionalization of polymers.

Conclusions. A new ATRP catalyst system, Co(ISQ-Me)$_2$/amines, was successfully used to catalyze the polymerization of MMA through ATRP mechanism.

Introduction. Development of novel methods for syntheses of nanomaterials and nanostructures possessing unique properties is one of the most promising and rapidly growing areas of modern chemistry. Block-copolymers, involving monomers of different nature, represent a basis for such highly-organized structures. Because of specific chemical nature, these molecules can self-assemble in strictly ordered systems.

Controlled radical polymerization in the presence of nitroxide radicals is one of the techniques, widely applied for design of block-copolymers incorporating various monomers and having strictly-determined structures. While, a convenient method for nitroxide radicals synthesis is based on the use of spin-traps, such as nitrones and nitroso compounds being commercially available. In particular, under conditions of vinyl monomers polymerization in the presence of nitrones or nitrozocompounds thus obtained polymer is a high-molecular-weight alkoxyamine. This alkoxyamine is capable to reinitiate polymerization upon the introduction of a new portion of a monomer. In the case of introduction of a monomer, different from a starting one, formation of a three-block copolymer of the type ABA occurs.

Results and Discussion. The processes occurring at vinyl monomers polymerization in the presence of alkoxyamines (derived from the spin-traps: C-phenyl-N-tert-butylnitrone (PBN) and nitrobenzene) were simulated with quantum-chemical methods. Effects of electronic and steric factors on **C-ON** bond energy in the alkoxyamines of interest were deduced. The calculations were carried out with the use of the density functional theory method (hybrid functional B3P86 and the basis set 6-31G(d)). On the basis of our simulations, possibility for radical polymerization of vinyl monomers to occur in the controlled regime in the presence of alkoxyamines was suggested for a wide temperature range. Meanwhile, temperature for the process to run in the controlled regime was revealed to depend largely on steric hindrance of the corresponding nitroxide radical, among all, on the chain length of a macroradical, attached to a spin-trap.

Our simulation results appear in good correspondence with the experimental data on the polymerization of styrene in the presence of alkoxyamines, *ex situ* generated from PBN, 2,2`-azobis(isobutyronitrile), and vinyl monomers. It was demonstrated that kinetic parameters of the process and molecular-weight characteristics of thus obtained polystyrene depend not only on the polymerization temperature, but also on alkoxyamine synthesis conditions. This is due to the fact that the presence of high-molecular-weight alkoxyamines leads to the controlled styrene polymerization with relatively high rates already at 80–90°C (in contrast, in the case of low-molecular-weight alkoxyamines, the controlled regime requires higher temperatures). Thus obtained polystyrene is characterized by the linear dependence of molecular weight on conversion and also by low polydispersity, decreasing in the course of polymerization (see: Figure).

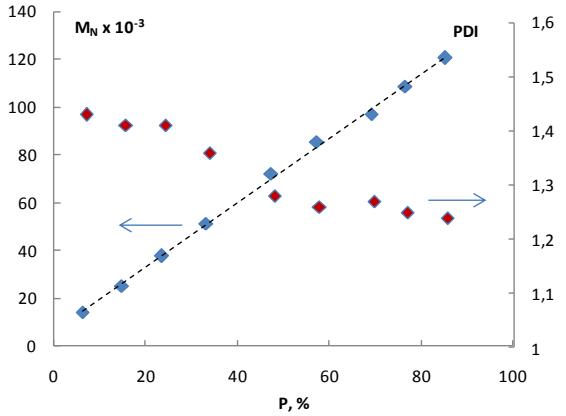

Figure. Molecular-weight characteristics of polystyrene obtained in the presence of a high-molecular-weight alkoxyamine (0.1 mol.%, 90°C).

Based on the obtained polystyrene, post-polymerization and synthesis of block-copolymers of acrylic and methacrylic monomers were conducted as well.

Upon methyl methacrylate polymerization at 90°C, "living" chains are being deactivated due to the formation of hydroxylamine derivatives from nitroxyl radicals. The polymer, derived under such conditions, has reduced initiating activity.

Upon synthesis of block-copolymers based on butylacrylate, deactivation of alkoxyamins is not observed.

Copolymerization of styrene and methyl methacrylate in the presence of high-molecular-weight alkoxyamines allows design of gradient copolymers. Meanwhile, the content of styrene chains in the copolymer is revealed to drop in the course of the process. Curves of the molecular-weight distribution corresponding to conversion higher than 20-30 % are unimodal. Polydispersity index of the copolymer samples decreases with the conversion growth from 2.2-2.4 to 1.2-1.3.

Summary. Therefore, the high-molecular-weight alkoxyamines, derived from PBN, allow controlled polymerization of styrene and butyl acrylate under moderate temperature and result in the formation of block-copolymers.

Over the past two decades, conjugated polymers have become an important group of electronic and optoelectronic materials. Their attractive properties, such as electrical conductivity and electroluminescence, together with their high thermal stability and good mechanical properties allow them to find applications as photoconductors or in thin film transistors, organic light-emitting diodes and photovoltaic systems.[1] Polymers containing carbazole units are particularly good hole-transporting materials due to the electron-donating capabilities associated with nitrogen in carbazole which only can substituted by one chain enhancement the control of pendant groups. Also, it has been demonstrated that the incorporation of 3,6-carbazole units into fluorene-based polymer chains will improve the luminescent stability by interrupting the linear conjugate structures of polymers.[2]

In recent years, electronic energy transfer has experienced a resurgence of interest due to the fact that it is a very attractive method to modulate optical and electronic properties of conjugated polymers. Fluorene based copolymers are particularly attractive as energy donors in Förster Resonance Energy Transfer (FRET) because of their high fluorescence quantum yields and blue emission[3] that allow efficient transfer to acceptors emitting over the whole visible and near infrared spectrum. With appropriate heavy-metal acceptors, it is possible to capture both singlet and triplet state energy. However, blends of luminescent conjugated polymers with electronic energy acceptors tend to phase separate,[4] which can lead to losses in efficiency. This can be avoided by attaching the acceptor covalently to the polymer,[5] or by forming self-assembled systems.[6]

We report the synthesis and characterization of a novel group of polymers, incorporating fluorene-carbazole units as energy donor and porphyrin as pendant acceptor group. Also, a comparative study will be presented of singlet-singlet energy transfer between a system involving a covalent attachment of the acceptor to the polymer and a self-assembled system.

Introduction:

Polypropylene (PP) is a linear, high melting point polyolefin with excellent chemical resistance and acceptable range of mechanical properties[1]. There are various grades of polypropylene available in the market to cover wide range of applications. Heterophasic ethylene-propylene copolymers (HECO) were developed by in situ sequential homo-polymerization of propylene monomer and copolymerization of propylene and ethylene monomers to improve low temperature impact resistance of polypropylene homopolymers[2].

The modification of PP by high energy beams has been used widely to introduce desirable changes in its molecular architecture. The effect of irradiation on thermal stability of PP was the subject of some researches [4]. In this work, irradiated PP heterophasic copolymers were prepared by electron beam irradiation in different doses and the kinetic methods are applied to the thermogravimetric analysis data in order to determine the non-isothermal degradation kinetics and the results of these methods are compared.

Materials and Methods:

The polypropylene copolymer used in this study was the commercial grade Irapol EP-D60R. The samples were irradiated by a high power industrial electron beam accelerator [5] under nitrogen atmosphere. After irradiation the samples were annealed under nitrogen atmosphere for 30 min at 80°C, to enhance the mobility of free radicals and then 60 min at 130°C to deactivate the residual free radicals. Gel content of the samples was measured in boiling toluene solvent. Thermal properties of heterophasic PP copolymer were investigated by TGA.

Results and Discussion:

The main reactions that take place during irradiation are crosslinking and chain scission [3]. Gel content values correspond with the network structure formed in amorphous region of PP which is not soluble in the solvents. In TG curve of heterophasic PP copolymer, the initial weight loss occurred at 300 ^{o}C is related to the thermal decomposition of bond of polymer. Results also show that there is a shift in the decomposition process to higher temperatures at higher heating rates. The activation energies (*Ea*) of the samples are calculated by three methods [6]: the Kissinger method, the Flynn–Wall–Ozawa method and the Coats-Redfern method. It is clearly observed that the activation energy values computed using the Kissinger and Flynn–Wall-Ozawa methods are in good agreement. The trend observed here for the activation energies is possibly related to the competition of the chain scission and crosslinking reactions occurring in the copolymer during irradiation. The results show that crosslinking reactions are increased in the samples by increasing the irradiation dose, leading to a high molecular weight fraction and increased activation energy. There is a big difference between the *Ea* values of the samples computed by Coats-Redfern method and those computed by Kissinger and Flynn-Wall-Ozawa methods, and the trend is not similar. This discrepancy is possibly related to the fact that the Coats-Redfern method for the kinetic analysis of non-isothermal TGA data is unsuitable and inconsistencies exist in published kinetic results obtained using this approach

Conclusions

It can be concluded that there is a competition between crosslinking and chain scission reactions during irradiation of polypropylene heterophasic copolymer. The polypropylene homopolymer phase is more likely to undergo chain scission and the ethylene propylene rubbery phase is more likely to undergo crosslinking.

The values of activation energies calculated by Kissinger and Flynn-Wall-Ozawa methods were in good agreement and followed a similar trend. But the values obtained from Coats-Redfern method were different and did not show the same trend as the other methods.

Effect of Process Conditions on the Compatibilization of In-Reactor Alloys

H. Bagheri[1], M. Nekoomanesh[1], S. Hakim[1], Y. Jahani[1], Z. Q. Fan[2]*

1. Iran Polymer & Petrochemical Institute, P. O. Box 14965/115, Tehran, Iran

2. Department of Polymer Science and Engineering, Zhejiang University, Hangzhou, 310027, PR China

Introduction

The versatility of an in situ copolymerization of an alloy in a process known as "in-reactor alloy" facilitates the production of an immiscible alloy in one single reactor.[1] In this way, alloys with high ethylene-propylene rubber content are produced in two steps. In the first step, propylene is polymerized into a polypropylene homopolymer by a stereospecific catalyst system. In the second step, a mixture of ethylene and propylene are copolymerized using the same catalyst.

Materials and methods

PP/EPR in –reactor alloy was produced via multi-stage sequential gas-phase polymerization of propylene and gas-phase ethylene-propylene copolymerization in circular mode.[2] In this way, three samples were produced, named EP20, EP10, EP5. The sample EP20 was synthesized by ethylene-propylene copolymerization for 20 min and then propylene homopolymerization was carried out for 60 min. The switching number of this sample was designated as 1. The sample EP10, as switching number 2, was synthesized by ethylene propylene copolymerization for 10 min followed by propylene homopolymerization for 30 min. Overall, the total copolymerization time was 80 min. Analogically, the switching number 4 for EP5 was proceeded as above. The samples were studied with respect to the rheological behavior and final properties of the alloy. The polymer alloys based on different structural morphologies were characterized by SEM, GPC, ^{13}C NMR, DSC, rheological analysis, and mechanical testing.

Results and discussion

The results indicated that altering switch frequency has no effect on the microstructure and molecular weight distribution of the polypropylene with very low effect on the synthesized EPR phase Fig. 1. However, the morphological studies combined with rheological and mechanical investigations showed that increasing the switch frequency, reduces the size of the dispersed EPR leading to increase in mechanical performance due to increased interfacial adhesion and partial enhancement of crystalline content Fig. 2

Abstract

In this investigation, the expanded graphite (EG) was prepared by graphite intercalation compound (GIC) and thermal shock treatment (TST). Results indicated that the effect of thermal treatment caused the expansion degree of EG. By the TST, the EG owned high aspect ratio, and the electrical conductivity was no change that compare with the original nature graphite (NG). The EG were treated by ultrasonic method to get the expanded graphite nanoplatelet (EGP). In order to improve the conductivity of EGP, the key of modification was used acid treatment. The NG, EGP and Carbon Black (CB) were added to EVA (ethylene–vinyl acetate) for preparing the conductive composite, and analysis in EMI shielding.

Experimental

The EG were manufactured by GIC at 350, 650, 950, 1050 ℃ for 1 min. The EG were immersed in a 70% of aqueous alcohol solution and subjected to powdering in an ultrasonic bath for various hours. The resulting dispersion then was filtered and dried to get EGP. The 10g EGP were added in 500ml acid bath (3M HNO_3) with stirring (washing) for 2 hours and washed by distilled water until the filtering solution reached the pH value of original distilled water. The NG, EGP and CB were used as conductive fillers which were blended in the polymeric matrix. The polymeric composites possessed the EMI shielding effectiveness.

Results and discussion

Graphite is a form of carbon with the carbon atoms bonded in layer held together by the weak Van Der Waals force, allowing intercalation atoms or molecules that occupy spaces between the graphite sheets to form graphite intercalation compound GIC [1] which by TST method to form the EG. Tab. 1 showed the effect of TST related the expanded volume (EV) with the high aspect ratio.

Tab. 1 showed the EV of EG with various TST conditions.

TST(℃)	350	650	950	1050
EV(cm^3/g)	13.8	26.1	33.8	33.8

Fig. 1 showed the composites with the TST in 950℃ and 1050℃ of EG displayed the better EMI SE, and that of enhanced the EG dispersal to form the conductivity path in the polymer matrix [3].

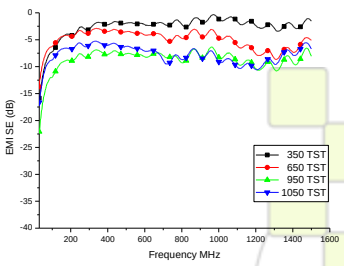

Fig. 1 EMI SE of EVA/EG (100/40) composites with various EG of TST conditions.

Fig. 2 showed the surface resistance of NG, EGP and acid treatment EGP (ACT-EGP). By the acid treatment of EGP, the surface resistance of ACT-EGP was decreased from 8.52 mΩ to 6.50 mΩ and possessed good electrical behavior. In summary, the acid treatment is inevitable for the purposes of purification [4], and modification of EGP increased the conductive properties.

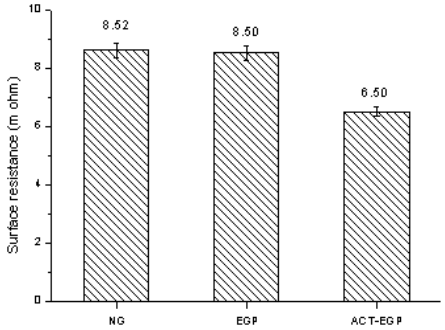

Fig. 2 The surface resistance of NG, EGP and ACT-EGP.

Fig. 3 showed the EMI SE of 40, 60 phr EGP and 40 phr EGP/20 phr CB composite. When the contents of 2D-nanaplate of EGP were added the 40 to 60 phr, it has no obvious that the EMI SE (10 dB-15dB). Therefore, the CB was extra added in the composite to improve the conductivity path between the EGP. In the same volume percent (60%), the composite of 40 phr EG/20 phr CB was exhibited the better EMI SE (25 dB). In this study, the carbon black were used for the bridge to conduct the 2D-graphite nanoplatelet forming continue conductive network in the polymer matrix,it enhanced the EMI SE from 8 to 25dB.

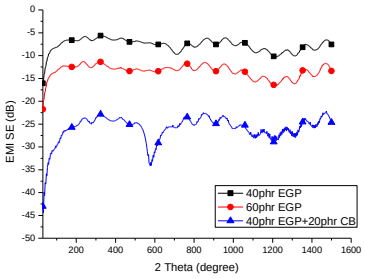

Fig. 3 The EMI SE of 40 phr EGP, 60 phr EGP and 40 phr EGP/20 phr CB composites.

One of prominent aspects of use of polymers in medicine is working out thromboresistant polymeric materials and coverings on their basis of metal implants(stents).

By us possibility of electrosedimentation of composite polymeric coverings on purely iron electrode on the basis of a copolymer vinilacetat-krotonic acid both flouroplast marks F-40D and F-4D in a water-alkaline solution is shown.

Level-by-level heterogeneity composite flouroplast fully coverings that is connected with the mechanism of their formation is established. The analysis of coverings on the flourine maintenance has shown that in the first seconds electrolysis on a metal surface is formed the coverings, not containing flourine, i.e. the covering on an electrode is formed at the expense of electrosedimentation.

Then covering formation follows the account electroforetics the mechanism for which the induction period is characteristic. Research of dependence of change of potential of the anode from time for various compositions in the course of electrochemical sedimentation in galvanostatic a mode confirms the prospective mechanism of formation of composite polymeric coverings.

Have been studied thromboresistant properties of coverings, interaction with modeling solutions fibrinogen and thrombocyte in vivo, and also with integral blood.

On the basis of medical and biologic researches it has been shown that the synthesized polymeric coverings are biocompatible, biodegraded and thromboresistant materials, suitable for use as coverings metal stents.

Temperature Effects in the Dynamics of Bipolaron in Polymer Chains

Introduction

Conjugated polymers have been receiving increasing attention as suitable materials for electronic applications because of their flexibility and amenability to solution processing [1]. These materials for example can be used as the active layer of organic TFTs (thin-film transistors) and are great for the design of Organic Light Emitting Diodes (OLEDs). OLEDs promises superior performance in brightness and color resolution, thin aspect ratio and better physical characteristics. In its turn organic TFTs has various advantages over inorganic amorphous silicon TFTs and low-cost processing.

Defects in the chain are responsible for charge transport. These quasi particles can be polaron, bipolaron and exciton. Bipolarons and Polarons are self-localized particle like defects associated with characteristic distortions of the polymer backbone and with quantum states in the energy gap due to strong electron-lattice coupling.

Recently it was verified that interchain bipolaron transport is impossible with electric field typically used in conjugated polymer based devices. However, a recent work [2] has shown the importance of considering temperature effects in the charge transport for both intra and interchain process. It was obtained that the temperature raise increases inter and intrachain mobility of polarons. In this work we study the temperature effects over the dynamics of bipolarons on two coupled pi conjugated polymer chains.

Model

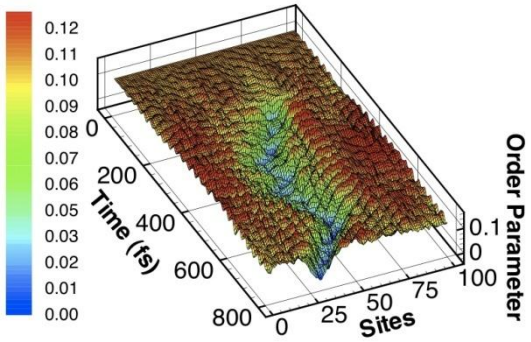
The systems are studied combining the one-dimensional tight-binding Su-Schrieffer-Heeger (SSH) model and the Langevin equation to include temperature effects. The SSH Hamiltonian is written as

$$H = \frac{1}{2}M\sum_i |\dot{u}|^2 + \frac{1}{2}K\sum_i (u_i - u_{i+1})^2 + \\ + \sum_{ij}[t_{i,i+1}|i><i+1| + t^*_{i,i+1}|j+1><j|]$$

The first term is the kinetic energy of motion of the sites in the chain. The second is the bond energy of the lattice atoms. $T_{i,i+1}$ in the last term is the hopping integral, which can be expanded to first order as $T_{i,i+1} = T_0 + \alpha(u_{i+1} - u_i)$. We study the dynamics performing numerical calculations within the time-dependent Approximation.

Results and Discussion

In the simulations we considered a system composed of a single and two coupled chains with 100 sites and periodic bond conditions of cis polyacetylene. The figure shows the result of a simulation with the previous described system under a 100K temperature regime. It was observed a greater charge delocalization compared with the 0K regime. This result suggests that thermal effects increase the charge carrier mobility [3]. When both temperature and electric field are present a level of bipolaron mobility even higher is achieved.



Conclusions

It was studied the dynamics of bipolarons in pi-conjugated polymers chains under several temperature regimes within the time-dependent Approximation.

We observed that the temperature effects are very important to the charge transport in conjugated polymers. Similar to the polaron equivalent simulation performed in [2], the temperature increase causes bipolaron delocalization and this fact leads to rise in its mobility, improving thereby the inter and intrachain charge transport.

Introduction

Conjugated polymers are central structures in the recently increasing field of molecular electronics. As the technology employed to design systems based in these molecules reached the current level, the interest in these devices increased drastically due both to the low cost of the processing techniques and to interesting features of the devices itself, such as low weight, controlled charge carriers concentration, etc.

A simple, yet very useful device concerning molecular electronics is the so called PN junction. These structures are obtained when different kinds of semiconductors are mechanically joined. A PN junction is actually the basic kind of device in electronics for many other devices derive from it. As examples of devices created out of PN junctions we have organic diodes, bipolar junction transistors and OLEDs [1].

Also, it is a well known fact that devices made from semiconductor polymers usually employ several types of polymer in order to achieve higher efficiency [2]. The reason for doing it so lies essentially in the dissociation process of the structures responsible for charge supply, i.e. excitons.

In this sense, the present work is devoted to the study of exciton dissociation as the result of the structure interaction with the junction potential. We also investigated how temperature affects the exciton lifetime and obtained a pair of polarons as resulting charge carriers.

Simulation

Numerical simulations were performed to investigate excitons dynamics and their subsequent dissociation. Our code consists on a modified version of the SSH model [3]. Within the Unrestricted Hartree-Fock Approximation we included electric field through the inclusion of a vector potential. Electron-electron interaction was taken into account via a Parr-Pariser-Pople mean field Hamiltonian and the temperature effects were considered in the lattice by applying the Langevin formalism on the equation of motion. Finally, we used a Brasovskii-Kirova type symmetry breaking parameter to simulate a cis-symmetry polymer.

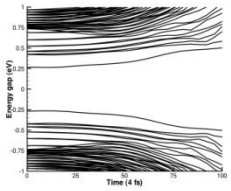
The lattice and electronic equations of motion are simultaneously solved. The latter was traditionally carried out through the consideration of the time dependent Schrödinger equation via the UHF approximation. As for the former, we considered the Euller-Lagrange formalism modified to include a white noise in order to simulate thermal excitations [4].

Starting from a typical cis-polyacetylene chain, the used model parameters were suddenly modified in a particular site of the chain to simulate the heterojunction. We, then, prepared an initial state consisting of an exciton in the neighborhood of the PN junction.

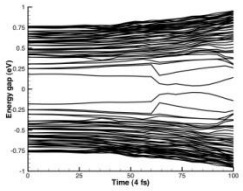
Results and Discussion

We simulated two different chains of conjugated polymer by changing the model parameters of the molecule at a specific point defined as the PN junction. It was then considered an exciton in the neighborhood of the PN junction subjected to thermal effects implied through a classical Langevin equation.

The temperature behavior investigation has shown that exciton stability is critically decreased with temperature. The left figure shows the energy levels of a stable exciton at 0K. In the right, it can be noted the exciton dissociation into a pair of polarons when submitted to a 300K temperature regime.



Stable exciton at 0K



Exciton dissociation at 300K

The random walk imposed to the exciton subjects the structure to the action of the junction potential thus dissociating it into a pair of oppositely charged polarons. The external electrical field applied throughout the molecule accelerates the polarons in opposite directions, giving rise to the electrical current in the device.

Conclusions

We numerically obtained the experimentally observed fact of exciton dissociation in a pair of oppositely charged polarons [5].

It was observed that thermal effects are of major importance in the dissociation process as excitons subjected to the higher thermal regimes tends to dissociate faster, thus giving a more efficient contribution to the charge transport mechanism in PN junctions.

Modification of linear low-density polyethylene in single-screw extruder

Kazuya Ono[1], *Masayuki Yamaguchi*[2]

[1] Research and Development Division, Nihon Tetra Pak K. K.
[2] Japan Advanced Institute of Science and Technology

Kazuya.ono@tetrapak.com

Introduction

Linear low-density polyethylene (LLDPE) has been widely used in flexible packages as a sealant layer material owing to better low-temperature heat sealability, hot tack, and transparency than low-density polyethylene (LDPE). Further, LLDPE synthesized by metallocene catalyst are known to have better mechanical properties than LLDPE by Ziegler catalyst. However, it is generally said that the processability of LLDPE is inferior to that of LDPE. For instance, LLDPE tends to cause surface melt fracture phenomenon at lower shear rate in the extrusion processing.[1] The underlying cause of poor processability in LLDPE is considered to be lesser existence of long relaxation time components compared to LDPE. Therefore, the approaches to improve processability of LLDPE are focused on the control of MWD[2] and incorporation of LCB in the polymer. When LLDPE is extruded, the polymer undergoes structural change by heat and shear. It is very important to know the influence of processing conditions on thermal and rheological properties as the LLDPE is responsible for heat sealability in packages.

Materials and Methods

Two types of commercial ethylene-1-hexene copolymer, synthesized by metallocene catalyst; LLDPE-1 (MFR is 7.6 [g/10min], density is 912 [kg/m^3], M_n is 1.7 x 10^4, and M_w is 7.4 x 10^4) and LLDPE-2 (MFR is 3.8 [g/10min], density is 913 [kg/m^3], M_n is 3.0 x 10^4, and M_w is 7.1 x 10^4) were used. No additives were compounded in the materials. The extrusion tests were carried out by laboratory 20mm single-screw extruder with a circular strand die mounted on the head. The temperature of barrel and die was varied from 170 °C to 350 °C in increments of 30 °C. The extruded strands were trapped and quenched in a water bath. The SEC measurements were carried out to obtain the average molecular weights. The linear and non-linear rheological properties were evaluated by rotational and capillary rheometer, respectively. The shreds of strand were compression molded into sheet for FT-IR measurement and thermal analysis.

Results and Discussion

In the SEC measurement of extruded samples, the reduction of molecular weights at 350 °C extrusion indicates that the chain scission reaction is predominant at this temperature. When the extrusions are carried out at 320 °C or lower, however, the molecular weights and M_w/M_n ratio are not largely influenced by the extrusion processing. The SCB peaks in the FT-IR spectra and the melting points in the DSC curves are not affected by the extrusion processing, indicating that the number of SCB is unchanged. In regard to the rheological properties, the linear viscoelastic response sensitively describes modification of LLDPE by extrusion when the MWD is narrow. The van Gurp-Palmen plot of extruded LLDPE-2 samples, shown in Fig. 1, indicates that long relaxation time components are created by extrusion processing and the development is processing temperature dependent. Further, the relation of zero share visosity η_0 and M_w reveals that the increase of η_0 with increase in the temperature is due to branching caused by cross-linking reaction. On the other hand, the non-linear measurement can only depict the change in the LLDPE-1, which is supposed to contain long relaxation time components. The drawdown force measurement indicates that the polymer shows shear modification when extruded at 200 °C or lower. On the contrary, the strain-hardening in uniaxial elongation is enhanced to some extent when extruded at higher temperatures.

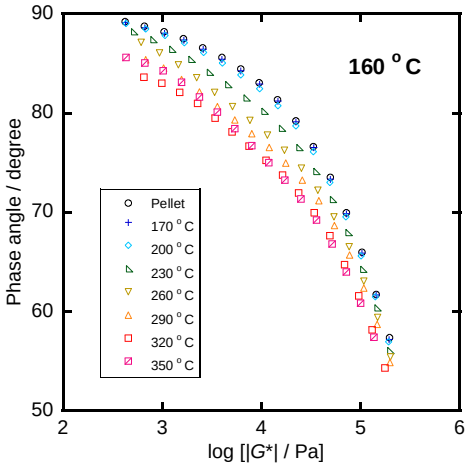

Fig. 1 van Gurp-Palmen plot of extruded LLDPE-2.

Conclusions

Influence of extrusion processing on structure and rheological properties of LLDPE were investigated by employing commercial polymers in which additives were not compounded. The FT-IR measurement and thermal analysis indicates that the SCB is not changed by extrusion. Further, the molecular weights obtained by SEC measurement are not drastically altered except for samples extruded at 350 °C. On the other hand, the rheological measurement reveals the development of long-chain branching structure by extrusion processing. The non-linear measurement is particularly important to evaluate modification of LLDPE in which long relaxation time components are involved.

Introduction. Polyethylene terephthalate (PET), a thermoplastic polyester is widely used in soft drink and mineral water bottles which constitute the third largest food packaging that is being regularly consumed after packaged tea and biscuits [1]. In order to reduce PET contamination, polymer blending, mechanical and chemical recycling are used [2]. Particularly, solid state mechanochemistry is applied to enhance the compatibility and control the molecular weight and morphology of polymers [3]. It has been reported that PET powders, when are processed by high-energy ball milling, showed a reduction of the average particle size, local orientation of the polymer molecules due to the stress, and a decrease in crystallinity [4]; and PET treated by vibratory milling in inert atmosphere, generated active particles sensitive to the radical acceptors and able to initiate the grafting of vinyl monomers whenever they present in the reaction medium [5]. In this work, the synthesis of PET-polylactic acid (PLA), PET-chitosan and PET-PLA-chitosan blends are reported, as well as the results of FT-IR, DRX and SEM analyses.

Materials and methods. PET from bottles, PLA and chitosan (Sigma Aldrich) were used to produce polymer blends by ball milling at 300 rpm. Cylindrical stainless steel grinding jar of 50 cm^3 and balls made of the same material in a 50:1 ratio was used. The proposed proportions were 5, 10, 15 wt% chitosan and 5 wt% PLA, samples were taken every 10 hours with a total time of 50 hours. The mixtures were analyzed using a PerkinElmer Spectrum one infrared spectrophotometer (range 4000-650 cm^{-1}), X-Ray Diffractometer D8 Advance type (range 5-60 θ (º)) and a SEM (JSM-6300) operating at 15kV.

Results and Discussion. Figure 1 shows the FT-IR results of PET, PET-chitosan in different proportions and PET-PLA for a milling time of 50 h. There were no changes in the signals, suggesting that the bonds in PET do not react or form secondary bonds with the PLA and chitosan biopolymers.

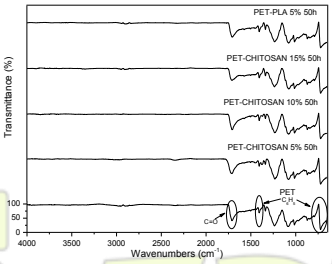

Figure 1. FT-IR Spectra of PET, PET-Chitosan (5, 10, 15 wt%) and PET-PLA (5 wt%).

From XRD spectra (Figure 2) it is confirmed the PET triclinic structure which is modified with the biopolymer type and milling time.

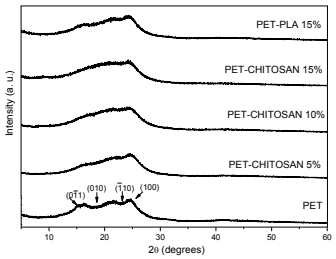

Figure 2 XRD patterns of PET, PET-Chitosan and PET-PLA for milling time of 50 h.

The slightly rounded particles are flattened into flakes because PET has a high impact resistance (Figure 3), and maybe more energy is required to reach a better blending.

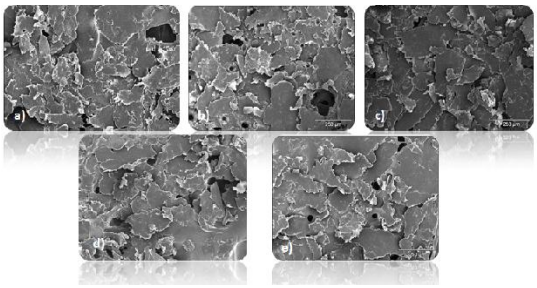

Figure 3. SEM micrographs of PET-PLA powder: a) PET; milling time of b) 20 h; c) 30 h; d) 40h, e) 50h.

Conclusions. PET-chitosan and PET-PLA blends were obtained by ball milling technique. Results suggest that there are no new bonds between PET and chitosan or PET and PLA, the biopolymer type and milling time greatly influences the crystallization of PET phase.

Abstract: Composites of postconsumer high-density polyethylene with agave fiber (*Agave tequilana*) were prepared by singlescrew extrusion; Composites of natural fibers with thermoplastic materials provide engineers with new options for novel product development. One of the principal purposes of composite production is to improve matrix mechanical properties, for example, by reinforcing its toughness and strength. The low cost of fillers from recycled material makes them attractive for the production of these solids. Among other desirable properties, the composites should possess enhanced biodegradability and should be reusable. It was found that tensile and flexural moduli increased with fibre concentration while they decreased for impact strength.

Introduction

Pollution due to waste materials has been an important issue in the last decades. Millions of tons of synthetic polymers are discarded each year. For example, the European Union discards more than 13 million tons of plastic waste per year, mainly polyethylene, polypropylene, polystyrene, polyethylene terephthalate and polyvinyl chloride (Williams and Slaney, 2007). Unfortunately, these synthetic polymers are not biodegradable, remaining in the environment almost indefinitely (Friedrich et al., 2007; Gu, 2003). Another specific pollution problem taking place in South-west Mexico is the fiber wasted throughout the process of Tequila production, which is an alcoholic drink produced in some states of Mexico (90% in the state of Jalisco); it is obtained from distilled must prepared from juice extracted from Agave Tequilana Weber var. Azul(Consejo Regulador del Tequila, http://www.crt.org.mx). After the juice extraction process is carried out, fibers from Agave are disposed and they become a serious waste problem. Several research groups have proposed different alternatives to employ these fibers; however, these applications are not enough to dispose of the enormous amount of agave-fibers produced each year (during 2005 alone the production of agave-fibers was 711,000 tons; Iniguez et al., 2001a, 2003; Leduc et al., 2008). Natural fibers are abundant, with low cost, low density, high specific properties and non-abrasive (Saheb and Jog, 1999). Thus, the recycling of polymers and fibers is a very important aspect and it is necessary to find alternatives for the reprocessing of these materials. One of these alternatives is the production of natural fiber composites which is an emerging area in polymer science. Nowadays the main application of natural fiber composites is the production of materials for construction like panels, doors, windows, furniture and decorative pieces (Saheb and Jog, 1999). In this research, we studies the mechanical properties of postconsumer agave/polyethylene composites

Methods

Composite components

The materials used to produce the composites were recycled high-density polyethylene (HDPE) from scrapped milk bottles originally prepared using Paxon AD60-007 (Exxon Chemical, Houston,TX) with a medium molecular weight homopolymer, melt index 0.7 g/10 min and density 0.960 g/cm3, and fibers of *A. Tequilana* Weber var. Azul, obtained from residues of a local tequila company.

Fiber treatment

Fibers from *A. Tequilana* Weber var Azul were treated mainly in two steps: First, they were cleaned and second they were chemically treated (digestion). To clean the fibers, a sifting was made to eliminate the solids, later the pithy fibers were soaked in a container with tap water for 24 h, to hydrate the fibers and to facilitate pith separation. This separation was made in a Sprout–Waldron refiner(D2A509NH) with two 30 cm diameter discs, one fixed and the other rotating at 1770 rpm. Using centrifugation, the excess water in the fibers was eliminated and they were dried outdoors. The digestion of the fibers is performed to eliminate the lignin present in the fibers (Iniguez et al., 2001b). A lab scale digester was used with a 20% (wt/wt) NaOH solution and a temperature of 170 ^{0} C during 90 min.

2.3. Composite preparation

Once the fibers were treated, composite preparation was the next step. Foamed composite extrusion was carried out in a single-screw extruder Haake Rheomex 254 controlled by a Haake Rheocord 9000 control system (Thermo Fisher Scientific Inc.,USA). An amount of 0.5% of ACA (wt/wt) was added to a blend of

30% fiber and 70% recycled polymer and extruded with a screw speed of 30 rpm. The temperature profile from the hopper to the die of the extruder was set to 150/160/170/180 ^{0}C. After the extrusion process, the foamed composites were pelletized.

Conclusions: It was found that tensile and flexural moduli increased with fibre concentration while they decreased for impact strength.

Introduction

Conductive polymers have numerous applications in biomedical industry or in electrocromic applications (smart windows, optical filters…). In particular, the polyaniline (PANI) is one of the most used conductive polymers owing to its ease of synthesis[1] and their good electrical properties. However, its low processability and solubility as well as their poor mechanical properties limit their applications. To solve these problems, conductive compounds were made mixing the synthesized PANI with different thermoplastic polymers[2]. In this way, an improved processability was obtained at the expense of decreasing the conductivity of the synthesized PANI. Therefore, it is necessary to establish a commitment between conductivity and processability.
In this work, we study the effect of conductivity on the type of processing (compression and extrusion).

Materials and Methods

Ammonium peroxydisulfate (APS) and aniline chloride were used for the synthesis of PANI. Both products were supplied from Aldrich. This polymer was characterized chemically by Elemental Analysis (EA) and Fourier Transform Infrared Spectroscopy (FTIR), thermally by Differential Scanning Calorimetry (DSC) and Thermogravimetry (TG) and electrically (Van Der Paw method).
The used thermoplastic matrixes were polycaprolactone (PCL, melting point 75 ºC, from Union Carbide) and polybutylentherfthalate (PBT, mp=235 ºC, from BASF Chemical Company). Both matrixes were dried before use.
Compounds were processed by extrusion using a miniextruder with two conical and contrarotary screws (Haake MiniLab II). The optimum conditions of the processing were 100rpm for 10min. The compounds were also processed by extrusion using a hydraulic press (Telergon Hydraulic Press 40 Tn) applying 40 Tn of pressure for 30 min. For both processes, the processing temperature was slightly higher than the melting point of the thermoplastic polymer, respectively.

Results and Discussion

The chemical structure of the PANI was checked by EA and FTIR and was obtained a conductivity of 8 S/cm.
The compounds were processed at a 20 % and 40 % (percolation threshold)[3] from conductive polymer.

The aspect of the obtained compounds by compression and extrusion are shown in the following Figure:

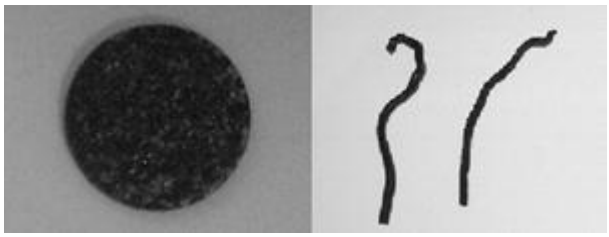

Figure 1: Pressed pellets and threads of conductive compounds.

The threads obtained with PCL are more flexible than the extruded with PBT. However, the pressed pellets have a similar aspect for both cases.

Comparing the results obtained for both processing, the values of conductivity decrease more notably for the compounds obtained by extrusion. This can be related to the shear speed because the channels of electron circulation can be broken.

The study of thermal properties exhibits that the melting point of PCL increases dramatically up to 120ºC (mp= 75ºC for pure PCL) when the compounds are processed. For the case of PBT, the melting point remains constant, due to the rigidity of that polymer.

Conclusions

- New conductive compounds have been obtained using PANI as the conductive filler.
- The samples processed by compression have much higher conductivities than the obtained by extrusion.
- The compounds obtained with PCL are much more flexible and homogeneous.

Rheological Modeling of Single-Screw Extruders

Hossein Hosseini[1] *and Faezeh Aghazadeh*[2]

[1] Department of Chemical Engineering, University of Tabriz, Iran
[2] Tabriz petrochemical Company, Tabriz, Iran

h_hosseini@tabrizu.ac.ir

Polymer processing for production of all forms of polymeric articles has found a great place in chemical industries. One of the most widespread practical methods of polymer processing is the extrusion method that is based on pressing a polymeric melt through channels of the molding tool which have different geometrical cross-sections. The principal technical characteristic of extruders, named flow /pressure balance, and also modeling of deformation processes permit to evaluate their practical output in processing various polymers as a function of the hydraulic resistance which depends on the flow of an extruded polymeric material through the channels of the forming tool. The validity of obtained and presented results permits to recommend them reasonably not only for estimation of extruder output, but also for making calculations necessary in extruder equipment design: checking calculation of strength and stability of a screw; calculation of driving power of the equipment being designed; strength calculation of a plasticizing cylinder, etc.

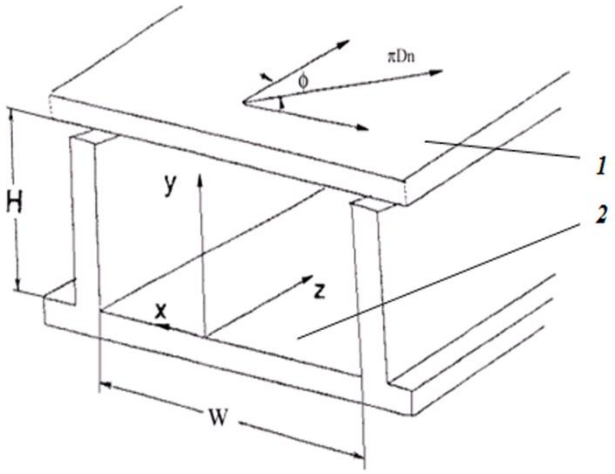

Figure 1. The Scheme of inverse motion of the working parts of a extruder:1 – cylinder wall; 2 – screw channel.

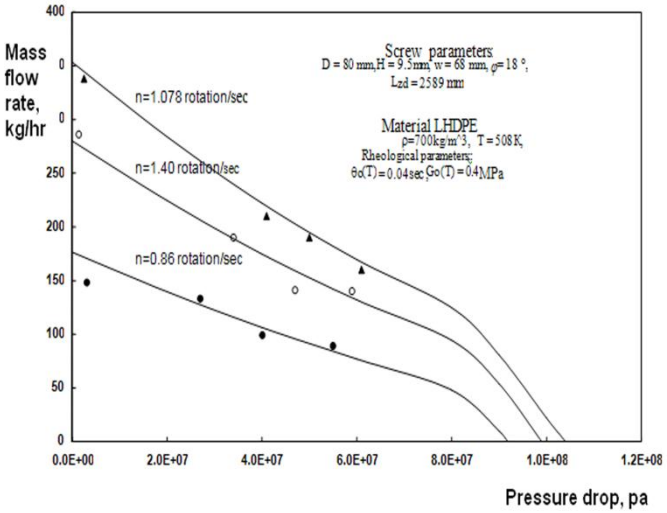

Figure 2. Flow/Pressure characteristics of the extruder at different screw rotation frequency.Lines: equation 19; Points: experimental data.

Introduction: Nanocomposites have been increasingly studied because of their unique characteristics. Many processes have been envisaged to overcome the resulting problems like phase dispersion and agglomeration. We used a new single step process to produce inorganic nanoparticles of silica fixed on polymer particles and to reduce their agglomeration. In this novel process, simultaneous polymerization prevents the agglomeration of surface active, nano-sized silica particles. We used methyl methacrylate as monomer and silica as mineral emulsifier to produce these structures. In this study, we show that a single step process of precipitation and polymerization can be used under controlled process conditions e.g. amount of water soluble initiator and silica. Moreover, we studied the effect of added cationic surfactant on the morphology of final hybrid nanostructures.Emulsion polymerization is a routine commercial route for production of nano size polymer particles. A typical recipe consists of monomer, water, organic surfactants, initiator, and minor other additives. Inorganic emulsifiers, howevrer, are particles in nano to micrometer range that can be absorbed on the oil/water interface, minimize their surface energy and as a result, stabilize droplets and/or particles in their inevitable continuous collisions with each other [1]. Up to now, myriads of chemists have studied different aspects of such inorganic emulsifiers [2, 3].

Material and methods:

Materials: Methyl methacrylate was provided by Acros Organics. Sodium silicate (solid content of 35% wt. by carbon dioxide precipitation method) was technical grade and used as received. Cetyl trimethyl ammonium bromide (Merck) as catonic surfactant and Ammonium persulphate (Fluka) as water soluble initiator was used without prior treatment.

Typical Polymerization run: A conventional emulsion polymerization method with minor modification to generate silica nanoparticles at the interface of oil/water hybrid particles was used. At first, 1g catonic surfactant was dissolved in 30ml water from which 1ml was added to completely sealed container during the reaction process. Vacuum and argon purge was applied to the system three times. MMA and Sodium silicate solution were added to a round-bottom reactor and then agitated by an egg-shaped magnet at 1000 rpm. The temperature of the solution was raised to 70 °C and then initiator solution was added to the reactor. CTAB solution and Carbon dioxide were added to the reactor through 11 steps during the polymerization process.

Results: As mentioned in the experimental section, the procedure was performed through a one-pot polymerization system. At first, it was turned out that this one-step precipitation/ polymerization method is a reliable method in order to prepare hybrid particles. Our results demonstrate that, the precipitation of silica nanoparticles takes place in the presence of carbon dioxide. Freshly produced inorganic nanoparticles sit at the oil-water interface and can also stabilize emulsions of oil in water. Figure1shows SEM and TEM images of inorganic particle stabilized latex of Poly methyl methacrylate, produced via in-situ emulsion polymerization.

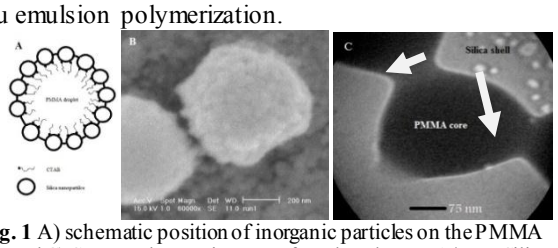

Fig. 1 A) schematic position of inorganic particles on the PMMA core, B and C) SEM and TEM images of produced PMMA/nano Silica latex via a new single step precipitation/polymerization method

Anchoring process of nano-silica particles happens spontaneously and decreases the interfacial tension of oil in water emulsion, and as a result, makes them thermodynamically stable. Stabilizing silica particles on the surface of polymeric core are in the range of 30-45(Fig.1 A). Energy dispersive X-ray microanalysis (EDX) clearly proves the presence of silica particles on the surface of hybrid latex (Figure 2).

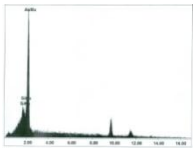

Fig. 2 EDAX spectrum for the surface of hybrid latex.

This proves the ability of oil-water surface to trap freshly produced silica nuclei. Trace amount of cationic surfactant simplify the generation of hybrid microspheres. As a result, CTAB molecules can be considered as a binder between organic and inorganic parts of final hybrid structures.

Conclusion:A facile and effective approach has been developed to prepare hybrid organic-inorganic microsphere via the one-pot emulsion polymerization. These hybrid microspheres would find applications in catalysis, cosmetics, and drug delivery. This method can be extended in order to prepare hybrid latexes from other organic monomers and inorganic particles.

Introduction

In order to reduce the environmental impact of plastic wastes, there is necessary to look for new ways of recycling and new fields of application for these recovered materials. In this work, mixtures of residual plastic of different origin, underwent different percentages of peroxide treatment in order to increase their compatibility and improve their behaviour as matrices of composite materials.

Materials and Methods

There were prepared different mixtures from agricultural waste recycled plastic (AF, BEFESA), and urban residual plastic wastes (RU), using a roll mixing machine, and adding different percentages of stabilizer (Irganox B900, Ciba) and crosslinker additives (Trigonox 145-E85 and Trigoniox 145-45B, Azko Nobel)

The different mixtures named as AFxx in function of the added percentage of AF and RU, were characterized, before and after the treatments, by means of spectroscopy techniques, thermal, mechanical and rheological measurements. MI measurements were made according to UNE-EN-ISO 1133 standard, working at 190 ºC with 2, 15 kg piston weight .

Results and discussion

Figure 1 shows the variation of the vinyl index, giving by the relationship between two absorbing bands in Infrared spectroscopy (VI= I908/I1461) in relation to the peroxide percentage addition for the AFRU64 mixture. There is observed that VI decreases as the percentage of peroxide increases due to a crosslinking process through the double bonds, mainly, of the HDPE macromolecular chains.

This figure also shows that the addition of 0, 3 wt-% stabilizer inhibits the peroxide action and the following disappearance of the double bonds.

On the other hand, the rheological characterization of the different mixtures is really important considering that these materials are going to be processed by extrusion and/or injection. An excess of peroxide added to the residual plastics mixtures, can cause an excessive increase of their viscosity, even avoiding their processing.

The MI values were lower for the peroxide treated mixtures and those decreased as the peroxide content increased. There were added to the AFRU64 mixture, from 0,10 to 0,20 wt-% liquid and solid peroxides, obtaining the highest MI mixture value for 0,12 wt-% solid peroxide added formulation, and so that, the least viscosity, making the processing easier.

The addition of 0, 3 wt-% antioxidant does not produce a significant change in the rheological properties of AFRU64 sample treated with 0,12 wt-% peroxide.

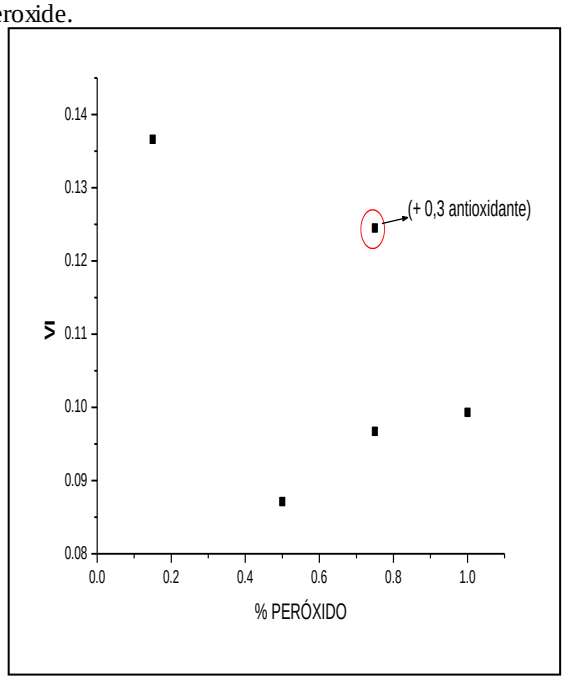

Fig 1. Variation of AFRU64 mixture residual double bonds by addition of liquid peroxide

Moreover, Young modulus and impact strength of the residual plastic mixtures increased with the percentage of added peroxide.

Introduction

The recovery and recycling of rubber waste is a very urgent problem that is related to their high resistance to biodegradation when they are buried and the evolution of toxic gaseous products upon their combustion [1]. In the same time the waste rubber articles are an enormous source of starting materials and their using makes it possible to extract and recycle valuable polymer materials. Previous recycling methods of rubber waste such as landfill disposal, incineration, and recycling have failed to provide opportunities for the complete reuse of plastic waste.

An application that has potential to utilize large volumes of waste rubbers is the use of this material as a filler in plastic compounds which retain processability and physical properties after incorporation of significant proportions of rubber.

The preparation of rubber powder (RP) by grinding is a general trend of rubber wastes treatment. The method of high-temperature shear deformation (HTSD) is based on the grinding of a material in a complex strained state by the action of uniform compression pressure and shear forces under elevated temperatures. This method is available for the production of finely rubber powder.

Materials and Methods

The polymers used in this study were iPP, commercial oil-free ethylene-propylene-diene rubber EPDM Dutral TER 4044 and oil-extended EPDM Dutral TER 4334 (Polimeri Europa, Italy).

Rubber vulcanizates of different crosslink densities were obtained by varying the amount of sulfur in the recipes, changing the ratio of sulfur to accelerator system. Blends were prepared in a Brabender plasticorder mixer at room temperature.

Using high-temperature shear deformation technique, the rubber powder (RP) was obtained from model vulcanized rubbers based on ethylenepropylenediene monomer (EPDM) with different content of vulcanizing agent (sulfur).

Results and Discussion

The particle size distribution of the rubber powders was determined by the method of vibratory sieving. Sieve analysis showed that for all types of RP had a majority of particle size of $0.315<d<0.63$ mm. The increasing of sulfur concentration in the rubber vulcanizate decreased percent of particles size of $d>0.63$ mm, while percent of particles size of $d<0.315$ mm increased. The RP particles have an asymmetrical shape. Two characteristic regions with a distinct boundary are observed at the surface of particles: a region of plastic fracture with highly developed surface and the region of brittle fracture with a smooth surface. The increasing of sulfur concentration in the original rubber vulcanizates leads to a decrease in the plastic fracture on the RP surface.

The rheological behavior of TPEs and dynamically cured TPVs with RP was determined by capillary rheometer. It is found that the addition of rubber powder into rubber phase of TPE increases its viscosity, and a partial replacement of EPDM on RP results in a significant decrease in the viscosity of blends in TPV. The viscosities of TPE and TPV depend on the content of rubber powder and crosslink density of vulcanized EPDM.

Blends EPDM/rubber powders, PP/rubber powders were also studied. It is shown that the performance of rubber powder in TPE and TPV depends on particle size, surface area, and composition.

Characterization of Induced Thermo-mechanical Degradation on Poly (ethylene terephthalate)

J.D. Badía [1], *E. Strömberg* [2], *S. Karlsson* [2], *A. Ribes-Greus* [1,*]

[1] Institut de Tecnología de Materials (ITM), Universitat Politècnica de València (UPV)
[2] School of Chemical Science and Engineering, Fibre and Polymer Technology, Royal Institute of Technology (KTH)

*corresponding author: A. Ribes-Greus (aribes@ter.upv.es)

Introduction: The effects of thermo-mechanical degradation on poly(ethylene terephthalate) induced by mechanical recycling were simulated by successive injection molding cycles, and assessed in terms of a three-phase model involving crystalline, mobile amorphous fraction (MAF) and rigid amorphous fraction (RAF). The effects on the segmental dynamics and on the macroscopic mechanical performance were analyzed.

Materials and methods: Commercial bottle-grade poly (ethylene terephthalate) (PET) SEDAPET SP04 from Catalana de Polimers S.A., Grup LaSeda (Barcelona, Spain), in the form of pellets, was used. Successive 5 processing steps (RPET-i, with i: 1-5) by injection moulding employing an Arburg 420 C 1000-350 injector were applied. Temperature gradient set from hopper to die was 270, 275, 280, 285 and 280 ºC. Moulds were set at 15 ºC. Cooling time residence was 40 s and total residence time ca. 60 s. After injection, a fraction of the samples was kept as test specimen and the rest was ground by means of a cutting mill Retsch SM2000 (UK), which provided pellets of size $\Phi < 20$ mm to be fed back into the recirculation process.
Fourier-Transform Infrared Analysis with Attenuated Total Reflection (FTIR-ATR), Differential Scanning Calorimetry (DSC) and Scanning Electron Microscopy (SEM) were used for structural, morphological and thermal characterization. Dynamic-Mechanical-Thermal Analysis (DMTA) was performed for assessing the segmental dynamics and dynamic fragility of reprocessed PET. Tensile testing and Charpy Impact testing was carried out to determine the influence of morphological changes on the macroscopic mechanical performance of PET recyclates.

Results and Discussion/Conclusions: The application of the three-phase model to assess the evolution of the ratios of crystalline (X_C), mobile amorphous (X_{MAF}) and rigid amorphous (X_{RAF}) fractions is shown in the table. An initial (X_C, X_{MAF}, X_{RAF}) distribution of ~(29, 53,18) % was found for virgin PET. The crystalline fraction showed a slight overall increase, whereas MAF and RAF suffered the main effects of reprocessing, differing at RPET-5. Interestingly, the major change happened from the first to the second recyclate, involving a marginal modification close to a 10 % for X_{MAF} and X_{RAF}. The results suggest that the MAF is principally attacked due to thermo-mechanical degradation, releasing shorter chains that may fold among themselves and rearrange into inter-crystalline domains (RAF) with each reprocessing cycle, which may affect the mechanical performance of the material.

	X_{MAF} (%)	X_C (%)	X_{RAF} (%)
VPET	53,7 ± 0,6	29,0 ± 0,8	18,4 ± 1,1
RPET-1	52,8 ± 0,9	27,7 ± 0,9	20,3 ± 0,2
RPET-2	44,3 ± 0,8	24,9 ± 0,3	28,8 ± 0,7
RPET-3	41,1 ± 0,1	29,6 ± 0,4	32,0 ± 0,8
RPET-4	40,5 ± 1,9	29,0 ± 2,3	32,6 ± 2,4
RPET-5	35,2 ± 0,4	30,3 ± 0,3	36,9 ± 0,6

Evolution of crystalline (X_C), and rigid (X_{RAF}) and mobile (X_{MAF}) amorphous phases along the reprocessing cycles.

FTIR-ATR experiments showed that degradation reactions were mainly driven by the reduction of dyethylene glycol to ethylene glycol in the flexible part of the PET backbone, and chain scission processes that produced –OH terminated species with shorter chain length, which increased the yellowish aspect of PET recyclates. The packing behavior after rearrangement of shortened chains by thermo-mechanical degradation showed important variations in thermal, viscoelastic and mechanical properties. After each reprocessing step, the crystalline fraction was formed earlier and steeper during cooling, thus altering PET processability. Despite the overall crystallinity fraction scarcely changed, a deep characterization of the bimodal melting behavior indicated the segregation of the crystalline phase into populations with smaller lamellar thickness. The role of the MAF reveals that reprocessing affects the dynamic fragility of PET, as drawn from the study on the segmental dynamics of the glass-rubber relaxation, converting it into a stronger glass-former. The reduction of the MAF, which is mainly converted into RAF, and the shortening of chain lengths in the MAF might increased the free volume and had produced new conformations in which the change from a glassy to a rubbery state was overcome easier and involving less activation energy. The role of RAF is relevant in the behavior at break during macroscopic mechanical testing, due to it might act as precursor of crystallinity and/or vitrify, thus promoting a strain-induced crystallization during tensile drawing and enhance the embrittlement of PET.

Introduction

Carbon nanotubes (CNT) – one of the most promising materials in recent years is constantly the object of doubts and disputes, starting from the issue of good dispersion in composites [1-3]. The outstanding mechanical and electronic properties are dumped down by non-uniform CNT distribution – problem party solved by chemical or physical modification of carbon nanotubes. In context with industrial applications of polymer–carbon nanotubes systems, melt mixing is the preferred method of composite preparation. The aim of our work was to investigate the influence of carbon nanotubes modification on the final properties of nanocomposites produced by melt-mixing with various nanofiller addition methods and extrusion conditions.

Materials and Methods

The matrix polymer PC/ABS used in this study (T85) was supplied by Bayer Material Science. The MWCNTs were produced by catalytic carbon vapor deposition and purchased from Nanocyl (Belgium). The nanotubes were NC-7000 (Thin MWCNTs) and NC-3101 (COOH functionalized MWCNTs).

Nanocomposites with different content of MWCNT were produced by melt-mixing with a co-rotating twin-screw extruder. In this work, two ways of introducing nanotubes into the polymeric matrix were used. In the first case, nanotubes in powder were directly incorporated through the first or second extruder feeding gate. In the other case, MWCNT were previously dispersed in EtOH (with and without surfactants), and added into the extruder. Various screw speed of 400 rpm and 600 rpm and barrel temperatures in a range of 220-280 °C were applied.

Results and Discussion

Among the extensive characterization, optical and electronic microscopy (SEM, TEM) supported by Raman spectroscopy were used to confirm structure and morphology of the final material. Thermal and mechanical properties were evaluated by DSC, TGA, DMA, tensile testing. The study was completed by rheology and electrical conductivity tests.

Effect of Nano particles on Mechanical Properties of Biodegradable LDPE/ Starch/Nanoclay Composite

Abdulrasoul Oromiehie[1]*and Pegah Gusheh*[2]

1- Iran Polymer and Petrochemical Institute, Tehran, Iran
*a.oromiehie@ippi.ac.ir
2- Azad University, science & Research Unit, Tehran, Iran

Abstract
In this work the effect of nano particles on the properties of LDPE/starch/nanoclay were studied. Nanclay can be used to improve the mechanical, barrier and thermal properties of biodegradable composites.
The composites were prepared by varying starch content from 30 to 50% and 5% of nanoclay
The result showed that the mechanical properties were improved in the presence of nanoclay with increasing the starch content

Introduction:
Biodegradable polymers are materials that can be degraded by microorganisms and enzymes.
Application of biodegradable polymers includes disposable food service items food packaging, foams and agricultural mulch film. Increasing public concern over dwindling landfill space and accumulation of surface litter has promoted the developed of degradable plastics [1]. Nan clay was added to the blends in order to improve the interfacial strength of LDPE/Starch blends by exploiting the concept of nanocomposites [2,3]. Nan clay have antimicrobial properties as well. This article describes the effect of nanoclay on the in biodegradable composites (LDPE/Starch biopolymer) such as mechanical properties.

Experimental:
Materials:
Corn starch, low density polyethylene(LDPE), glycerol, nanoclay, Polyethylene grafted malice anhydride(PE-g-MA) and Polypropylene(PP).

Methods:
LDPE/Starch/Nan clay composites were prepared by mixing varying starch (plasticized with glycerol) content from 30 -50 wt% and 5 wt% of nanoclay in Brabender twin screw extruder at the following condition: 160/165/170/175/170/165^{0}C and 100rpm.

Results:
The result showed that the mechanical properties were improved in the presence of nanoclay when the starch percentage was increased, (table1) (table2). So this condition helps to have nanocomposites with high biodegradability this result of showed into fig(1,2.3).

Conclusion:
The effect of nanoclay in LDPE/Starch biocomposites improved the mechanical, barrier, thermal properties of the composites and biodegradability of nanocomposites.

farayde@gmail.com

After processing, contamination by microorganisms is the major reason of food spoilage (*1*). Active packaging is an innovative food-packaging concept, particularly antimicrobial films or coatings (*2*). Edible films containing natural antimicrobials can minimize post-packaging contamination, reducing product lost and increasing food safety (*3*). It is well established that fatty acids and their corresponding esters are one group of compounds with antimicrobial activity and little or no toxicity (*4, 5*).

In this work, antimicrobial fatty acids (FA) were incorporated into gluten-gelatin films (5 wt-% to 50 wt-%) with the aim to improve their barrier properties and check their physical properties to be used in food packaging applications.

The fatty acids chosen were caproic, caprilic, capric, lauric, miristic and palmitic fatty acids. A 10 % solution of GLU/GEL (1:1) was used to obtain films by the traditional solvent casting technique. They were homogeneous and easy to handle. For all cases, the film thickness increased with an increase in FA amounts. Films containing palmitic acid had a thickness increment of 179 % while films containing miristic, lauric and caprilic acid had the thickness value increased by 104, 137 and 34 %, respectively. The biggest variation in thickness was obtained for films containing capric acid (from 0.036 mm to 0.146 mm).

The water vapor permeability (WVP) of samples is showed in Figure 1.

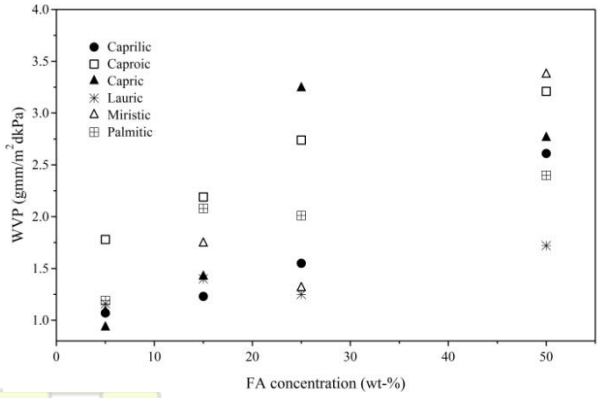

Figure 1. WVP of GLU/GEL/FA films

The WVP containing capric acid, decreased up to 15 % of FA in the film composition in relation with films without FA (data not shown), while for other FAs, the WVP decreased up to 25%. The values of WVP obtained for GLU/GEL/FAs are comparable with the values obtained for hydroxypropyl methyl cellulose and methyl cellulose, which presented values of 1.92 e 1.48 gmm/m^{2}dkPa, respectively. However, they are lower than 7.27 gmm/m^{2}dkPa, the value found for cellophane.

The water solubility of samples containing palmitic and caprilic FA increased from 29.0 % to 34.6 % and from 37.2 % to 41.0 %, respectively, which could be caused by the FA release in water. The addition of other fatty acids did not cause any change in the water solubility of samples. The opacity of films increased with the increase in the FA concentration. Among all, the films containing caproic acid, in the range of 5 % – 30 %, showed the lowest opacity values.

The results showed that the antimicrobial FA addition improved the barrier properties and the performance of GLU/GEL/FA films.

Introduction: Mercury pollutant poses a huge threat because of the lethal effects that it cause on the environment and living organisms due to its long residence, bioaccumulation and permanent damage in central nervous and endocrine systems[1]. Thus, highly sensitive and selective detection of Hg^{2+} in the environmental and biological milieus is an important goal. There are many studies in the literature dealing with mercury chemosensors in aqueous phase; however, with regard to the immobilization of chemosensors in solid phase, for our knowledge, little information is available. The main problem for the immobilization of Hg^{2+}-probes is due to the hydrophilic character of these dyes. There are not many polymers which can be used and which can be chemically compatible with these dyes. One promising Hg^{2+}-chemosensor (FC1) was developed by Bohoyo et al.[2]. It is based on a spirocyclic Rhodamine 6G phenylthiosemicarbazide derivative. The reagent shows a highly selective and sensitive colorimetric and fluorimetric reaction with Hg^{2+}. The obvious color change of the solution from colorless to pink upon the addition of Hg^{2+} demonstrates that FC1 can be used for ''naked-eye'' detection of Hg^{2+} in water effluents. The fluorescence intensity is proportional to the amount of Hg^{2+} at $ng{\cdot}mL^{-1}$ levels. In this work, we have synthesized a water-insoluble copolymer by Reverse Atom Transfer Radical Polymerization (ATRP) to immobilize the mercury chemosensor FC1, in order to develop an optical Hg^{2+}-sensing film.

Materials and Methods: An HEMA-co-MMA copolymer was synthesized by Reverse ATRP technique. It was obtained by dissolving MMA (168 mmol) and HEMA (66 mmol) in 15 ml DMSO and adding $CuBr_2$/PMDETA catalyst system. The mixture was stirring at room temperature and then 12 ml m-xylene and AIBN (0.27 mmol) were incorporated. The mixture was purged with highly pure nitrogen stream and then it was heated with continuous stirring. The polymerization was carried out at 80 ºC for 3 h. After that, the copolymer was recovered and purify by precipitation in distilled water at pH 6.6.

The cocktail used for developing the Hg^{2+}-sensing film was done by dissolving 60 mg of HEMA-co-MMA with 1.5 mg of FC1 and 1.5 mg of potassium tetrakis(4-chlorophenyl)borate salt (KTCPB), which was used to maintain the electroneutrality of the polymeric film. The membrane support was Polyethylene terephthalate (PET). The spin-coating technique was applied to obtain the membranes.

Results and Discussion: There are a variety of chemosensors based on Rhodamine 6G which are hydrophilic, but there is no information in the literature of this kind of chemosensors in solid phase.

Initially none of the polymers studied (PVC, Nafion, etc…) were successful for the FC1 immobilization due to the chemosensor is hydrophilic, and its luminescent characteristics are affected with the pH; emitting fluorescence below pH 4. Therefore we proposed the design of a new neutral copolymer which does not modify the properties of the chemosensor after its immobilization. This copolymer should have hydrophilic groups, it has to provide a neutral or basic media, and its optical properties do not overlap which the FC1 ones. Thus, we designed a copolymer based on the copolymerization of MMA and HEMA: HEMA was used to increase the hydrophilic character of the copolymer; none MMA nor HEMA provide acid media; and the optical properties of these co-monomers are different than those of FC1.

In order to demonstrate the applicability of this copolymer for the immobilization of FC1, we developed a sensing film by dissolving the copolymer and the Hg^{2+}-probe in a volatile solvent, in order to generate a polymer liquid membrane. In addition, KTCPB was added in order to maintain the electroneutrality of the film and glycerol was used as plasticizer to decrease the response time. This polymeric membrane was tested by immersing in an Hg^{2+} aqueous solution for 50 min and measuring and comparing its fluorescence and absorbance with other membrane which was immersed just in clean water (control). Satisfactory results were obtained; the proposed copolymer can be used for immobilizing FC1 without missing their properties against Hg^{2+}.

Conclusions: We have achieved the immobilization of the mercury chemosensor FC1 into a polymeric membrane. This copolymer has been synthesized by Reverse ATRP, and it is constituted by HEMA (28%) and MMA (72%). Currently we are optimizing the milieus conditions to improve the signal intensity. This work is a preliminary step for the development of a new optical Hg^{2+}-sensing film.

This copolymer opens a wide range of possibilities for the immobilization of these chemosensors and their application in optical sensors.

Fluoroparaffins are attractive as materials capable of enhancing tribological properties of objects they are applied to. Fluoroparaffins are superior to hydrocarbon lubricants in some aspects: they are generally more hydrophobic, more liophobic, and have smaller friction coefficient. The method used in this study for preparation of fluoroparaffins is based on fluorination of gaseous paraffin hydrocarbons of a specific molecular weight (ranging from C_{12} to C_{36}). A sequence of technological processes was used for extraction of perfluorinated paraffins which were later studied using a number of physical methods in order to reveal their morphological, topological, and molecular structure. The parameters of the fluorination process were identical for samples with different molecular weights of the initial paraffin hydrocarbons.

All the samples prepared are wax-like materials with no marked morphological structure, but SEM micrographs reveal the presence of layered formations in them. XRD studies of the pristine paraffins and perfluorinated samples confirm the presence of those structures, which is indicated by reflections at small angles. According to the experimental data, the perfluorinated paraffins also contain topologically unordered formations, which is indicated by two halos in XRD patterns at 2θ = 30-50° and 72°. Such halos are specific for low molecular weight fractions of polytetrafluoroethylene. Peaks attributable to crystalline components (the most prominent of them is at 2θ = 18°) which are specific for high molecular weight fractions of polytetrafluoroethylene are observed in patterns of high molecular weight paraffins.

A prominent dependence of thermal properties (weight loss onset temperature and melting temperature) of the perfluoroparaffins as function of their molecular weight was observed. Thermogravimetric curves of low molecular weight paraffins revealed smaller dispersion of molecular weights in them.

Infrared spectra of the fluoroparaffins studied generally resemble the IR spectrum of polytetrafluoroethylene but have some distinctive features. Specifically, the main bands (1228, 1154 cm^{-1}) are narrower than those in the spectrum of polytetrafluoroethylene, which unmasks some other bands. The fluoroparaffins' spectra do not contain bands attributable to amorphous formations. Besides the bands attributable to CF_2 groups of the molecular helix, the spectra also contain components at 1371 and 986 cm^{-1} which correspond to the terminal and lateral trifluoromethyl groups (CF_3), respectively, as follows from quantum chemical calculations for fluorocarbon conformer models. There are also bands which can be ascribed to hydrocarbon groups.

The samples were studied using high resolution magic angle solid state nuclear magnetic resonance (MAS NMR) on ^{1}H, ^{13}C, and ^{19}F nuclei. Attribution of peaks in the experimentally acquired NMR spectra was performed via comparison of the experimental data with the values of chemical shifts calculated using quantum chemistry. The studies revealed that the fluorination process does not result in complete substitution of hydrogen atoms by fluorine, and the spectra of all the samples contained peaks attributed to protons. The observed resonance lines indicate the presence of CH_2-, CFH-, CH_2F-, and CHF_2 groups. The ratios of functional groups in the samples prepared from paraffin hydrocarbons of different molecular weights were determined based on the intensities of the respective NMR peaks. These data are confirmed by ^{13}C spectra. ^{19}F NMR spectra reveal the presence of CF_3 groups in the samples; concentration of these groups depends on molecular weight of oligomers which comprise the fluoroparaffins.

The solubility of fluoroparaffins in supercritical carbon dioxide has been measured at temperatures of 318 - 383 K in the pressure range of 10 - 80 MPa and it was not lower than 50 g/L.

Bioactive Textile Materials Covered with Polymers as Continuous Layers, Microparticles or Microcapsules

Georgeta Mocanu[1], *Marieta Nichifor*[1], *Doina Mihai*[1] *and Loti Cornelia Oproiu*[2]

[1]"Petru Poni" Institute of Macromolecular Chemistry, Iasi, Romania e-mail
[2]National Research&Development Institute for Chemistry & Petrochemistry, Bucharest, Romania

gmocanu@icmpp.ro; nichifor@icmpp.ro

Introduction

The increasing demand for textile with improved properties led to new fabrics called "multifunctional" "active" or "smart" with large application in technical, domestic or medical fields. The purpose is realized mainly by covering a textile material with a functional layers able to include, retain or reject different chemical compounds.[1] Materials or clothes containing antibacterial agent or other compound providing care and comfort are already on markets.

The aim of the present work is the coverage of textile materials with multifunctional polymer layers able to provide simultaneous protection and treatment to sensitive and allergic skins. For this goal the cotton fabric was covered with cationic polymers, which have by themselves antibacterial properties, or with polymer microparticles containing plant extract with antibacterial, antioxidant and antiallergenic activity.

Materials and Methods

Chitosan (CH) of medium MW, poly(vinyl alcohol) (PVA) of MW 100000 and 98% hydrolysis, glutaraldehyde (GA) (25% in water), 1,1-diphenyl-2-picrylhydrazyl (DPPH), acid orange (AO) and tripolyphosphat (TPA) were from Aldrich. A cotton fabric (200 g/m^2) was purified by treating it with an aqueous solution of sodium carbonate, followed by distilled water and ethanol. An extract of Viola Tricolor (VT) (3.5 % solution in water/ethanol mixture) was used as a biologically active compound. Dextran carrying pendant N.N(dimethyl)-N-benzyl-N-(2-hydroxypropyl) ammonium chloride groups (Dex-Q) was prepared as previously described.[2]

Binding of cationic polysaccharides (CH and Dex-Q) to the cotton surface was performed in aqueous medium, using GA as a crosslinker. The amount of polymer bound was determined with AO method (for CH), and by chloride ion titration (Dex-Q). The coated fabrics were immersed in VT solutions, and then dried to constant weight. Microparticles of CH crosslinked with TPA were prepared in aqueous solutions of pH 6. .PVA microcapsule containing VT were obtained by water-in-oil emulsion, followed by PVA crosslinking with GA. Cotton fabric was covered with a layer of microparticles, in the presence of a binder. Polymer and coated fabrics were characterized by FT-IR, UV, and SEM. The amount of VT released from microparticles or coated fabrics was quantified by UV analysis (330 nm) or reverse phase HPLC. Antioxidant activity of bound VT was determined by DPPH method, and antibacterial activity by specific tests on cell cultures.

Results and Discussion

Antibacterial properties of CH are well known, and those of Dex-Q have been previously demonstrated.[2] Cotton fabric were coated with various amounts of cationic polysaccharides (5-20 g %) (Fig. 1), but the original textile touch could be preserved only when the polysaccharide content was lower than 8 g%. Preliminary antibacterial tests showed promising activity of the treated cotton against some bacterial strains. Cotton coated with crosslinked CH and impregnated with VT presented also antioxidant activity, which was proportional to VT content. Microparticles of CH containing VT (10 g%) were fixed on the cotton fabric with a binder. The release rate of VT from these fabrics (Fig. 2) was lowest in the case of microparticles (curve 4) and increase with increasing crosslinking degree (curves 1-3). Microcapsules of PVA had a spherical shape and a size of 20-60 μm (Fig. 3a) and contained about 12 g % VT. The release of VT from these particles was slow, and they preserve the shape after the complete release (Fig. 3 b) suggesting the diffusion as the main release mechanism, with low contribution of erosion.

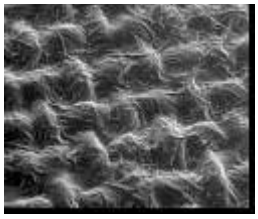

Fig. 1. SEM image of a cotton sample covered with CH layer

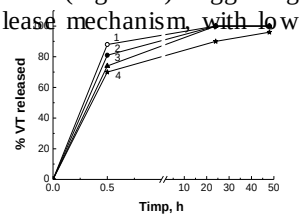

Fig. 2. Release profile of VT from cotton covered with CH formulations

a **b**

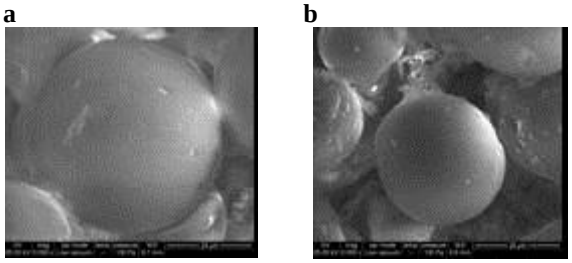

Fig. 3. SEM images of PVA microcapsule containing VT extract, before (a0 and after (b) complete release of the active compound.

Conclusion

Cotton fabrics were covered with different polymeric formulation (continuous layer, microparticles or microcapsules) with or without a bioactive compound (extract of Viola Tricolor). The results showed that these new functionalized textile have antibacterial and antioxidant activity and might be used as new biomaterials for medical or domestic applications.

Rheology Applied to the Study of Processing Behaviour of PVC-PBA Block Copolymers Obtained by LRP

Introduction

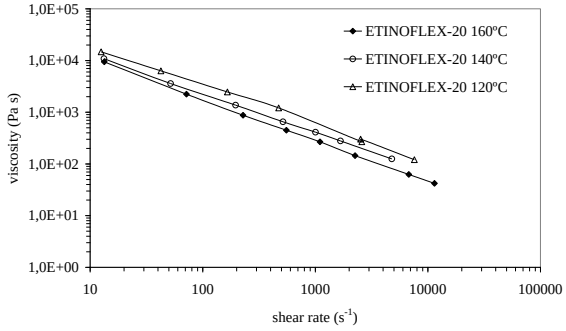
Living radical polymerization (LRP) represents nowadays a reliable alternative to usual synthesis routes based on free radical polymerization, because its capacity to effectively control the molecular architecture of the polymer. A punctual, but very interesting success of this technology concerns to the synthesis of block copolymers of Poly-vinyl chloride-b-poly-butyl acrylate (PVC-b-PBA)[1,2]. Since PBA has a low glass transition temperature (-41ºC)[2], these copolymers open new ways in the effort to develop flexible PVCs processed without any plasticisers, such as di ethyl-hexyl phthalate (DEHP), more known as DOP[3].

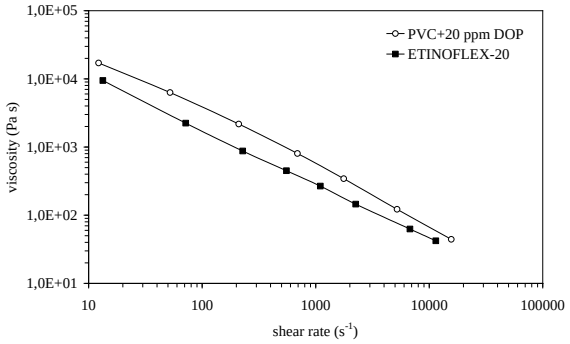
Materials and Methods

In this contribution, basic and applied rheological properties of PVC-b-PBA block copolymers obtained by LRP are investigated, within the framework of the correlation *Structure-Rheology-Processing*. All the samples show a molecular weight close to Mw= 100000 g/mole with a polydispersity index around 2.5, being the main difference the PVC/PBA ratio of each sample. Dynamic viscoelastic measurements in the linear regime have been carried out in a AR G2 (TA Instruments) rheometer. An extrusion capillary rheometer, Gotffert 2002, has been employed to determine the viscosity as a function of shear rate and temperature.

Results and Discussion

The effect of the microstructure of the copolymer on the linear dynamic viscoelastic results (in the terminal zone) is linked to the morphology developed as a consequence of the micro(nano) phase separation. The transition from an ordered state (or self-assembled phases) to a disordered or homogeneous melt is investigated using viscoelastic methods. The non-linear rheological results, obtained in an extrusion capillary rheometer in conditions similar to industrial processing, are discussed considering the eventual order or disorder state of the melt. The viscosity data extending over a wide range of temperatures, shear rates and pressures give significant information on the processing feasibility of the different samples. As an example, the viscosity curves of Etinoflex-20 (PVC-PBA block copolymer with 20% BA) determined at three different temperatures are depicted in Fig.1. A comparison with plasticised PVC is also shown.





With the aim of linking basic and applied rheology, the extrusion results are interpreted considering the evolution of the copolymers morphology during flow.

The effects of reprocessing cycles on the structure and properties of isotactic polypropylene (PP)/Cloisite 15A (OMMT) (5 wt. %) nanocomposites was studied in presence of maleic anhydride grafted polypropylene (PP-*g*-MA) (20 wt. %) used as the compatibilizer to improve the clay dispersion in the polymer matrix. The various nanocomposite samples were prepared by direct melt intercalation in an internal mixer, and further they were subjected to 4 reprocessing cycles. For comparative purposes, the neat PP was also processed under the same conditions. The nanocomposite structure and the clay dispersion have been characterized by wide angle X ray scattering (WAXS), transmission electron microscopy (TEM) and rheological measurements. Other characterization techniques such as Fourier transform infrared spectroscopy (FT-IR), tensile measurements, differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) have also been used to evaluate the property changes induced by reprocessing. The study showed through XRD patterns that the repetitive reprocessing cycles modified the initial morphology of PP/OMMT nanocomposites by improving the formation of intercalated structure, especially after the fourth cycle. Further, the addition of PP-*g*-MA promoted the development of intercalated/exfoliated silicate layers in the PP matrix after the second cycle. These results are in agreement with TEM observations indicating an improved silicate dispersion in the polymer matrix with reprocessing cycles displaying a morphology with both intercalated/exfoliated structures. The initial storage modulus (G') of the nanocomposites, which was highly improved in presence of PP-*g*-MA seems to be less affected by reprocessing cycles at very low frequencies exhibiting a quasi-plateau compared to pristine PP/OMMT and PP. In contrast, the complex viscosity was found to decrease for the whole samples indicating that the main effect of reprocessing was a decrease in the molecular weight. Moreover, the thermal and mechanical properties of the nanocomposites were significantly reduced after the first cycle; nevertheless they remained almost unchanged during recycling. No change in the chemical structure was observed in the FTIR spectra for both the nanocomposites and neat PP samples after 4 cycles.

These results demonstrate that the recyclability of PP-OMMT/PP-*g*-MA nanocomposites is more complex because the resulting structure affects strongly the performance of the nanocomposites. Many factors should be considered mainly: the interaction filler-matrix, the type and loading rate of organoclay, the amount of PP-*g*-MA compatibilizer and the processing conditions.

Obtaining Porous Polyimides with controlled Pore Size

Elizabeth Rangel-Rangel, Eva M. Maya, Javier de Abajo, Angel E. Lozano, José G. de la Campa

Departamento de Química Macromolecular, Instituto de Ciencia y Tecnología de Polímeros (CSIC)

erangel@ictp.csic.es

Introduction and objectives

Lately, increasing research has been focused on obtaining new organic covalent microporous materials, resembling zeolites, zeotypes, activated carbons, and metal organic frameworks (MOF), for diverse applications such as supporting metal catalysts. While the covalent bonds in such networks provide high thermal and chemical stability, especially compared to MOFs, the organic structure allows tailor-made incorporation of multiple chemical functionalities into the networks, which is not possible for zeolites or activated carbons. Also, some physical properties, such as ductility and light weight, add value to such materials.[1] Porous shape and porous size of the material are very important requirements to achieve a large volume fraction accessible to anchor the functionality and consequently the metallic catalyst.

This work describes the synthesis and characterization of new porous polyimides (**PPIs**) with controlled porosity by using a rigid aromatic triamine and dianhydrides with different length.

Results and Discussion:

The synthesis of the 3,5-diamino-N-(4-aminophenyl) benzamide (**DAPBA**), was carried out in two steps with good yield (Figure 1); a) acylation of 4-nitroaniline with 3,5 dinitrobenzoyl chloride and b) reduction of nitro groups with hydrazine hydrate using Pd/C as catalyst.[2]

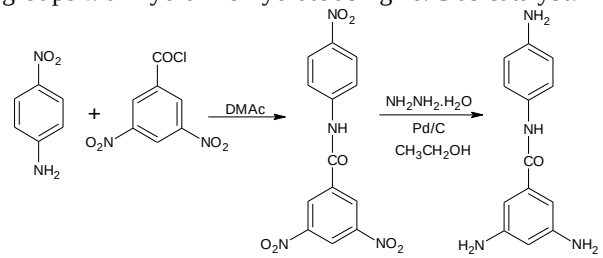

Figure 1. Synthetic route for obtaining **DAPBA**

The structure of **DAPBA** was confirmed by ^{1}H-NMR and FTIR.

The novel **PPIs** (Figure 2) were synthesized by reacting **DAPBA** with commercial dianhydrides (**PMDA, BPDA** and **BKDA**) and also with the dianhydride **IPPDA**, which has been previously described by our group.[3] The one-step polycondensation reaction was carried out in *m*-cresol at 180ºC for 6 hours following the procedure described elsewhere.[4]

ATR FTIR spectra of all porous polymers showed the characteristic bands of polyimides a 1773, 1713, 1348 and 731 cm^{-1} and the –NH- stretching band of the amide linkages at 3500 cm^{-1}. **PPIs** showed high thermal stability by thermogravimetrical analysis, with decomposition temperatures above 550ºC and one stage degradation pattern. DSC curves did not show any thermal transition below 400ºC. In Figure 3, an idealized structure of **DAPBA** with **PMDA** (dianhydride **1)** is depicted to show how pore is formed.

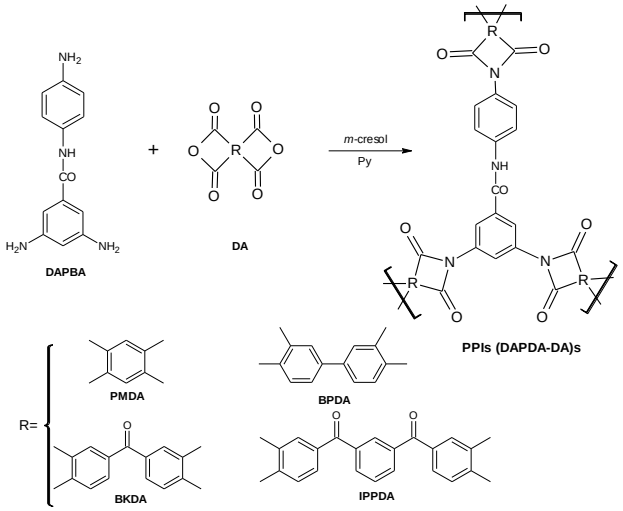

Figure 2. PPIs obtained in this work.

Pore size and pore distribution of the new materials by N_2 gas adsorption/desorption (BET) technique are in progress. Besides, CO_2 and CH_4 sorption experiments are being carried out.

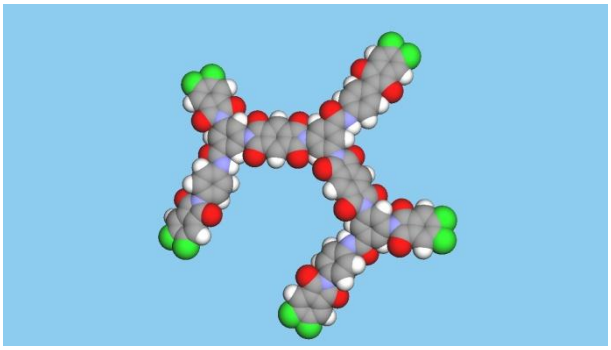

Figure 3. Molecular modeling of the reaction of **DAPBA** and **PMDA** anhydride. Green atoms mean points from where polymer network is growing.

Other **PPIs** with functional groups such as amino ones are being obtained to anchor metallic catalysts.

rcorvino@unisa.it

Introduction: Thermosetting polymers are susceptible to damage induced by mechanical, chemical, thermal, UV radiation, or a combination of these factors. This could lead to the formation of microcracks within the structure where detection and external intervention are difficult or impossible. The microcracks can lead to substantial delamination and fiber-matrix debonding. To overcome the drawbacks related to the composite materials we have developed self-healing materials that allow us to obtain a material with the ability to autonomically heal cracks without any manual intervention or application of a specific stimulus (e.g. heat, radiation etc.). The design of our composite was already proposed in literature [1]. It includes monomer-filled microcapsules and a solid catalyst embedded in a thermosetting polymeric matrix. In this system, the crack ruptures the microcapsules, releasing the healing agent into the crack plane through capillary action; the healing agent contacts the catalyst, triggering polymerization that bonds the crack faces closed. The metathesis product (in the crack) obtained by Ring-opening Metathesis Polymerization (ROMP) shows high cross-linked fraction. The results on the cure behavior of this material and the influence of the components related to self-healing function on the dynamic-mechanical properties were investigated in a previous paper [2]

Materials and Methods: The catalyst used in the matrix was Hoveyda-Grubbs'catalyst (HG1). The epoxy matrix used was a blend of diglycidyl ether of bisphenol A (trade name EPON 828 – Acronym DGEBA) and a high molecular- weight epoxy flexibilizer, Dimer Acid Diglycidyl Ester (trade name HELOXY 71 – Acronym DADGE) which was used in small percentages to improve the toughness of the material and consequently crack growth stability. Microcapsules containing 5-ethylidene-2-norbornene (ENB) were prepared by *in situ* polymerization in an oil-in-water emulsion.
Scanning electron microscopy (SEM) pictures were obtained with a LEO 1525 microscope. The samples were covered with a 250-Å-thick gold film using a sputter coater (Agar mod. 108 A). The fracture toughness and healing efficiency of the formulated composites were measured using a tapered double–cantilever beam (TDCB) test [3]. The experiments were conducted with an Instron 4301 tensile and compression tester 1kN load cell.

Results and Discussion:
Figure 1 shows the sample geometry (TDCB) used to obtain quantitative results on the self-healing functionality. The figure also reports the image of a healed sample after a controlled damage.

Fig 1. Samples for getting quantitative results on the self-healing functionality (a-b); healed crack faces closed by means of the metathesis product inside a crack after a (TDCB) test (c).

Crack healing efficiency, η, is defined as the ability to recover fracture toughness and for the TDCB [4] geometry, is simply calculated as the ratio of critical fracture loads for the healed and virgin samples.

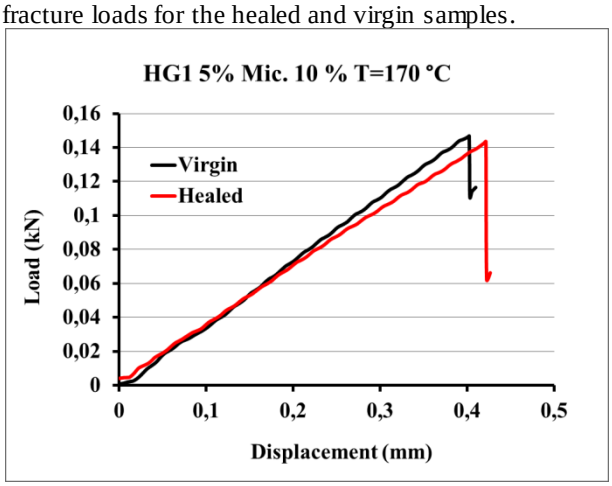

Fig 2. Load-Displacement curves for Virgin (black curve) and Healed (red curve) samples.

Figure 2 shows the Load-Displacement curves for a sample with 5% of Hoveyda-Grubbs I Catalyst and 10% of microcapsules ENB filled, cured up to 170 °C. The obtained efficiency is 97.75% .

Conclusions: We have formulated, prepared and characterized a multifunctional autonomically healing composite with a self-healing efficiency higher than 90%. The industrial scale production of this material is finalized to producing a new advanced structural composite with competitive advantage in the ratio cost/weight, product/process and performance/safety.

Relationships between structures and physical properties of PVDF/MWNT composite

Soon Man Hong, *Jong Min Koo*

Polymer Hybrids Research Center, Korea Institute of Science and Technology
39-1 Hawolgok Seongbuk, Seoul 136-791, Korea

smhong@kist.re.kr

In recent years, carbon nanotubes (CNTs)-reinforced polymer composites are attracting much attention due to their excellent electrical conductivity. The incorporation of CNTs with very high aspect ratio into the polymer matrix is expected to produce unique physical properties in comparison with those of composites with three-dimensional structured nanoparticle. Poly(vinylidene fluoride) (PVDF) has been extensively studied because of its potential applications as piezoelectric and pyroelectric materials.

WAXD was used to observe the effect of MWNT content on the microstructure of thin PVDF composite films. Figure 1 describes the WAXD patterns for these composite films. Within a given range of scattering angles, three characteristic diffraction peaks appear at 2θ = 17.7, 18.4, and 19.9°, which correspond to (100), (020), and (110) reflections, respectively. This is assigned to the α–phase crystal which has a non-polar trans-gauche-trans-gauche (TGTG) conformation. PVDF composites exhibit decreased peaks for α–phase crystal from 0.5 wt% content. In addition to the features associated with α–phase crystal, the introduction of MWNT produces a shoulder at a 2θ value of 20.7° and it is clearer with increasing the MWNT content. This is attributed to the formation of β–phase crystal, the most polar among other crystals. This exhibits piezoelectric and pyroelectric properties of PVDF matrix.[1] We investigated the effect of MWNT content on the permittivity, electrical conductivity and thermal conductivity of PVDF. As shown in Figure 2, The permittivity of the PVDF composite was proportionally dependent on the content of MWNTs. Permittivity is improved with increasing the content of MWNT. However, permittivity is decreased with increasing the frequency in the range from 10^{-1} to 10^{4} KHz. Ionic conduction phenomena are slightly observed above 5wt% of MWNT. These results implied obviously that the PVDF filled with MWNTs could be prospective EMI shield material since we can enhance the permittivity and conductivity by controlling the content of MWNT. Figure 3 shows the variation of the electrical conductivity of PVDF composites with the MWNT content (conductivity of MWNT : 75 S/cm, conductivity of PVDF : 10^{-14} S/cm). The electrical conductivity was increased from 10^{-14} to 10^{0} S/cm with increasing the content of MWNT from 0 to 5wt%. However, when the content of MWNTs went over 5wt%, the electrical conductivity was almost independent of the MWNTs content. This indicates that there is conductivity saturation from a critical content because of formation of an infinite cluster.[2] Similar tendency was also observed in thermal conductivity above 3wt% of MWNT, as shown in Figure 4. In addition, the ferroelectric properties of PVDF composites will be discussed in this paper.

Introduction

In recent years, there has been a growing interest in preparing polymer composites containing renewable organic reinforcements, such as lignocellulosic or protein fibers. Natural fibers provide several advantages since they are renewable and biodegradable, lighter than glass fibers while presenting reasonable strength and elastic modulus.[1-2]

Among these, keratin fibers, which are the major component of hair, wool and feathers, are abundantly present in wastes from textile industry, stock-farming and butchery. However, their compatibility with hydrophobic polymers like polyolefins is low. In fact, wool fibers have a hydrophilic character due to the presence of about 70 % of hydrophilic amino acids in the amino acidic sequence of keratin.[3] The treatment of the fiber surface with coupling agents, such as alkoxysilanes, or the use of maleated polyolefins as compatibilizers can improve the interface between fibers and matrix. Otherwise, better compatibility can be obtained with biodegradable polymer matrices with high hydrophilic character.

In this work, composite materials based on wool fibers, raw or chemically modified, and thermoplastic matrices, either polyolefins or biodegradable polyesters, were prepared and thoroughly characterized in terms of morphology, thermal properties and mechanical performances.

Materials and Methods

Composites based on polypropylene (PP) or biodegradable polyesters containing different amounts (up to 60 wt%) of wool fibers were prepared. In order to enhance the compatibility between fibers and matrix, maleated polypropylene (PP-*g*-MA) or wool fibers modified with 3-(trimethoxysilyl)propyl methacrylate were used. Composite materials were obtained mixing thermoplastic matrices with wool fibers using an internal batch mixer. In order to limit wool degradation, that occurs at around 200 °C, the mixing conditions, such as temperature, rotor speed and mixing time, were optimized.

Fiber surface modification was performed by hydrolyzing the silane in methanol - water (90/10 v/v) at 25 °C and adjusting the pH at 3.5 with acetic acid. The fibers were bathed in this solution, dried first at 60 °C for 24 h and then kept up at 120 °C for 2 h to complete the reaction. In order to remove unreacted silane, the treated fibers were finally extracted with acetone for 2 h.

Results and Conclusions

The FTIR spectrum of treated wool fibers indicates the presence of the C=O band at 1720 cm^{-1} relative to the chemically linked silane moieties. Chemical anchoring of the alkoxysilane on the fiber surface was confirmed and the amount of the grafted silane calculated by using thermogravimetric analysis.

Composite materials with up to 60 wt% of wool fibers were prepared. A thorough characterization of the samples was conducted by SEM, tensile tests, dynamic-mechanical, thermogravimetric and calorimetric analyses in order to understand the effects of fiber loading and compatibilizing agents on the final properties of the composite materials.

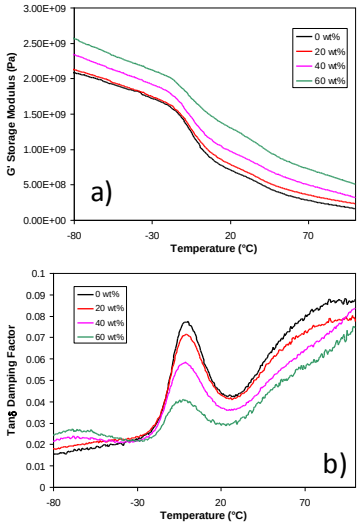

Fig. 1. Temperature dependence of G' (a) and tanδ (b) for compatibilized PP/wool fibers composites.

The adhesion between wool fibers and polymer, investigated by SEM, depends on the matrix, the presence of compatibilizer and the surface modification of the fibers. In general, the modulus of the composites (Fig. 1) increases with fiber loading, while the tensile strength of the composites decreases with increasing the fiber content. In particular, for the PP-based composites, the tensile strength was less reduced using maleated PP.

Research supported by CARIPLO Bank Foundation Project KEBAB 2009-2011

Interfacial interactions in Flax fibre/PLA biocomposite: from model surfaces to real fibres

Eric Balnois, Gijo Raj, Christophe Baley, Yves Grohens

The overall mechanical properties of natural fibre reinforced biocomposites are largely governed by the intrinsic strength of reinforcement fibres as well as by the level of adhesion between the fibres and the matrix polymer. In order to gain a better understanding on the nature of the complex interactions between the fibre and the PLA matrix, Colloidal force microscopy (CFM) was adapted to this specific system to probe direct interaction forces between model surfaces and the PLA matrix. We develop the CFM set up to build a *layer model* that systematically allows to probe interactions between the main polysaccharides within the flax fibre, cellulose, hemicellulose and pectin and the PLA matrix to identity the weakest interaction system in a biocomposite. The results highlight important interactions of PLA with the hydrophilic pectin, even at low humidity rate, thus underlying the presence of several adhesion mechanisms, such as the presence of hydrogen bonds, capillary forces or interdiffusion processes. In parallel, adhesion force mapping of the flax fibre's surface by AFM force-volume technique revealed complementary results and highlight an important adhesion of the AFM probe with pectin materials on raw flax fibre.

Valorisation of Maghnite-H$^+$ as a catalyst for the synthesis of various biodegradable polyesters and polyacetals

Souad Bennabi[1,2], Nabahat Sahli[1], Mohamed Belbachir[1], Claire-Hélène Brachais[2], Jean-Pierre Couvercelle[2]

e-mail: souad_bennabi02@yahoo.fr

In our laboratory, we were interested in the synthesis of biodegradable polymers by cationic way, by using an ecological catalyst : Maghnite-H$^+$. Maghnite-H$^+$ is a nontoxic catalyst issued from the proton exchange of Algerian Montmorillonite clay. Our results show that Maghnite-H$^+$ is active for the synthesis of polyesters upon heating and polyacetals at room temperature.

Introduction :

Biodegradable polymers have attracted rising attention because of their numerous applications in the medical materials (sutures, pins, surgical implants) or for pharmaceutical uses (matrix with controlled release of active ingredient). Many other uses are planned in order to replace polymers with high industrial tonnages (polyethylene, polyvinyl chloride) and limit their significant harmful effects on ecology. Maghnite-H$^+$ is a new catalyst based on Montmorillonite which was developed at the Chemistry Laboratory of the Polymers (LCP) and showed remarkable catalytic capacities in the reactions of polymerization of several vinyl and heterocyclic monomers[1-4]. The aim of this work is first, to study the structure of the H$^+$ activated Maghnite and then to compare the activity of this natural initiator towards various monomers yielding to biodegradable polymers.

Materials and Methods :

Maghnite, Algerian Montmorillonite clay, is provided by BENTAL (Algerian Society of Bentonite). The preparation of the Magnite-H$^+$ was carried out by using a method similar to that described by Belbachir and coworkers[1]. Indeed, the raw-Maghnite (20 g) was crushed for 20 min using a Prolabo ceramic balls grinder. It was then dried by baking at 105°C for 2 h. The Maghnite was then weighed and placed in an erlenmeyer flask together with 500 mL of distilled water. The Maghnite/water mixture was stirred using a magnetic stirrer and combined with 0.25M sulfuric acid, until saturation was achieved over 2 days at room temperature. The mineral was washed with water until it became sulfate free, and then dried at 150°C. Monomers were purchased from Aldrich, except ethyl glyoxylate (aldehyde monomer) kindly supplied by Clariant.

Results and discussion :

Maghnite-H$^+$ was characterized by XRD and IR. The results showed that the acid treatment of Maghnite involves the substitution of the intercalated cations by H$^+$. This phenomenon results in the increase in interlayer distance of 12 A° corresponding to a single layer water intercalated in Maghnite untreated, towards 15 A°, distance attributed to two layers water intercalated in Maghnite-H$^+$ [5].The Elemental Analysis (EA) of Maghnite-H$^+$ also shows decreased levels of impurities such as calcite, iron oxide, but enrichment in silica.

The following table summarizes the polymerization ability of Maghnite-H$^+$ clay towards e-caprolactone[a] [6], 1,3-dioxolane[c][2] ,D,L-Lactid[b] and ethyl glyoxylate[d]:

monomer	Conversion of monomer	Mn (g/mol)	Mw/Mn
e-Caprolactone	97.86%	3600	2,12
1,3-Dioxolane	85.8%	5 922	2.16
D,L-Lactide	94%	1890	1.70
Ethylglyoxylate	76%	17 016	1,17

[a]Maghnite-H$^+$/e-Caprolactone, weight ratio = 10%. (Reaction temperature 80°C and time 18h)
[b]Maghnite-H$^+$/D,L-Lactid, weight ratio = 5%. (Reaction temperature 120°C and time 20h)
[c]Maghnite-H$^+$/1,3-Dioxolane, weight ratio = 5%. (Reaction temperature 25°C)
[d]Maghnite-H$^+$/Ethyl glyoxylate, weight ratio = 5%. (Reaction temperature 25°C and time 18h)

Conclusion :

Maghnite-H$^+$ is able to convert in high yields various monomers leading to biodegradable materials. Molar masses arise between 3600g/mol and 17000g/mol. Moreover, this initiator seems to be very active even at room temperature for the synthesis of polyacetals. From these results it is clear that proton exchanged Montmorillonite clay, is an effective initiator for cationic polymerizations of cyclic esters, ether and aldehyde monomers .

Thermal Decomposition of PVC Plastisol Foams. Influence of the concentration of plasticizer

A. Marcilla, A. Zoller and M.I. Beltrán

Chemical Engineering Department. University of Alicante (Spain)
PO Box 99 Alicante

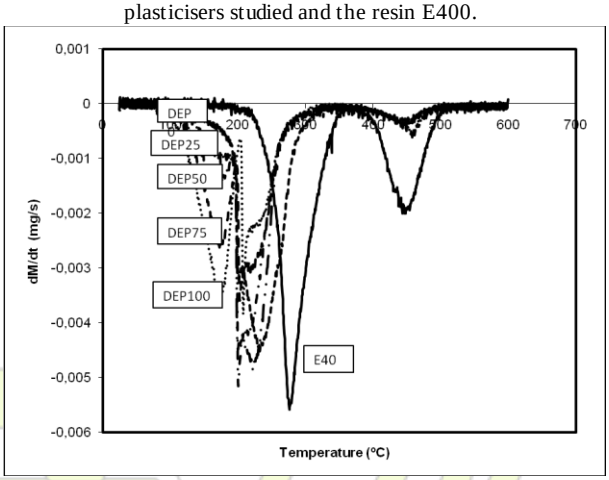
antonio.marcilla@ua.es

Thermal decomposition of flexible PVC foams prepared with mixtures of two commercial plasticizers has been studied. Five PVC plastisols were prepared by mixing 100 phr (parts per hundred resin) of the ETINOX 400 from AISCONDEL (a poly vinyl chloride-vinyl acetate copolymer), 100 phr of a mixture of DEP (diethyl phthalate) and DIDP (di-isodecyl phthalate) of DEP concentration of 0, 25, 50 75 and 100%, respectively. Each formulation also included 2 phr of Reagens CL4 commercial Zn/Ca-stearate stabilizer, 6 phr of Lankroflex 2307 epoxidized soybean oil as co-stabilizer, and 2 phr of zinc oxide. After mixing, the pastes were subjected to a degassing process for 15 min with a maximum vacuum of 1 mbar for air removal. These plastisols were cured in an open mould at 180ºC during 10 min.

Approximately 6 mg of each sample, were subjected to TGA in a nitrogen atmosphere at heating rates of 5 K/min from room temperature to 873 K in a Termobalance METTLER TOLEDO, model TGA/SDTA 851e/SF/1100. A high purity nitrogen gas was fed at constant flow rate of 50 mL/min as an inert purge gas, thus avoiding unwanted oxidation of the sample. The continuous on-line records of weight loss and temperature were obtained to plot the thermogravimetric (TGA) curve and the derivative thermogravimetric analysis (DTG) curves.

Figure 1 shows the DTG curves obtained for the five plastisols studied. The DTG of the resin E400 has been included in both figures for comparison.

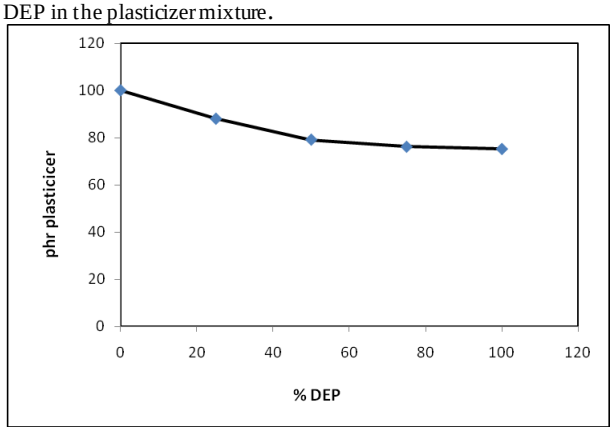
Figure 1. DTG of the plastisols prepared with the five mixtures of plasticisers studied and the resin E400.



The thermograms obtained show the presence of four weight loss steps. The first one corresponds to the evolution of the DEP, the second one correspond to a sharp peak that may be ascribed to the decomposition of the stabilizer and co-stabilizer used, the third peak corresponds to the overlapping of the evolution of the DIDP plasticizer and the first decomposition step of the resin, including the dehydrochorination[1,2,3,4] and the loss of acetic acid from the vinyl acetate dominies of the resin. The third one corresponds to the final carbonization of the residue formed in the first step of the resin decomposition.

The area of the first peak is, as expected correlated with the concentration of DEP but its quantification reveals that this plasticisers has been partly volatilized during the curing of the paste, consequently the foams obtained have plasticizer concentration lower than the 100 phr programmed. Figure 2 shows the phr of plasticizer remaining in the foam obtained considering that the plastisol with 100% has lost no plasticizer.

Figure 2. Plasticizer remaining as a function of the concentration of DEP in the plasticizer mixture.



The peak corresponding to the first decomposition step of the resin shifts to lower temperatures as the amount of DEP in the plasticizeer increases, showing a type of destabilizing effect of the more compatible palsticizer.

[2]Polymer Engineering Department, Yalova University Yalova 77100, Turkey

aabay@yalova.edu.tr

Plastics became indispensable items within our daily lives as well as other technological advances. On the other hand, these tecnological advances pose threats in an increasing manner even if they serve us via vast number of applications. One of these threats comes from chemical wastes that are disposed to environment in an uncontrolled fashion. Environmental pollution has become a major concern for all developed nations as a consequence of continious advancement in technology which is closely related with the increasing demand in industrial production. Plastic wastes are the most persistent chemical wastes in nature. Due to the extremely slow decomposition rates, plastic wastes generate a significant environmental problem. Thus, in Turkey as well as advanced societies, plastic wastes play an important role within total environmental pollution. Lack of environmental concerns such as sustainability combined with the misusage and uncontrolled use of technology increases the rate of pollution day by day. Plastic and other waste problem peaked in recent years and public awareness has formed due to the tremendous efforts of governmental, academic and media institutions. Thus recycling of plastic wastes has an extreme importance in preventing the chemical wastes as well as economical benefits. This report will primarily emphasize on the nationwide impacts of plastic wastes and discuss the alternative ways to achieve recycling and improving the public awareness

Keywords: plastics, waste recycling, public awareness

Thermal Decomposition of PVC Plastisol Foams. Influence of the type of plasticizer

Approximately 6 mg of each sample, were subjected to TGA in a nitrogen atmosphere at heating rates of 5 K/min from room temperature to 873 K in a Termobalance METTLER TOLEDO, model TGA/SDTA 851e/SF/1100. A high purity nitrogen gas was fed at constant flow rate of 50 mL/min as an inert purge gas, thus avoiding unwanted oxidation of the sample. The continuous on-line records of weight loss and temperature were obtained to plot the thermogravimetric (TGA) curve and the derivative thermogravimetric analysis (DTG) curves.

Figure 1 and 2 show the DTG curves obtained for the linear and branched phthalates studied. The DTG of the resin E400 has been included in both figures for comparison.

Figure 1. DTG of the plastisols prepared with the 4 linear phthalates studied and the resin E400.

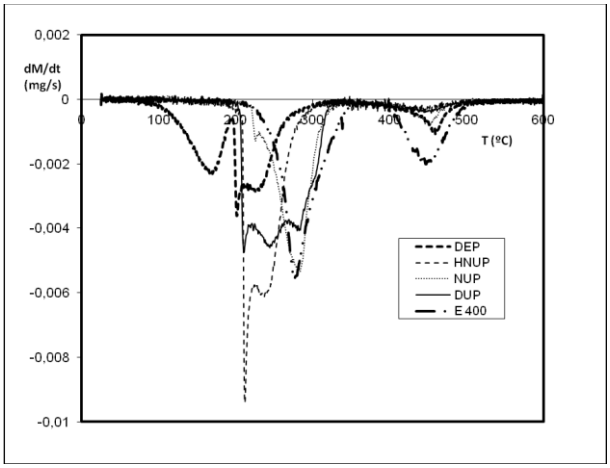

Figure 2. DTG of the plastisols prepared with the 5 branched phthalates studied and the resin E400.

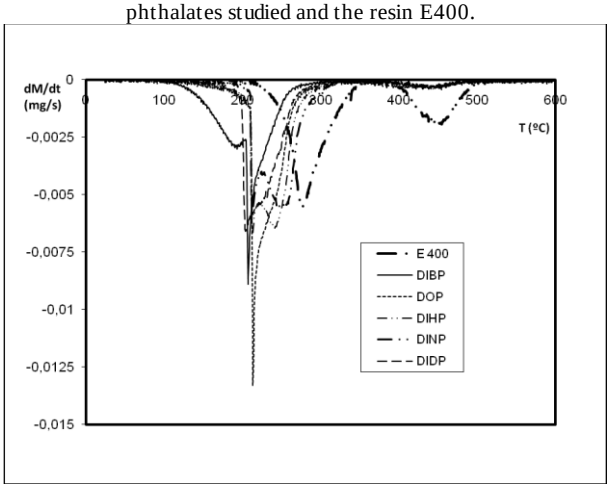

The thermograms obtained clearly show the presence of up to four weight loss steps. The first one corresponds to the evolution of the plasticizer in clear correlation with its corresponding boiling point. The rest are related with the dehydrochlorination and loss of acetic acid of the copolymer resin and the products of decomposition of the stabilizer and co-stabilizer, and the last one, at temperatures higher than 400 °C corresponding to the carbonization of the residue of this first step [1,2]. It can be observed that the lower the molecular weight of the plasticizer the lower the temperature of the first decomposition process of the resin.

Monitoring of Recycled AAO Templates. An Exhaustive Characterization after Polymer Extraction.

Iwona Blaszczyk-Lezak, Jon Maiz, Javier Sacristan, Carmen Mijangos*
Instituto de Ciencia y Tecnología de Polimeros, CSIC
*iblezak@ictp.csic.es

Introduction

Over the last decade one-dimensional (1D) nanostructures have attracted much attention due to their useful properties and many potential applications. One of the ways to prepare 1D polymer nanostructure is by use the porous anodic aluminum oxide (AAO) template and subsequent infiltration of the polymer into the nanocavities of the AAO templates [1-5]. Templates of this type are prepared electrochemically from aluminum metal. AAO templates are characterized by uniform tailored pores with hexagonal symmetry and long-range ordered architecture.

In order to exp and the use of nanostructured polymers it is mandatory to improve and scale-up the fabrication process from laboratory to an industrial level. But because of the time needed for preparation and the price of aluminum, it is first necessary to try to recover used AAO templates. Our group has chosen controlled high temperature treatment of infiltrated AAO membranes in an oven to eliminate the polymer from the template pores by thermal decomposition of the compound.

Materials and Methods

In order to investigate the possibility of thermal elimination of infiltrated PEO from AAO templates, several analytical techniques and procedures have been employed such as: thermogravimetric analysis (TGA), Raman microspectroscopy, wide angle X-ray diffractometry (WAXD), scanning electron microscopy (SEM). AAO templates with pore sizes of 35 nm and pore thickness of 110 mm have been used in this study. The infiltration of polyethylene oxide (PEO, M_W = 100 000 g/mol) was carried out by melt precursor film wetting method.

Results and discussion

Thermal properties of PEO nano rods into the AAO templates were investigated by means of TGA to select the temperature and time range where the thermal decomposition of infiltrated PEO takes place. From these results it is concluded that there is only small window that allows the total PEO elimination from the AAO nanopores in a reasonable time. The preferred conditions are T = 450^{O}C and 3 h long treatment.

In order to identify if some polymer still remains inside AAO template pores, the presence of characteristically PEO bonds has been investigated by means of Raman spectroscopy (Fig.1). Looking at the spectra corresponding to the AAO template infiltrated with PEO and subjected to a 3 hours of thermal treatment at 450ºC (spectra *c* and *d*), it seems clear that no one of the characteristic PEO Raman bands can be observed in this spectrum. It means that PEO have been successfully eliminated from the template.

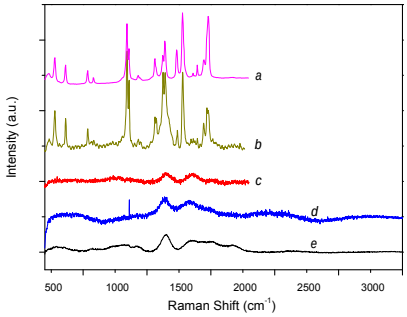

Figure 1. Raman spectra of: *a)* PEO in bulk, *b)* AAO with infiltrated PEO, *c)* recuperated AAO at T = 450 ^{O}C at 10 mm inside the pores, *d)* recuperated AAO at T = 450^{O}C and *e)* AAO template as reference.

The spectra WAXD corresponding to the thermally treated AAO samples does not show any character peak of the PEO, only amorphous halo of the alumina is observed. This is in agreement with results obtained by Raman spectroscopy. What is more, from the results of SEM, the hexagonally close-packed structure of AAO templates has not been changed during the high temperature process and even the shape of pores is maintained.

Conclusions

Results from this work highlight the importance of selecting appropriate conditions; temperature and time to successfully eliminate PEO from AAO template nanopores. The preferred conditions are T = 450 ^{O}C and 3 h long treatment. This methodology seems to be a promising route to re-use AAO templates especially for infiltration of new polymers under different experimental conditions.

Fluoropolymer dispersions: new environment-friendly products and technology

S.Musio, V. Kapeliouchko, T.Poggio*

Solvay Solexis S.p.A., p.le Donegani 5/6, 15047 Spinetta Marengo (AL), Italy

stefana.musio@solvay.com

Polytetrafluoroethylene (PTFE) has seen increasing demand in sophisticated industrial applications since 1938, due to its thermal and chemical inertness, release properties, and outstanding dielectric characteristics[1]. Aqueous dispersions of PTFE are particularly suitable for cookware antistick coatings and endless conveyor belts for the food industry: such dispersions are commonly obtained via emulsion polymerization in the presence of a non-telogenic perfluorinated anionic emulsifier, leading to 150-300 nm particles. Alternatively, a proprietary Solvay Solexis technology[2,3,4] using microemulsion polymerization allows the synthesis of 10-60nm particles, which are advantageously exploited in bimodal dispersions. This results in a more compact and less porous PTFE film structure leading to better application performances in terms of coating appearance, mechanical strength, and durability.

Recent developments in PTFE dispersions combine knowledge on new fluorosurfactants developments with yet available processes to reduce the content of fluorosurfactant in the dispersions[5] and with appropriately selected phenol-free non-ionic surfactant to eventually obtain environmentally friendlier PTFE dispersions that match or even improve the processing performance compared to standard products.

The formulation of fluoropolymer dispersions, purified from anionic fluorinated surfactants used in polymerization, requires re-design of specific ingredients in order to maintain the performance profile of the product in the whole range of applications, e.g. coating, impregnation, etc.

Starting from the colloidal properties of the initial systems, this presentation discusses in particular stability to shear and sedimentation as well as rheological behavior of PTFE dispersions.

In particular the environmentally friendly fluoropolymer dispersions obtained by substituting APE surfactants with "Green" Ethoxylated Alcohols and by extracting perfluorinated surfactants are discussed, which impart the following features:

- More newtonian rheological behavior resulting into better properties under a wider range of applicative conditions of temperature and shearing.
- Lower surface tension, both static and dynamic values, which imparts outstanding wetting ability especially under critical high-speed impregnation conditions.
- Excellent stability to shear and sedimentation due to better interaction of the surfactant with the polymer surface: the adsorption behavior is very similar to that of APE surfactants

Cleaner thermal degradation of the surfactant system resulting in higher quality of the final objects.

Properties enhanced PU coating using (Desmodure Z 4470) as isocyanate and the different Desmophens as polyalcohols

A. Shokuhi Rad

Chemical engineering group, Department of Engineering, Islamic Azad University, Ghaemshahr Branch, Ghaemshahr, Iran

Ashokuhirad@yahoo.com

Polyurethanes (PU) are engineering polymers since they show unique physical and mechanical properties. An isocyanate agent (Desmodure Z 4470) and three polyalchol agents (Desmophen 670BA, 1800 and A665, respectively) were used for formulation of the polyurethane coating with considering to self-healing property. The effect of the chain extender agent (ethylene glycol) and the optimum ratio of the isocyanate to polyalchol agent were studied. The attained results show that a hard polymer coating is obtained using Desmophen A665 polyalcohol in the absence of any chain extender, however a corrosion resistant and transparent coating is obtained using Desmophen 1800 and a ratio of NCO/OH=2 for pre-polymer formation stage and NCO/OH=0.85 in polymerization stage by adding proper amount of ethylene glycol. This obtained PU shows the best self-healing properties.

Introduction

Epoxy resins are widely employed in technological applications, among them they are applied as electric insulating materials, adhesives or coatings. Epoxy resins can be considered as versatile materials because in addition of their structure and/or molecular weight they can be cured in different conditions depending on the curing agent selected. Epoxy resins can be cured by stoichiometric curing agents as for example aromatic or aliphatic amines, acid anhydrides, or isocyanates. Curing agents that show no activity under normal conditions but show activity by external stimulation, like temperature, can be called "latent curing agents". In this way, curing temperature can be conveniently selected by using the proper latent curing agent.

The versatility of epoxy thermosets can be broadened and some improvement in their characteristics can be accomplished by the use of hyperbranched polymers (HBPs) as modifiers. Generally, they have been used as tougheners[1] but some other characteristics such as the reduction in the shrinkage on curing and reworkability have been also improved.[2]

Depending on the hyperbranched structure and the reactivity of the end-groups, the HBP can be chemically incorporated to the network structure or lead to micro or nanophase separation. Also, the chemical nature of the final chains affects the kinetics of the curing and even the conversion at the gelation.

Materials

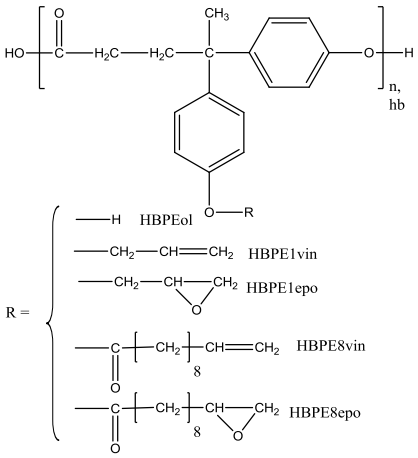
DGEBA epoxy resin (EPIKOTE™ 828, 187 g/eq, HEXION). 4,4-Bis(4-hydroxyphenyl)valeric acid, N,N'-dicyclohexyl carbodiimide, diethyl adipate, 10-undecenoil chloride, allyl bromide, hydrazine hydrate and m-chloroperbenzoic acid (Aldrich) were used as received. 4-(N,N-dimethylamino)pyridinium p-toluene sulfonate (DPTS) was prepared as described in the literature.[3]

Adipic dihydrazide was prepared by reaction of diethyl adipate with hydrazine hydrate in ethanol. This product was recrystallized in ethanol

Synthesis of the hyperbranched polymers

The hyperbranched polyester ($HBPE_{ol}$) was synthesized according to a previous procedure.[4] The structures of the modified HBPs are shown in the scheme.

$HBPE8_{vin}$ was synthesized by acylation reaction of $HBPE_{ol}$ with undecenoyl chloride in the presence of triethylamine as hydrochloric acid acceptor. This polymer was converted into $HBPE8_{epo}$ by epoxydation with m-chloroperbenzoic acid in CH_2Cl_2. $HBPE1_{vin}$ was obtained by modification of $HBPE_{ol}$ with allyl bromide in the presence of K_2CO_3. The allylated polymer was epoxydated to obtain $HBPE1_{epo}$. All these polymers were characterized by GPC and NMR measurements.



By differential scanning calorimetry the kinetics of the curing process was studied. The curing of neat DGEBA with adipic dihydrazide takes place by heating at 170 ºC in a latent manner. The addition of $HBPE_{ol}$ to the formulation accelerates the curing much more than when the other HBPs were added to the formulation and the latent character was not much affected.

The addition of $HBPE_{ol}$ to the formulation leads to an increase in the Tg of the thermosets without affecting the thermal stability, determined by TGA. However, the addition of a 10% wt. of the polyesters having vinyl groups as chain ends reduces the Tg of the final thermosets.

The materials obtained have better mechanical characteristics than the neat materials, which confirms the goodness of the modification proposed in this communication.

Inhibition of the migration of low molecular weight moieties to rubber-polyurethane coating interface by incorporating filler

Rafael Torregrosa-Coque, José Miguel Martín-Martínez

Adhesion & Adhesives Laboratory. University of Alicante. 03080 Alicante (Spain)

jm.martin@ua.es

Introduction

One of the causes of poor adhesion of vulcanized rubbers to polyurethane adhesives is the existence of surface layers of antiadherent moieties, mainly antiozonants [1]. These weak-boundary layers are generally produced by migration of low molecular moieties (mainly paraffin wax) from the bulk to the rubber surface [2-4]. After coating application, the adhesion can be deteriorated by migration of the paraffin wax to the rubber-coating interface.
Fillers cause crosslinking of polymeric chains. Therefore, it could be feasible that the addition of fillers produces a change in the diffusion of low molecular weight moieties throughout the polymer, and therefore our hypothesis is that the addition of fillers in the polymeric coating can retard or even inhibit the migration of paraffin wax to rubber-polyurethane interface.

Materials and Methods

A vulcanized styrene-butadiene rubber was coated with unfilled and 2wt% nanosilica filled polyurethane solutions; their thicknesses were about 2 µm. The evolution of wax migration to the rubber-polyurethane interface was monitored by contact angle measurements and ATR-IR spectroscopy of the polyurethane coating with time after coating application.

Results and Discussion

Figure 1 shows the methylene groups of the wax bands in the ATR-IR spectra obtained with the two prisms, whereas the rubber bands (butadiene and styrene) appear only when the ZnSe prism is used. Therefore, the paraffin wax appears in a depth of about 2 µm from the external surface of the as-received rubber.

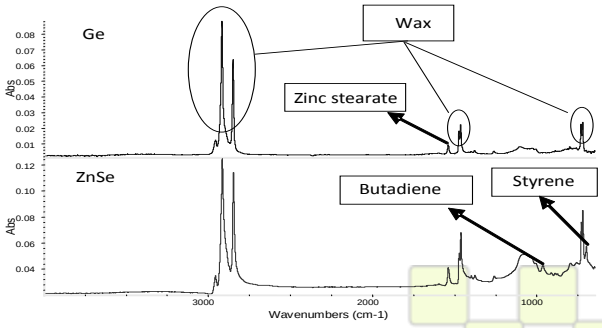

Figure 1. ATR-IR spectra of the as-received R2 rubber.

By increasing the time after PU coating application up to 14 days (Figures 2 and 3), the ATR-IR/Ge spectra show an increase in the intensity of the wax bands whereas the intensity of these bands does not change in the ATR-IR/ZnSe spectra. Therefore, the wax migrates mainly into the PU surface throughout the two PU coatings on the rubber.

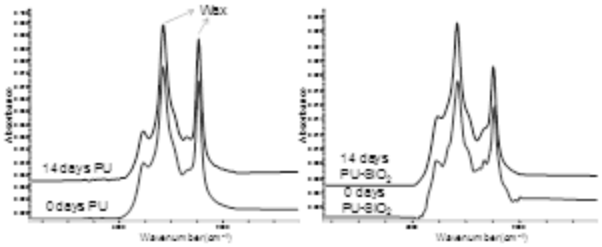

Figure 2. 3100-2700 cm^{-1} region of the ATR-IR spectra of the unfilled and nanosilica filled PU coatings on rubber with time. ZnSe prism.

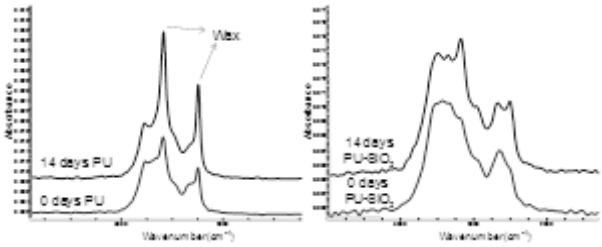

Figure 3. 3100-2700 cm^{-1} region of the ATR-IR spectra of the unfilled and nanosilica filled PU coatings on rubber with time. Ge prism.

Addition of nanosilica filler inhibits the extent of wax migration to the polyurethane coating. Because of the interactions by hydrogen bonds between the silanol groups on the nanosilica and the urethane groups in the polyurethane coatings, the degree of crosslinking increases avoiding the diffusion of the low molecular weight additive into the polyurethane coating.

Conclusions

A layer of about 2 µm of paraffin wax exists in the as-received rubber surface. By increasing the time after polyurethane coating application up to 14 days, an increase in the intensity of the paraffin wax bands was obtained, less markedly in the nanosilica filled coating.

Epoxy Polymers and Composites for Advanced Applications

Roberto J. J. Williams

Institute of Materials Science and Technology (INTEMA), University of Mar del Plata and National Research Council (CONICET), Av. J. B. Justo 4302, 7600 Mar del Plata, Argentina

e-mail: williams@fi.mdp.edu.ar

Introduction: Due to their excellent properties epoxy polymers are extensively used in traditional applications such as adhesives, coatings and composites. In recent years there has been an increasing use of epoxies in the development of advanced functional materials.[1] Some examples will be given in this presentation.

Reversible Epoxy Networks: The reaction of diglycidylether of bisphenol A (DGEBA) with an *n*-alkylamine leads to a linear epoxy polymer. However, linear chains can be assembled by tail-to-tail associations between *n*-alkyl groups leading to a network with physical crosslinks. The strength of the physical bonds decreases with temperature and with the length of the *n*-alkyl group.[2] By increasing temperature the material reversibly transforms from a gel to a liquid, a fact that may used to develop self-healing epoxies.

Shape Memory Epoxies: When epoxies are heated above their glass transition temperature (T_g) they can be deformed to a temporary shape by applying a relatively small stress. By fixing the deformation and cooling below T_g, a glass is obtained that stores elastic energy in chain conformations removed from their equilibrium values. When the material is released from any constraint and is heated again above T_g, a rapid recovery of the initial shape is obtained as chains recuperate their equilibrium conformations. But if the heating step is performed keeping the initial deformation, the material develops a recovery stress. Actuators based on epoxies can make use of the shape recovery or the stress recovery. They can be designed for large tensile elongations (e.g., 75 % or higher) or large recovery stresses (e.g. 3 MPa or higher). However, meeting both requirements simultaneously is a difficult task because changes in the crosslink density affect both variables in opposite ways. An epoxy formulation based on the reaction of DGEBA with *n*-dodecylamine (DA) and *m*-xylylenediamine (MXDA) gives a network with both chemical and physical crosslinks that can be used for a shape memory material verifying both requirements.

Epoxy Networks Containing Silver Nanoparticles (NPs): Ag NPs can be introduced into epoxy coatings to obtain specific electrical or antimicrobial properties. Different methods can be employed to obtain a uniform dispersion of NPs. A DGEBA/DA gel was swollen with a 6mM solution of $AgNO_3$ in THF/H_2O (90:10). After rinsing with THF and drying in vacuum, the epoxy network was heated at 100 °C for 1 h, generating a uniform dispersion of Ag NPs with an average size close to 10 nm.[3] The reduction was performed by the secondary alcohols present in the epoxy backbone. The T_g increased from 20 °C (neat epoxy) to 28 °C (nanocomposite). A different strategy to obtain a uniform dispersion of Ag NPs in an epoxy matrix was to introduce reactive groups in the organic chains stabilizing the NPs. Silver NPs with an average size of 4nm and stabilized with an organic group containing secondary hydroxyls, were synthesized and dissolved in DGEBA. The epoxy was polymerized using a tertiary amine as initiator. Ag NPs were covalently bonded to the epoxy network through chain transfer reactions to the secondary hydroxyls of the organic ligands. The nanocomposites were strongly colored and showed a dependence of T_g on the concentration of NPs.[4]

Epoxy Networks Containing Single-Wall Carbon Nanotubes (SWCNT): Epoxy nanocomposites containing SWCNT exhibit significant improvements in mechanical, thermal or electrical properties. Surface functionalization of SWCNT enables to obtain an adequate dispersion of the nanotubes in the epoxy formulation. A problem that is present in some formulations is the different partition of the epoxy monomer and the hardener in the interphase, a process favored by the large specific area per unit volume. This leads to a heterogeneous network characterized by two relaxation peaks and a significant decrease of the glass transition temperature. This problem was avoided by a convenient functionalization of the SWCNT, producing a localized formation of bundles of nanotubes in the course of polymerization. The T_g of the nanocomposite was the same as the one of the neat epoxy.[5]

Epoxy Networks Containing POSS Crystalline Platelets: The dispersion of intercalated/exfoliated clays in polymers decreases their permeability due to geometrical effects. However, processing is difficult due to the initial high viscosity. An alternative is to produce the crystallization of an initially soluble precursor during polymerization. The feasibility of this idea was proved using a polyhedral oligomeric silsesquioxane (POSS) dissolved in the epoxy precursors.[6]

aurelie.cayla@ensait.fr

Introduction

These works fall under the European research project Inteltex (FP6), which is created of the relationship between the use of nanotechnology and the need for textile innovation. One objective was to develop a flexible temperature sensor to be integrated in the Personal Protective Equipment (PPE) to prevent the pain threshold by firefighters. This sensitivity is ensured by the use of biphasic Conductive Polymers Composites (CPC) loaded with Carbon NanoTubes (CNT) in the form of multifilaments. These conductive fillers are introduced in the phase which is sensible to the temperature elevation (Polycaprolactone (PCL)) and protected by the second polymer whose melting temperature is higher (Polypropylene (PP)). For our application, an interpenetration of two phases (co-continuous morphology) and a selective localization of CNT in the PCL are privileged to obtain a good electrical conductivity at relatively low CNT contents [1]. But this one should be adapted to succeed to observe a Positive Temperature Coefficient (PTC) effect to detect the critical temperature. The main difficulty is to combine detection properties with mechanical properties to support the melt spinning process and the implementation of weaving textile).

Materials and methods

Poly(ε-caprolactone), namely CAPA 6400 from Solvay, is a biodegradable polymer with a relatively low melting temperature of about 58°C. Polypropylene (PP) was supplied by DOW under the reference H777-25R, which presents an appropriate spinning grade to lead to a good spinning ability of the blends with PCL. Multi-wall carbon nanotubes (MWNTs) were supplied by Nanocyl (Belgium) under the reference Nanocyl®-7000 and present a purity equal to 90%. The realization of multifilament composite is made in two main steps. The first one is to load the PCL with 4wt% of CNT using a Thermo-Haake co-rotating intermeshing twin-screw extruder with a screw diameter of 16 mm and a length to diameter ratio of 25. In a second step, the pellet issued from the first extrusion are blend with the matrix PP directly in the feed hopper of the melt spinning machine (driver SPINBOY I, Busschaert Engineering in Belgium). A spun multifilament contained 80 monofilaments (2 dies*40 holes) is obtained, and he is rolled up on two heated rolls with varying speeds (S1 and S2) to ensure a draw. The theoretical drawing of multifilament is given by the ratio DR = S2/S1. All characterizations: electrical, mechanical, and detection were made in this twisted multifilament (81tr/m).

Results and discussion

Electrical properties for temperature detections

In *Fig.*1, we can observe that the resistance decrease when we introduce the filled PCL. We can check by selective extraction that the morphology of the biphasic system became co-continuous with 50% of filled PCL. We see on Fig.1 that this content is necessary to obtain an interesting the conductivity became interesting for detection application.

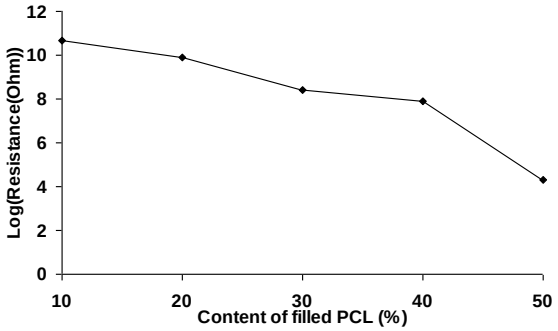

Fig. 1: Electrical resistance of PP/PCL+4%CNT (DR=1.06) measured on 1cm length of multifilament

In this study, to obtain good properties of detection a low DR was applied (S1= 80m/min, S2=90m/min and DR=1.12) to keep a satisfactory electrical conductivity. If the DR is too high the conductivity decreases due to depercolation of CNT and reduction of continuity of filled PCL.

Mechanical properties

Introduction of filled PCL decreases the mechanical properties of multifilament: Young modulus (*Fig.2*) and also stress at break decrease due to the low cohesion between PP and PCL but also by the presence of CNT leads defects due to agglomerates.

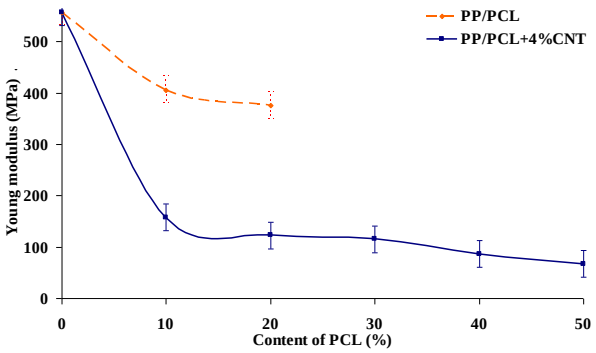

Fig. 2: Young modulus of PP/PCL with and without CNT measured on multifilaments (DR=1.06)

Conclusions

The presence of a PTC effect can be observed on the multifilament bit stretched with a content of 50% of filled PCL. Indeed, we observed a depercolation CNT due to volume expansion when the temperature reaches the melting temperature of PCL (58 ° C). However the low cohesion between the phases (PP and PCL) causes a sharp decrease of Young's modulus and stress at break. However these values are sufficient to support the steps of textile implementation.

New Polytricyclnonenes and Polytricyclononadienes: from Monomer Synthesis to Polymer Gas Permeability

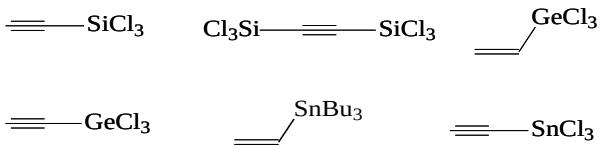
B.A. Bulgakov, M.V. Bermeshev, L.E. Starannikova, E.Sh. Finkelshtein

A.V.Topchiev Institute of Petrochemical Synthesis RAS

bbulgakov@gmail.com

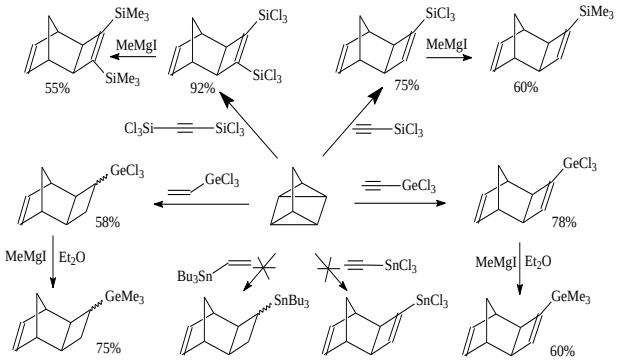
Introduction. In our previous researches we have shown Me_3Si-substituted tricyclononenes to be active in ring-opening metathesis polymerization (ROMP) and addition polymerization. Resulting polymers demonstrated prospective gas-transport parameters comparable to known the highest-permeable polymers [1]. For example, permeability of addition poly(3,4-bis(trimethylsilyl)tricyclononene-7) is more than 2000 Barrers. So the structure of substituted tricyclononene appeared to be attractive basis for macromolecular design of new highly permeable polymers. The way to obtain substituted tricyclononenes is [2+2+2] cycloaddition between quadricyclane and corresponding olefins leading to only *exo*-products [2].

Results and Discussion. In this work we decided to expand range of "dienophiles" with, germanium- and tin-containing ethylenes and various acetylenes including sinlicon-containing ones:



The main aim of this work was to study and compare behavior of monomers obtained in polymerization following by the comparison of gas-pemeability of corresponding polymers.

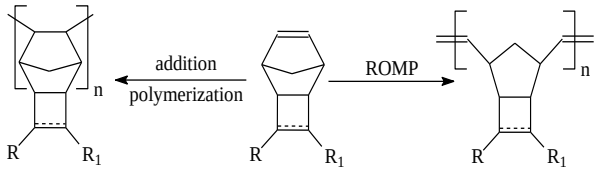
We have synthesized several new trichlorosilyl- and trichlorogermylsubstituted tricyclononenes and tricyclononadienes according to the scheme:



It should be noted that in contrast to $GeCl_3$- or $SiCl_3$-containing olefins interaction between Cl_3Sn-substituted ethylenes or acetylenes and quadricyclane does not result tricylononenes or tricyclononadienes. A presence of chlorostannanes induces immediate isomerization of quaricyclane into norbornadiene.

Products of condensation were methylated by use of common Grignard procedure to reach desired monomers. They were isolated as individual compounds -and characterized with NMR-spectroscopy and GC-MS. The relative activities of "dienophiles" in [2+2+2] cycloaddition were measured and some structure-activity correlations were considered.

We involved the monomers obtained into addition polymerization and ROMP:



R = $SiMe_3$, $GeMe_3$ R_1 = H, $SiMe_3$

Addition polymerization was performed using a Pd-based catalytic system. We utilized $B(C_6F_5)_3$ and MAO as activators. Yields of polymers were up to 70% and M_w up to 450 000. For all addition polymers glass transition temperatures were not observed till decomposition.

ROMP was performed using the 1st generation Grubbs catalyst with yields up to 98% and M_w up to 800 000. T_g of polymers obtained are in the range from 99 to 127°C depending on nature of a substituent in monomer unit.

The polymers demonstrated high gas-transport characteristics. For example, carbon dioxide permeability of addition poly(3-(trimethylgermyl)tricyclononene) is more than 3800 Barrers. Selectivity coefficient for a pair of butane/methane is about 17,5.

Conclusions. Behavior of various substituted ethylenes and acethylenes in the reaction of [2+2+2] cycloaddition with quadricyclane was studied. Addition and metathesis polymers were obtained from monomers presented above with yields up to 98%. Gas-transport characteristics of these polymers were measured and correlations were discussed. The polymers concerned could be attributed to a class of the highest permeable polymers.

e-mail: ramis@mmt.upc.edu

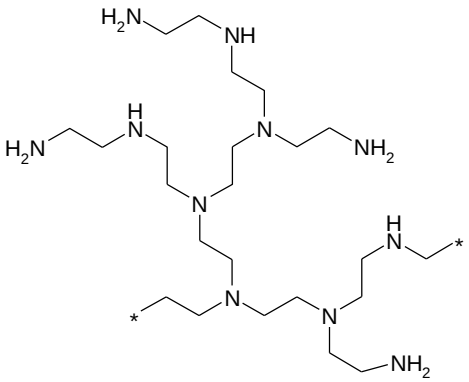
Introduction

In the recent years, the use of hyperbranched polymers (HBPs) as polymeric modifiers has gained attention due to their advantages in comparison with their linear counterparts: low melt viscosity and high concentration of functional end groups.[1] Depending on the hyperbranched structure and the reactivity of the end-groups, the HBP is either incorporated into the network structure or phase-separates, producing a significant enhancement in toughness.[2]

In this work it is proposed the use of a commercial hyperbranched, poly(ethyleneimine) (LUPASOL™, BASF) as a reactive polymeric modifier for epoxy thermosets. To the best of our knowledge, the use of poly(ethyleneimine)s as curing agent has been hardly explored so far.[3,4] Our aim is to investigate in detail the curing process and properties of the resulting thermosets.

Materials and Methods

DGEBA epoxy resin (EPIKOTE™ 828, 187 g/eq, HEXION) and LUPASOL™ PR 8515 (BASF), ethylenediamine (EDA, Aldrich) and 1-methylimidazole (1MI, Aldrich) were used as received. The following scheme depicts an idealized structure of LUPASOL.



The following formulations were studied:

epoxy/amine eq ratio	1MI
1:1 (LUPASOL)	-
1:0.5 (LUPASOL)	1 phr
1:0.25 (LUPASOL)	1 phr
1:1 (EDA)	-

The curing kinetics was studied by DSC in non-isothermal experiments at different heating rates and isothermal experiments at different temperatures, and isothermal FTIR/ATR. Gelation was determined using TMA, rheometry and DSC. Thermal-mechanical properties were studied using DSC and DMA. Thermal stability was determined using TGA. Curing shrinkage was evaluated by density measurements of the uncured and cured formulations and dilatometric measurements using TMA. The curing of these systems was modelled by simple phenomenological and more complex mechanistic models taking into account the effect of vitrification and volume changes.

Results and discussion

The curing of DGEBA and LUPASOL takes place by an epoxy-amine condensation mechanism. The resulting tertiary amines are unable to promote the etherification of DGEBA epoxy groups. As a consequence, addition of an active tertiary amine such as 1MI is necessary for the complete curing of under-stoichiometric LUPASOL formulations. The curing takes place then in two overlapping processes: epoxy-amine condensation and alkoxide-propagated epoxy polyetherification initiated by 1MI. The epoxy-amine reaction generates a high number of hydroxyl groups which favours initiation of polyetherification by 1MI, which can be used in very low amounts. Combination of LUPASOL and 1MI has thus a synergistic effect in the completion of cure using small amounts of both components. Significant changes in the network development and final network structure are observed between LUPASOL- and EDA-stoichiometric mixtures. Also, important differences are observed between LUPASOL-stoichiometric and under-stoichiometric formulations.

Preparation of L-Arabinitol-Based Functional Polyurethanes

Cristina Ferris, M. Violante de Paz, Francisca Zamora, Belén Begines, Juan A. Galbis

Organic and Pharmaceutical Chemistry Dept., University of Seville, Spain

cferris@us.es

The use of polyurethanes in medical applications is being widely investigated due to their low toxicity, potential biodegradability, biocompatibility, and versatile structures, which make them useful for different applications [1].

Various hydroxyl-containing polymers have been synthesized for biomedical applications: for example, drug release systems based on poly(2-hydroxyethyl methacrylate) and poly(2-hydroxy-propyl methacrylate) hydrogels were recently reported for use in ophthalmology [2]. In addition, Harada *et al*. reported the synthesis of a polyethylene glycol and polyaspartic acid *block*-copolymer which can be used as drug carrier of the anticancer Docetaxel, covalently attached by ester bonds to the polymer chains [3].

Three new polymerizable diols — based on mono-, di-, and tri-*O*-allyl-L-arabinitol derivatives — were prepared from L-arabinitol as versatile materials for the preparation of tailor-made polyurethanes with varied degrees of functionalization (Figure 1). Their allyl functional groups can take part in thiol-ene reactions, to obtain greatly diverse materials.

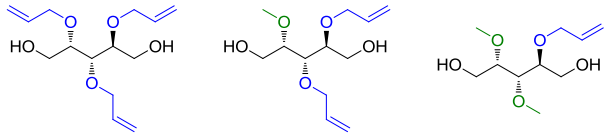

***Figure 1**: Chemical structures of allyl-containing L-arabinitol-based diol monomers.*

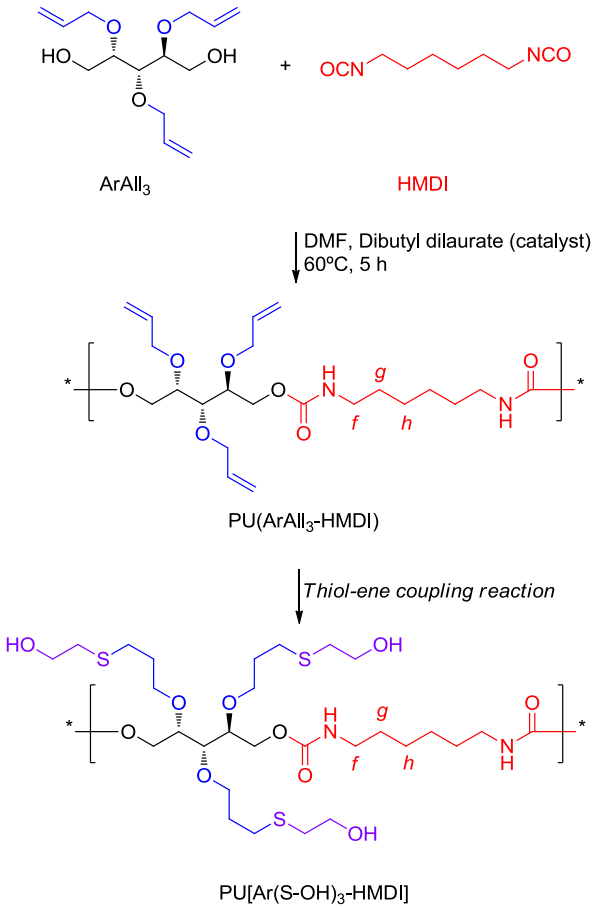
This "click" reaction with 2-mercaptoethanol was firstly studied on the highly hindered sugar precursor 2,3,4-tri-*O*-allyl-1,5-di-*O*-trityl-L-arabinitol, in order to apply it later to macromolecules. A polyurethane with multiple pendant allyl groups was synthesized by polyaddition reaction of 2,3,4-tri-*O*-allyl-L-arabinitol ($ArAll_3$) with 1,6-hexamethylene diisocyanate (HMDI), and then functionalized by thiol-ene reaction (Scheme 1). The coupling reaction took place in every allyl group, as confirmed by standard techniques.

The thermal stability of the novel polyurethanes was investigated by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). This strategy provides a simple and versatile platform for the design of new materials whose functionality can be easily modified.



***Scheme 1**: Polymerization reaction of compound $ArAll_3$ with HMDI and subsequent thiol-ene coupling reaction with 2-mercaptoethanol.*

Thiol-ene Coupling Reactions: A new Approach to Functionalized Polyurethanes

M. Violante de Paz, Cristina Ferris, Juan A. Galbis

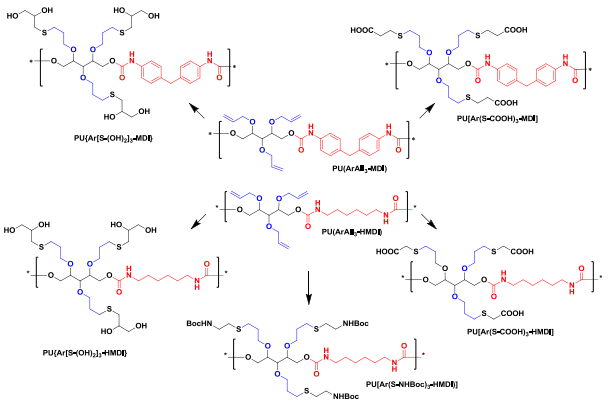
Organic and Pharmaceutical Chemistry Dept., University of Seville, Spain

vdepaz@us.es

The rational design of polymers tailored to exert distinct biological functions plays an important role in the development of controlled drug delivery systems. Thus, the controlled release of therapeutic molecules of both, hydrophilic and hydrophobic drugs, is achieved by anchoring the active agent to polymer structures by means of physical interactions or by covalent linkages.

The thiol-ene reaction shows all the desirable features of a click reaction, i.e., it is highly efficient, simple to execute with no side products, and proceeds rapidly to high yields [1]. The thiol-ene method was applied to the preparation of highly functionalized linear polymers through the combination of different thiols and multi-ene polymers with enhanced properties namely, higher hydrophilicity, increased wettability, and improved biodegradation behavior. As far as we are aware, this method was first used by us in polyurethane chemistry to get a highly hydroxylated material [2].

The aim of the present work is the preparation of aliphatic and aromatic polyurethanes with varied degree of allyl groups and analyze the scope and limitations of click chemistry (CC) in the preparation of polyanionic, polycationic and polyolic linear PU for diverse applications. Consequently, its development may be a new approach to well-defined reactive polyurethanes useful for a variety of biomedical and nanotechnological applications.



***Scheme 1**: Synthesis of polyanionic, polycationic and polyolic linear PU via click chemistry.*

1-Thioglycerol, thioglycolic acid and the freshly prepared *tert*-butyl (2-mercaptoethyl)carbamate were the thiols of choice in the present study because of their simple and convenient chemical structure. Complete coupling of thiol fragments to every allyl group was achieved in every experiment. With illustrative purpose, Figure 1 displays the reaction scheme and the ^{1}H-NMR spectra of both, the starting polymer PU(ArAll$_3$-MDI) and the final functionalized polyurethane PU{Ar[S-(OH)$_2$]$_3$-MDI}. Of note in the upper spectrum is the complete disappearance of signals from the vinyl protons (4.95 to 5.88 ppm) and the appearance of the peaks corresponding to the –OH groups (3H, 4.50-4.92 ppm) and to the *d*, *e*, *f*, *g*, and *i* methylene groups as well as the *h* methylidyne group present in the final compound.

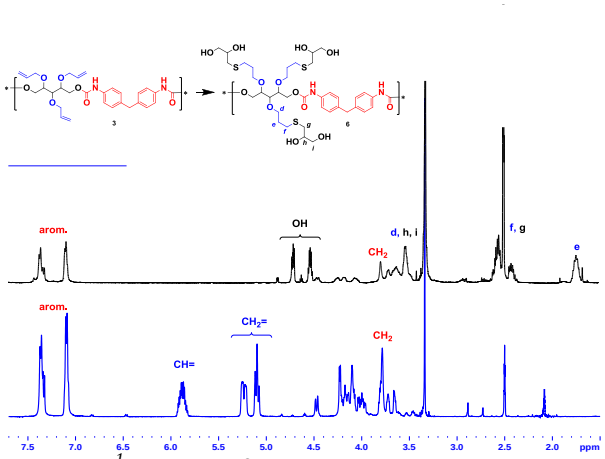


***Figure 1**: ^{1}H NMRs of PU(ArAll$_3$-MDI) (bottom spectrum) and PU{Ar[S-(OH)$_2$]$_3$-MDI} (upper spectrum) synthesized by thiol-ene reaction with 1-thioglycerol.*

All the new polymers were fully characterized by FTIR, NMR, GPC and elemental analysis, and their thermal properties were also studied. The DSC analysis of the polyurethanes studied in this work revealed that most of them are essentially amorphous polymers and the allyl MDI-based polymers are stiffer than the HMDI-counterparts, as come be deduced from their Tg values. Most of the polymers functionalized via CC exhibit a lower Tg value than the starting materials, with a marked increase in flexibility. The thermal stability of the polyurethanes was evaluated by thermogravimetry under an inert atmosphere. The presence of the hydroxyl, carboxylate and amine moieties in polyurethanes had a marked effect on the degradation profile compared with allyloxy pendant groups in PU.

Hydrolytic degradation studies under physiological conditions and the anchorage of an anticancer agent was also tested.

Biodegradable linear sulfur-containing polyurethanes derived from carbohydrates

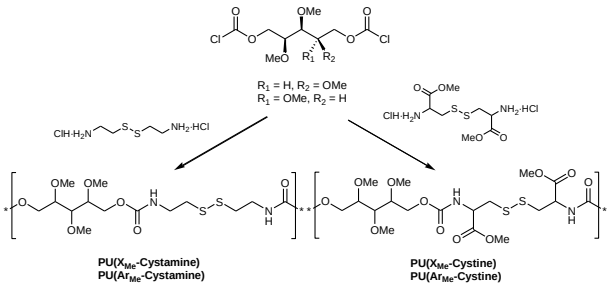
Belén Begines, Francisca Zamora, Violante de Paz, Cristina Ferris y Juan A. Galbis

Departamento de Química Orgánica y Farmacéutica. Facultad de Farmacia. Universidad de Sevilla. C/ Prof. García González nº 2, 41012, Sevilla. España. Fax: +34 95 455 6737; Tel: +34 95 455 6739

E-mail: bbegines@us.es

Polyurethanes are widely used in many different fields, such as engineering, construction, textiles, and for various applications, such as insulating, elastomers, adhesives, fibres, etc[1]. However, homogeneus polyurethanes obtained from alkanediols and diisocyanates are chemically stable polymers with and outstanding resistance to hydrolytic degradation[2]. The incorporation of sugar units into tradicional condensation polymers such as polyamides, polyesters and polyurethanes is considered as an interesting method for the preparation of new biodegradable and biocompatible materials for use in biomedical applications.[3-4]

In this article, we investigate the preparation of new aliphatic and aromatic polyurethanes from sugar-based monomers with cystamine dihydrochloride and cystine dihydrochloride by interfacial polycondensation.



Polyurethanes were obtained with weight-average molecular weights between 6700 and 29000. The chemical structure of the resulting polymers were analysed by NMR and elemental analysis. The TGA studies demostrated that they are stable up to temperatures of about 240 ºC. The new polyurethanes were hydrolytically degradated in buffer solutions at pH 7.02 or pH 8.0 and 37 ºC and in the presence of glutathione under physiological conditions.[5]

Sugar-based Polyurethanes and Polyureas

Francisca Zamora, Belén Begines, Isaac Roffé, Manuel Mancera and Juan A. Galbis

Departamento de Química Orgánica y Farmacéutica. Facultad de Farmacia. Universidad de Sevilla. C/ Prof. García González nº 2, 41012, Sevilla. España. Fax: +34 95 455 6737; Tel: +34 95 455 6739

E-mail: khfz@us.es

Polyurethanes are presented as linear, branched, cross-linked polymers, block copolymers, etc. showing multiple industrial applications[1] such as fibres, foams, elastomers, coatings, and biomedical applications due to its biocompatibility and low toxicity. So, among other uses, they have been used as drug carriers in controlled release systems[2]. The polyureas present a great resistance to abrasion, UV radiation, fats, oils, and solvents so they are used in the agri-food industry as coatings, etc. Likewise, polyureas-urethanes with possible biomedical applications have been obtained[3].

Both the polyurethanes and the polyureas are very resistant to degradation what makes impossible their use in applications in which the material is aimed to be destroyed after the use. For this reason, we have included hydrophilic units in these polymers with the aim of making them more sensitive to hydrolytic degradation. In this way, we have used monomers derived from attainable carbohydrates[4,5] with free or protected hydroxyl groups[6].

In this communication, we report on the synthesis and characterization of new aliphatic and aromatic xylitol-based polyurethanes by polymerization in solution or in bulk by using diisocyanates or dicarbamates as co-monomers. In this way, a series of polyurethanes were prepared by polyaddition reaction of xylitol to hexamethylene diisocyanate (HMDI), 4,4´-methylenebis(phenylisocyanate) (MDI), and by polycondensation reaction of xylitol with dimethyl hexamethylen dicarbamate or di-*tert*-butyl-4,4´-diphenyl methyl dicarbamate. We also describe the preparation of sugar-based polyureas by polyaddition reaction of 1,6-diamino-1,6-dideoxy-D-mannitol and 1,6-diamino-1,6-dideoxy-3,4-*O*-isopropylidene-D-mannitol with HMDI and MDI. As far as we are aware, this kind of polyhydroxilated polyureas has not previously been described in the bibliography. The new polymers were characterized by standard methods (Elemental analyses, GPC, IR, NMR). Polyurethanes were hydrolytically degradable under physiological conditions in contrast with less hydrophilic linear polyurethanes previously described[6]. The thermal properties of the novel polymers were investigated by thermogravimetric analysis and differential scanning calorimetry.

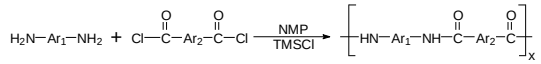
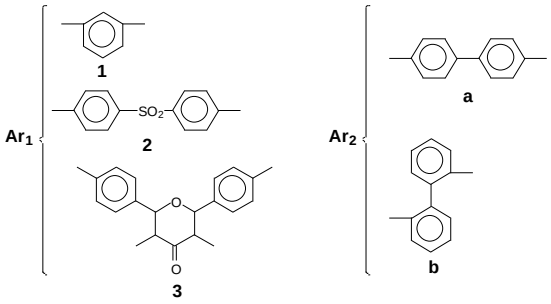
Introduction

In order to achieve materials with good properties, for advanced applications, polymers with high enough molecular weight have to be synthesized. Even though diacid chlorides are condensation monomers considered highly reactive species for the properties of aromatic polyamides, there are big differences of reactivity between monomers structurally related. It has been demonstrated that geometrical and electronic parameters can greatly affect the reactivity of diacid chlorides of varied structure against the attack of nucleophiles such as aromatic diamines.

Herein, we report the synthesis and characterization of two sets of aromatic polyamides derived from two isomeric diacid chlorides, which distinguish from each other only in their geometry: 2,2'-biphenylenedicarbonyl chloride (22BPC) and 4,4'-biphenylenedicarbonyl chloride (44BPC).



1a, 1b, 2a, 2b, 3a, 3b



Materials and Methods

2,2'-BPC and 4,4'-BPC were prepared by treating the dicarboxylic acids with thionyl chloride according to the classical procedure. Aromatic diamines were thoroughly purified. Anhydrous aprotic polar solvents and all other materials and solvents were commercially available and used as received.

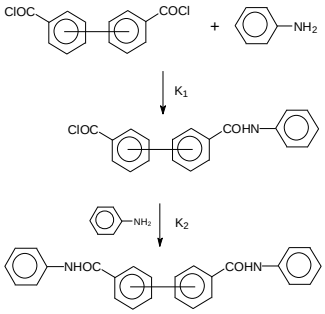
A typical polymerization reaction is as follows: a double-walled glass flask was charged with diamine and DMA under a blanket of nitrogen. After diamine dissolved, the stirred solution was cooled to 0ºC and diacid chloride was added. The mixture was allowed to react under nitrogen for 1h at 5 ºC, and then at 20 ºC for 3h. Yields were quantitative for polymers from 44BPC and over 90% for those from 22BPC.

Results and Discussion

On using the general synthetic method of solution polycondensation at low temperature, the monomers 22BPC and 44BPC were combined with three aromatic diamines, with very different chemical composition and reactivity, to obtain model polyamides.

It is also observed that the viscosities of polyamides from 22BPC were very low when compared with 44BPC.

As the formation of a condensation polymer starts with a first reaction on one edge, which could modify the reactivity of the remaining reactive group on the other one, models formed by reaction of aniline with one and two reactive group of the monomers were studied.



The charge values of the chloroformyl carbons were very similar for all the molecules. The 22DAC_aniline model showed the highest charge value.

LUMO energy differences permitted to state that 44DAC was a little more reactive than 22DAC. Also, the monoreaction process also slightly lessened the reactivity. Anyway, the LUMO energy value did not seem to give a good explanation for the low molecular weight of polymers obtained from 22DAC.

A molecular simulation using the AM1 semiempirical method was employed in order to figure out how the polycondensation reaction proceeded. It was observed that the existence of steric effects in the case of of 22DAC was the main responsible of the decrease of reactivity.

Conclusions

The molecular weight achieved in for these polyamides is strongly dependent on the geometry of the isomeric diacid used as monomer. Thus, 44BPC gave higher molecular weight polymers than 22BPC. It has been found that there are no critical electronic differences between the monomers 22BPC and 44BPC, both of them showing similar values for the energy of the lowest LUMO, however, the existence of important sterical factors affecting the amidation process seems to account for the high different reactivity against diamines experimentally found.

INTRODUCTION

The poly(amide)s use (PAs) in industrial applications, it depends largely on their properties. Special attention presents the glass transition temperature (Tg) and the solubility, this last one related to the formation of films.

In this work, diverse properties of two PAs that differ in the presence of an oxyarene unit in their structure are compared.

EXPERIMENTAL PART

Two new monomers were synthesized according to the figure 1. In this way, starting from bis(4-hidroxyphenyl)dimethylsilane (1)[1], a dinitro derivative (2) was prepared, which was reduced to the diamine respective (3)[2]. Likewise, the compound (1) originated the dicarboxylic acid (3), which presents two oxiarene units if it is compared with the monomer (4).

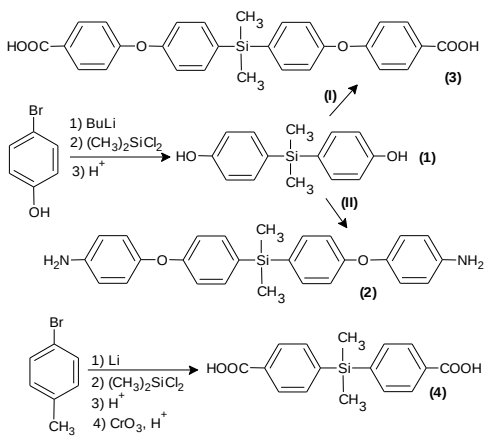

Fig. 1. Synthesys of silarylene-containing monomers.

These monomers were employed in the synthesis of two PAs, which were obtained by direct polycondensation methodology (Fig. 2). For this last, the system triphenylphosphite (TPP), $CaCl_2$, pyridine, and NMP was used.[3] Monomers and polymers were characterized spectroscopically (1H, ^{13}C, ^{29}Si NMR and FT-IR). Additionally, thermal, optic and solubility analysis to the PAs were developed.

RESULTS

Our group has published diverse works where the synthesis of condensation polymers derived from bis(4-aminofenil)difenilsilano is shown.[4] This diamine has been obtained with a yield of 40-50% and it corresponds to a stable solid of high melting temperature. However, when the phenyl groups are substituted by methyl, the obtained product is highly unstable.[5] In this work, we have obtained and characterized (Fig. 3) a derivative with the unit -$PhSi(Me)_2Ph$ - highly stable (yield = 45%, m.p. = 83-85 °C). The incorporation of the -OPh - moiety as much in the diamine as in the prepared dicid, it allowed to maintain the conjugation in the polymeric chain and to improve thermal and solubility parameters among others.

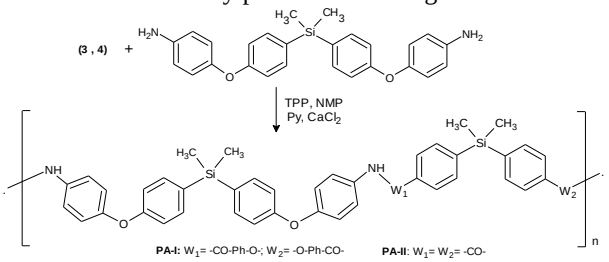

Fig. 2. Preparation of poly(amides)s.

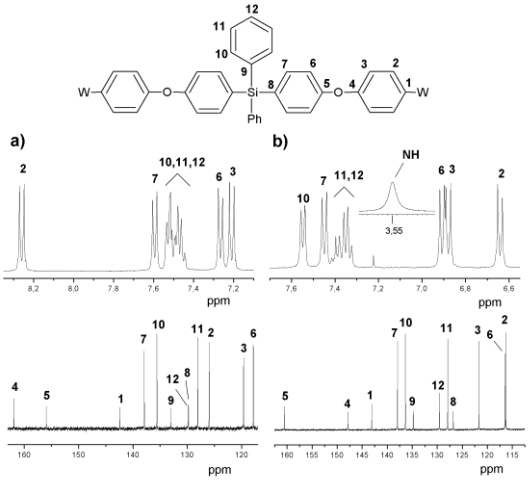

Fig. 3. NMR spectra of (a) dinitro and (b) diamine (2) compounds.

The need of maintaining human welfare in developed countries and a moral duty to increase it in developing and third world ones, has forced to our society to improve in a large scale its industrial efficiency. Thus, with regards to gas separation processes by membranes, new materials with much better productivity are greatly sought.

It is well known the existence of a trade-off between the main two parameters defining gas productivity: permeability and selectivity[1]. Albeit not many structures have been able to circumvent that limitation, in this decade the development of the as-known PIMs materials [2] and principally the thermally rearrangement, TRs, polymers have marked a milestone giving materials with outstanding properties for gas separation applications. TRs polymers are materials where a solid state thermal rearrangement from a rigid structure to another rigid one, is carried out. Thanks to this conversion, materials with very high permeability and good selectivity have been obtained[3-5].

In particular, Park et al has developed a set of new gas separation membranes based on polyimides with o-hydroxy groups which undergo a thermal change to polybenzoxazole, PBOs[3]. These new membranes are extremely efficient on separate condensable gases and CO_2. These materials are so efficient that can be compared with carbon molecular sieves but having much better mechanical properties.

However, the relationship between chemical structure and its properties as a membrane for gas separation has only been insufficiently explored up to now. In this context, this work tries to figure out the effect of isomeric monomers on the final physical and gas separations properties (Figure 1). Thus, two nucleophilic aromatic biphenyl diamines with o-hydroxy groups have been used to make polyimides with o-hydroxy groups which were characterized by a wide variety of techniques (Figure 2). Furthermore, gas separation properties were also measured.

Thermal treatment processes were carried out in order to attain TR structures and properties were compared with the goal of achieving relationships to design in a controlled way new materials with enhanced properties.

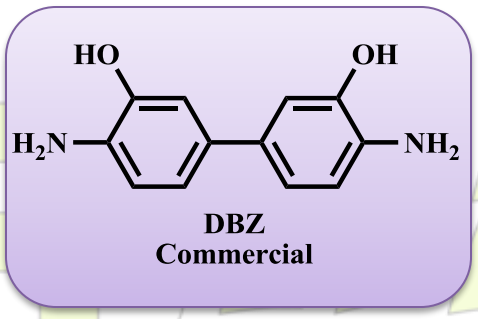

Figure 1

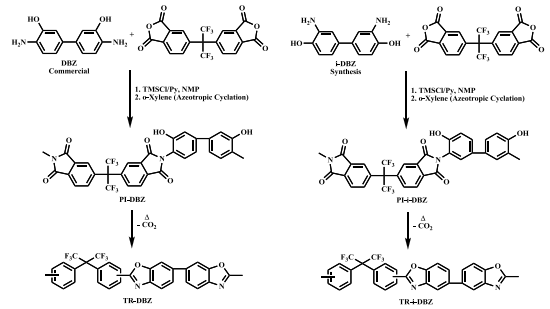

Figure 2

Also, another target of this work has consisted of finding out the differences on properties obtained by synthesizing PBOs from 3 different methods (Figure 3). It is important to assert that PBOs are mostly formed during this thermal process, and it is critical as well to explore how the rearrangement affects the material. This study could give us clues to search new structures suitable to undergo TR processes.

e-mail: ivanchev@SM2270.spb.edu

The copolymerization of tetrafluoroethylene with functional perfluorinated comonomers in aqueous emulsions was attempted in a series of recent studies [1-3].

In this report we present the analysis of kinetic features and mechanistic study of the copolymerization of these monomers in water emulsion systems.

An important condition providing a water emulsion copolymerization of the considered monomers is their preliminary dispersing according to various procedures. A conventional pre-emulsification method is found to provide copolymers with the composition remaining almost constant up to high (~85%) conversions of a functional comonomer featuring with a low reactivity.

We studied the changes in the dispersity of the initial monomer droplets and resulting polymer particles in the latex at different monomer conversions by light scattering using a Malvern Zetasizer Nano-ZS analyzer.

The dispersing of monomer droplets and polymer-monomer latex particles are found to proceed during the copolymerization.

A mechanism of elementary reactions at copolymerization is suggested upon the analysis of the solubility of the polymerization system components and the resulting copolymer in the water emulsion system.

The obtained data indicate a promising potential of water emulsion copolymerization of these monomers for obtaining a high quality copolymer useful for the production of proton conducting membranes.

Application of Pulverized concrete cement powder as filler in PVC pipe

*Muralisrinivasan Natamai Subramanian**, *Arunachalam Thamaraichelvan***

*Plastics Technology consultant
** Head, Department of Chemistry, Thiagarajar College, Madurai.

plasconsultant@hotmail.com

The use of pulverized concrete powder for the production of rigid PVC pipes has been evaluated in comparison with calcium carbonate as filler. The powdered concrete powder is formulated with PVC at rate of 2, 4, 6, 8, and 10% with other additives for processing purpose. In this article, the focus is on understanding the pulverized concrete cement powder as a substitute for calcium carbonate used in PVC formulations. Short term hydraulic, impact, tensile and elongation tests are used as techniques of choice for the evaluation of PVC pipe and concrete cement blends for mechanical and processing properties. The results are very encouraging with powdered concrete cement in comparison to calcium carbonate.

New Copolymers of Norbornene and vinyl Monomers

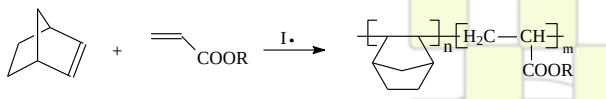
Popov D.S., Bykov V.I., Makovetskii K.L., Bermeshev M.V., Butenko T.A., Finkelshtein E.Sh.

Topchiev Institute Of Petrochemical Synthesis RAS

del87@yandex.ru

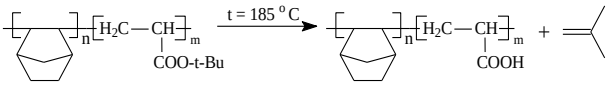
Introduction. Interest in amorphous saturated norbornene polymers is due to a complex of useful properties, including chemical and thermal stability, high transparency, low water absorption. However, additive norbornene polymers have a very rigid chain, which leads to high glass transition temperature - close to the decomposition temperature (~ 410 °C). This prevents to the possibility of their processing by conventional methods. For the same reason its films are very brittle. To reduce the chain rigidity it is necessary to introduce flexible units, such as ethylene [1, 2]. The obtained copolymers contain 45-55% of norbornene units, have a structure close to the alternant, high molecular weight and glass transition temperature, which enable their processing. They have also high transparency, low birefringence, and have good film-forming properties. Later it was shown that as a flexible link you can use the available acrylic monomers [3]. These copolymers are of interest as a matrix stabilizing semiconductor nanoparticles, and can also be used for photo-and electroluminescent devices (diodes, flexible displays, optical devices with low power consumption, solar energy converters, etc).

Results and discussion. This work provides new data on the double and triple-norbornene radical copolymerization with cheap vinyl monomers (tert-butyl acrylate, methyl acrylate and decylacrylate). Introduction of polar groups to polymers cause the range of useful properties such as increased impact strength, rheological, adhesive and barrier properties, the ability to coloring and blending with other polymers. Norbornene and its derivatives increase the rigidity of the main chain, which allowed, in particular, to obtain copolymers with higher glass transition temperatures 116-62 °C than homopolymers of tert-butyl acrylate (T = 52 °C) and methyl acrylate (T = 10 °C). The main objectives of this work were the synthesis of macromolecular copolymers (Mw> 300000) with controllable composition. As vinyl monomers have been investigated tert-butyl acrylate, acrylic acid, decyl acrylate and methyl acrylate. The synthesis of high molecular weight samples of copolymers of specified composition succeeded in carrying out the copolymerization at 30 °C by a radical mechanism, using as the initiator benzoyl peroxide. To determine the effect of the molar composition of the feed mix on a molecular weight of polymer and its composition, the copolymerization of norbornene and vinyl monomers were carried out at a ratio of 10:1, 5:1, 3:1 and 1:1.



R = H, COO^{t}Bu, CH_3, $C_{10}H_{21}$

It was found that the decrease at this ratio leads to an increase in molecular weight, but it reduces the percentage of occurrence of norbornene in the chain. The composition of the copolymers was determined by elemental analysis, in the case of methyl acrylate addition 1H NMR spectroscopy. One of the possible applications of these copolymers with functional groups are materials (photoresists) for microlithography. The use of lasers operating at 193 or 157 nm wavelengths, allows to give specified surface nanoscale relief. Photoresists in its composition must contain a readily leaving under the action of the laser beam group, usually tert-butyl.



On the example copolymer of norbornene with methyl acrylate 3:1 (choice is the ability to easily determine the content of norbornene by 1H NMR spectroscopy) were obtained the dependence yield of copolymer and content of norbornene on time and temperature of the reaction and the dependence of molecular weight on temperature.

Conclusions. A new method of radical copolymerization was successfully used to obtain copolymers with high molecular weight. Norbornene copolymers with vinyl monomers were obtained and characterized by methods of elemental analysis, 1H NMR spectroscopy, DSC, GPC and laser light scattering. Also described its's potential application as photo-and electroluminescent devices.

Macromolecular Design of Energetic Tetrazole-containing Olygomers and Polymers

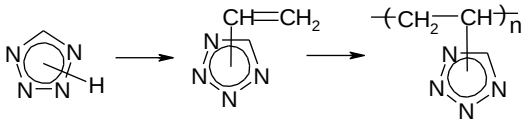
Kizhnyaev V.N., Pokatilov F.A., Vereschagin L.I., Smirnov A.I.

Department of Chemistry, Irkutsk State University

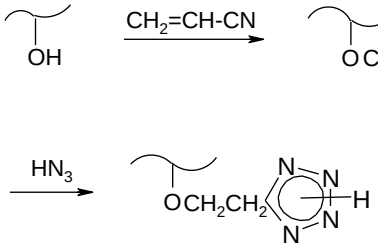
kizhnyaev@chem.isu.ru

Relative simplicity of the tetrazole fragment formation, its high reactional ability open great possibilities to the synthesis and macromolecular design of tetrazole-containing polymers. In the present work, the problems of synthesis and modification both carbon chain and hetero chain olygomers and polymers with tetrazole cycle are considered.

Polymerization method of the synthesis and macromolecular design of carbon chain tetrazole-containing polymers offer no difficulties owing to the combination of relative accessibility of tetrazole vinyl derivatives on the one part and high vinyltetrazole activity in radical homo- and copolymerization on the other part.

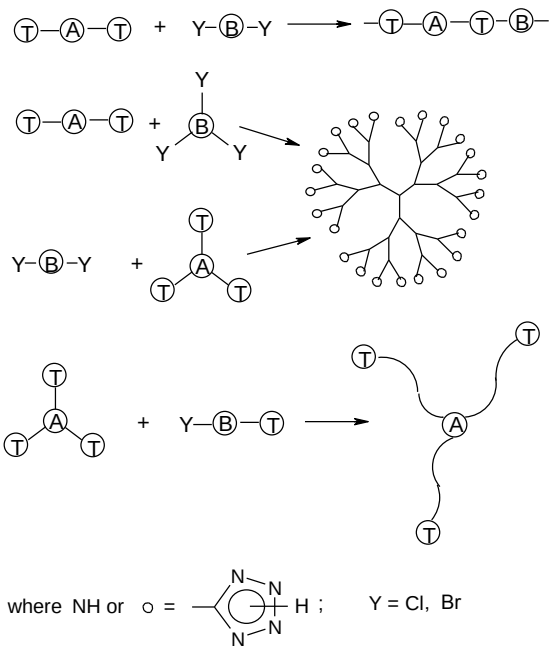


Another approach to the formation of tetrazole-containing high molecular compounds is application of azide/nitrile-"click" reaction with participation of the polymers already obtained. Apart from a well-known method to obtain poly-5-vinyltetrazole by polyacrylonitrile azidation, a wide range of low or high molecular hydroxyl-containing compounds may serve as starting substances to the method mentioned. This method includes two reactions: cyanoethylation of hydroxyl-containing compounds by acrylonitrile and azidation of the synthesizing compounds with nitrilic groups.



As the result monomer and polymer substances, containing N-H unsubstituted tetrazole fragment can be obtained.

Last circumstance gives possibility to formed olygomeric and polymeric substances of different architecture obtained by the condensable way from low molecular polytetrazoles. In case of high molecular compounds the branch and bloc polymers are formed. Alkylation reaction of N-H unsubstituted tetrazole cycle by compounds, containing halogenalkyle reactional centers is in base of these transformation. On dependence of tetrazole-containing compound functionality by polycondensed way, one can synthesize linear, branch, hyperbranch olygomeric and polymeric structures.



When using alkylation reaction various explosive groups may be inserted into tetrazole-containing polymers. It promotes to essential rise energy capacity given class of high molecular compounds.

The effect of fiber orientation on the thermal behavior of polypropylene fibers

Parviz, A. , *Dadashian, F.*

Department of Textiles,Islamic Azad University- South Tehran Branch, Tehran, Iran
Department of Textiles, Amirkabir University of Technology, Hafez Ave, Tehran, Iran

az.parviz@gmail.com

ABSTRACT: Polypropylene fibers(PP) as one of the most used synthetic fibers are treated under thermal conditions in different stages, such as production, texturizing and in some final uses.In this paper,the orientation is considered as a function of draw ratio ,they increase simultaneously. The effect of orientation on thermal behavior of PP fibers, by using Thermo Mechanical Analysis (TMA) and Differential Scanning Calorimetry (DSC) are studied.TMA results show that increase in orientation, causes increase in thermal range in which fiber has dimensional stability, although this range differs for fibers with different orientation and the best is about 104-139 ° C. DSC curve show that melting point is 161 °C for all of samples and not affected by orientation . An endothermic peak in this curve refers to the second melting point or the equilibrium melting point located around 221 ° c for fiber with most orientation and 223° C for two other samples with less orientation .

Generation of conductivity through transfer charge properties in flourene and diphenylsilane-containing poly(ester)s and poly(amide)s.

INTRODUCTION

Poly(silylene)s are compounds very important due to their potential applications and photochemical properties, which have lead to additional applications as semiconducting polymers, as photoreceptors in electrophotography and as devices that require nonlinear optical material.[1,2] Their electronic properties are associated with electron conjugation in the silicon atom. Likewise, the incorporation of a Si atom in the main chain of a polymer increases the solubility due to the reduction of the packing force and the increase of the free volume of the system. Most of the silicon-containing aromatic polymers maintain a high thermal stability due to the ionic character of the Si-C bond.[3]

EXPERIMENTAL PART

Dicarboxylic acid (3) was synthesized by hydrolysis of the dinitrile derivative (2) which was obtained from 2,7-dibromo-9*H*-fluorene (1), CuCN and $FeCl_3$ system (Fig. 1). Diacid reacted with bis(4-aminophenyl)diphenyl silane and bis(4-hydroxyphenyl)diphenylsilane for obtaining PAF and PEF respectively (Fig. 1).

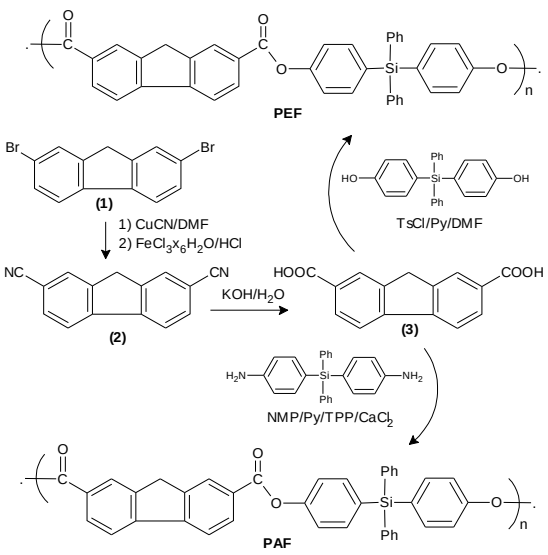

Fig. 1. Preparation of PEF and PAF.

The polymers were obtained in good yields and were characterized by IR, NMR, ESI, Raman, UV (*optical gap*), fluorescence spectroscopy, SEM-EDX, DSC and TGA. Electrical conductivity was evaluated after and before exposure to iodine vapor, utilizing polymeric films. Ellipsometric studies were used for the determination of the film thickness.

RESULTS

All polymers were successfully prepared by the direct polycondensation of the monomers. Diacid (**3**) and bisphenol was polymerized using thionyl chloride/DMF/pyridine as condensing agent to prepare PEF, and the reaction of diacid (**3**) and diamine, using TPP and pyridine, as condensing agent to prepare PAF. The influence of the reaction time on the physical and electrical properties of the polymer was studied. These compounds were soluble in various polar aprotic solvents and have moderate thermal stability. The incorporation of amide group in the chain reduces the Tg based on free surface effect. The time and temperature of crystallization was related with the morphology assumed by the polymeric chain.

Preliminary conductivity measurements showed adverse effects when oxidation of the polymer films is induced, these effects being related to a certain grade of disorder within of the systemor due to a structural change.

Table I. Conductivity of the polymers with and without doping to different reaction time and thickness.

	Time[a]	Film[b]	Without[c]	With[d]
PEF	2	2744 (±) 250	2.15	1.30
PEF	12	2805 (±) 250	3.30	1.44
PAF	3	2763 (±) 250	4.63	1.54
PAF	12	5877 (±) 250	1.90	7.70
PAF	12	2576 (±) 250	2.38	1.90

[a] Polymerization time (h), [b] Thickness of film (Å), [c,d] conductivity without and with doping respectively.

Barrier Performance of Gelatin Coated PLA Films

Mercedes Leobono, Cristina Frova, Ruth Zacur, Daniel Ercoli, Graciela Goizueta

Planta Piloto de Ingeniería Química, PLAPIQUI (UNS-CONICET)
Camino La Carrindanga Km 7 – Bahía Blanca (8000) - Argentina

dercoli@plapiqui.edu.ar

Introduction: Most commercial films for food packaging applications requiring high barrier to oxygen and water vapor are made of multilayer structures of oxygen barrier polymers such as poly(ethylene-co-vinyl alcohol) and other polymers which provide useful mechanical properties and moisture-proof layers (polypropylene, polyethylene, polystyrene, etc.) (1,2). Due to the increasing need of minimizing environmental effects associated with polymers from fossil fuels, the development of environmentally benign plastics has attracted much of attention. One of the most promising candidates for this purpose is Poly(lactic acid) (PLA), a linear thermoplastic polyester produced from renewable resources (whey or corn) and biodegradable in compost (3). Particularly among proteins gelatin is cheap and abundant. Its good film forming characteristics, extremely high barrier to oxygen and inherent biodegradability make it a very attractive candidate to be considered as a coating material for PLA. Performance of PLA films coated with pure and glycerol plasticized gelatin are presented in this work in terms of their Oxygen (OP) and Water Vapor Permeability (WVP), mechanical and friction properties.

Materials and Methods: PLA (Mw≈140000, D% <1.5 wt %), Gelatin (practical grade) and Glycerol (analytically pure) were used as raw materials. Dried PLA was press moulded and films (≈100 μm) were obtained. Gelatin solutions were prepared dissolving 10 g of gelatin in 100 ml of water. For plasticized gelatin coatings 5 g of glycerol was also added. Coatings of PLA with pure and plasticized gelatin were obtained using a Bird applicator and allowing further evaporation of water at ambient conditions. Before proceeding with properties characterization the films were stored in a controlled-environmental chamber at 25ºC and 50%RH for several days. Table 1 shows the composition of each sample prepared. The thickness of films before and after coating was measured at different points with an inductive probe (Millimar) and the average was taken. Wetting tension of PLA films was determined using ASTM D2578. Films OTR were measured in an Ox-Tran 2/21 (Mocon) at 23ºC and 0%RH exposing PLA side of coated samples to the carrier gas (nitrogen) and the gelatin side to the test gas (oxygen). The WVTR was measured according to the desiccant method detailed in ASTM E96. Samples were sealed to the open mouths of acrylic test dishes containing dried calcium chloride and placed in a chamber under controlled atmosphere at 50 %RH and 25ºC. The weight of cells against elapsed time was plotted for at least 7 days. The slope of the linear portion of this curve is the rate of water vapor transmission (w/t). All tests were carried out in at least three repetitions for OTR and WVTR determinations. Static coefficients of friction (COF) and tensile stress-strain behavior at 25 mm/min were assessed in an Instron 3369. A minimum of ten samples were tested and the average values of Elastic Modulus (E) and Elongation at Break (Elb) were calculated.

Results and Discussion: Films of PLA showed good transparency and a high wetting tension ≈42 dyn/cm. It resulted in a very good adhesion and uniformity of gelatin coatings onto PLA surface. The average thickness of coatings was about 3–4 μm and did not affect optical properties of base PLA films. The use of glycerol as a plasticizer for gelatin improved its processability onto PLA surface and reduced its brittleness when dried. Static COF and mechanical properties of PLA with and without coatings are included in Table 1. COF values of coated films increased 2.5 times from that of uncoated PLA which could also be related to the greater surface rugosity observed. Elastic modulus (E) and Elb values of coated and uncoated films did not differ significantly from each other, meaning that the thin coating did not affect the base film mechanical performance. Moreover PLA films were fragile and would need to be plasticized in order to improve its ductility.

Table 1.Samples, Friction and Mechanical Properties

Film Sample	Coating		COF	E [MPa]	Elb [%]
	Gelatin	Glycerol			
PLA	NO	NO	0.13	2666	2.8
PLA/G	YES	NO	0.35	2700	3.6
PLA/GG	YES	YES	0.32	2640	3.5

OP and WVP results are shown in table 2. In earlier studies we have shown that OP for pure and plasticized gelatin films was ≈1 and 1.4 cc.mil/m^2.day respectively (4). The application of such an excellent oxygen-barrier coating led to a significant improvement of ≈75% in oxygen barrier performance of PLA base films. Meanwhile WVP values of PLA films were not significantly affected when coated.

Table 2.Oxygen (OP) and Water Vapour Permeabilities (WVP)

Film Sample	OP [cc.mil/m^2.day]	WVP [ng.m/m^2.s.Pa]
PLA	1036	0.015
PLA/G	228	0.017
PLA/GG	273	0.015

Conclusions: Pure and plasticized gelatin coatings onto PLA films produced a significant improvement in its oxygen barrier without modifying the WVTR. Although mechanical performance of PLA films is not affected by the presence of coatings, the coefficient of friction of coated films increased significantly.

Polypropylene Films of High Oxygen and Water Vapor Permeability for MAP Applications

Mariela Acosta, Daniel Ercoli, Graciela Goizueta, Jorge Lozano, Numa Capiati

PLAPIQUI – UNS – CONICET, Bahía Blanca, Argentina

dercoli@plapiqui.edu.ar

Introduction: Harvested plant products respire and transpire continuously, consuming oxygen (O_2) from the surrounding environment and producing carbon dioxide (CO_2) and water vapor [1]. The aim of modified atmosphere packaging (MAP) is to reach the most suitable storage atmosphere of a given product minimizing the time required to achieve it. This objective can be reached by matching the respiration rate of the packaged produce and the gas exchange through the plastic film [2]. An attractive way to obtain new materials with tailored properties for MAP applications is the blending of different polymer species [3].

The objective of this work was to develop Polypropylene (PP) based films for packaging of fresh produce. Particularly, we were interested in studying the effects of the addition of an elastomeric Polyethylene co-octene (POE) of high permeability to oxygen and water vapor to PP. The effects of blend composition as well as the mixing and processing conditions on blend permeabilities, mechanical properties and morphology were analyzed.

Materials and Methods: A commercial grade of PP (MFI 8 g/10min) and POE (MFI 1.0 g/10min) were used to obtain press molded and blown films. Blends of PP with 20, 30 and 40 wt% of POE were prepared in a counter rotating batch mixer (Brabender) at 205 or 215 °C and at 50 or 80 rpm. Films samples were obtained by two different procedures: in a hydraulic press at 205 °C (thickness ≈100 μm) and in a PP blowing machine (thickness ≈35 μm). The morphological aspects of the press and blown films were studied by scanning electron microscopy (SEM) using a LEO EVO 40XVP microscope. The oxygen permeability coefficient (OP) was measured in a Mocon Ox-Tran 2/21 at 23 °C and 0 %RH using a standard method (ASTM 3985). The water vapor permeability coefficient (WVP) was measured gravimetrically according to the desiccant method detailed in ASTM E96 at 25 ºC and 50 %RH. Tensile stress-strain behavior of film samples was determined in an Instron 3369 machine at 23 °C and 50 %HR for elastic modulus (E) and tensile elongation at break (%El_b) determinations.

Results and Discussion: SEM micrographs of press molded films showed a spherical and homogeneous POE phase distribution in the PP matrix through the whole transverse area of the film, irrespectively of the composition or blending conditions. Figure 1a shows as an example, a micrograph of a blend with 20 wt% of POE. Moreover, the sizes of domains increased when the content of POE in the blends increased. Blown films micrographs showed that the POE domains had different sizes when the surface of fracture was made in the machine (MD) or transverse direction (TD). For TD fractures domains were spherical, meanwhile MD fractures showed elongated domains (Figure 1b). These effects indicated that forces in MD and TD were unbalanced, being higher along MD.

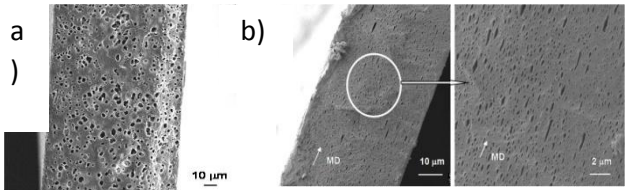

Figure 1. SEM micrographs of press molded film (a) and blown film (b) with 20 wt% of POE

It was found that in both series of blends OP and WVP increased mainly with POE content. This behavior could be directly attributed to the more permeable characteristics of POE.

For a given amount of POE, the OP or WVP of press molded films were higher than those of the corresponding blown films. For example, OP for a press moulded film of a blend with 40 wt% POE was about 175 % higher than that of pure PP film, meanwhile for the blown film the increase was about 55 %. These results could be mainly assigned to the morphological differences observed between blends obtained by both procedures.

All the blends studied showed E values lower than pure PP and a higher %El_b due to the elastomeric characteristics of POE. For example, blends with 40 wt% of POE exhibited the maximum decrease in E, being almost half the value for neat PP.

Conclusions: The addition of POE to PP is a valuable way for obtaining PP based blends with higher oxygen and water vapor transmission rates. Both permeabilities were found to be dependent mainly on the POE content and the morphology of the blends. Moreover, press molded and blown films exhibited good mechanical properties which were in the range of commonly used flexible packaging materials.

Abstract

Triphenylamine has a good electron-hole conductive property; so many scholars used triphenylamine derivatives as a hole-conductive material. The structure of triphenylamine has characteristics of photoluminescence or electroluminescence through intermolecular charge transfer, it can be combined with other materials to form a novel photoluminescence (fluorescent) material [1-2].

Hydrogel, a 3-D crosslinked network, can swell but does not dissolve in aqueous solutions [3]. Hydrogels have stimuli-responsive properties, which would be affected by the change of surrounding conditions such as temperature, pH value, ionic concentration, or electric field, etc. All of these can alter their swell ratio, volume, and drug release behavior [4]. When a hydrogel is introduced into a triphenylamine structure, the hydrogel can exhibit photoluminescence or electroluminescence characteristics. These functional polymers or their devices can be used in many practical applications such as light-emitted tracer or synthetic chemical sensors.

A novel photoluminescence monomer as crosslinker, dimethacryloyloxy ethylene oxycarbonyl triphenylamine (DMETPA), was synthesized firstly. Then, the composition and yield of two series of thermosensitive hydrogels based on NIPAAm using different crosslinkers DMETPA (N-TPA series) and EGDMA (N-EGDMA series) as Table 1 were prepared by UV-irradiation polymerization.

The appearance of the N-TPA series hydrogels shows yellow turbid opaque, but the N-EGDMA series hydrogels shows white translucent as Figure 1. Under UV irradiation, the hydrogels crosslinked with DMETPA exhibit blue fluorescent, but the hydrogels crosslinked with EGDMA does not have a photoluminescence effect as Figure 1. Moreover, the maximum PL emission of N-TPA hydrogels appeared around 458nm, the fluorescence intensity increase with increasing DMETPA content, but for the gels crosslinked with EGDMA exhibits no fluorescence.

The swelling ratios decreased with increased amount of crosslinker in the hydrogel. This is because the crosslinking density of the hydrogel increases with increasing amount of crosslinker, resulting in denser structure in the hydrogels, so the water does not easily enter into the hydrogels. However, comparing N-TPA3% gel and N-EGDMA3% gel, we find that the swelling ratios of the hydrogel containing DMETPA is significantly lower than the hydrogel containing EGDMA. This is because DMETPA bears triphenylamine structure; its hydrophobic property is stronger than the EGDMA structure. So the swelling ratios for the N-TPA series hydrogels are lower than those of the N-EGDMA series hydrogels, that is, the trend of swelling ratios for the hydrogels is N-EGDMA3% > N-EGDMA6% > N-TPA3% > N-TPA6%.

When the hydrogels were attained to equilibrium swelling ratio, the mechanical properties were measured with uniaxial compression by Universal Tester. The results indicate that the shear modulus (*G*), Young's modulus (*E*), and the effective crosslinking densities (ν_e) of the hydrogels increase with an increase of the content of crosslinker. The reason is that the gel structure becomes denser when the crosslinker amount increases, that results from effective crosslinking densities increase, hence, the values of *G*, *E*, ν_t and ν_e all increase. But the molar mass per crosslinked unit (M_c) decreases due to $M_c \propto 1/\nu_e$. Hence, M_c values decrease with increasing of the crosslinker amount.

Introduction: Recently, there has been a surge of interest in lead sulfide (PbS) nanostructured films because of their potential applications in optoelectronic devices. PbS has a large exciton Bohr radius of 18 nm and hence it exhibits strong quantum size effects. Their absorption edge can be tuned to anywhere from nearinfrared to visible [1]. For this reason, nanostructured PbS films are emerging materials for multilayer photovoltaic devices [2]. The objective of the present work is to develop an inorganic/organic heterojunction photovoltaic cell composed of size-quantized PbS and poly[2-methoxy-5-(2'-ethylhexyloxy)-p-phenylene vinylene] (MEH-PPV) layers deposited on indium tin oxide (ITO) coated glass substrate. PbS is used as an electron-transporting layer and MEH-PPV conjugated polymer is used for hole transport. **Experimental:** Aqueous solutions of lead acetate trihydrate (PbAc) and triethanolamine (TEA) were mixed in order to prepare PbAc-TEA complex. An aqueous solution of thiourea was then added into the PbAc-TEA complex solution and liquid ammonia was added into the resulted solution for complex decomposition. The ITO substrate was then inserted vertically and after 1 hour, a thin layer was deposited on the ITO surface. A viscous solution of MEH-PPV was prepared in toluene then deposited on this PbS layer using spin coating technique. Aluminum cathode was finally deposited on the heterojunction by thermal evaporation. **Results & Discussion:** Thickness and surface parameters of PbS nanostructured layers were characterized by AFM. It was found that these layers were highly uniform and show a porous network of PbS nanoparticles of around 11nm in size (Figure 1(a)). Film thickness (measured from Figure 1(b)) was uniform and was around 400nm. The composition of PbS film layer was characterized by XRD. The peaks shown in Figure 2 were identified to be those of cubic PbS. The average grain size estimated by the 'Scherrer equation' was around 11 nm, approximately the same as that measured by AFM. XPS was carried out in order to study the surface stability of PbS layer (Figure 3). It was observed that the surface of PbS layer is highly stable and there is no evidence of PbO phase (no surface oxidation). Figure 4(a) shows the optical absorption spectrum of the heterojunction. MEH-PPV layer absorbs strongly around 589 nm and after formation of junction with PbS layer, the total absorption shifted more towards the visible region. Total absorption of the device cell shows a band gap of around 1.65eV (Figure 4(b)). Figure 5 shows the voltage/current (I-V) characteristics of the developed heterojunction ITO\PbS\MEH-PPV\Al cell. Light power conversion under AM1.5 spectral conditions at 100 mW/cm^2 was around 0.39%.

Introduction.

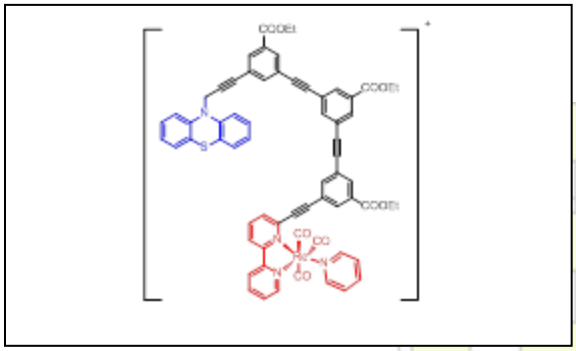
Photoinduced long-range electron transfer (ET) plays a key role in artificial photosynthesis,[1-4] and optoelectronic devices.[5] The design of molecular systems for artificial photosynthesis and optoelectronic devices, that are capable of moving charge efficiently over long distances through molecular bridges, requires a fundamental understanding of ET in donor–bridge–acceptor (D-B-A) systems. Critical to all of these systems is the precise control of ET rates of long distances.

D-B-A complexes allow systematic investigation of parameters that control these ET processes. Previous studies of ET in D-B-A complexes showed that highly π-conjugated systems such as oligo(phenylene vinylenes),[7] oligo(fluorenes),[8] and oligo(para-phenylene ethynylenes)[9,10] as attractive materials. While there are numerous studies on D-B-A complexes para-phenylene ethynylene systems, [9,10] to the best of our knowledge, there is only one report of ET through conjugated chains of oligo(meta-phenylene ethynylenes) where organic compounds are used as electron acceptor and donor.[11] This is likely due to a combination of their time-consuming synthesis as well as a less conjugated structure that disfavors wire-like behavior. Despite these potential drawbacks, these systems possess many attractive qualities. Their relative flexibility allows for ET *via* through-space contacts and may favor efficient forward ET over charge recombination.

Here we report the synthesis and photophysical properties of the first D-B-A complex based on a transition metal derivative, rhenium tricarbonyl diimine, linked *via* oligo(meta-phenylene ethynylene) bridge to phenothiazine.

Materials and Methods.

Synthesis and Characterization. D-B ligand was constructed in a stepwise approach using zinc-mediated palladium-catalyzed cross-coupling reactions in a microwave reactor and protecting group strategies. The D-B-A complex (Scheme 1) was obtained by metalating the D-B ligand. The chemical structure of the complex was confirmed by nuclear magnetic resonance and mass spectroscopy. Steady-state and transient emission spectroscopy were employed to investigate the photoinduced electron transfer properties of the D-B-A.



Scheme 1. Chemical structure of D-B-A

Results and Discusion.

Emission Properties. The steady-state emission spectrum of the D-B-A complex in dichloromethane solution has a broad band centered at 575 nm, which is characteristic of metal-ligand-charge-transfer emission of Re(I) complexes. Time-resolved emission spectroscopy was used to characterize the metal-to-ligand charge-transfer excited state of the D-B-A complex. The luminescence showed monoexponetial decay with reduced lifetimes compared to the reference compound, Re (I) $(CO)_3$(bipyridine)(pyridine). This suggests quenching attributed to phenothiazine → *Re ET. Rate constant for the electron transfer reaction is calculated as 1.8×10^5 s^{-1}.

Excited-state Electron Transfer. Deactivation of the D-B-A likely occurs through a combination of intermolecular and intramolecular ET processes. The rate of intermolecular ET and intramolecular ET were determined as 1.1×10^6 M^{-1} s^{-1} and 6×10^4 s^{-1}, respectively.

Conclusions.

A new D-B-A complex, where a rhenium tricarbonyl electron acceptor is linked *via* an oligo-*m*-phenylene-ethynylene bridge to a phenothiazine donor, was prepared. A combination of steady-state and transient emission spectroscopy indicate the D-B-A undergoes photoinduced long range ET.

Synthesis and Photopolymerizations of New Hydrolysis-Stable Dental Monomers Containing Phosphonic Acids

Burçin Akgün, *Duygu Avci*

Department of Chemistry, Bogazici University 34342 Bebek Istanbul Turkey

avcid@boun.edu.tr

Introduction:

Monomers with phosphonic, mono- or dihydrogenphosphate or carboxylic acid groups have been synthesized and used in dental composites and dentin adhesives (1,2). These groups increase biocompatibility and adhesion to tooth by chelating with calcium in the tooth. However, monomers generally contain ester linkages which causes a serious problem due to hydrolysis under acidic conditions (3,4).

In this study, new phosphonated monomers that do not contain hydrolytically instable ester bonds have been designed to improve stability of dental materials. Besides hydrolytic stability, the synthesized monomers are expected to have other properties such as high rate of homo- and copolymerization, low polymerization shrinkage and high mechanical properties.

Materials and Methods:

Monomer and polymer characterization involved FTIR, ^{1}H-, ^{13}C-, ^{31}P-NMR. The photo-polymerizations were performed using a photo differential scanning calorimeter. Representative monomer synthesis is given below.

Synthesis of monomer **1a**

To a solution of diethyl 1-aminomethylphosphonate (0.099 g, 0.59 mmol) and anhydrous pyridine (0.047 g, 0.59 mmol) in 1.13 mL of dry dichloromethane, 2-(2-chlorocarbonyl-allyloxymethyl)-acryloylchloride (0.0598 g, 0.268 mmol) was added dropwise in an ice bath under N_2. After stirring overnight at room temperature, 5 mL of chloroform was added and the solution was extracted with water (2x2 mL), 2M HCl (2x3 mL), 2M NaOH (2x 3 mL) and brine (3 mL). After drying the organic phase with anhydrous Na_2SO_4, the solvent was evaporated. The yellowish viscous product was obtained in 67% yield.

Synthesis of **2a**

TMSBr (0.43 g, 2.78 mmol) was added dropwise to a solution of monomer **1a** (0.2245 g, 0.463 mmol) in 2 mL dry dichloromethane in an ice bath and under N_2. Then the solution was refluxed for 4 hours at 40 ^{0}C. After evaporation of the solvent, methanol was added and the mixture was stirred at room temperature overnight. The methanol was evaporated and the residue was washed with chloroform.

Results and Discussion:

The monomer synthesis involved the following steps: i) synthesis of TBEED from the reaction of t-butyl acrylate and paraformaldehyde in the presence of 1,4-diazobicyclooctane as catalyst, ii) conversion to acid by cleavage of t-butyl groups using trifluoroacetic acid, iii) conversion to acid chloride by using oxalyl chloride iv) reaction of the acid chloride and diethyl 2-aminoethylphosphonate and diethyl 1-aminomethylphosphonate to give monomers **1a** and **1b**, v) hydrolysis of phosphonate groups using trimethylsilyl bromide to give monomers **2a** and **2b** (Figure 1).

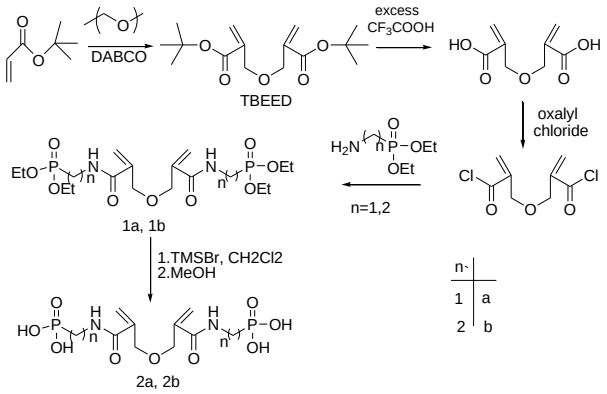

Figure 1. Synthesis of phosphonated-monomers.

Monomers were obtained in good yield as pure products. ^{1}H-, ^{13}C-, ^{31}P-NMR spectra confirmed the structure of the monomers. Phosphonated monomers **1a** and **1b** showed high crosslinking tendencies during thermal bulk and solution polymerizations. The homopolymerization and copolymerization behaviors of these monomers were also investigated with ethyl 2-hydroxy methacrylate (HEMA) using photo differential scanning calorimeter at 40 ^{0}C with 2,2'-dimethoxy-2-phenylacetophenone as initiator. Rate of polymerization of these monomers were found to be higher than TBEED.

Monomers **2a** and **2b** were found to be soluble in water and ethanol which is important for dental applications.

Conclusions:

Four novel monomers containing phosphonate or phosphonic acid groups have been prepared. The hydrolytic stability, binding efficiency and copolymerization studies of these monomers with HEMA and Bis-GMA are continuing.

yilser@gmail.com

Fuel cells are one of the most promising alternative power sources, with efficiencies of up to 60%, higher energy densities relative to batteries, and the ability to operate on clean fuels while producing no pollutants. Among fuel cells, Proton Exchange Membrane (PEM) Fuel Cells have received particular attention as a possible mobile electrical power source with high energy density. Proton exchange membrane is the key component of the PEM fuel cell for transferring protons from the anode to cathode as well as providing a barrier to the fuel gas cross-leaks between the electrodes.

Nafion is the PEM material most frequently used for this type of application because of its high proton conductivity, excellent mechanical properties, good chemical stability and commercial availability. However, the high cost, low stability at high temperatures, low conductivity at low humidity or high temperature limits the extent of its further application. Several approaches have been used to overcome this problem, such as the use of nanometer size inorganic filler in the Nafion matrix. The results showed that the modification of the polymer host membrane by the incorporation of hygroscopic oxides, such as ZrO_2, SiO_2, and TiO_2 particles, into Nafion has effectively extended the working temperature range. The inclusion of inorganic fillers improves the mechanical properties, the membrane water management and also contributes to inhibiting the direct permeation of reaction gases by increasing the transport pathway tortuousness.

Among the inorganic materials used in this field, TiO_2 and SiO_2 nanoparticles is good candidate as hydrophilic filler for the polymer membranes because it helps to maintain a suitable hydration of the membrane under fuel cell operating conditions, and the mechanical properties are improved.

In the present study, Nafion/Titanium Silicon Oxide ($TiSiO_4$) nanocomposite membranes for use in PEM fuel cells were investigated. Composite membranes were prepared using the recasting procedure and membrane thickness around 80µm was obtained from 10 wt.% $TiSiO_4$ loading. Nafion/$TiSiO_4$ nanocomposite membranes characterized by FTIR, thermal analysis, water uptake, XRD, SEM, EDS analysis and single cell performance. The introduction nanometer size $TiSiO_4$ supplies the composite membrane with a good thermal resistance and electrochemical performance. The physico-chemical properties studied by means of scanning electron microscopy (SEM) and X-ray diffraction (XRD) techniques have proved the uniform and homogeneous distribution of $TiSiO_4$ and the consequent enhancement of crystalline character of these membranes.

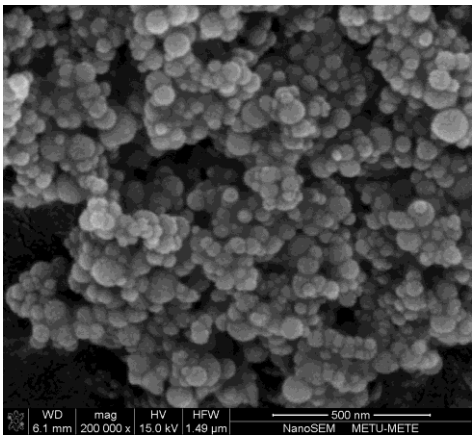

Figure 1. SEM image of $TiSiO_4$

The energy dispersive spectra (EDS) analysis indicated that the distribution of $TiSiO_4$ on the surface of the composite membrane was uniform. The membranes were tested in a single cell with a 5 cm^2 active area operating at 70 to 120°C. The results show that Nafion/ $TiSiO_4$ are promising membrane material for possible use in proton exchange membrane fuel cells.

Effect of processing conditions on the performance of polymer-based materials for biomedical applications.

Introduction: Biocompatible polymers like polycaprolactone (PCL) and polyvinylalcohol (PVA) have several interesting properties that make them very interesting for biomedical applications; nevertheless many of them depend of the processing method.

In the case of wound dressing, the incorporation of nancoclays into PCL improves mainly the barrier [1] and mechanical properties [2]. This enhancement is strongly related with the clay dispersion degree [3]. The properties of PVA cryogels mostly depends on the crosslinking [4] and crystallinity degree [5]. On the other hand, it is still unclear the role that processing variables, such as the numbers of freezing/thawing (F/T) cycles, the cycle extent, the freezing temperature, , the polymer concentration and its molecular weight (*Mw*) play on the significant properties of the material.

The aim of this work was to analyze the effect of processing variables on the improvement of specific properties of of PCL-clay and PVA-hydrogel to be used as wound healing.

Materials and Methods: PCL-clay nanocomposites with 5 wt.% of organo-modified clay (Cloisite 20A, C20A, Southern Clay Inc.) were prepared by melt-intercalation in a micro-double-screw extruder DSM Xplore. The effect of processing conditions was analyzed by changing the residence time (2, 3 and 4 min), the temperature profile along the barrel ([60,80,100]°C; [60,90,120]°C; [70,100,130]°C) and the screw rotation speed (50, 100 and 150 rpm) . Materials were characterized by Differential Scanning Calorimetry (DSC): crystallinity (X_{cr}) and melting temperature (T_m) and by Gas Permeation Chromatography (GPC) to study the possible reduction of *Mw*. Then, films 0.5 mm thick were prepared by compression moulding and characterized by static tensile tests.

PVA-hydrogels were obtained from a aqueous solutions of 5, 10 and 15wt.% of PVA with different *Mw* (18000, 40500, 93500 and 155000) purchased by Sigma-Aldrich were prepared in distilled water at 85ºC for 4 h under constant stirring. Once the solutions were at room temperature, they were placed in ant adherent container and frozen (-18ºC) for 1, 12 or 24 h, then left at room temperature (25ºC) for the same times; cycle was performed 1 to 4 times. These obtained hydrogels were characterized by Thermogravimetric Analysis bound water content and degradation temperature and DSC: X_{cr} and T_m . Moreover, swelling behaviour, gel fraction (*GF*) and tensile properties were also determined.

Result and Discussion: The stiffness as well as the tensile strength and the deformation at break, of PCL and nanocomposites, were not substantially affected by processing conditions. Changing the extrusion parameters also had a negligible effect on the *Mw* and the X_{cr} of the matrix. It has been found [6] that shear forces in the melt-preparation of polymer layered silicates nanocomposites facilitate the brake-up of large sized agglomerates, whereas the extent of further exfoliation of the mineral layers is determined by the compatibility between the matrix and the mineral layers rather than by shear forces.

The strength and swelling ratio of the PVA-hydrogels were a function of the PVA concentration, the number of F/T cycles and *Mw*. As the number of F/T cycles, *Mw* and polymer concentration increased; the X_{cr} and *GF* increased too.

Conclusions: In the case of PCL-nanocomposites, the final properties will be strongly dependent on the clay dispersion degree. Once good polymer/clay compatibility is achieved, intense shear forces during processing (avoiding polymer matrix degradation) may accelerate the formation of the final clay morphology by breaking up large sized agglomerates but changing processing parameters will not modify the extent of clay dispersion.

For PVA-hydrogels an increment on the mechanical properties as a function on F/T cycles, *Mw* and polymer concentration were found. The results can be attributed to higher X_{cr} and crosslinking density. The repeated cooling and thawing back the hydrogel results in the formation of a stable three-dimensional network held together by crystals; the stability of the structure is reinforced by an increasing number of F/T cycles [7-8].

The obtained results suggest that it is possible to obtain polymers with controlled properties and to be optimist about their future use as wound dressing.

jimena.gonzalez@fi.mdp.edu.ar

Introduction: The crosslinking method, based on freeze and then thaw (F/T) solution of Poly vinyl alcohol (PVA) several times, results in the formation of crystallites that serve as physical crosslinks making a three-dimensional network [1-2] that become the material insoluble in water. PVA molecules are aggregated during ice formation and hydrogen bonding is established between molecular chains. By increase the number of F/T cycles, residual free molecular chains are successively included in linking zones [3]. On the other hand, the glass transition temperature (T_g) of these kind of materials sharply decreases with the water content [4].

Heat treatments above the T_g [1-2] as well as repeated F/T cycles, are also used to achieve the same results mainly by increasing the amount of crystals of the polymer, which act as a physical crosslinkers of the network. When PVA films are annealed at constant temperature (between T_g and the melting temperature; T_m), the macromolecular chains have enough mobility to align themselves and fold to form crystals [2]. It is well known that the increasing in the polymer crystallinity degree (X_{cr}), results in a more resistant material [5].

The aim of this work was to investigate the effect of the annealing temperature over the structural and swelling characteristics of the PVA hydrogels obtained by F/T technique.

Materials and Methods: PVA hydrogels were obtained from a aqueous solutions of 10 wt.% of PVA (Mw 40500 g/mol, Sigma-Aldrich) were prepared in distilled water at 85ºC for 4 h under constant stirring. Once the solutions were at room temperature, they were placed in ant adherent mold and frozen (-18ºC) for 12 h, then left at room temperature (25ºC) for the same time; this cycle was repeated for 3 times. Then, dried (37ºC, 24 h) PVA hydrogel samples were annealed at different temperatures: 100, 110, 120, 130 and 140ºC in an oven for 1 h. These temperatures were selected because they were over the water evaporation temperature, and between the T_g and the T_m of the polymer. Hydrogels were characterized by Differential Scanning Calorimetry (DSC), to obtain T_g , T_m and X_{cr}; Scanning Electron Microscopy (SEM) to observe the porous structure, Thermogravimetric Analysis (TGA) to obtain the bound water content (*BW*). Moreover, swelling behavior (Equilibrium swelling degree, M_t and Thickness change, *TC*) in saline solution and gel fraction (*GF*) were also studied.

Results and Discussion: The porous of PVA hydrogles showed a wide distribution; the average size was 0.51± 0.22 µm. **Figure 1** shows the changes on T_g as a function of annealing temperature (AT). **Table 1** displays the main characteristics of hydrogels as a function of the heat treatment applied.

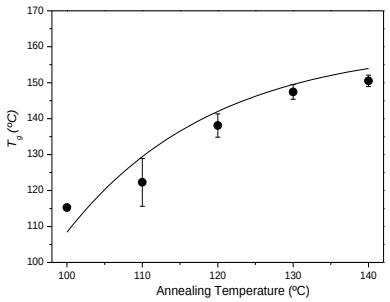

Figure 1. Effect of AT on the T_g

Table 1: Main characteristics of PVA hydrogels as a function of AT.

AT ºC	X_{cr} %	M_∞ %	BW %	GF %	TC %
none	28.8±8.9	186.2±2.2	9.5	44.7±0.1	142.3±32.8
100	33.2±4.1	194.6±9.4	7.8	63.9±1.4	100.3±6.7
110	52.2±1.9	177.7±10.2	*	77.3±1.7	*
120	34.7±3.6	146.3±5.2	7.2	83.5±2.1	85.57±13.9
130	38.6±1.9	109.6±9.4	6.9	96.3±4.4	*
140	42.7±5.2	70.7±6.0	7	98.1±1.0	43.6±10.2

* It was not possible to measure

T_g increasing exponentially with annealing temperature. T_g is related to the crosslinking degree and with the plasticize content, so that, the previous result can be attributed to a raise on the crosslinks and a decrease on water content (bound and unbound) [6]. According to that, GF increases and BW decreases.

It can be observed that the thermal annealing of PVA hydrogels have a direct influence on relevant hydrogels characteristics. Both, the X_{cr} and the T_g, which are measurements of crosslinking degree, increased as a function of the annealing temperature. Moreover all the most important properties of the hydrogels were influenced by these changes: the maximum swelling degree, the *TC* and the *BW* decreased whereas the *GF* increased as a function of AT. An exponential relationship between the main characteristics *GF* and X_{cr} was found. All these result were independent of the polymer concentration.

Conclusions: The obtained results indicate that PVA-hydrogels with desired characteristics can be obtained by means of a thermal treatment.

Highly-Ordered Nanoporous TiO_2 Films with Hierarchical Order directed by Self-Assembly

*Wonho Kim, Su Yeon Choi, Young Chan Kim, Seung Hyun Kim**

Division of Nano-Systems Engineering, Inha University, Incheon 402-751, South Korea

shk@inha.ac.kr

Introduction: Self-assembly has well been established as promising alternative to fabricate well-ordered nano-structures and nanoscale devices. Block copolymers, one class of self-assembling materials, have shown that they can be effectively utilized as templates and scaffolds for nanofabrication.[1] Furthermore, combining with chemical contrast between components enables block copolymer self-assembly to guide the formation of inorganic nanomaterials with well-defined structure that otherwise would be hardly produced. On the other hand, colloidal particles are also well-known to spontaneously produce crystal arrays with two- or three-dimensionally periodic lattices of monodisperse colloidal spheres,[2] providing opportunity for wide range of applications including photonic/electronic devices, nanoporous materials for catalyst supports, sensors, data storage media, and nanolithography.[3] However, self-assembly of one class can only produce simple pattern with regular periodicity, and highly-ordered colloidal crystals composed of particles of sub-100 nm diameter are very difficult to achieve via self-assembly.[4] In our work, two self- assembling materials are sequentially combined to produce nanoporous TiO_2 films with well-defined yet hierarchical order.

Materials and Methods: Polystyrene-*b*-poly (ethylene oxide) (PS-*b*-PEO) diblock copolymer having the molecular weight of 30,000 g mol^{-1} with 77 wt% PS was purchased from Polymer Source Inc., and used as a structure-directing agent. Titanium isopropoxide, hydrochloric acid and isopropyl alcohol were used for inorganic precursor solution. Suspensions of polystyrene (PS) spheres with 100 nm (4.5 nm Std Dev; 4.6 % CV) and 50 nm (7.2 nm Std Dev; 15.7 % CV) diameter were purchased from Duke Scientific. For preparation of template, PS-*b*-PEO diblock copolymer was first dissolved in 1,4-dioxane. As an inorganic precursor, titanium isopropoxide and hydrochloric acid was added into isopropyl alcohol and then stirred for 2 hours. Polymer solution and inorganic precursor were mixed at various volume ratios and stirred 1 hour. Organic/ inorganic hybrid film were deposited by spin-coating onto Si wafer substrate and were calcination at 500 °C for 1 hour or exposed to UV irradiation for overnight to remove PS-*b*-PEO. Titania films obtained so were used as a template for fabrication of colloidal crystals. Titania templates and colloidal crystals were characterized with multimode V scanning probe microscope (AFM, Digital Instruments/Veeco), and FE-SEM (Hitachi S-4300SE).

Results and Discussion: PS-*b*-PEO block copolymers used in this work can act as a structure-directing agent since titanium precursor is selectively incorporated into hydrophilic PEO domains through the coordination bonds. Figure 1 exhibits such results where different TiO_2 nanostructures including hole, line and cup patterns were directed by block copolymer self-assembly, depending on the amount of precursor added to block copolymer solution. As second step, nanoporous TiO_2 films shown in Figure 1 were used as a template for colloidal crystallization, and

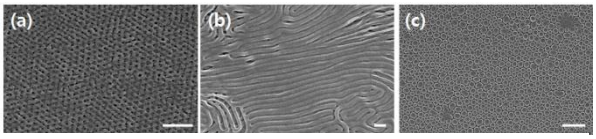

Fig. 1 SEM images on TiO_2 films after calcination for PS-*b*-PEO/ TiO_2 precursor 100/200 (a), 100/30 (b), and 100/10 (c).

the results are presented in Figure 2. Generally colloidal particles with 50 nm in diameter are very difficult to generate regular crystal arrays due to polydispersity in size. However, as seen in Figure 2(a), when the template with highly-ordered nanostructure was used, small nanoparticles can produce well-order arrays along template pattern. Small colloidal particles were also found to be guided by cup pattern, where PS nanoparticles sit on the cup template as well as between cups, as shown in Figure 2(b). When titanium precursor was applied for PS colloidal crystals and then calcined, inverted and nanoporous structure was generated, as seen in Figure 2(c). Nanopores are highly ordered according to PS colloidal crystals. Their size in Figure 2(c) is different from that produced from block copolymer self-assembly, and consequently, hierarchical nanoporous TiO_2 films with two different lengths was produced successfully.

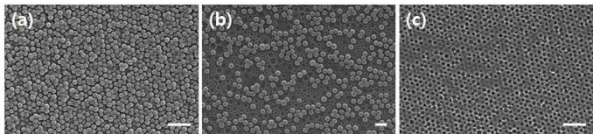

Fig. 2 SEM images on colloidal crystals and their inverted structure guided by TiO_2 nanoporous films shown in Figure 1.

Conclusions: It has been here demonstrated that nanoporous TiO_2 films with hierarchical order can be produced by combining self-assembly of two different systems, block copolymers and colloidal particles. These films with well-ordered, hierarchical structure can potentially be utilized for energy-conversion/energy-storage devices with enhanced efficiency.

Synthesis of Regioregular Poly(3-hexylthiophene) with Low Polydispersity Using Zincate Complex: Toward a Purification-Free System

Tomoya Higashihara and Mitsuru Ueda

Department of Organic and Polymeric Materials, Graduate School of Science and Engineering, Tokyo Institute of Technology, 2-12-1-H-120, O-okayama, Meguro-Ku, Tokyo 152-8550, Japan

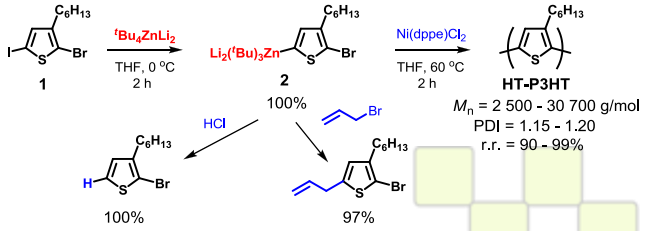
e-mail: thigashihara@polymer.titech.ac.jp

There has been growing attention paid to poly(3-alkylthiophene)s (PATs) in many fields of polymer electronic devices, because PATs are the best class of balanced high-performance materials as *p*-type semiconductors in terms of solubility, chemical stability, charge mobility, and commercial availability. Since the quasi-living GRIM polymerization system based on chain-growth polymerization has been discovered by McCullough et al.,[1] followed by the improvement by Yokozawa et al.[2], it becomes possible to yield head-to-tail (HT)-PATs with controlled molecular weights (MWs) and low polydispersity indices (PDIs). However, thorough purification steps of monomers and solvents are often necessary in this system, because highly-reactive and moisture-sensitive Grignard agents are employed.

Herein we report the first demonstration of quasi-living catalyst-transfer polycondensation for the synthesis of high-MW regioregular HT-poly(3-hexylthiophene) (P3HT) using a dianion-type zincate complex, dilithium tetra(*tert*-butyl) zincate (^{t}Bu$_4$ZnLi$_2$), toward a purification-free polymerization system.

We first investigated the halogen-metal exchange reaction of 2-bromo-3-hexyl-5-iodothiophene (**1**) with an equivalent molar of ^{t}Bu$_4$ZnLi$_2$ in THF at 0 °C. After quenching the reaction with HCl solution or allyl bromide, 2-bromo-3-hexylthiophene or 5-allyl-2-bromo-3-hexylthiophene, respectively, was obtained quantitatively, which indicates that the halogen-metal exchange reaction took place quantitatively and selectively at 5-position to afford a zincate complex of thiophene monomer, dilithium tris(*tert*-butyl)-(2-bromo-3-hexyl-5-thienyl) zincate (**2**) (see Scheme 1). Based on these successful results, the catalyst-transfer polycondensation of **2** was performed with a Ni catalyst in THF (see also Scheme 1). The results are summarized in Table 1.

Scheme 1. Halogen-Metal Exchange Reactions and Catalyst-Transfer Polycondensation for Synthesis of Regioregular HT-P3HT Using ^{t}Bu$_4$ZnLi$_2$



The polymerization of **2** proceeded in a controlled manner using 1,3-bis(diphenylphosphino)ethanenickel dichloride (Ni(dppe)Cl$_2$) as the catalyst in THF at 60 °C to afford HT-P3HTs with predicted M_n values (2.50 to 30.7 kDa) and low PDIs (<1.2) in high yields (run 1-5).

Table 1. Characterization Results of P3HT Obtained by Catalyst-Transfer Polycondensation of **2** Using ^{t}Bu$_4$ZnLi$_2$ in THF[a]

The regioregularity (r.r.) of high-MW P3HT (>10 kDa) was more than 97%, as determined by ^{1}H NMR.

run	Additive[b]	Yield[c]	[**1**]$_0$/[Ni]$_0$	M_n[d] (kDa)	PDI[d]	r.r.[e]
1		90	15	2.50	1.20	90
2		88	30	5.40	1.18	94
3		90	60	10.2	1.15	97
4		85	120	21.7	1.15	98
5		80	180	30.7	1.19	99
6[f]		75	60	11.5	1.17	97
7	^{i}PrOH	60	60	10.9	1.15	97
8	H_2O	50	60	16.8	1.72	97

[a]The polymerization was carried out using Ni(dppe)Cl$_2$ at 60 °C for 2 h. [b]Additives ([Additive]$_0$/[**1**]$_0$ = 1.0) were placed before the halogen-metal exchange reaction. [c]The yields of P3HT were determined by gravimetry after precipitation. [d]M_n and PDI were determined by SEC using polystyrene standards without soxleht extraction. [e]The regioregularity (r.r.) was determined by comparing the peak intensities of thienyl methylene protons in ^{1}H NMR spectra after soxleht extraction with methanol, acetone, and chloroform. [f]Undistilled THF (dehydrated, stabilizer-free, Wako Pure Chemical Industries Ltd., 99.5%) was used.

We next intended to apply the developed polymerization system to purification-free media, such as undistilled THF or THF containing protic impurities, toward low-cost mass production of HT-P3HT. The halogen exchange reaction of **1** with ^{t}Bu$_4$ZnLi$_2$ followed by polymerization of **2** with Ni(dppe)Cl$_2$ was carried out in undistilled THF (dehydrated, stabilizer-free, Wako Pure Chemical Industries Ltd., 99.5%) (run 6). As a result, HT-P3HT with controlled MW and low PDI could be obtained. Surprisingly, a similar experiment in THF containing a protic impurity of ^{i}PrOH ([^{i}PrOH]$_0$/[**1**]$_0$ = 1.0, [^{i}PrOH]$_0$/[Ni(dppe)Cl$_2$]$_0$ = 60) was also successful (run 7). Furthermore, high-MW HT-P3HT could be obtained in 50% yield in THF containing 1000 ppm water ([H_2O]$_0$/[**1**]$_0$ = 1.0, [H_2O]$_0$/[Ni(dppe)Cl$_2$]$_0$ = 60), although PDI increased to 1.72 (run 8). As a comparison, the GRIM polymerization system was attempted in purification-free media of THF. However, no polymerization took place at all in undistilled THF or in THF containing ^{i}PrOH or water under typical conditions, probably due to the termination of highly-sensitive Grignard agents toward impurities.

In conclusion, the selective halogen-metal exchange reaction of **1** with ^{t}Bu$_4$ZnLi$_2$ and quasi-living catalyst-transfer polycondensation of **2** with Ni(dppe)Cl$_2$ have been first demonstrated for the synthesis of high-MW regioregular HT-P3HT in high yields. This system was also realized in a purification-free polymerization media of THF, even in the presence of water.

Improvement of Mechanical Properties of Soy Protein-Based Films

Pedro Guerrero, Tania Garrido, Sara Cabezudo, Koro de la Caba

Escuela Universitaria Politécnica. Plaza Europa 1. 20018 Donostia-San Sebastián, Spain

koro.delacaba@ehu.es

Introduction

Plastics are one of the most important materials employed in daily life. However, environmental pollution from their consumption has become a serious issue, particularly when they are used as one-time use packaging materials. To overcome this problem, biopolymers produced from natural resources are regarded as an attractive alternative since they are abundant, renewable, inexpensive, environmentally friendly and biodegradable. Among biopolymers, soy protein is a potential replacement for petroleum-based products due to its low cost, easy availability and biodegradability (1). Moreover, soy protein is extracted from soybeans used to obtain soy oil. During this process, soy flour is obtained as a secondary product and it can be purified to obtain soy protein concentrates (SPC) and soy protein isolates (SPI), which would add value to agricultural by-products. Although optimization in processing methods is required, this kind of proteins could offer significant opportunities to develop improved packaging materials in the future. These soy-based plastics could be employed as sort-term use or one-time use plastic products in place of the non-biodegradable materials currently used. Once disposed of, soy-based plastic does not take long to biodegrade and is safer for the environment than more durable petroleum based plastics. Furthermore, soy protein could be used for food packaging purposes since it meets food grade standards.

Materials and Methods

Soy protein isolate PROFAM 974 was supplied by Lactotecnia, S.L. (Barcelona, Spain). The commercial bovine gelatin type A (bloom 200/220) was obtained from Sancho de Borja S.L. (Zaragoza, Spain). Glycerol used in this study was food grade reagent obtained from Panreac.

SPI-based films with different gelatin contents (5, 10, and 15% by weight on SPI dry basis) were prepared by dispersing SPI and gelatin in distilled water. Dispersions were heated at 80 ºC and stirred. The pH of the dispersions were adjusted to the desired values (pH 1.4, 4.6, 7.5 and 10.0) with 0.1 M HCl or NaOH solutions. Then, glycerol was added as plasticizer at SPI/glycerol ratio: 70/30 (w/w), which was chosen on the basis of previous experiments (2). After that, dispersions were maintained at 80 ºC under stirring. Subsequently, these samples were dried at room temperature or freeze-dried and hot-pressed at 150 ºC and 12 MPa.

SPI-based films were designed as a function of gelatin content (5, 10, or 15%). Gelatin-free films were also prepared as control films and designed as SPI30.

Samples for tensile tests were bone shaped with a thickness of about 70-100 µm. Before testing, the samples were maintained for 48 h in a relative humidity of 50% at 25 ºC in a climatic chamber.

An electromechanical testing system (MTS Insight 10) was used to determine mechanical properties. Elastic modulus (E), tensile strength (σ) and elongation at break (ε) were determined according to ASTM D1708-93. Bone-shaped specimens (4.75 mm wide and 22.25 mm long) were cut. Five replicates were tested for each composition.

Results and Discussion

Soy protein is a polymer with polar and non-polar side chains, which present strong intra- and inter-molecular interactions, and restrict segment rotation and molecular mobility, leading to brittle films. The addition of glycerol makes them easy to handle because glycerol molecules reduce the strong interactions among the protein chains, so thus increasing elongation at break, but also decreasing tensile strength. However, this effect is greater for the films processed by casting than for the ones obtained by compression due to the natural plasticization effect of water, so it can be said that compression molded films present better balanced mechanical properties. Taking the above in consideration, the effect of pH on mechanical properties has been studied for the compression molded films. Increasing pH increases elongation at break because the grade of protein denaturation is favored at basic pHs, at which protein polar groups are exposed and can interact with glycerol molecules, so thus the strong hydrogen bonding among the protein chains is reduced, and the extensibility of the films is increased.

The highest tensile strength with a similar elongation at break, were obtained when 15% of bovine gelatin was added in the system plasticized with 30% of glycerol at pH 10. This improvement could be due to the high proline and hydroxyproline content in bovine gelatin, which could promote the formation of more ordered networks.

Conclusions

Experimental results reveal that films obtained by compression exhibit better mechanical properties than the ones processed by casting, allowing the processing of soy proteins by the methods employed for conventional plastics. On the other hand, films prepared at pHs higher than the one corresponding to the SPI isoelectric point (pH 4.6) exhibit much better strength and elongation at break than the ones processed at lower values. In all the cases, the films were transparent, and in the case of pH 10.0, apart from the best mechanical properties, the films present less yellow colour.

Mechanical properties of the gelatin-incorporated SPI-based films were affected by gelatin concentration. When gelatin was added, SPI-gelatin interactions were induced, leading to a great reinforcement of the film.

Polyaniline–silver composites: Oxidation of aniline with silver nitrate accelerated by *p*-phenylenediamine

Patrycja Bober, Miroslava Trchová, Jaroslav Stejskal

Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, 162 06 Prague 6, Czech Republic

bober@imc.cas.cz

Polyaniline is one of the most famous conducting polymer, on account of its high electrical conductivity, environmental stability, ease of preparation from common chemicals, good processibility, and relatively low cost. In the last years, the interest in polyaniline–silver composite is growing; the presence of silver still improving their conductivity. Such materials may also potentially be useful in applications, such as water treatment, noble-metal recovery, antibacterial substances, electrode materials, electrocatalysis, *etc.* [1].

Aniline, *p*-phenylenediamine, or their mixtures of various compositions were oxidized with silver nitrate in 1 M nitric acid or 1 M acetic acid at room temperature. Products, the composites of polyaniline or poly(aniline-*co*-*p*-phenylenediamine) and silver, were characterized by Fourier-transform infrared, UV–visible spectra, conductivity and density measurements, and transmission electron microscopy.

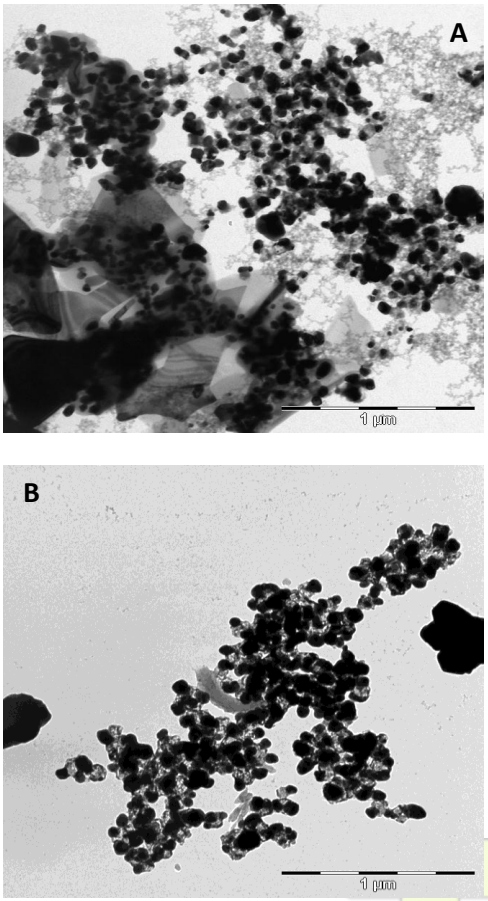

Figure 1. Micrographs of composites prepared with (A) 5 mol% *p*-phenylenediamine and (B) 60 mol% *p*-phenylenediamine mixtures with aniline in 1 M acetic acid, using silver nitrate as oxidant.

The oxidation of aniline with silver nitrate in is slow and takes over several months [2,3], an addition of a small amount of *p*-phenylenediamine, even 1 mol. % relative to aniline, shortens the reaction time to several hours or even minutes. Higher concentration of *p*-phenylenediamine produces conducting copolymer composites. Also *p*-phenylenediamine alone is similarly able to be oxidized to poly(*p*-phenylenediamine) and produce a composite with silver. Silver is present in the composites as nanoparticles of ~50 nm size (Figure 1) and as larger objects. The composites had conductivity in the range of the order of 10^{-3} to 10^{3} S cm^{-1} at comparable content of silver, which was close to the theoretical expectation, 68.9 wt.%. The composites prepared in 1 M acetic acid always have a higher conductivity, compared with those resulting from synthesis in 1 M nitric acid [4].

The acceleration of aniline oxidation with silver nitrate by small amounts of *p*-phenylenediamine is one of new ways to the preparation of polyaniline–silver composites. The composites are produced in short time with relatively high yield and very good conductivity.

dcosta@fcsaude.ubi.pt

Introduction. We gained a deeper understanding of the release of different molecular weight solutes from photodegradable cross-linked DNA gels. In a first approach, the gel mesh size was determined and the ultraviolet range that causes the maximum network degradation was characterized. Then, we investigated how the disruption-dependent network swelling relates to the mesh size and the latter to the solute release behaviour.
Results and Discussion. Different cross-linker densities (0.5 %, 1 %, 3 % and 5 % ethylene glycol diglycidyl ether) DNA gels were studied as photodegradable systems, by ultraviolet light exposure, to control the release of DNA and high molecular weight, hydrophilic solutes. Network mesh size and the extent of swelling during degradation have been determined to characterize the effect of hydrogel degradation kinetics and simultaneous changes in gel structure on solute release profile. Modelling release kinetics, using Weibull function, can predict the DNA release pattern, which are dependent on both wavelength radiation and cross-linker concentration, and its mechanism of desorption, rather complex. Moreover, concerning the solutes release it can be inferred that not only hydrated radii play an important role, but other effects are also involved in the release mechanism and there is a clear difference between the mechanism for lysozyme and BSA and FITC-dextran. Conclusions. The Weibull function can describe the DNA release profiles and shows that they are dependent on both radiation wavelength and cross-linker concentration; the mechanism of DNA desorption is rather complex. There is no effect on the gel matrix with low energetic radiation and the diffusion of DNA is controlled by its concentration, whereas, by increasing radiation energy some interaction with DNA and/or EGDE takes place at the surface acting as an obstacle. Solute release from DNA gels is strongly affected by the relative value of the network mesh size and the hydrodynamic radius of the solute. In the presence of light, the release mechanism for lysozyme and BSA follows a Fickian diffusion, while FITC-dextran release presents a sigmoid curve indicating a more complex mechanism. In the absence of light, the solute release behaviour is significantly different. Although, lysozyme release is quite analogous to that occurring in the presence of light, BSA and FITC-dextran show a three-step released mechanism. The latter two steps are similar for both molecules, presenting a Super Case II transport, while the initial step indicates a different behaviour, probably related to the size of the desorbed particles.

Surface properties of cationic polyelectrolytes hydrophobically modified

Hernán E. Ríos, Javier González and Marcela D. Urzúa.*

Department of Chemistry. Faculty of Sciences. University of Chile

hrios@uchile.cl

Amphipathic hydrophilic polyelectrolytes display in water solution two kinds of behavior depending on their hydrophobic/hydrophilic balance. The stabilization in the water phase is related with the trend of these systems to hypercoiling by hydrophobic interactions adopting a micelle-like structure. These polymers can eventually migrate spontaneously at the air-water surface or to a liquid-liquid interface. Works considering surface properties of polyelectrolytes have been focused to anionic systems. Therefore, poly (N,N-dimethyl-N,N-diallyl ammonium) chloride, a highly hydrophilic cationic polyelectrolyte, was hydrophobically modified and the surface properties of the resulting amphipathic polyelectrolytes were determined. The chemical modification was performed according to the method of Quina[1] et al., as follows:

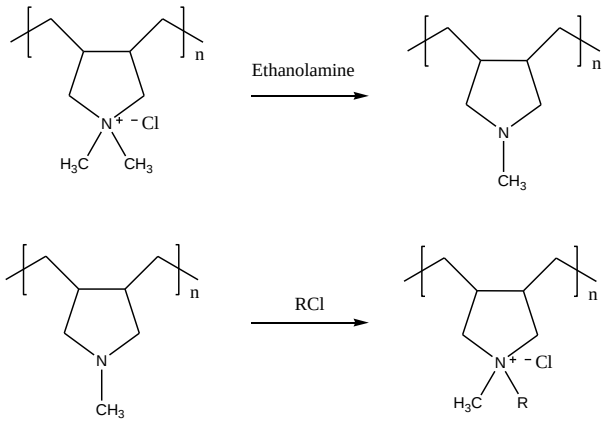

Figure 1. Surface tension behavior of PC12 (∇), PC10 (O), PC8 (Δ) and PC6(□) at 298 K

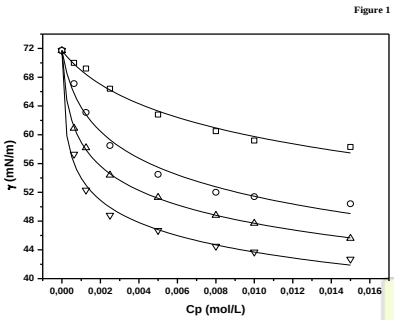

The surface tension curves were treated according to the Gibbs-Szyszkowski equation[2] and the results are summarized in the following Tables

Table 1. Limiting excess surface concentration, areas covered by monomer and PC_{20}

T(K)	*PCn*	$\Gamma^{\infty} x10^{10}$ $(mol\ cm^{-2})$	$\sigma x10^{16}$ (cm^2)	pC_{20}

	PC8	30.3	21.7	8.6
	PC10	32.6	23.4	9.2
	PC12	35.7	25.8	9.9
308	PC6	26.8	17.7	9.1
	PC8	32.0	22.5	9.5
	PC10	35.4	25.4	10.0
	PC12	38.1	27.3	10.8

Table 4.Standard entropies and enthalpies of adsorption.

PCn	$T\Delta S^{o}_{ads}$ $(kJ\ mol^{-1})$	ΔH^{o}_{ads} $(kJ\ mol^{-1})$
PC6	68.6	44.9
PC8	61.4	32.1
PC10	59.6	26.9
PC12	51.5	15.5

The standard free energy of the adsorption process, ΔG^{o}_{ads}, was a linear function of the number of carbon atoms in the lateral chain as well as their transfer and interfacial contributions to the adsorption process with a -1.73 $kJmol^{-1}$ of methylene group to ΔG^{o}_{ads}. From the dependence of the surface tension with the temperature the ΔS^{o}_{ads} was determined. The latter parameter was always positive regardless the polyelectrolyte side chain length, thus the main driving force to ΔG^{o}_{ads} arises from the large positive ΔS^{o}_{ads} values.

Release of amoxicillin embedded in cellulose acetate-poly(vinyl pyrrolidone) fibers by coaxial electrospinning

M.M. Castillo-Ortega[1], A.L. Nájera-Luna[1], D.E. Rodríguez-Félix[1], F. Rodriguez-Félix[1], J. Romero-García[2], P.J. Herrera-Franco[3]

monicac@guaymas.uson.mx

Introduction

Electrospinning is a method that has been widely used in recent years, because of its simplicity and versatility and it can be used to prepare polymeric fibers with diameters ranging from a nanometer to a micrometer scale, for any polymer soluble in a volatile solvent. Electrospun scaffolds prepared from biodegradable polymers have great potentials in tissue engineering, drug delivery, and gene therapy [1]. According to a literature review, in the last years the number of related publications has increased. In these publications, a large number of different materials have been reported, including cellulose acetate and poly(vinyl pyrrolidone) [2], and other materials. Appropriate materials to produce nano and micrometric fibers with possible applications in tissue engineering, controlled release of drugs and as a bactericide are cellulose acetate (CA) and poly(vinyl pyrrolidone) (PVP) [3,4]. There exists the possibility of producing in a co-extrusion fashion both the CA and the PVP, with embedded amoxicillin, and then, after dissolving one of the polymers, PVP, to study amoxicillin release. The main goal of this work is to show the feasibility and to determine the optimal conditions for the preparation of fibrous composite membranes of CA and PVP with embedded amoxicillin, via coaxial electrospinning, and their use for the release of this drug at both pH 3 and 7.2.

Materials and Methods

For the preparation of the fibers, a careful study of all the variables was performed. The variables studied were, the concentration of the polymer solution, the applied voltage, the flow of the solution, and the distance between the needle and the collector plate. In the case of CA solution, an acetone-water mixture was used as a solvent with a polymer concentration of 8% W. For the PVP solution an ethanol-water mixture was used, with a polymer concentration of 8% W, containing 2 ml of an amoxicillin aqueous solution 1M. The solutions were transferred to plastic syringes of 10 ml capacity together with a syringe pump kds Cientific, whose flow velocity was varied in the range of 0.1-1.0 mL h^{-1}. A high voltage of 15-30 kV was applied to the polymer solution, using a high-voltage power supply Spellman, model CZE 1000R. Finally the distance between the needle and the collector plate was set at 15 cm. A square plate of aluminum (10 cm x 10 cm) was used as a collector. In order to study the drug release kinetics, the membrane samples containing amoxicillin were immersed in 400 ml of a buffer solution and were maintained in magnetic agitation at 25 °C. The release at both pH 3 and 7.2 was investigated. At certain time intervals, 50 µl of the buffer solutions were taken out from each release system and were diluted to a final volume of 3 ml (dilution factor of 60). The amount of amoxicillin released at that time was determined by UV-vis spectroscopy to 273 nm using a Perkin Elmer Lambda 20 UV-vis spectrophotometer system. This experiment was repeated until the absorbance values were constant, that is, when the equilibrium of released drug was reached. The amounts of amoxicillin released were determined by interpolation of absorbance values in a calibration curve previously developed. The IR characterizations were done using a Perkin-Elmer Spectrum GX FTIR spectrometer by the KBr pellet technique.

Results and Discussion

The optimal conditions for the preparation of cellulose acetate-poly(vinyl pyrrolidone) fibers with embedded amoxicillin, CA/PVP-amoxicillin/CA, were found to be: the flow rate was 0.2 mL h^{-1}, applied voltage value and the distance between the needle and the collection plate were found, 25 kV and 15 cm respectively. The FTIR spectroscopy of the fibers was performed in order to corroborate the existence of amoxicillin in CA/PVP-amoxicillin/CA. The following characteristic peaks were observed: for CA, ester stretching peak at around 1750 cm^{-1}; for PVP, the band at 1662 cm^{-1} is attributed to C=O stretching vibration of the amide group; for amoxicillin, amide stretching wide band at 3456 cm^{-1}.

The effect of the pH on the amoxicillin release (pH 3.0 and pH 7.2) was analyzed through the kinetics of release, the release at pH = 7.2 is higher than at pH = 3.0.

Conclusions

The optimal conditions for the preparation of fibers of cellulose acetate, poly (vinyl pyrrolidone) containing amoxicillin were found; FTIR spectroscopy characterization of fibers was performed. The effect of the pH on the release of amoxicillin was also studied. These materials have the potential application in both oral administration and fabrication of release transdermal patch administration of amoxicillin.

Effect of Fatty Acids on the Functional Properties of Biofilms for Packaging Applications

Pedro Guerrero, Itsaso Leceta, Nagore Gabilondo, Koro de la Caba

Escuela Universitaria Politécnica. Plaza Europa 1. 20018 Donostia-San Sebastián, Spain

pedromanuel.guerrero@ehu.es

Introduction

Many methods have been investigated to modify properties of biofilms, including physical, chemical and enzymatic treatments. An alternative to improve water barrier properties could be the combination of the biofilm with lipids, polysaccharides or proteins which could give rise to synergistic effects between the components and make the properties of the film suitable for use in packaging applications: reduced water vapour permeability, optimum flexibility, transparency and gloss.

The combination of soy protein with lipids is an interesting alternative to optimise film properties since some components, such as oleic acid, impart flexibility, whereas others, like beeswax can enhance the efficiency of the water vapour barrier properties. Gloss and transparency of the films, which are very relevant to the appearance of the coated product, are also modified by the incorporation of different lipids, to a different extent depending on the kind of lipid and the development of the film structure during the film drying (1).

Materials and Methods

Soy protein isolate (SPI) PROFAM 974 was supplied by Lactotecnia, S.L. (Barcelona, Spain) and commercial bovine gelatin type A (bloom 200/220) by Sancho de Borja S.L. (Zaragoza, Spain). Lactic acid was obtained from Panreac, epoxidized soybean oil from Hebron S.A. (Barcelona, Spain), and olive oil from Cooperativa La Carrera (Jaen, Spain). Glycerol used in this study was food grade reagent obtained from Panreac.

SPI-based films with gelatin content (15% by weight on SPI dry basis) and different contents of fatty acids (5, 10 and 15% by weight on SPI dry basis) were prepared by dispersing SPI, gelatin and fatty acid in distilled water. Dispersions were heated at 80 ºC under stirring. The pH of the dispersions was adjusted to 10.0 with 0.1 M NaOH (2). Then, glycerol was added as plasticizer at 70/30 (w/w) SPI/glycerol ratio. After that, dispersions were maintained at 80 ºC under stirring. Subsequently, these samples were freeze-dried and hot-pressed at 150 ºC and 12 MPa. Fatty acid-free films were also prepared as control films.

A contact angle meter (model Oca20, dataphysics instruments) was used to perform contact angle measurements on the surface of films and image analyses were carried out using SCA20 software.

Fourier transformed infrared (FTIR) spectra of the films were carried out on a Nicolet Nexus FTIR spectrometer using ATR Golden Gate (Specac).

Total soluble matter (TSM) expressed as the percentage of film dry matter solubilized after 24 h immersion in distilled water and moisture content (MC) of films were measured.

The light-barrier properties of films were determined by measuring their light absorption at wavelengths ranging from 200 nm to 800 nm, using a UV-Jasco spectrophotometer (Model V-630).

Color values of films were measured using a portable colorimeter (CR-400 Minolta Croma Meter) and CIELAB color scale.

Results and Discussion

Water contact angle values are good indicators of the degree of hydrophilicity of films, being higher when hydrophilicity is lower, so thus the final state of the water drop on the film surface can be taken as an indication of surface wettability. To understand the effect of fatty acids on film wettability, contact angles were measured for films with different content and type of acid and were related to control films. In this study, contact angle increased with the addition of lactic acid. This behavior indicates that SPI-lactic acid interactions could result in a decrease of hydrophilic groups of SPI, increasing hidrophobicity of the films. However, lower contact angles were obtained for films with olive and soybean oils due to the estherification reaction observed by FTIR spectroscopy. These values were in agreement with the decrease of TSM values for these systems.

Packaging films should maintain moisture levels within the packaged product. Therefore, the knowledge of water solubility and moisture content of the film is very important for food packaging applications. MC values were similar for all systems, and did not depend on the type or concentration of acid used in this study.

Control films showed excellent barrier properties to UV light in the range of 200-280 nm, which were not affected by the addition of fatty acids, regardless acid content and type. In the case of transparency values, the addition of olive or soybean oils diminished transparency, whilst the addition of lactic acid slightly affected transparency values. There was no change in lightness (L) when fatty acids were added, whilst redness (a) increased, independent of acid content, and yellowish (b) diminished, which showed that the addition of fatty acids improved the visual aspect of films, diminishing the typical yellowish of SPI films.

Conclusions

Contact angle values, indicators of surface wettability, increased with the addition of lactic acid. The best results on the outer surface were obtained when the content of lactic acid was 15%. Transparency and colour values of the films modified with lactic acid also showed the improvement of the properties of the SPI-based films for packaging applications.

Block Copolymers of Polypyrrole with 4-Vinylaniline Modified Cyclohexanone Formaldehyde Resin

Esin Ateş and Nilgün Kızılcan

Istanbul Technical University, Department of Chemistry, Istanbul 34469, Turkey

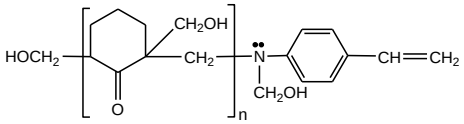
esinatess@gmail.com

Homopolymers, copolymers, composites and blends of polypyrrole prepared in the presence of persulfate have been studied widely. Persulfate chemistry was applied in copolymerzation of polypyrrole with monomers such as aniline, o-toluidine, styrene, 2-ethylaniline and o-anisidine [1-5].

Persulfate initates emulsion poliymerization for several unsaturated monomers as styrene, acrylonitrile, allyl acetate, methyl vinyl ketone, methacrylonitrile, butadiene, vinyl acetate, acrylamide and vinyl chloride. Initiation mechanism of vinyl polymerisation by persulfate and aliphatic amine systems was proposed by several authors [6-9]. It was demonstrated that in these initiation systems the aliphatic amine component also took part in the initiation reaction of vinyl polymerization. Type of free radicals coming from aliphatic amines depends on number of alkyl groups bounded to nitrogen atom [7].

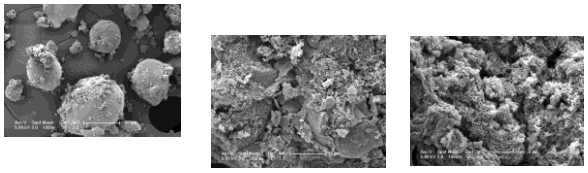
In the case of aromatic amines, persulfate is able to oxidize amine group and generates radical cation which reacts with another aromatic ring and in leads to form polymer [8].

In present study, block copolymers of polypyrrole with 4-vinylaniline modified cyclohexanone-formaldehyde resin(CFVAn) were synthesized in presence of $K_2S_2O_8$.



(CFVAn)

Solutions of resin and oxidant were prepared in dimethylsulfoxide and mixed together. Pyrrole was added to the mixture; a) at the beginning of stirring (t=0min.) and b) 15min. later (t=15min.). Reaction was carried out at 35°C for 1h. Reaction mixture was poured into water and polymer was precipitated slowly. Block copolymers were prepared with different molar ratios of pyrrole/modified resin to obtain solubility for copolymers. ESEM analysis indicates clearly that time of inserting pyrrole to reaction media is important and effects morphology of copolymers. Copolymers have particles with average size of 65-80nm. Conductivity value for copolymers is 1-3 S/cm.



(a) **(b)** **(c)**

Fig. ESEM micrographs of modified resin CFVAn (a) and copolymers of polypyrrole with CFVAn, pyrrole added at t=0min. (b) and pyrrole added at t=15min. (c).

Sustainable Anaerobic Adhesive Technology Development

Dr David Birkett

Henkel Adhesive Technologies, Dublin, Ireland

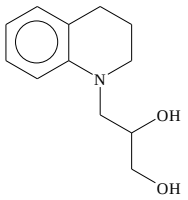
david.birkett@henkel.com

Introduction: Anaerobic adhesives are one-part methacrylate ester formulations that polymerize in the presence of transition metals (notably ferrous substrates) and the absence of oxygen. Being solvent-free and non-flammable, curing at room temperature and allowing weight reduction in many engineering applications they already have good sustainability credentials, but there is nevertheless room for improvement in terms of health and safety and the use of renewable raw materials. This paper summarizes recent developments in these areas.

Materials and Methods: Most of the work centres around commercially available Loctite™ adhesives and modifications thereto. Nuts and bolts testing is according to ISO 10964.

Results and Discussion: Common accelerators for anaerobic polymerisation include the hazardous aromatic amines acetylphenylhydrazine and dimethyl-o-toluidine. We have shown that these can be suitably replaced by:

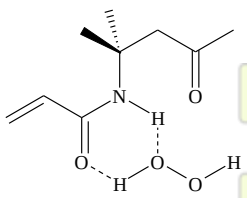
- Higher molecular weight acylphenylhydrazines such as succinylphenylhydrazine.[1]
- Polymers containing pendant acylphenylhydrazine groups.[2]
- Urethane methacrylate oligomers containing toluidine groups in the main chain.[3]
- A wide range of bicyclic aromatic amines, including the reaction product of tetrahydroquinoline and glycidol. [4]



This in turn can be built into a urethane methacrylate oligomer as in reference 3. [5]

The main initiator for anaerobic polymerisation is the toxic cumene hydroperoxide. This can similarly be replaced by:

- Polymer bound peresters.[6]
- Complexes of hydrogen peroxide with amides such as urea or the monomer "diacetone acrylamide"[7]:



In line with our sustainability focus we endeavour to keep animal testing down to a minimum. We are initiating a project to calibrate non-mammalian test result with previous animal studies on aromatic amines, and we have tested full low hazard formulations on human volunteers and proved them to be non-irritant. Finally, monomers and urethane methacrylate oligomers with a significant renewable carbon content can readily be incorporated into anaerobic adhesive formulations.

Conclusions: Using some of the techniques outlined here our Product Development colleagues have been able to develop Loctite™ 2400 and 2700 threadlockers that have no hazard classification and in which there are no hazardous raw materials listed in Section 3 of the MSDS. Efforts in both Technology Development and Product Development continue to repeat this success for gasketing and retaining applications and to increase the use of renewable raw materials.

Nanoporous membranes with controlled pore dimensions

Y. González – Lemus[1] *and Dirk J. Broer*

[1] *Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Den Dolech 2, Eindhoven, Netherlands*

Nanoporous membranes are of interest for a wide range of applications: separation processes for liquid and gaseous mixtures, catalysis (including fuel cell systems) or lab-on-a-chip technologies [1]. We present a new fabrication process for nanoporous systems based on the self-organization of reactive liquid crystals containing hydrogen bridges. Photo-polymerization in the smectic phase of a reactive monomer forms a layered polymer network [2]. The nanopores are formed by breaking the bridges by heat (>170°C) or by a dip in an alkaline solution [3]. The process and an example of materials are shown in Figure 1.

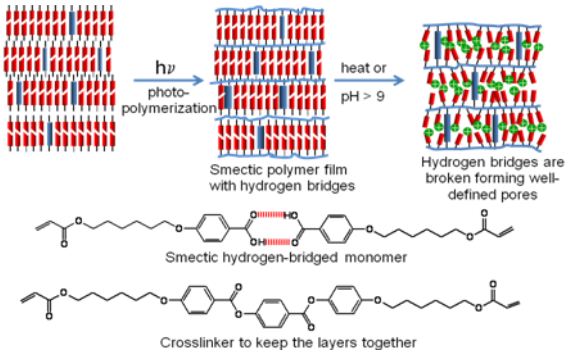

Figure 1 Schematic representation of the rupture of a hydrogen bonded smectic network under heat or high pH condition leading to sub-nanometer porous channels.

Upon breaking of the hydrogen bridges the integrity of the film is maintained by the presence of fully covalent cross-linkers connecting the smectic layers. These units are created by adding a small concentration of liquid crystal diacrylates to the monomer mixture prior to polymerization. This method allows for the creation of an organic nanoporous material that distinguishes itself from current nanoporous materials by its ease of manufacture, its ability to be formed only locally in a device, and its control over the pore dimensions down to or even below one nanometer [3].

The pores have a two-dimensional (sheet-like) shape. Figure 2 presents a cryo-TEM picture of the nanopores in cross-section, demonstrating a periodicity within the layers of 3 nm and a pore size in one direction of around 1 nm. The pores have been made visible by filling them with barium ions. It is the subject of our study to control this pore size by the choice of the crosslinker unit.

Critical step in the process is the breaking of the hydrogen bridges. We have studied this by various analytical tools such as FTIR, X-ray diffraction and DSC. As example we present here birefringent analysis which provides information on pH dependence of the bond rupture as well as on the local molecular order during and after this process (figure 3).

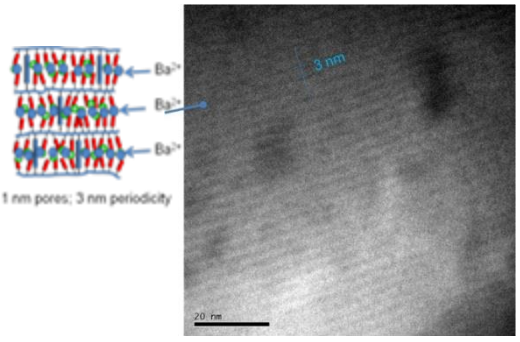

Figure 2. Cryo- TEM photograph of a cross-section of membrane film filled with $BaCl_2$ under alkaline.

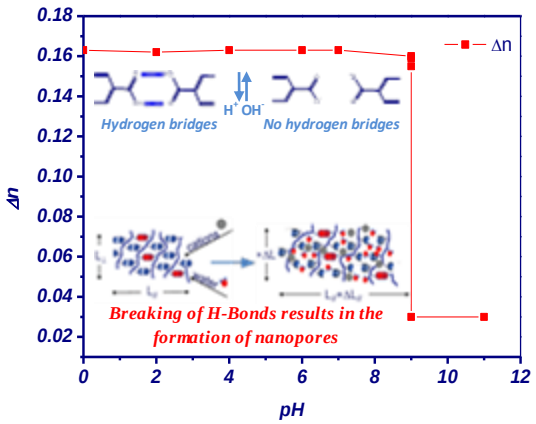

Figure 3. Birefringence of a planar oriented film as a function of pH. The film is immersed in low-pH buffer after which the pH is gradually increased by adding ammonia while recording the pH.

Figure 3 demonstrates that the hydrogen bonds rapidly rupture as soon as the pH > 9. Upon rupture the smectic layers are preserved but the order within the layers is largely lost. The small remaining birefringence above pH 9 points to the remaining orientation of the crosslinker units.

In conclusion, we form well-ordered polymer network containing hydrogen bridges by *in-situ* photo-polymerization of smectic monomers. The hydrogen bridges can (reversibly) break by temperature or by treatment with an alkaline solution. When the hydrogen bridges are broken the smectic order within the layers is lost; but the layer structure is maintained by the presence of crosslinking molecules.

Introduction:

For a large majority of foodstuff, development of micro organisms begins in the material surface, before spreading to the whole of the food [1-6]. The best way to prevent such microbial growth is introduce antimicrobial agents into polymer matrix. This antimicrobial film is a kind of active packaging that increases the display life of contained products, and maintains their quality, safety and sensor properties [2].

Antimicrobial films have gained an increasing interest in food packaging application in recent years [2-5].

The aim of this work is to investigate and compare the effect of two antimicrobial biomolecules incorporated into polymer and compounds.

Materials and methods:

The active films were prepared through three steps.

Step 1 : Masterbatch in internal mixer
Rotation speed : 60 rpm to 100 rpm
Cycle time : 5 min to 10 min
Temperature : 150°C to 220°C

Step 2 : Grinding the mixture
Pellets suitable for extrusion

Step 3 : Production of film
laboratory twin-screw extruder
1% to 4% of active agent

Fig 1: Preparation of active film

Gas chromatography (GC-MS), Fourier transform infrared spectroscopy (FTIR) and thermal analytical techniques (TGA and DSC) were used to characterize the active films and to determine their retention ability and the release of antimicrobial agent. Overall migration analysis method was used to determine the total of bioactive molecules migrated into the extraction media [4].

In order to evaluate the antimicrobial activity of the bioactive packaging, *B. Subtilis*, *E. coli*, *L. Plantarum* and *P. Camemberti* were used for microorganism test [5]. The tests were carried out without contact with the microorganisms. The whole was incubated in an oven at 37 ° C except for *P. Camemberti* at 25°C. The cultures were analyzed by counting and observing the growth of colonies after 0, 4, 19, 24 and 48 h.

Results and discussion:

The homogeneous dispersion of the bioactive molecules into the polymer matrix was verified using optical microscopy, and Scanning Electron Microscopy (SEM).

No changes in glass transition and melting temperature of antimicrobial films were observed, suggesting that little or no effect of thermal processing and, moreover plasticising effect by the addition of antimicrobial agents have been occurred.

The results of TGA-IR and GC-MS confirmed the presence of the active biomolecules in the films thus the processing conditions did not deteriorate them *(Fig 2)*.

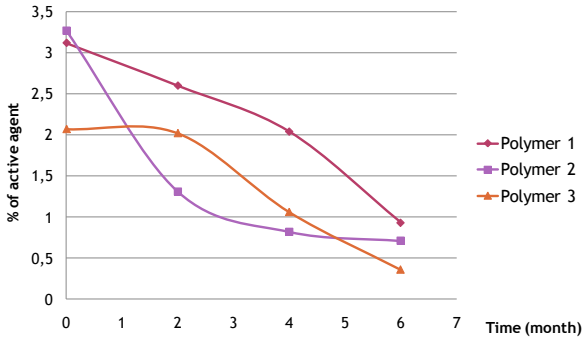

Fig 2: Release rate of active agent over time

Microbiological analysis confirmed the delay or the inhibition in growth or even no growth of bacteria in presence of active film *(Fig 3)*.

After six months of storage, the quantification tests have shown that some polymers retained better antimicrobial agent than the others and biomolecules were still active.

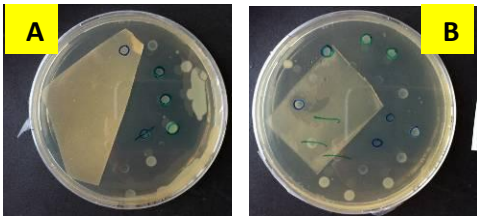

Fig 3: Test on Bacillus subtilis after 2 months of storage. A Polymer 1; B Polymer2 (2 day of incubation).

Conclusion:

In this work we developed antimicrobial films based on different polymers and compounds with two kinds of natural antimicrobial agents.

The processing data were optimized and the antimicrobial activities were validated after six months of storage. The release of active agents was influenced by the chemical structure of polymers.

The promising results obtained in this work are the basis for further study to be focus on the optimization of the active agent quantity in films.

The result of this study will be the subject of a patent.

Modeling migration of colored food compounds into thermoplastic polymers: application to food cooking in reusable polymer bags

Sébastien Narses, Nadège Lautard, Thomas Fichu, Faten Sadaka, Claire-Hélène Brachais, Jean-Pierre Couvercelle

ICMUB, UMR 5260, Université de Bourgogne - 9 Av. Alain Savary – 21000 DIJON - FRANCE

Introduction

In the food packaging industry, commodity polymers like polyethylene (PE), polypropylene (PP) or technical polymers like polyamide (PA) are used in the form of films, and are generally in contact with food for short durations. When they are used as disposable films staining and absorption of aroma compounds into the polymer matrix is not a problem. Currently, sustainable development represents a growing challenge for both science and industry. In this purpose, a new method of steam cooking is under consideration. The major axis of this study is to use plastic reusable bags. In this case, staining and absorption of aroma compounds into polymer matrix can lead to aesthetic and flavor problems, resulting in a reduced consumer acceptance. [1] In some cases, like silicone pie moulds, inorganic mineral colorants are added to the polymer matrix to hide the transfer of coloring molecules from food. This solution cannot be used here because the film has to be transparent to allow the consumer to see the cooking evolution.

The aim of this work is to find a transparent polymer unaffected by long time exposure to coloring substances. In this purpose, a large variety of polymers have been studied; this abstract will only focus on three films:

- a multilayer film made from polypropylene and polyamide,
- a film made from polypropylene only,
- a fluorinated film made from FEP (Fluorinated-Ethylene-Propylene).

For the tests, curry sauce and ketchup, containing respectively curcumin and lycopene as their main coloring molecules were selected.

Materials and Methods

Multilayer PP-PA (Combitherm Flex, thickness 100 µm) and PP (Borclear RB707CF copolymer, thickness 100 µm) film samples were supplied by Wipak Gryspeert S.A.S. France, and FEP film samples (Norton FEP, thickness 25 µm) were obtained from Saint-Gobain Plastics France. Curry sauce and Ketchup were purchased in a supermarket and pure curcumin comes from Aldrich Chemical. Samples were dipped in the coloring substance, placed 24h in an oven at 60°C, washed with distilled water and dried with absorbing paper. Staining was evaluated by UV-visible spectrometry (Varian Cary 1E) and by colorimetry (Konica Minolta CR 400 colorimeter).

Results and discussion

Before each test, calculations of solubility parameters of polymers and coloring molecules with the Hoftyzer-Van Krevelen method [2] were performed. A summary of the expected interaction is reported in Table 1. In order to experimentally evaluate curcumin transfer into polymers, a first UV-visible calibration curve was made using curcumin dispersed in ethanol. According to Beer-Lambert's law, results on tested film samples showed that curcumin can be well quantified when it migrates from curry sauce to polymer matrix. It has been shown that PA is able to extract curcumin: its concentration in PA matrix is much higher than in curry sauce, which is coherent with previous calculations. ΔE values calculated with L*a*b coordinates measured by the colorimeter were also in accordance with interaction calculations, as shown in Table 1.

For the evaluation of polymers colored by ketchup, UV-visible spectrometry is not sensitive enough to perform quantifications. On the other hand, colorimetry always provides a good evaluation of coloration [3], and thus measurements were possible. The ΔE values measured in the case of ketchup coloring do not fit with the calculations since PP and FEP are not affected by ketchup (see below).

		PA layer of PP-PA	PP	FEP
Interaction calculation	Curcumin	High	Low	Low
	Lycopene	Low	High	High
ΔE values	Curcumin	High	Low	Low
	Lycopene	High	Low	Low
Theory-experiment accordance ?		Yes for curcumin, no for lycopene		

Table 1: Summary of expected interactions and experimentations on films with curry sauce and ketchup.

The structure-properties relationships of materials and coloring molecules are not taken into account in the empirical calculations of solubility parameter. Precisely, glass transition (which modifies the mobility of chains) and crystallinity level (which modifies the migration ability of colored compounds) are important but not considered parameters. Thus, as sorption modeling is not sufficient, experiments are essential to evaluate the migration of coloring molecules into polymer matrices.

Conclusion

A large variety of polymers, from commodity to highly technical polymers could be used for this application of steam cooking, but some of them are affected by coloration. Polymers generally used for kitchenware manufacturing such as PE, PP, PA, do not fit with the requirements. Other polymers used for cooking devices such as PET and polycarbonate are not affected by coloration but cannot be employed in manufacturing reusable bags. Only fluorinated or chlorofluorinated polymers and technical polymers remain in the purpose of manufacturing durable polymer bags for steam cooking.

Poly Lactic Acid Active Packaging: Migration of Natural and Synthetic Antioxidants

Majid Jamshidian, Elmira Arab-Tehrany, Stéphane Desobry

École nationale supérieure d'agronomie et des industries alimentaires, Institut National Polytechnique de Lorraine, 2 avenue de la Forêt de Haye, 54501 Vandoeuvre, France

Majid.jamshidian@ensaia.inpl-nancy.fr

Introduction:

The concept of antioxidant's controlled release has been well examined in polymer food packaging for active compounds such as antimicrobials, antioxidants, enzymes, flavors and nutraceuticals. Traditionally, antioxidants are added into initial food formulations which have some limitations during the shelf-life of products. Active packaging provides active protection by continually releasing active compounds such as antioxidants, antimicrobials, enzymes, flavors and nutraceuticals to package content, thus generating longer shelf-life foods, lower usage of additives and preservatives in food formulations, higher protection of flavors and higher food qualities.

Poly-lactic acid (PLA) is highly versatile, biodegradable, aliphatic polyester made from 100% renewable resources which offers great promise in a wide range of commodity applications and strongly competes with polystyrene for many food packaging applications. Antioxidant-PLA active packaging has not well been studied in various food simulating solvents, so the aim of this study is to determine the migration parameters (diffusion and partition coefficients) of natural and synthetic phenolic antioxidants (SPAs) including α-tocopherol, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), propyl gallate (PG), and tert-butylhydroquinone (TBHQ) from PLA films to three food simulating solvents at tow temperatures.

Materials and Methods:

Pre-weighed PLA films (3cm×2cm×~100µm) containing 1% w/w of antioxidants made by solvent-casting method were placed in contact with 10 mL of three food simulating solvents including 95% ethanol, 50% ethanol, and 10% ethanol in distilled water and at tow temperatures of 20°C and 40°C for 60 days. Migrated antioxidants were regularly measured by high performance liquid chromatography (HPLC) until equilibration points. Food simulants in contact with PLA films containing BHA, BHT, PG and TBHQ were analyzed using isocratic mode of acetonitrile-0.1% trifluoroacetic acid (TFA) (90%) and H_2O-0.1% TFA (10%) at pH 3.0 (acidified with acid acetic 1% v/v) at a flow rate of 0.5 $mL.min^{-1}$. For PLA films containing α-tocopherol, pure methanol was used in isocratic mode at a flow rate of 0.5 $mL.min^{-1}$. The final antioxidants concentrations in PLA films were analyzed by nuclear magnetic resonance spectroscopy (NMR). The Diffusion coefficients of antioxidants (D) were determined from the experimental data using a relationship derived from the Fick's second law for a plane sheet with constant boundary condition and uniform initial concentration. The partition coefficients (K) of equilibrated antioxidants were calculated on the basis of suggested formulas.

Results and Discussion:

The results show that there is a high relationship between simulant's physicochemical properties and migration temperature, and antioxidants release. At 20°C, equilibration days for 95% ethanol ranged from 16 to 60 days, for 50% ethanol, 50 days and for 10% ethanol, from 38 to 60 days; the corresponding equilibration ratios (M_t/M_0) ranged from 0.25 to 0.75, from 0.003 to 0.067 and from 0.0 to 0.003, respectively.

At 40°C, equilibration days for 95% ethanol ranged from 2 to 4 days, for 50% ethanol from 8 to 40 days and for 10% ethanol, from 24 to 60 days; the corresponding equilibration ratios ranged from 0.67 to 0.91, from 0.14 to 0.90 and from 0.0 to 0.24, respectively. PLA-α-tocopherol in 50% ethanol and PLA-TBHQ in 95% ethanol showed antioxidant degradation causing antioxidant concentration reduction at consequent days. Liquid chromatography mass spectroscopy (LC/MS) showed new-formed compounds for α-tocopherol and TBHQ in these simulants. As be seen, the migration rates at 20°C are slower than at 40°C and antioxidants concentrations at equilibration point are totally different for these two temperatures. Migration of all antioxidants was in accordance with Fick's second law.

Conclusion:

A successful active packaging against oxidation can be achieved by continuous antioxidant release during designed product shelf-life. Three food simulating solvents used in this study mimiced the leaching action of aqueous, alcoholic and fatty foods which are more in risk of oxidation. The results show that by decreasing simulant polarity and increasing the migration temperature, the antioxidant release rates are accelerated which is confirmed by zero release of BHT after 60 days in contact with 10% ethanol and near all of α-tocopherol release after 2 days in contact with 95% ethanol. Different migration rates of natural and synthetic antioxidants from PLA into various simulants and temperatures suggests the possibility to provide suitable antioxidants concentrations in PLA matrix for an effective antioxidant controlled release to a wide range of foods with different physicochemical properties. As the antioxidants involvement and their distribution in PLA matrix are significantly changed by the polymer processing method type, this research study will be completed with extruded PLA films containing these antioxidants.

New Polyester Obtained From Ethylketene

Najib Hayki, Nicolas Desilles, Fabrice Burel

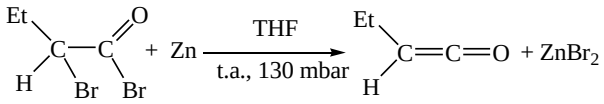
INSA de Rouen, Laboratoire Polymères Biopolymères Surfaces, CNRS UMR 6270 & FR 3038
avenue de l'Université BP8, 76801 Saint-Etienne du Rouvray Cedex, France

najib.hayki@insa-rouen.fr

Introduction:

Ketenes are derivatives of carboxylic acids which contain two consecutive double bonds (RR'C=C=O). This family begins with the parent ketene CH_2=C=O and can be divided into aldoketenes (monosubstituted) and ketoketenes (disubstituted) monomers. The presence of two double bonds in an adjacent position makes them highly reactive. One of the most interesting properties of these compounds is their ability to be used as monomers.

The first ketenes that were prepared and characterized are diphenylketene, dimethylketene, and dibenzopentafulvenone[1]. The reaction involves the dehalogenation of the corresponding α-halo carboxylic derivatives by zinc according to the Staudinger's procedure. This method was modified by McCarney in 1975, carrying out the reaction under vacuum, at room temperature, in various solvents such as ether, ethyl acetate or tetrahydrofuran (THF). In this updated procedure, ethylketene was formed in 60% yield (Scheme 1)[2].

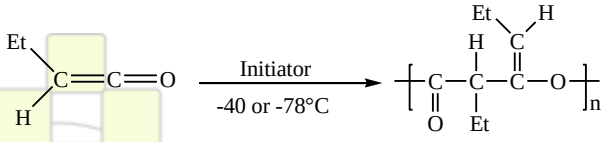


Scheme 1: Preparation of ethylketene

However, ethylketene and more generally aldoketenes, have never been polymerized successfully.

Materials and Methods:

In this work, we chose the Staudinger's procedure modified by McCarney for the synthesis of ethylketene. This latter was prepared in THF by reacting 2-bromobutyryl bromide with activated zinc, and the pressure in the apparatus was reduced to 130 mbar. This allowed THF to boil gently at room temperature. 2-bromobutyryl bromide diluted in THF was then added dropwise. Ethylketene was immediately formed and co-distilled with THF. The distillate was collected in the polymerization reactor cooled in liquid nitrogen (–180°C). The distillate was allowed to warm to –78°C, giving a green lime solution. Then, ethylketene was polymerized with various anionic initiators, at low temperature (Scheme 2).



Scheme 2: Polymerization of ethylketene

Results and Discussion:

The influence of temperature and initiator on the polymerization of ethylketene was studied, with a monomer/initiator ratio close to 250 for every synthesis.

When the reaction was conducted at –40°C, $\overline{Mn}$ ranging from 6 500 to 11 300 g.mol^{-1} and low polymer yields were obtained. Conversely, good polymer yields were obtained at –78°C, indicating that the polymerization is better controlled at this temperature. Except for naphthalene sodium, high $\overline{Mn}$, between 14 700 g.mol^{-1} and 24 000 g.mol^{-1}, were obtained. All alkyl lithium initiators such as BuLi and sec-BuLi, and alkoxy lithium initiators such as ter-BuOLi afforded reactive systems with elevated polydispersities (I >1.5).

Initiation by the LDA/BuLi aggregate was also studied; this system led to a polymer not only with a high molecular weight $\overline{Mn}$ = 24 000 but also with a lower polydispersity (I ≈ 1.50).

The influence of monomer/initiator feed ratio was evaluated in terms of molecular weights and polydispersities, with sec-BuLi and the LDA/BuLi aggregate as initiator at –78°C. No strong evolution of the polydispersity index could be highlighted. This behaviour tends to indicate that the anionic polymerization of ethylketene is not free from chain transfer reactions.

Making chain extension experiments is a convenient way to study a living polymerization. Thus, block copolymerization with tert-butyl methacrylate was undertaken. The block copolymer was not formed, and attested the presence of termination reactions.

FTIR-ATR and NMR (^{1}H, ^{13}C) analysis showed that the obtained polymers are polyesters. This result is consistent with the cleavage of the obtained polymer chains in contact with $LiAlH_4$[3]. The thermal properties of these polymers were studied by TGA and DSC. All polymers exhibited a negative glass transition temperature (around – 18°C) and were thermally stable up to 160°C.

Conclusion:

New polyesters were successfully synthesized via the anionic polymerization of ethylketene at –78°C in THF, with yields up to 91%, molecular weights up to 24 000 g.mol^{-1} and polydispersity index close to 1.8.

Synthesis of cyclo-aliphatic polyamide precursors by polycondensation of diamines with ketene symetric dimers.

Nasreddine Kébir, Magda Ben Haddi, Najib Hayki, Fabrice Burel

INSA de Rouen, Laboratoire Polymères Biopolymères Surfaces (PBS), UMR 6270 CNRS FR 3038, avenue de l'université, 76801 Saint-Etienne-du-Rouvray, France.

e-mail: nasreddine.kebir@insa-rouen.fr

Introduction

Polyamides are an important class of versatile polymers and are used in various life fields. They combine excellent mechanical properties with good thermal stability and high melting temperatures. Usually, polyamides exhibit aliphatic and/or aromatic chemical structures. There are a number of articles in the literature that discuss the synthesis of polymers with cycloaliphatic units in the main chain, but they are principally concerned with the synthesis of such polymers bycycloolefin polymerization or cyclophotoaddition of bisolefinic derivatives.[1] Only a few works contain information on polycondensation polymers using cyclohexyl moieties.[2,3] Replacement of an aliphatic section of a polyamide by cyclic segment reduces chain flexibility, but rises the T_m because of a decrease in the entropy of melting. Generally, cycloaliphatic polyamides possess intermediate properties between aliphatic and aromatic ones.

Materials and Methods

Reagents: Tetramethyl-1,3- cyclobutanedione, p-phenylene diamine, hexamethylene diamine, dodecamethylene diamine, p-toluene sulfonyle, Sodium triacetoxyborohydride.

Characterisations: NMR, IRTF-ATR (Diamond), Size Exclusion Chromatography (SEC), TGA and DSC.

Results and discussions

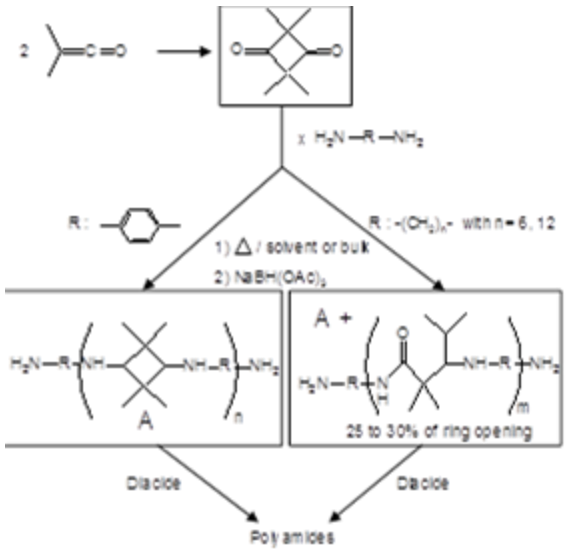
Dimer of dimethyl ketene (DMK) (Tetramethyl-1,3-cyclobutanedione) is a commercially available product. It is also the main under product formed during ketene preparation by Staudinguer method.[4] This compound possesses two ketone functions which can be chemically modified.

This work aims to study the reactivity of DMK dimer towards aliphatic and aromatic diamines in several operating conditions.

Reductive amination was first conducted in classical conditions, i.e. presence of sodium triacetoxyborohydride as reductive agent, acetic acid as catalyst, dichloroethane as solvent and temperature range of 25 to 50°C. Unfortunately, slight carbonyl conversion and chain extension were obtained although the increase of concentration, diamine excess, and time reactions. This suggested a very weak reactivity of the sterically encumbered carbonyl groups. Aromatic diamine (p-phenylene diamine) was more reactive than aliphatic ones and afforded (when 5% excess of diamine) oligomers of Mn around 1000 g/mol with cycloaliphatic structure (scheme 1).

Therefore, the reaction was conducted in toluene at reflux (110°C) using p-toluene sulfonyle as catalyst for 24h. The reaction with aliphatic diamines afforded oligomers with Mn~400 to 800 g/mol depending on amine excess (5 to 100%). The spectroscopic data showed a 25-30 % of ring opening leading to heterogeneous structure.

The reaction with aromatic diamines afforded oligomer of Mn~1000 g/mol (100% excess) and polymer of Mn~50000 g/mol (5% excess) with totally cycloaliphatic structure.



Scheme 1. Reaction of DMK dimer with diamines.

The reactions were also conducted in bulk at melt temperatures (100 to 150°C) using p-toluene sulfonyle as catalyst. Same results were obtained in terms of chemical structures (scheme 1). The molecular weights increased of about 40 to 50%.

The imine functions of these compounds were then reduced by reaction with $NaBH(OAc)_3$ (Scheme 1) to increase their chemical and thermal stability.

The thermal properties study of theses compounds showed Tg range values of 35-45°C for aliphatics and between 65 to 75°C for semi-aromatics. Aliphatic and semi-aromatic compounds were thermally stable until about 200 and 250°C, respectively.

Conclusion

Polycondensation of symmetric dimer of dimethyl ketene with excess of aromatic and aliphatic diamines afforded amino telechelic oligomers and polymers with partially and totally cycloaliphatic structures. These new compounds could be used for synthesis of new polyamides.

Self-assembling Waves in Nanocomposites on Hydrophilic Polymer Base and their Advanced Applications

Ibragim E. Suleimenov

Almaty University of Power Engineering and Telecommunications, Almaty, Kazakhstan

Esenych@yandex.ru

Introduction

Research of the waves spontaneously arising in solutions of polymers and nanocomposites on this base is of not only academic, but also practical interest. In present report, particularly, it is shown that such waves can be used for the recording of data into the distributed environments. The basis for this purpose is the earlier observed hysteresis phenomena occurring in solutions of some stimulus-sensitive polymers [1].

Experimental

The (poly)-N-isopropylacrylamide (PNIPA) solutions containing silver nanoparticles obtained by photochemical reduction at various concentrations of components have been researched. Investigated solution is characterized by the apparent hysteresis that accompany the phase transition (from transparent to the nontransparent media) at temperature rise up to 35^0C [1]. Namely, dependences of the optical density of the solution at its heating and cooling differ and are shifted in temperature up to 3-5^0C. The solution was heated by electrical current in the galvanostatic mode directly. Dependences of the intensity of light passed through the solution on time were registered.

Results

It is shown, that there are definite conditions when heating of the solution by the electrical current leads to occurrence of fluctuations of optical density that can convert into a wave mode (fig. 1). The curve corresponds to the conditions of transition from the transparent to the turbid media. One can see, that there are regular fluctuations in the transition region. The occurrence of such fluctuations depends both on concentration of low-molecular component and on concentration of nanoparticles.

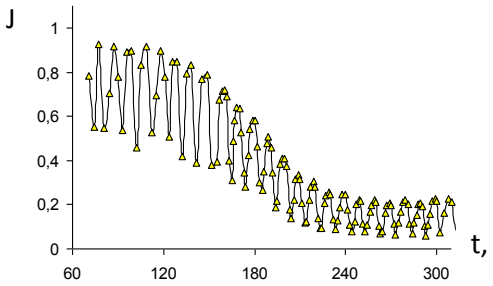

Fig. 1. Observed oscillations in PNIPA solution.

Discussion

The mechanism of occurrence of fluctuations is illustrated by Fig. 2. The S-like curve of dependence of optical density on temperature corresponds to occurrence of the hysteresis phenomena. Transition from one condition of the solution to another occurs at various temperatures (T_1, T_2).

It is shown, that oscillation takes place in such system according to the following mechanism. At the first stage the heating up to the temperature of phase transition occurs. It causes change of electrical conduction of the environment by jump, which is connected presumably with change of the state of the nanoparticle surface. Accordingly the electric power dissipated by the local region of the solution decreases, which results in its cooling and the subsequent transition to the initial condition (the second stage of oscillation). The hysteresis results in delay that provides for the stability of value of the registered fluctuations period.

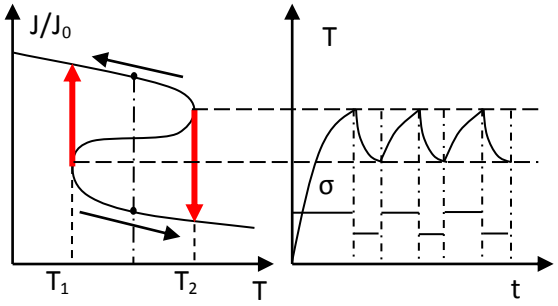

Fig. 2. Scheme of occurrence of oscillations.

It is shown also that in various points of the solution fluctuation occur in various phases, i.e. in the considered system the wave modes can be realized as well. Such waves can be used for recording of data in the distributed environment. Namely, with focusing waves in a certain point of the solution it is possible to achieve irreversible phase transition.

The design of the device is suggested in present report that provides stimulation of the waves of considered type. A set of equidistant point-electrodes is used that are arranged on the perimeter of an area filled with the polymer solution containing nanoparticles. It is shown, that artificial alteranting of phases between various sources allows synthesis of waves with arbitrary configuration of front (spacing between the electrodes should to be less than a half of the wavelength).

Conclusion

The phase transition in the thermosensitive polymer solutions containing nanoparticles is accompanied by the change of conductivity of the hysteresis character. The heating of such solution by electrical current results in the occurrence of steady fluctuations. They can convert into the waves. Such waves can be used for recording of data in the continuous media. It gives possibility for development of the display screens that do not require physical splitting into separate image elements (pixels).

Effect of Poly(amic acid)-treated $BaTiO_3$ on the Dielectric and Mechanical Properties of $BaTiO_3$/polyimide Composites

Jinhwan Kim

Department of Polymer Sci. and Eng., Polymer Technology Institute, Sungkyunkwan University, 300 Cheoncheon-dong, Jangan-gu, Suwon, Gyeonggi-do 440-746, Korea (South)

jhkim@skku.edu

A lot of attention has been paid to develop organic/inorganic composites utilized in electronics applications such as circuit board, packaging material, dielectrics, and passive protection materials. Among them, many efforts have been attempted to develop the embedded capacitor which can replace traditional discrete components. For this application, key materials are polymer/inorganic filler composites by taking advantages of polymers (processability) and inorganic fillers (high dielectric property and thermal stability). Incorporation of inorganic fillers having high dielectric constant (K) into a easily processable organic polymer matrix enables the resulting composite to retain the advantages of both materials.

For this purpose, barium titanate ($BaTiO_3$) is most widely employed among various inorganic fillers available commercially. On the polymer side, polyimide (PI) is widely used due to its excellent thermal stability and high mechanical strength not only in embedded capacitors but also in general purpose insulating materials. Therefore, combination of $BaTiO_3$ and PI would be a good choice for the above mentioned polymer/inorganic filler composite and thus many researches have been carried out to investigate various aspects of composites. One faces the difficulty of dispersing $BaTiO_3$ particles in PI precursor, which is a typical problem encountered in processing the polymer/inorganic filler composite. Since the properties of polymer/inorganic filler composites are significantly influenced by the dispersion of the filler particles, in addition to inherent properties of the polymer and inorganic fillers, the dispersion control is the key technology for obtaining the desired properties of polymer/inorganic filler composites.

Most common approach to control the dispersion of $BaTiO_3$ particles in PI matrix is to treat $BaTiO_3$ particles with a silane coupling agents. However, Chang et al. claimed very recently that as-received $BaTiO_3$ particles lack reactive functional groups on their surfaces and thus it is difficult to form chemical bonds with organic modification agents. They also showed that the treatment of $BaTiO_3$ particles with hydrogen peroxide (H_2O_2) can produce –OH groups on the surfaces.

In this presentation, we first modify the surfaces of as-received $BaTiO_3$ by adopting Cheng's method to induce –OH groups that will be further reacted with a coupling agent. If this approach is valid, the surfaces of $BaTiO_3$ particles would have significantly increased numbers of –OH groups, which enables further reaction with a coupling agent. Then, with the proper choice of a coupling agent, we may induce the reaction of coupling agent. Thus, modified $BaTiO_3$ particles are able to react with the PI precursor (poly(amic acid)) even at low temperature such as below 100 ^oC and are able to obtain poly(amic acid)-wrapped $BaTiO_3$ particles can be obtained. The schematic diagram of this sequential treatments is presented in Scheme 1. By employing this approach, we hope to obtain improved dispersion and consequently better electrical and mechanical properties.

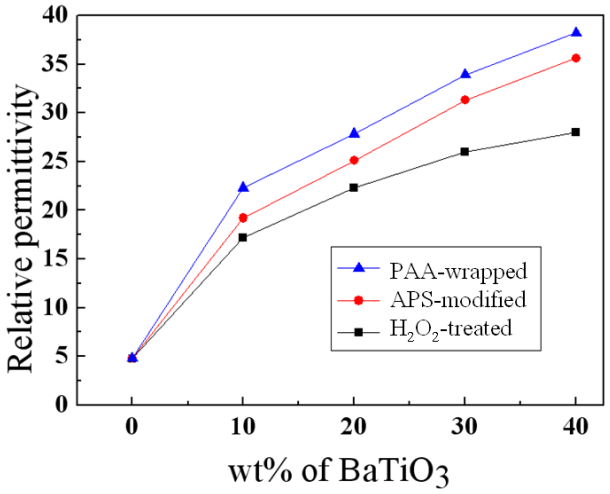

Figure 1. Relative permittivity at 1 MHz various surface modified $BaTiO_3$/PI composites as a function of $BaTiO_3$ concentration: (a) H_2O_2-treated, (b) APS-modified, and (c) PAA-attached $BaTiO_3$.

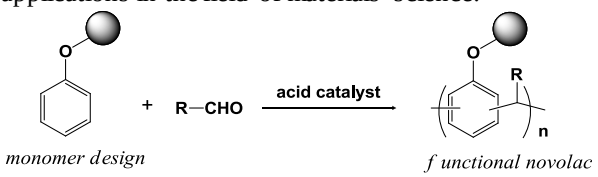
New Phenolic Resins for Advanced Materials

Gen-ichi Konishi

Tokyo Institute of Technology, Department of Organic and Polymeric Materials

konishi.g.aa@m.titech.ac.jp

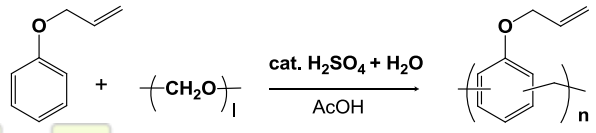
Phenolic resins and related polymers are a very important class of common organic polymers, and they have numerous applications in the development of materials such as thermosetting resins, adhesives, photoresists, and polymer composites. The main characteristics of phenolic resins, such as heat stability and mechanical properties, are attributed to their rigid rod-like polymer backbone of *poly(phenylenemethylene)*. From this viewpoint, we have synthesized a wide variety of aromatic polymers from alkoxylated phenol derivatives such as anisole, phenethol, and diphenyl ether *via* a method similar to acid-catalyzed phenol-formaldehyde condensation. The obtained polymers exhibit good solubility in organic solvents and they are more resistant to heat and oxidation than phenolic novolacs. Furthermore, using hydroxyl-group-functionalized phenol derivatives, a functional novolac can be prepared via a one-step procedure. Therefore, a desired polymer can be designed using this methodology (Scheme 1).[1,2] It is very important to extend the use of this methodology to a wide variety of applications in the field of materials science.



Scheme 1

In this presentation, we report the direct synthesis of a functional novolac having allyl ether in the side chain by the addition-condensation of designed phenol derivative with formaldehyde and the polymer reactions of the obtained polymers are also described.

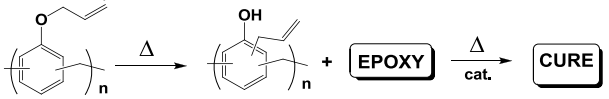
We attempted the preparation of an allylated novolac. The addition-condensation of allyl phenyl ether (**1**) with formaldehyde was carried out; however, a novolac having allyl ether and phenolic hydroxyl groups was obtained *via* simultaneous phenol-formaldehyde condensation and Claisen condensation processes. In order to suppress the Claisen rearrangement, the addition-condensation of **1** with formaldehyde was carried out by using aqueous sulfuric acid and stirring at room temperature (25°C).



Scheme 2

The obtained novolac **2** had good solubility in common organic solvents. From the viewpoint of the procedure for preparing novolac, an advantage of this polymerization method is that it is quite easy to obtain a high-purity polymer. The ^{13}C-NMR spectrum provided details of the polymer structure of **2**. In particular, we focused on the zone at around 150 ppm of the aromatic carbon attached to the allyloxy group. The mono- (terminal moiety), di- (linear moiety), and tri-substituted (branch moiety) moiety can be identified by chemical sifts such as 153 (-CH_2-Ar), 156 (-CH_2-Ar CH_2-), and 150 (-CH_2-Ar-CH_2-(-CH_2-)-), respectively. The ratio of terminal, linear, and branch were 20%, 80%, and ~0%, respectively. It is noted that the main-chain structure of the obtained novolac was different form that of conventional novolac having a branch moiety. *The allylated novolac was linear structure*.

In order to investigate the applicability of the obtained allylated novolac for the curing reaction of thermosetting resins such as epoxy and phenolic resin, we examined the thermal Claisen rearrangement of the allylated novolac (**2**) by using DSC apparatus. From the DSC chart, large endotherms (88.9 and 153.6°C) and exotherms (140.1 and 217.5°C) were observed. The Claisen rearrangement is exothermic. At 150°C, ca. 40% of hydroxyl group have been generated; therefore, this allylated novolac can potentially be used as a thermal latent curing system (**Scheme 3**).



Scheme 3

In addition, we reported a novel optical materials based on lignin as a new phenolic polymer.[3] We successfully prepared lignophenols (**LP**) having hydroxyl groups alkoxylated with different types of alkyl halides via Williamson ether synthesis. We found that hydroxyl-group-alkoxylated **LP**s can be used as optical materials because the refractive indices and birefringences of these **LP**s are comparable to those of **PC**. The obtained polymers exhibited good film-forming abilities with transparency. These results suggest that natural polymer **LPs** are highly advantageous in that they have very good material properties and they can be produced from biomass.

Covalent Attachment of Cholesterol Oxidase on Transparent Polyaniline Film for Cholesterol Sensing

T. Del Castillo-Castro, M.M. Castillo-Ortega, A. Ortiz Rascón, E.F. Placencia Fontes

Departamento de Investigación en Polímeros y Materiales, Universidad de Sonora, Apartado Postal 130, Hermosillo, Sonora CP 83000, México

e-mail: terecat@polimeros.uson.mx

Introduction:

The immobilization of biomolecules, such as proteins and peptides, is quite useful for practical applications due to their potential to improve the stability of enzymes [1,2]. The immobilization of enzymes can allow repeated use, facile separation from reaction mixtures, and prevent enzyme contamination in products [3].

In this work, a potential optical biosensing system composed by a poly(methyl methacrylate) (PMMA) support, a transparent thin film of polyaniline (PANI) and a covalent immobilized cholesterol oxidase (ChOx) is presented (Figure 1).

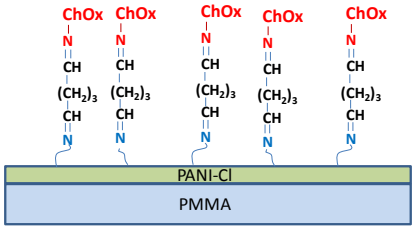

Figure 1. PMMA/PANI-ChOx system.

Materials and Methods:

Transparent and conductive thin films of PANI on PMMA support were obtained by the chemical bath method. PMMA substrates were introduced into a freshly prepared chemical bath of HCl, doubly distillate aniline and $(NH_4)_2S_2O_8$ at room temperature. The deposition of PANI was carried out at different reaction times and the resulting films were characterized by electrical measurements (multimeter Agilent 34410A), FTIR (Perkin Elmer, Spectrum GX), UV-vis spectroscopy (Perkin Elmer, Lambda 20) and atomic force microscopy (JSPM-4210).

Cholesterol oxidase was immobilized onto PANI films using covalent linkage through glutaraldehyde. First, 5 µL of 0.1% glutaraldehyde was spread over 1cm^2 surface of PANI film and allowed to dry. Later, 15 µL of cholesterol oxidase was added onto the same surface and left overnight. After immobilization, the PANI-ChOx films were rinsed with deionized water to remove any unbound enzyme molecule.

Results and Discussion:

The electrical measurements showed that the superficial conductivity of PANI film increased with the deposition time up to the 30 min, afterwards the value remained constant till the 80 minutes. The monitoring of the characteristic absorption band of *–NH-* group by FTIR confirmed the PANI deposition since the 5 min of chemical bath. Figure 2 depicts the UV-vis spectra of PMMA/PANI films as function of deposition time.

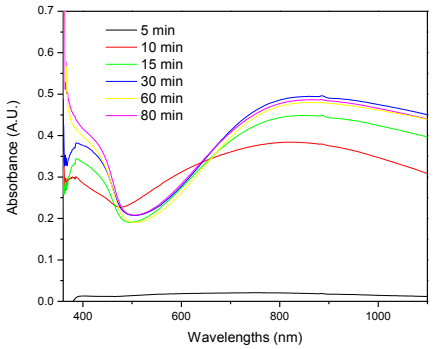

Figure 2. UV-vis spectra of PMMA/PANI system.

The UV spectra are characteristic of PANI salt in extended coil conformation: (*i*) band at 430 nm associated to π-polaron transition and (*ii*) broad free-carrier tail in the NIR. The intensity of absorption increases up to 30 min of deposition that can be attributed to the increase of PANI film thickness. Further deposition time does not produce significant optical changes. The AFM analysis showed that the PANI homogeneously deposited in globular form and this morphology persists up to 80 minutes of chemical bath.

The PMMA/PANI system obtained at 30 minutes of reaction was selected for the enzyme immobilization on the basis of its electrical, optical and morphological properties.

The immobilization of ChOx onto the PANI film produced a decrease of the superficial electrical conductivity as well as changes in FTIR and UV-vis spectrum.

Conclusion:

A potential biosensing platform of PMMA/PANI-ChOx was obtained by the PANI deposition using chemical bath and the subsequent covalent immobilization of the enzyme on the electroconductive polymer. The detailed studies of the effect of the pH and the temperature on the activity of the immobilized ChOx and the use of the PMMA/PANI-ChOx system for estimation of free cholesterol by optical methods are in progress in our laboratories.

Two-dimensional 4T-acceptor conjugated polymers have been shown to have excellent charge-transport characteristics and solar cell performances.[1] In this study, new two-dimensional conjugated homopolymer poly(5,5'''-di-(2-ethylhexyl)[2,3';5',2'';4'',2''']quarterthiophene) (P4T) and their copolymers, P4TT, P4TSe, P4TFT, P4TBDT, and P4TDTS, were synthesized by Stille coupling reactions under microwave heating. The effects of chemical structures on the electronic energy level, charge transport, and photovoltaic properties were explored systematically. Among these copolymers, P4TFT showed the highest organic field effect transistor (OTFT) hole mobility of 0.12 $cm^2 V^{-1} s^{-1}$ due to its highly crystalline packing structure. The performances of bulk heterojunction polymer solar cells based on the blends of these 4T-based copolymers and 1-(3-methoxycarbonyl) propyl-1 - phenyl-[6,6]-C-71 ($PC_{71}BM$) were also characterized. P4TSe/ $PC_{71}BM$ based photovoltaic device showed the highest power conversion efficiency (PCE) of 2.6% under AM 1.5 illumination (100mW/cm^2). The above results exhibited that two-dimensional conjugated copolymers emerged as a promising candidate for organic electronics.

Obtaining and stability of iodine-cationic starch complexes

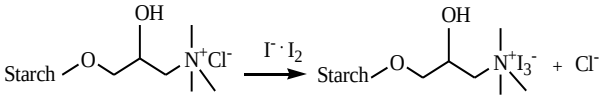
Rima Klimaviciute, Joana Bendoraitiene, Ramune Rutkaite, Algirdas Zemaitaitis

Kaunas University of Technology, Radvilenu pl. 19, LT-50254 Kaunas, Lithuania

rima.klimaviciute@ktu.lt

Iodine has traditionally been available in solutions or tinctures but shows a high degree of instability. This problem was overcome by the development of iodophores (iodine carriers or iodine releasing agents). In the presence of potassium iodide iodine crystals dissolve in aqueous solution forming triiodide ions (I_3^-). One of the possibilities to obtain iodophores is the formation of complexes between I_3^- and cationic groups of polymer.

Starch is a low-cost natural renewable polymer that can be cationized with 2,3-epoxypropyltrimethylammonium chloride by reaching a high reaction efficiency [1]. Obtained cationic starches (CS) can interact with anionic iodine compounds and form ionic iodine-CS complexes possessing antimicrobial activity:



Depending on the conditions of cationization reaction and source of starch the CS with different properties have been obtained (see Table).

Table. CS used for iodine-CS complexes formation

Source of starch	Cationic starches (CS)	
	Solubility	Abbreviation
Hydroxyethyl starch (HOES)	Water soluble	CHOES
	Nanoparticles in water	Nano-CHOES
Native starch	Paste in cold water	PCS
	Water soluble	SCS
Cross-linked starch	Microparticles	CCS

Nano-CHOES were obtained by aqueous polyelectrolyte complex formation between water soluble CHOES and sodium tripolyphosphate. The formation of CHOES nanoparticles of spherical shape was verified by dynamic light scattering and scanning electron microscopy measurements. The nano-CHOES of different constitution and containing various amount of free quaternary ammonium groups were produced.

For formation of iodine-CS complexes nano-CHOES, CHOES, SCS or CCS with degree of substitution (DS) from 0.14 to 0.85 were used. The nano- or microparticles of iodine-CS complexes or water soluble complexes were formed. The iodine content introduced into iodine-CS complexes depended on the amount of free cationic groups in nano-CHOES, DS of SCS or CCS and the concentration of iodine in the aqueous iodine-potasium iodide solution used in the experiment. The maximum amount of iodine attached to CCS with DS=0.85 was 6.5 mmol/g and supported the presumption that more than two molecules of iodine could be attached to one cationic group of CCS.

Both the thermal stability and the ability to release iodine into the water or aqueous solution of HOES were assessed for iodine-CS complexes containing different content of incorporated iodine. The thermal stability of iodine-CCS complexes depended on the DS of CCS, the counter-ion of quaternary ammonium group and the amount of attached iodine. The thermal stability of nano-CHOES complexes increased with the introduction of polysalt into polyelectrolyte complex. The amount of released iodine into the water and aqueous solution HOES was lowest in the case the CCS-iodine microgranules or nano-CHOES-iodine were used.

The main advantage of the use of iodine-CS complexes as antimicrobial agents is the biodegradability of the polymeric matrix. As could be seen from the photographs presented in Fig. the CCS microgranules were easily destroyed during enzymatic treatment. Thus after the iodine consumption for antibacterial actions the remaining matrix of CS will be biodegradable.

Stabilization of Liposomes by Multilayer Films of Modified Polysaccharides

Anna Karewicz, Dorota Bielska, Anna Socha, Maria Nowakowska

Nanotechnology of Polymers and Biomaterials Research Group, Faculty of Chemistry, Jagiellonian University, 30-060 Cracow, Ingardena 3, Poland

karewicz@chemia.uj.edu.pl

Introduction: Liposomes are widely used as effective carriers of the biologically active agents, especially those of low bioavailability or low stability. Despite their many advantages (easy penetration of the cell membranes, low size, biocompatibility) liposomal vesicles suffer from their tendency to aggregate, significant leaking of the encapsulated drug and fast elimination by the reticuloendothelial system. The presented results illustrate our approach to limit these disadvantages and to enhance the efficiency of the carrier. Our method is based on coating of the liposomes with ultrathin films of biocompatible polyelectrolytes using layer-by-layer technique. The previous studies conducted in our group proved the supremacy of so-called "one-component" multilayer films, where polycation and polyanion chains possess the same backbone. Such films are more easily built and are more stable [1]. We have chosen three different natural polysaccharides and modified them in order to form stable coatings on the liposomes. Nanocarrier systems composed of liposomal vesicles coated with various mono and multilayer ultrathin polymeric films are discussed and compared.

Materials and Methods: To characterise modified polysaccharides ^{1}H NMR, elementary analysis and IR spectroscopy were used. The formation process and properties of the multilayered polymeric films were followed by UV/Vis absorption spectroscopy and AFM measurements. Stability of the obtained nanocarrier systems was tested using DLS, zeta potential and Cryo-TEM measurements, as well as the spectroscopic and conductometric titration.

Results and Discussion: Chitosan, dextran and hydroxypropylcellulose were modified by introducing the ionic groups and hydrophobic chains to their backbones. 2-Hydroxypropyl-1-trimethylammonium unit was introduced to obtain cationic derivatives while the anionic ones was obtained by the modification with sulfate moieties. Both groups were chosen in a way to assure the stable charge of the chain (positive or negative, respectively) for the wide range of pH values. All derivatives were characterized to confirm the successful modification of the initial polymer and the properties of the obtained compounds were determined. The ability of the obtained derivatives to form stable multilayer films was studied in detail. For all the "one-component" films an effective growth of the film thickness upon addition of subsequent layers was observed. However, while for the chitosan film a monotonous growth of the film was found up to ten bilayers, in the case of dextran the distinct substrate effect was observed. The coating procedures were developed and the effective coating of the liposomal vesicles by all the multilayer films studied was confirmed by following the size and zeta potential changes. Finally the efficacy of obtained films to stabilize liposomes was tested. Triton X-100, the non-ionic detergent causing disintegration of the liposomal bilayer was used to study the stabilizing effect of the coating. It was found that already a single monolayer increases the vesicle's stability for all polymers studied, provided that it is additionally anchored into the liposome's bilayer by the alkyl chain. Additional layers tend to increase further the stability of the liposome-polymer systems.

Conclusions: A series of ionically modified polysaccharides was obtained and they properties were characterised. Additional derivatization of the cationic chains was done in order to introduce the anchoring alkyl chains. All three polysaccharides used for further modifications can form stable multilayer systems. Chitosan-based "one-component" films, unlike the dextran-based ones, do not show the substrate effect during formation. Several polymer-coated liposomal carriers differing in the type of the coating and the number of the layers deposited on the vesicle's surface were studied. Already a monolayer polymer coating increases vesicle's stability, provided it is additionally anchored to the liposomal bilayer by the covalently attached alkyl chain, but multilayer coatings are even more promising.

smadriga@una.ac.cr

Instroduction: Natural polysaccharides, due to their outstanding merits, have received more and more attention in the field of drug delivery systems. The present work is focused on the formulation of multilayered polysaccharide-coated liposomes based on layer-by-layer (L-b-L) self-assembly via electrostatic deposition technique as a novel drug carrier for delivery of macromolecules, such as proteins. The building up of the polysaccharide-coated liposomes was achieved through the alternate adsorption of several layers of anionic (dextran sulfate or alginate) and cationic (chitosan) polysaccharides on a core composed by anionic nanosized soybean lecithin vesicles. The resulting nanoparticles were characterized according to their size, surface charge, morphology, encapsulation efficiency, loading capacity, as well as their protein release profiles.

Materials and Methods: *Formulation of liposomes:* Soybean lecithin liposomes were prepared from concentrated soy lecithin dispersions (250 g/L) according to procedures previously described. *L-b-L self-assembly of polysaccharide-coated liposomes by electrostatic deposition:* Fresh solutions of chitosan (CHT), alginate (ALG) and dextran sulfate (DXS) in concentrations ranging 0.01-0.25% w/v were prepared, in acetic acid (HOAc) 0.5% v/v for chitosan biopolymer and sodium chloride 10^{-5} mol/L for dextran sulfate and alginate, respectively. For the L-b-L build-up, the anionic liposomes from soybean lecithin were coated with alternating layers of positively charged CHT and negatively charged DXS or ALG (volume ratio of 1:1, respectively) until the desired number of polysaccharide layers was achieved. Addition of the newest layer was always carried out by adding the previous formulation dropwise, under continue stirring, into the coating solution, in order to avoid flocculation depletion and potential cross-linking caused by the lacking of the coating polysaccharide.

Results: Stable polysaccharide-coated liposomes were formed within only a narrow concentration range ($c_{min} < c < c_{max}$), and below and above this optimal range the liposomal system aggregated and eventually phase separated from solution. The minimal concentration required to form stable multilayered coated liposomes can be estimated from the change in ζ-potential with addition of each biopolymer layer. The L-b-L self-assembly electrostatic deposition technique succeeded in building a nanosized, spherical, monodisperse and stable hybrid protein delivery system (Figure 1) with a cumulative apparent hydrodynamic diameters between 357.3 ± 25.3 and 498.2 ± 69.6 nm and surface charges (ζ-potential) between -30.66 ± 1.55 and -26.74 ± 1.04 mV for the liposomal systems coated with 8 alternating monolayers of chitosan and dextran sulphate or alginate, respectively.

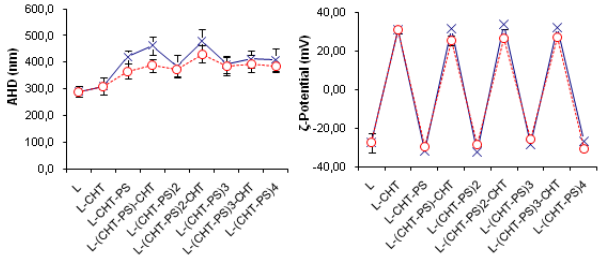

Figure 1. Apparent hydrodynamic diameter (AHD) and ζ-potential change with the adsorption of alternate polysaccharide layers onto soybean lecithin liposomes.

The systems offer good properties for encapsulation on its liposomal aqueous core and sustained release of a model protein, *in vitro* (Figure 2).

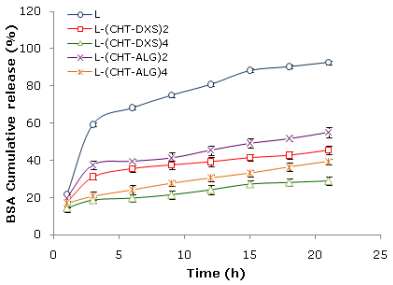

Figure 2. Bovine serum albumin (BSA) cumulative release from liposomes and polysaccharide-coated liposomes assembled with 2 and 4 polymeric bilayers. (L, uncoted liposomes; CHT, chitosan; DXS, dextran sulfate; ALG, alginate).

Conclusions: This study has shown that L-b-L self-assembly of polysaccharide-coated liposomes can be achieved by adding cationic (chitosan) and anionic (dextran sulfate or alginate) polysaccharides to a suspension of anionic liposomes (soybean lecithin) under carefully controlled solution compositions. The polysaccharide-coated-liposomes exhibited better release properties of a model protein, bovine serum albumin, than uncoated liposomes during cumulative release studies. Polysaccharide-coated liposomes may subsequently be of significant interest as novel biomaterial for the improved delivery of macromolecules such as, polymeric drugs or vaccines.

Microparticles of the natural polymer Chitosan in aqueous suspension: stability of particle size distribution

Barboza, Ana Claudia R. N.[1,2]*; Pessine, Francisco B. T.*[1]

1. University of Campinas (Unicamp); 2. 3M Company

anabarboza@iqm.unicamp.br

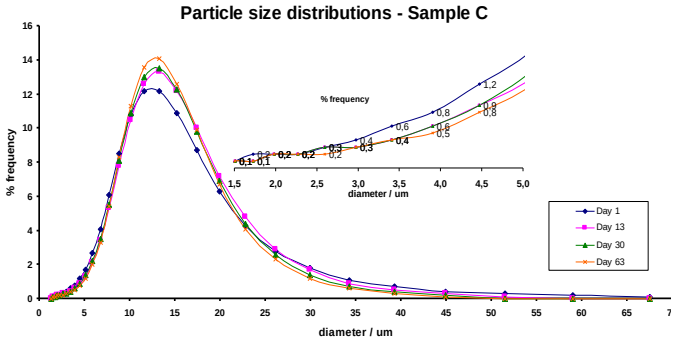
Introduction: Polymers have proved to be effective carrier systems for sustained release of active substances. Biocompatibility and biodegradability in physiological conditions, generating innocuous degradation products, as well as safe formulations, are essential for this end use. The use of Chitosan (CTS) for that purpose has been extensively described in scientific literature and patents[1].
Preparations free of organic solvents help assure safety and avoid costly purification steps. Investigation and optimization of ionic crosslinking processes to obtain Chitosan micro and nanoparticles in water[2,3] are required to enable release profiles of actives suitable to various physiological media and administration routes, meeting a wide applications range. Stability of microparticles suspensions is also a critical feature.
This study aims to verify the stability of Chitosan microparticles aqueous suspensions ionically crosslinked by sodium triphosphate (TPP), in the presence of a polysorbate to avoid microparticles aggregation over time.

Materials and Methods: Chitosan (Chitopharm S) was kindly supplied by Cognis Brasil. Sodium Triphosphate (TPP) was acquired from Sigma Aldrich. Polysorbate (PS, Alkamuls 80) was kindly supplied by Rhodia.
Microparticles were prepared according to methodology[4] modified at our laboratory[5]. TPP solution at pH 5 was dropped on aqueous CTS solution at pH 4.5 with 1% PS during agitation using a high shear mixer at 5000 rpm for 12 min., and magnetic agitation for 6h.
Particle average diameter and particle size distribution (PSD) were measured by laser scattering with HORIBA LA-900 equipment on days 1, 13, 30 and 63.

Results and Discussion: Average particle diameters are summarized in the following table. For each sample, median particle diameter(µm), mean and standard deviation are presented; * values are averages of replicates.
Variation of initial (Day 1) particle diameter from one sample to another is inherent to the preparation process and can possibly be improved by a steadier dropping of TPP on the chitosan solution.
Particle size distributions (PSD) of Sample C are shown in the following figure; other samples behaved similarly. Analyzing the slight variations in PSD from Day 1 to Day 63, one sees a trend towards higher number of average-size particles and lower number of larger particles. Possible interpretation of this trend is that large ionically crosslinked microparticles are less stable and break apart into smaller particles.
When the section of the curve corresponding to smaller particles (< 5 µm) is looked closer, a slight decrease in the number of those particles is also seen. This gives indication of successful stabilization by PS, since only a small number of particles tend to aggregate into larger ones.

	Day 1			Day 13		
Sample	median	mean	std dev	median	mean	std dev
A	7,2*	11.3*	9.7*	7.7*	15.8*	14.4*
B	3.1	7.9	7.4	7.5*	10.6*	8.9*
C	6.9	12.9	11.5	5.9*	13.0*	12.0*

	Day 30			Day 63		
Sample	median	mean	std dev	median	mean	std dev
A	14.1	17.2	25.0	14.3	16.9	9.9
B	8.8	10.1	5.6	8.4	9.1	4.2
C	11.8	12.7	5.6	11.8	12.6	5.3



Conclusions: Chitosan microparticles obtained by direct ionic crosslinking with TPP in aqueous media showed to be adequately stabilized by PS on a 2 months time range, encouraging further studies of sustained release formulations using these particles as carriers.

Preparation and Evaluation of Novel Absorptive and Antibacterial Polyurethane Membranes for Wound Dressing Application

Abbas Yari, Hamid Yeganeh, Hadi Bakhshi*

Polyurethane Department, Iran Polymer and Petrochemical Institute, P.O.Box: 14965/115, Tehran, Iran

E-mail: h.yeganeh@ippi.ac.ir

Introduction

The skin is the first barrier of body against bacteria that cause infections. Thus, when skin damage the protection of the skin is a vital problem. Wound dressings can be used as a barrier against bacterial contamination and provide condition for wound healing [1]. An ideal wound dressing should has some specific characteristics such as hydrophilicity, permeability to water vapor, oxygen permeability, transparency for follow up wound healing, ability to absorb body fluids, good handling, proper adhesion, sufficient resilience, and antibacterial activity [2]. Due to excellent mechanical and physical properties as well as promising blood compatibility, polyurethanes have been widely used for biomedical applications. Additionally, because of their good barrier properties and oxygen permeability they are often used in wound dressings [3]. Functionalization of polymers by proper quaternary ammonium components, is an effective route for the induction of antibacterial activity [4] In the current study, wound dressing polyurethane membranes with strong antibacterial activity against both gram positive (Staphylacoccus aureus) and gram negative (Escherichia coli) bacteria as well as promising physical properties were prepared.

Experimental

The crosslinked membranes were synthesized by co-curing of epoxy terminated polyurethane prepolymers (EPUs) and glycidyltriethylammonium chloride (GTEACl) at different molar ratios with proper amount of 1,4-tetramethylenediamine as curing agent.

EPUs were prepared from polyethylene glycol at M_n= 1000 and 2000 g/mol, hexamethylene diisocyanate and glycidol. GTEACl was also synthesized from the reaction of epichlorohydrine with triethyl amine.

Results and discussion

The structure of prepared membranes was evaluated by FTIR spectroscopy and uniform incorporation and distribution of quaternary ammonium chloride groups in the polymers matrix was proved via Energy-Dispersive X-ray Spectroscopy and following the concentration of chloride ions.

The mechanical properties of membranes were evaluated from stress-strain curves. The molecular weight of EPU and GTEACl content were influenced the crosslink density (υ_c) and consequently the tensile properties of membranes. As it was expected, the υ_c decreased with increasing molecular weight of EPU and increasing of GTEACl content (because it was a monofunctional reagent). Depend on aforementioned variables the tensile strength and elongation at break of membranes were in the range of 1.0-10 MPa and 70-400% respectively.

It is well known that surface drying not only impedes delivery of nutrients and immune defenses to the wound surface but also markedly impedes the ability of cells to migrate across the wound surface. Therefore, among major parameters of the ideal wound dressing, water vapor transmission rate (WVTR) and equilibrium water absorptive capacity (EWA) of the dressing, which control the fluid balance are important parameters. The measured data are collected in Table 1, which showed direct dependence of these parameters to both υ_c and GTEACl content. For QPN-2000 samples, WVTR is much better than commercially available wound dressings, Tagaderm and Opsite. The water absorption data of prepared films clearly showed that these wound dressings are absorptive, so they can be employed for high exudative wounds.

The biocompatibility of membranes was evaluated by their cell culture with both L929 Fibroblast and MCA-3D Keratinocyte cell lines. As well, MTT assay showed excellent cells viability for all of the prepared membranes. Therefore, these membranes displayed good level of biocompatibility for wound dressing application. The antibacterial activity of membranes was evaluated by shaking flask and Agar plate methods (Table 1). All of membranes containing GTEACl showed good antibacterial properties. The bacteria reduction (BR%) increased with increasing the quaternary ammonium groups' content.

Conclusion

Due to acceptable tensile properties, excellent biocompatibility and antibacterial properties as well as optimum WVTR and EWA these membranes are promising candidates as wound dressing for high exudative wounds.

Introduction: Macroporous polymer beads containing a permanent well-developed porous structure in dry state have a wide range of applications such as catalyst,[1,2] immobilization of enzymes,[3] HPLC supports, liberation of active substances, adsorbents,[4] among others. Their porous structure facilitates the diffusion of different solutes through the polymeric network.[5] Since these networks have particular properties such as a high crosslinking degree and a rigid structure in both swollen and dry state,[6] the study of their synthesis is therefore of considerable interest.[7] The influence of crosslinking agent content and stirring speed on the structure of the polymer network obtained for the system 2-hydroxyethyl metacrylate (HEMA) and ethylene glycol dimetacryclate (EGDMA) by suspension polymerize-tion was studied. The matrix pore system and its crosslinking degree were evaluated, principally, from their swelling in water. Characteristics parameters of the porous network were also obtained from a simple mathematical model.

Results and discussion: The water distribution between empty spaces of the network (w_{abs}^{water}) and the water adsorbed by polymer chains (w_{ads}^{water}) were obtained from water evaporation kinetics of swollen samples (Figure 1).

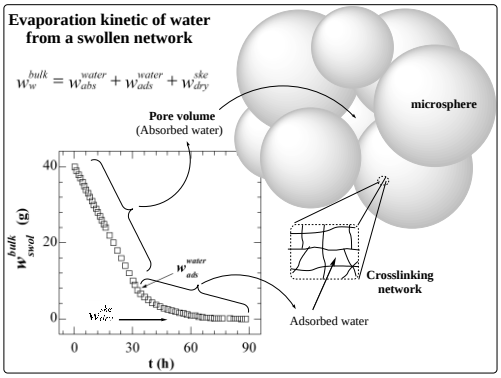

Figure 1. Evaporation kinetics of water from a swollen network indicates that water is retained by the matrix through the adsorption phenomenon and between empty spaces by absorption into the pores.

The development of a simple mathematical model for swollen networks allowed us to achieve relevant parameters such as the porosity (Eq. 1), and the volume increase of both pore and network.

$$\varepsilon_{swollen} = 1 - \left[\frac{(Q_{w_{ads}}^{water} - 1)}{\delta^{water}} + \frac{1}{\delta_{dry}^{ske}} \right] \cdot \frac{\delta_{dry}^{bulk}}{Q_v^{bulk}} \qquad (1)$$

Where the equilibrium water content, $Q_{w_{ads}}^{water}$, represents the fraction of water adsorbed by the network and the swelling volume degree, Q_v^{bulk}, corresponds to the network expansion. On the other hand, the true, δ_{dry}^{ske}, and apparent density, δ_{dry}^{bulk}, were determinated by pycnometric measurements.

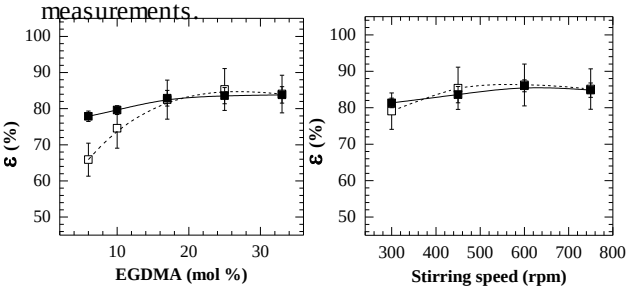

Figure 2. Porosity of the network in dry (filled symbols) and swollen state (open symbols).

Macroporous polymer networks synthesized with an EGDMA content higher than 10 mol% or using a stirring speed above 300 rpm exhibited a stable pore architecture (Figure 2). This behavior agrees with a high crosslinking density of the network formed, which depends, principally, on the crosslinker content.

Conclusions

The kinetics of water evaporation from swollen networks and the mathematical model proposed were used to describe the morphology of macroporous polymer networks. Water distribution into the network was used to determine parameters of interest such as porosity and volume increase of both pore and network. Results shown that samples with higher degree of crosslinking have stable pore architecture.

Abstract

Two high performance polymers, polytetrafluoroethylene (PTFE) and Ultra high molecular weight polyethylene (UHMWPE) are investigated using several tools. The failure behavior exhibited by both polymers at different extrusion rates are discussed as a function of the time factor. The time at which both polymers failed is shown to be constant. These results reflect that the failure is independent on the rate of stretch, at least in specific range of stretching rates. The change of the maximum attainable draw ratio with the initial polymer concentration is investigated at different temperatures. At 130 ºC, the maximum attainable draw ratio increases as the initial polymer concentration decreases. The effect of drawing on the melting endotherm at different rates is also demonstrated for the drawn UHMWPE. Two peaks are observed, and may represent two components of morphology within the film and not a reorganization phenomenon. The second peak starts to disappear at draw ratio 4 and completely disappear at draw ratio 7. The melting point of the drawn gel films is shown to be nearly the same. The changes in morphology of the stretched UHMWPE are investigated by the scanning electron microscopy. The morphological changes in relation to specimens with different concentrations are given. Disentangled network and fibril structure are formed at the final stage. Several attempts are made to etch and to replicate UHMWPE to reveal the internal microstructure using the transmission electron microscope. Permanganic etching and both one and two-stage replication methods are used for this purpose.

Nonvolatile Memory Transistors using Ferroelectric P(VDF-TrFE) and Printed Semiconducting Channel

Organic non-volatile memories are the emerging research field due to its unique characteristics in charge storage properties and a relatively low manufacturing cost. Conjugated molecules and solution processable charge storage materials enable to realize the memory device by simple and cost-effective solution processes such as spin coating or various graphic art printing techniques. Among the many possible configurations for ONVMs, organic field effect transistors (OFETs)-based memory has many advantage including non-destructive read-out, complementary integrated circuit architectural compatibility, and single transistor realization.

To realize high performance ferroelectric OFET memory, ferroelectric polymer materials must show both robust mechanical properties as a gate dielectric and large dipole polarization as a memory element. Poly(vinylidene fluoride-trifluoroethylene) [P(VDF-TrFE)] copolymer is one of the promising materials to fulfill both properties at once.

There have been many reports on the memory characteristics of P(VDF-TrFE) with metal-ferroelectric-metal, metal-ferroelectric-insulator-semiconductor capacitors, or OFETs. Although these results clearly suggest a high feasibility of P(VDF-TrFE) for nonvolatile memory, there are a few challenges must be addressed such as a high programming voltage, low switching speed, and insufficient data retention time and various approaches including modifications of material and/or device structure have been proposed.

In this study, we demonstrate a low voltage operated top gated ferroelectric polymer transistor memory with a inkjet-printed organic semiconductor active channel and a poly(vinylidene fluoride-trifluoroethylene) ferroelectric gate insulator. Key features of our ferroelectric memory devices are all-solution process and a relatively low operating voltage. The low operating voltage was achieved by single P(VDF-TrFE) dielectric layer and the memory device typically operated a low gate and source-drain bias below 15 V.

Abstract Body: The intra- and inter-chain interactions in polyamide 6 (PA6) molecules are responsible for their thermal stability, high toughness and tensile properties that make PA6 possess bright perspective and advantage in developing high tensile strength with superior performance in textile field [1]. Several attempts have been made to improve the draw ratio and tensile strength values of polyamide fibers by disrupting the strongly interacted hydrogen bondings present in melt-crystallized PA6 fibers by adding crystallization inhibitors [2-5]. However, as far as we know, no investigation has ever been reported regarding the effects of $CaCl_2$ contents on the drawing and tensile properties of PA6 composite fibers. In this study, the beneficial effect of crystallization inhibitors on the drawing properties of the PA6 fibers was investigated using PA6/$CaCl_2$ composite fibers prepared at varying compositions. The compositions of the PA6/$CaCl_2$ specimens prepared in this study are summarized in Table 1. The influence of calcium chloride ($CaCl_2$) contents on the drawing and tensile properties of polyamide 6 (PA6) /$CaCl_2$ composite fibers prepared at varying drawing temperatures were investigated. At any fixed drawing temperature, the achievable draw ratio (D_{ra}) values of $PA6_x(CaCl_2)_y$ as-spun fiber specimens approach a maximum value, as their $CaCl_2$ contents are close to the 3 wt% optimum value. The maximum D_{ra} values obtained for $PA6_x(CaCl_2)_y$ as-spun fiber specimens prepared at the optimum $CaCl_2$ content reach another maximum as their drawing temperatures approach the optimum drawing temperature at 120 °C. The initial modulus, tenacity and birefringence values of the PA6 and $PA6_x(CaCl_2)_y$ fiber specimens were found to improve consistently with D_{ra} or with drawing temperatures when they were stretched to a fixed D_{ra}. Similar to those found for their achievable drawing properties, the ultimate modulus, tenacity and birefringence values of $PA6_x(CaCl_2)_y$ fiber specimens approach a maximum value, as their $CaCl_2$ contents and drawing temperatures approach the 3 wt% and 120 °C optimum values, respectively. The above interesting thermal and tensile properties of $PA6_x(CaCl_2)_y$ fiber specimens are attributed to the complex interactions between Ca^{2+}, Cl^-, carbonyl and amide groups of PA6 molecules during their preparation processes.

Table 1 Compositions of PA6 and $PA6_x(CaCl_2)_y$ as-spun fiber specimens.

Samples	PA6 (wt %)	$CaCl_2$ (wt %)

Abstract The drawing properties of the modified PA 6 (MPA) fiber specimens prepared at varying drawing temperature were systematically investigated, wherein the MPA resins were prepared by reactive extrusion of PA 6 with the compatibilizer precursor (CP). At any fixed drawing temperature, the achievable draw ratio (D_{ra}) values of MPA as-spun fiber specimens increase initially with increasing CP contents, and then approach a maximum value, as their CP contents are close to the 5 wt% optimum value. The maximum D_{ra} values obtained for MPA as-spun fiber specimens prepared at the optimum CP content reach another maximum as their drawing temperatures approach the optimum drawing temperature at 120 °C. The tenacity and birefringence values of PA 6 and MPA fiber specimens improve consistently as their draw ratios increase. Similar to those found for their achievable drawing properties, the ultimate tenacity and birefringence values of MPA fiber specimens approach a maximum value, as their CP contents and drawing temperatures approach the 5 wt% and 120 °C optimum values, respectively. Investigations including Fourier transform infrared, melt shear viscosity, gel content, thermal and wide angle X-ray diffraction experiments were performed on the MPA resin and/or fiber specimens to clarify the optimum CP content and possible deformation mechanisms accounting for the interesting drawing and ultimate tensile properties found for the MPA fiber specimens prepared in this study.

Experimental The polyamide 6 (PA 6) and compatibilizer precursor (CP) used in this study were obtained from Zig Sheng Industrial Corporation and Formosa Chemicals and Fiber Corporation, Taipei, Taiwan, wherein PA 6 (Zisamide HP1101) is nylon 6 and CP is a 40% zinc-neutralized ethylene/acrylic acid copolymer (95:5). The Irganox B225 antioxidant was purchased from Ciba-Geigy Corporation, Basel, Switzerland. Before melt blending, PA 6 was dried at 80 °C for 16 hours. The dry-blended PA 6/ CP resins with 1000 ppm antioxidant were then fed into atwin-screw extruder (SHJ-20, Nanjing Jiant Corp., Nanjing, China) at varying weight ratios to make MPA resins. The extruder was operated at 210 °C in the feeding zone and at 230 °C towards the extrusion die with a screw speed of 100 rpm. The CP modified polyamide (MPA) resins obtained from the twin screw extruder was quenched in cold water at 15 °C and cut into pellet form. The compositions of the MPA specimens prepared in this study are summarized in Table 1.

Table 1 Compositions of PA 6 and MPA specimens.

Samples	PA 6 wt %	CP wt %	Samples	PA 6 wt %	CP wt %
PA 6	100	0	MPA_{10}	90	10
$MPA_{2.5}$	97.5	2.5	MPA_{15}	85	15
MPA_5	95	5	MPA_{20}	80	20
$MPA_{7.5}$	92.5	7.5			

Results and discussion

Fig. 1 summarized the values of achievable draw ratio (D_{ra}) of PA6 and MPA as-spun fiber specimens drawn at varying temperatures but at a fixed drawing rate of 50 mm/min. In a way similar to those found for their birefringence properties, at any fixed drawing temperature, the D_{ra} values of MPA as-spun fiber specimens increase initially with increasing CP contents, and then approach a maximum value, as the CP contents are close to the 5 wt% optimum value.

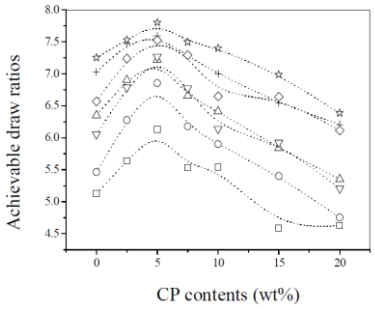

Figure 1 The achievable draw ratios of MPA_x specimens drawn at 25 °C (□), 60 °C (○), 80 °C (△), 100 °C (◇), 110 °C (+), 120 °C (☆) and 140 °C (▽) drawing rate 50 mm /min.

Abstract. Systemic investigation of the influence of the plain and functionalized carbon nanotube (CNT) contents on the ultradrawing properties of ultrahigh molecular weight polyethylene/carbon nanotubes and UHMWPE/functionalized CNTs as-prepared fibers are reported. In a way similar to those found for the orientation factor values, the achievable draw ratios (D_{ra}) of the FC_y and FC_{fx-y} as-prepared fibers approached a maximum value as their CNT and/or functionalized CNT contents reached their corresponding optimum values. The maximum D_{ra} values obtained for $FC_{fx-0.001}$ as-prepared fiber specimens prepared at varying maleic anhydride grafted polyethylene (PE_{-g-MAH})/modified CNTs weight ratios were significantly higher that of the $FC_{0.0015}$ as-prepared fiber specimen prepared at the optimum plain CNT content. Tensile property analysis further suggested that excellent orientation and tensile properties of the drawn FC_y and FC_{fx-y} fibers can be obtained by ultradrawing the fibers prepared at their optimum plain CNT and/or functionalized CNT contents. To understand the interesting orientation, ultradrawing and tensile properties of FC_y and FC_{fx-y} fiber specimens, FTIR, specific surface area, and SEM morphology analysis of the plain and functionalized CNTs were performed in this study.

Experimental. The UHMWPE resin used in this study is associated with a weight-average molecular weight (Mw) of 7.6 x 10^6, which will be referred to as resin U in the following discussion. The carbon nanotubes (CNTs) used in this study will be called C. Maleic anhydride grafted polyethylene (PE_{-g-MAH}) resin with a grafting ratio of 1.5 wt% was used to modify and functionalize CNTs for well-dispersing in UHMWPE/CNTs gel solutions. The sample designations of functionalized CNTs and weight ratios of modified CNT/ PE_{-g-MAH} used in the functionalizing experiments are summarized in Table 1. The ultrasonicated plain CNT or functionalized CNT solutions were then mixed with U resin at varying weight ratios and concentrations at 150 °C for 4 hours, during which 0.1 wt % of di-*t*-butyl-*p*-cresol was added as an antioxidant.

Table 1 Designations of functionalized CNT specimens and weight ratios of modified CNT/PE_{-g-MAH} used in the functionalizing experiments.

Functionalized CNT specimens	Weight ratios of PE_{-g-MAH}/ modified CNT
C_{f1}	5
C_{f2}	10
C_{f3}	15
C_{f4}	20

Results and discussion. The plain CNT specimens had a large specific surface area of 100.5 m^2/g. After oxidation by acid, the specific surface areas of the modified CNT specimens increase significantly to 184.7 m^2/g. The specific surface areas of the functionalized CNT specimens are even higher than those of the plain and modified CNT specimens. The specific surface areas of the functionalized CNT specimens increase significantly and reach the maximum value at 272.7 m^2/g as their weight ratios of PE_{-g-MAH} to modified CNTs increase to the optimum value at 10. Fig. 1 summarized the achievable draw ratios (D_{ra}) of the FC_y and FC_{fx-y} as-prepared fibers prepared at varying CNT and functionalized CNT contents. After addition of the plain and/or functionalized CNTs in UHMWPE, the D_{ra} values of both FC_y and FC_{fx-y} fiber series specimens increase significantly with the initial increase in plain and/or functionalized CNT contents. Note that the D_{ra} values of both FC_y and FC_{fx-y} fiber series specimens reach a maximum as their plain and/or functionalized CNT contents approach the optimum value at 0.0015 and 0.001 wt%, respectively.

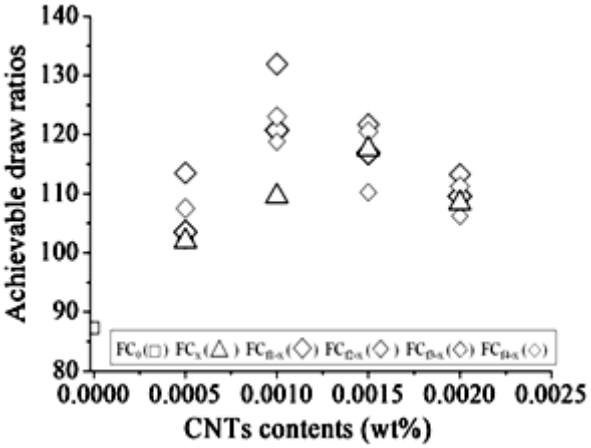

Fig. 1 The achievable draw ratios of FC_0, FC_x, FC_{f1-x}, FC_{f2-x}, FC_{f3-x} and FC_{f4-x} as-prepared UHMWPE fiber specimens prepared at varying CNTs contents.

Abstract

In the investigation, effects of surface modification by argon plasma on peel strength of woven type ultra high molecular weight polyethylene (UHMWPE) were studied. After plasma treated, the free radicals were generated on woven type UHMWPE surface and then converted to peroxide offer exposed to air. The concentration of peroxides were estimated by the 1,1-dipphenyl-2-picrylhydrazyl (DPPH·) method. From the results, the optimum free radical content for offering high T-peel strength was 1.27×10^{-9} mol/mm^2 at 40 W plasma-treated for 4 min. The plasma treated woven type UHMWPE possessed the hydrophilic property and introduced the number of anchors. The 3M 4475 adhesive possessed functional groups of N-H stretching vibrations (3333.36 cm^{-1}) and carbonyl stretching vibrations (1731.76 cm^{-1}). As it reacted with plasma treated UHMWPE, the chemical bonding significant increased in the adhesion strength between woven type UHMWPE and adhesive. This fibrils peel mechanism can offer peel strength as T-peel testing. As Surface modification by plasma treatment, the peel strength of UHMWPE fiber with adhesive 4475 composites was increased from 1.17 to 2.26 kgf/in.

Experimental

The woven type ultra high molecular weight polyethylene (UHMWPE) fiber was used as matrix, in which Spectra® fiber made by Honeywell, USA. 3M™ Scotch-Weld™ Nitrile High Performance Plastic Adhesive 4475 made by 3M Adhesives Division, USA. 1,1-dipphenyl-2-picrylhydrazyl (DPPH·) made by Tokyo Kasei, JAPAN. The UHMWPE fibers just were put into the cylinder and subjected to Ar plasma treatment. Ar plasma treatment was carried operating at 40 Watt and time of 4 min. The sample was cut into 100 × 25 mm by length and width. T-peel test was carried out using a tensile machine at room temperature in velocity of 10mm/min provided by ISO. The woven type UHMWPE fiber (25×50 mm^2) was immersed in a 1.0×10^{-4} M benzene solution of 1,1-diphenyl-2-picryhydrazyl (DPPH·) and kept at temperature 70 °C for 24 h to decompose the peroxide formed on the UHMWPE fiber surfaces. The DPPH· consumed was measured by the change of absorbance at 521 nm of UV–VIS spectra. The characteristic absorption peaks of functional groups of plasma-treatment UHMWPE fiber or UHMWPE fibers/adhesive composite were detected by a JASCO FT/IR-6200 IR (infrared) spectrometer.

Results and discussion

Fig. 1 showed that the optimum free radical content was 1.27×10^{-9} mol/mm^2 in plasma (40 W, 4 min) [1].

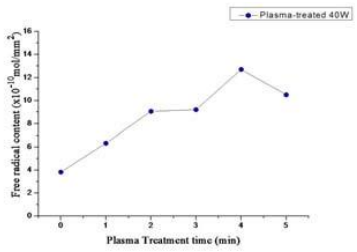

Fig. 1 Free radical content vs. times of various plasma treatments for woven type UHMWPE fiber.

Adhesive 4475-treated UHMWPE fiber and untreated UHMWPE fiber (Fig. 2) showed a new absorption appearing at 3341 and 1733 cm^{-1}, which had been assigned to amide groups and carbonyl groups. These new absorptions suggest that amide groups and carbonyl groups were formed on the adhesive 4475 surfaces [2].

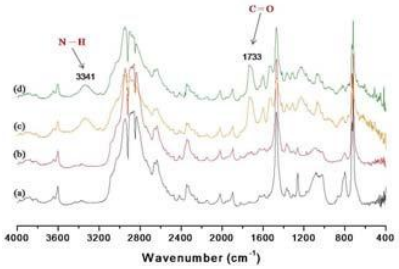

Fig. 2 The FTIR spectum of UHMWPE fibers using PR method in 60º (a) Un-treated fiber (b) Plasma-treated fiber (c) Fiber/Adhesive4475 (d) Plasma treated fiber/Adhesive 4475.

Fig. 3 showed that the optimum plasma treatment that could be induced at the UHMWPE fiber/adhesive 4475 peel strength was increased to 2.26 kgf/in [3].

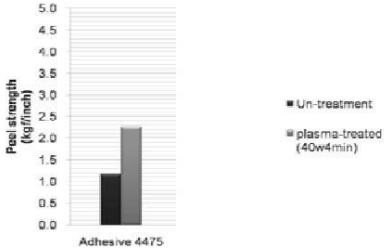

Fig. 3 Peel strength of woven type UHMWPE bonded by adhesive and after woven type UHMWPE fiber surfaces treatments (plasma 40w 4min).

Design and Synthesis of Low Refractive Index, Organosoluble, and Thermally Stable Fluorinated Polyamides Having *Ortho*-Linked Aromatic Units in the Main Chain

Ali Javadi, *Abbas Shockravi*

Faculty of Chemistry, Tarbiat Moallem University, No. 49, Postal Code 1571914911, Tehran, Iran

a.javadi@hotmail.com

Introduction

Wholly aromatic polyamides (PAs) are considered to be high-performance materials due to their high thermal stability, chemical resistance and outstanding mechanical properties, which make them useful for advanced technologies. However, most PAs are usually difficult to process due to their limited solubility in common organic solvents and high glass-transition temperatures. Therefore, many efforts have been made to improve the processing characteristics of these relatively intractable polymers. It has been demonstrated that incorporation of both flexible ether linkages and bulky naphthalene units into the polymer backbones can enhance the solubility and processability of aromatic polyamides without any significant reduction in thermal stability [1]. Another attractive approach employed to increase the solubility of polyamides is the incorporation of less symmetric units such as *ortho*-catenated aromatic rings in the main chains which leads to a reduction in crystallinity [2]. Recently, considerable attention has been devoted to the synthesis of fluorinated aromatic polyamids, especially the trifluoromethyl (CF_3)-containing poly(ether amide)s (PEAs) [3]. It has been recognized that the incorporation of bulky $-CF_3$ groups into PA backbones resulted in an enhanced solubility and optical transparency together with a lowered refractive index and dielectric constant, which was attributed to the low polarizability of the C–F bond and the increase in the free volume [4]. As part of our recent efforts to develop high-performance fluorinated polymers with excellent solubility and high thermal stability, as well as low refractive index and low birefringence for advanced optical and electronic applications, the current work reports the synthesis and characterization of a series of fluorinated PEAs from a high-purity CF_3-containing diamine, (DA), with various commercially available aromatic dicarboxylic acids.

Materials and Methods

The new CF_3-containing bis(ether amine), 1,1'-sulfide-bis-[(2-trifluoromethyl)4-aminophenoxy) naphthyl ether], was prepared in a two-step process. The first step is the chloro-displacement reaction of 2-chloro-5-nitrobenzotrifluoride with the potassium phenolate of 1,1'-thiobis(2-naphthol) formed in situ by the treatment with potassium carbonate in DMSO. The target bis(ether amine) was readily obtained in high yields by the Pd/C-catalyzed reduction of the intermediate dinitro compound (DN) with hydrazine hydrate in refluxing ethanol. The direct polycondensation was adopted here to prepare aromatic poly(ether amide)s.

Results and Discussion

All of the polymers were amorphous in nature, showed good solubility and could be readily dissolved in amide-type polar aprotic solvents (e.g., NMP, DMAc, DMF, and DMSO) and even dissolved in less polar solvents (e.g., *m*-cresol, THF, pyridine, and chloroform). The amorphous nature and good solubility of these PEAs can be attributed to the effect of the packing-disruptive $-CF_3$ and naphthyl groups and the *ortho*-linked structure, which could inhibit close packing and reduced the interchain interactions to enhance solubility. The presence of flexible ether and thioether linkages in the bis(ether amine) moiety also contributed to the enhancement in solubility. The thermal properties of the PEAs were evaluated by thermogravimetry analysis (TGA) and differential scanning calorimetry (DSC). The T_g values of aromatic PEAs were in the range of 221–263 °C, which follows the decreasing order of the chain flexibility and steric hindrance of the polymers backbones. The temperatures at 10% weight loss (T_{10}) values of the PEAs were in the range of 483–537 °C in nitrogen and in the range of 461–527 °C in air, respectively. The amount of residue of all PEAs at 700 °C in nitrogen atmosphere was higher than 50%. The data from thermal analysis showed that the resulting PEAs had fairly high thermal and thermooxidative stability. The in-plane (n_{TE}) and out-of-plane (n_{TM}) refractive indices of the PEA films measured at 1320 nm range from 1.5633 to 1.5844 and 1.5578 to 1.5754, respectively. In general, the low refractive indices of the resulting polymers are obviously attributed to the introduction of flexible ether and thiother linkages and large free volume of the C–F bond that interrupts chain packing and increase free volume. In this work, all the PEA films exhibited positive birefringence (Δn =0.0055–0.0097), indicating that the molecular chains were preferentially aligned in the film plane. The low birefringence of the PEAs can be mainly attributed to the flexible linkages, which effectively reduce the in-plane orientation of the PA main chains. The dielectric constants (ε) of the polymers can be estimated from the refractive index according to Maxwell's equation ($\varepsilon = n_{AV}^2$). All the synthesized PEAs had relatively low ε (2.44–2.50).

Multiple bicolor fluorescent micropattern formation on a single polymer film based on the polymeric photobase generator containing oxime-urethane and anthracene groups

Kyu Ho Chae and Hak Soo Kim

Department of Polymer Engineering, Chonnam National University, Republic of Korea

khochae@chonnam.ac.kr

Introduction

The formation of fluorescent micropattern on a thin polymer film has attracted considerable interest due to their possible application to the areas of photonic/ elctronic devices such as displays, optical memory devices and molecular switches, as well as the biosensor chips and imaging industries. Several methods for preparing fluorescent micropatterns in polymer films have been reported. Most of these preparation methods are based on photogenerated acids. Recently, photogenerated free radicals and photobleaching of fluorescent polymers were also applied to obtain fluorescent micropattern in polymer films.

In previous work, we have reported on fluorescence imaging based on a polymeric photobase generator containing oxime-urethane groups through the use of a prefluorescent dye for amino group.[1] Another study described the polymer containing phthalimido carbamate groups as a bicolor fluorescent imaging material.[2]

Here, we report on the multiple bicolor fluorescent micropattern formation on a single polymer film through the use of the photobase generation of oxime-urethane groups and photobleaching reaction of anthracene groups. The formation of bicolor micropatterns in a polymer film is of potential interest for the incorporation of photonic/electronic polymers in optical data storage devices or displays.

Materials and Methods

Polymerization: Typical polymerization conditions were as follow. A solution containing methyl methacrylate (0.2 g, 2.0 mmol), 9-anthracenylmethyl methacrylate (0.19 g, 0.7 mmol), benzophenone oximinocarbonylaminoethyl mehacrylate (0.23 g, 0.7 mmol) AIBN (3.1 mg) in 5 mL of THF was charged into a cap tube and purged with nitrogen for 15 min. After sealing the cap tube containing the reaction mixture, polymerization was carried out at 60 ^{o}C for 20 h. The polymer was isolated by double precipitation from THF into methanol.

Fluorescence micropatterning: A polymer film on the silicon wafer was covered with a photomask and irradiated with 310 nm UV light (6.0 J/cm^2). The irradiated film on the silicon wafer was dipped in rhodamine B solution for 10 s and subsequently washed in methanol. The dyed film on the silicon wafer was dried at room temperature under reduced pressure. The fluorescence micropatterns were observed by confocal microscopy.

Results and Discussion

Scheme 1 shows the photochemical reaction of terpolymer containing anthracene and oxime-urethane groups. The terpolymer bearing anthracene groups is fluorescent, but it became no fluorescencent upon irradiation due to the dimer or endoperoxide formation. Concomitantly, the oxime-urethane groups in the terpolymer photodecomposed to form amino groups. Treatment of the amino groups with rhodamine B led to the formation of amine and rhodamine adduct. Thus, the non-irradiated part of the terpolymer film has blue fluorescence, while the irradiated part became fluorescent through the formation of rhodamine-amine adduct.

Scheme 1.

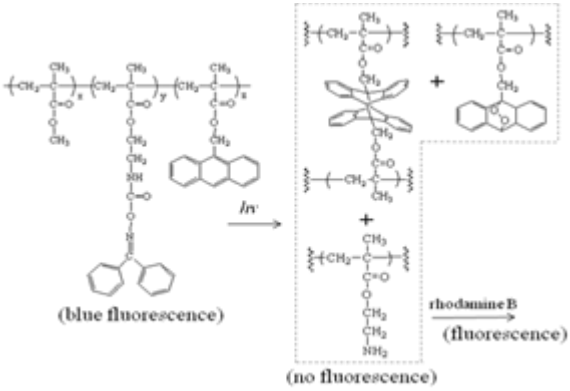

Figure 2 shows bicolor fluorescent micropatterns observed by the conforcal microscopy. Various bicolor micropatterns in a single polymer film were observed depending on the excitation wavelength.

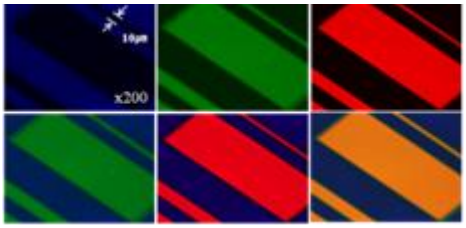

Figure 1. Fluorescent micropattern images obtained for a thin film of terpolymer on a silicon wafer.

In conclusion, we can create multiple bicolor micropatterns on a single polymer film through the use of photobleaching reaction of anthracene groups and photobase formation of oxime-urethane groups. This multiple bicolor micropatterning method may potentially be useful for the development of full-color displays or multiple optical data storage media.

Starburst Triarylamine-Containing Electroactive Aramids with Ultra-Stable Near-Infrared and Multicolor Electrochromism

Guey-Sheng Liou, Hung-Ju Yen, and Hung-Yi Lin*

Functional Polymeric Materials Laboratory, Institute of Polymer Science and Engineering, National Taiwan University, 1 Roosevelt Road, 4th Sec., Taipei 10617, Taiwan

E-mail: gsliou@ntu.edu.tw (Liou, G.-S.)

Electrochromic materials exhibit a reversible optical change in absorption or transmittance upon electrochemically oxidized or reduced, such as transition-metal oxides, inorganic coordination complexes, conjugated polymers, and organic molecules.[1]

Intramolecular electron transfer (ET) processes were studied extensively in the mixed-valence (MV) systems,[2] and usually employed one-dimensional MV compounds contain two or more redox states. According to Robin and Day,[3] the *p*-phenylenediamine (PD) (cation radical)s have been reported as a symmetrical delocalized class III structure with a strong electronic coupling (the electron is delocalized over the two or more redox centers), leading an intervalence charge transfer (IV-CT) absorption band in the NIR region.[4]

Our strategy in this work is to design and synthesize the electroactive NIR and multi-electrochromic starburst triarylamine-based materials with the incorporation of electron-donating substituents at the *para*-position of phenyl groups, thus could greatly prevent the coupling reactions by affording stable cationic radicals and lowering the oxidation potentials.[5] The advantage of more electroactive sites and better processability than the conventional linear polymer was due to the introduction of starburst triarylamine derivatives into polymer system.

In this contribution, we therefore synthesized the diamine monomer, *N*,*N*-bis[4-(4-methoxyphenyl-4'-aminophenylamino)phenyl]-*N'*,*N'*-di(4-methoxyphenyl)-*p*-phenylenediamine, and their corresponding aromatic polyamides containing starburst triarylamine units with *para*-substituted methoxy groups. The incorporation of electron-donating methoxy substituents is expected to reduce the oxidation potential associated with increasing electrochemical and electrochromic stability of the result polyamides. Thus, we anticipate that these novel polyamides should be excellent in many aspects such as electrochemical stability with multiple electrochromic switchings, optical response times, coloration efficiency, and high optical contrast in both NIR and visible light regions.

Abstract:
The reaction between epoxy and amine groups is one of the most efficent and studied reactions in the literature, especially for the synthesis of thermosetting polymers from α, ω functionalized reagents as diglycidyl ether of bisphenol A (DGEBA) with primary diamines. In the past, interesting researches have allowed to understand the mechanisms and the kinetics involved in the epoxy-amine reaction [1]. However, the reaction between α, ω functionalized-epoxy reagents and a monoamine was much less studied, especially with functionalized epoxy polydimethylsiloxane (PDMS-epoxy). Generally, these siloxanes are used for either cationic polymerization or photopolymerization [2].
Our work deals with the synthesis between a short functionalized glycidyl PDMS (PDMS AGE) and a long alkyl chain terminated primary amine without catalyst (Figure 1). All experiments have been carried out in a flask of 100mL using the same amount of reagents. The reaction has been studied for the molar ratio 1:1. We would like combining the good properties of PDMS such as wide temperature range use, flexibilty, good gas permeability, resistance to UV radiation with those of alkylamine in order to develop a product leading to a $(A_2B_2)_n$ copolymer structure with promising properties.

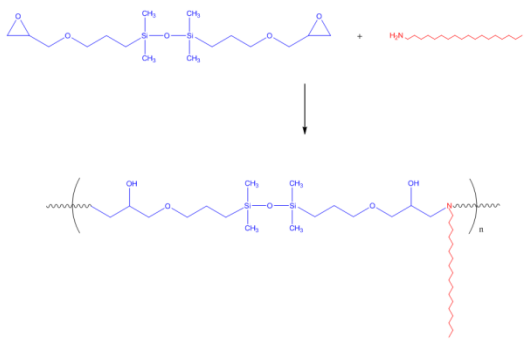

Figure 1: Reaction scheme between PDMS AGE and octadecylamine

First, the kinetic of the reaction was determined from PDMS AGE model compounds at different temperatures, evaluated by ^{1}H NMR. The reaction was efficient at low temperature (80°C) and the conversion of glycidyl groups reached at least 95% in all cases.

Then modelisations were performed using existing kinetic model. The adjustment between experimental data and Kamal and Sourour's model was excellent. Thefore the energy of activation could be determinated. The properties were studied by ATG and DSC. No residual alkylamine was observed by ATG. The structure was characterized by MALDI-TOF spectrometry and confirmed by GPC. We perfectly obtained the expected copolymer structure which is $(A_2B_2)_n$.

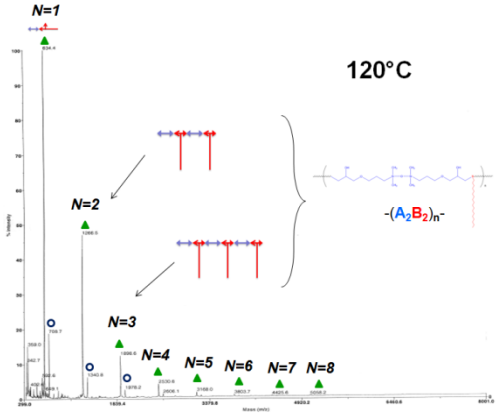

Figure 2: MALDI-TOF spectrum of copolymer obtained from PDMS AGE and oactadecylamine at 120°C.

We were able to prepare a copolymer based on polydimethylsiloxane and alkylamine using no catalyst. We reached the targeted copolymer structure which gave good stability properties. Finally, increasing the length of the "hard" part into the copolymer (like amino-functionalized polymers), we could imagine that the new product could be included to the thermoplastic elastomers class.

Ion conducting solid electrolytes based on different macromolecular architecture containing PEO

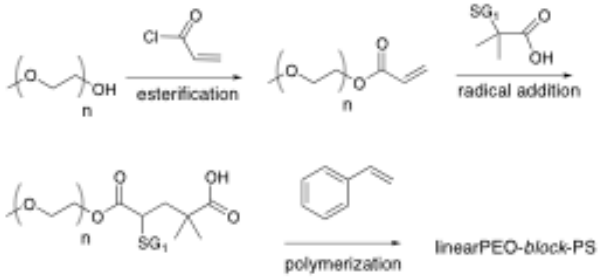
David Glé, Didier Devaux, Trang Phan, Renaud Bouchet, Michael Robinet, Denis Bertin and Didier Gigmes

UMR 6264 Laboratoire Chimie Provence, Université de Provence, Marseille, France

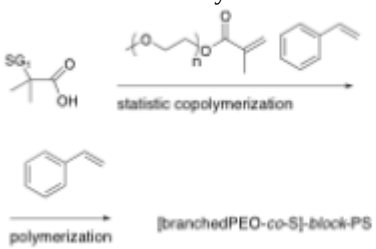
david.gle@univ-provence.fr

Since the first Armand's discovery of polyethylene oxide (PEO) containing a lithium salt as ion conductive solid polymer[1], the solid polymer electrolytes based PEO have been extensively studied and applied to lithium rechargeable batteries[2-3]. However, the ideal electrolyte material with the ionic conductivity of a liquid and the mechanical strength of a solid remains somewhat elusive. To satisfy the performance requirements which are quite contradictory, new solid polymer electrolytes based block copolymers have been prepared. Because of the net repulsion between the polymer blocks which are covalently bonded end-to-end, block copolymers segregate into periodically spaced, nanoscale domains. The PEO and their derivatives, a lithium-salt solvating polymer, are usually chosen as one block component providing ionic conductivity. The ordered morphology meanwhile confers global mechanical rigidity to the material. By this way, polymer electrolytes with microphase separation structures have been proposed by several groups. Sadoway and al.[4-5] have developed a Li^+ ion conductive polymer electrolyte based on a similar concept; a lithium polymer battery exhibits an ionic conductivity of 10^{-5} $S.cm^{-1}$ at room temperature was successfully fabricated. Niitani and al.[6-7] used a block copolymer consisting of a poly(ethylene glycol) methyl ether methacrylate (MAPEG) and polystyrene as solid polymer electrolyte; this polymer electrolyte exhibits a high conductivity 10^{-4} $S.cm^{-1}$ at room temperature.

In this study, the concept of microphase separation structure was used to prepare our solid polymer electrolytes (SPE). These SPE are block copolymers consisting of a glassy mechanical block (Tg≥ 100°C) and a linear (scheme 1) or (scheme 2) branched PEO moiety to provide ionic conductivity synthesized by controlled polymerization technique called Nitroxide Mediated Polymerization (NMP).



Scheme 1: Synthesis of SPE with linear PEO



Scheme 2: Synthesis of SPE with branched PEO

Various copolymers with different composition or architectures (di or triblocks, linear or branched PEO (figure 1)) were synthesized and characterized by Size Exclusion Chromatography (SEC) and Liquid Chromatography at Critical Conditions (LCCC). The SPE performances for ionic conductivity and mechanical strength were evaluated by Electrochemical Impedance Spectroscopy (EIS) and Dynamic Mechanical Analysis (DMA) respectively.

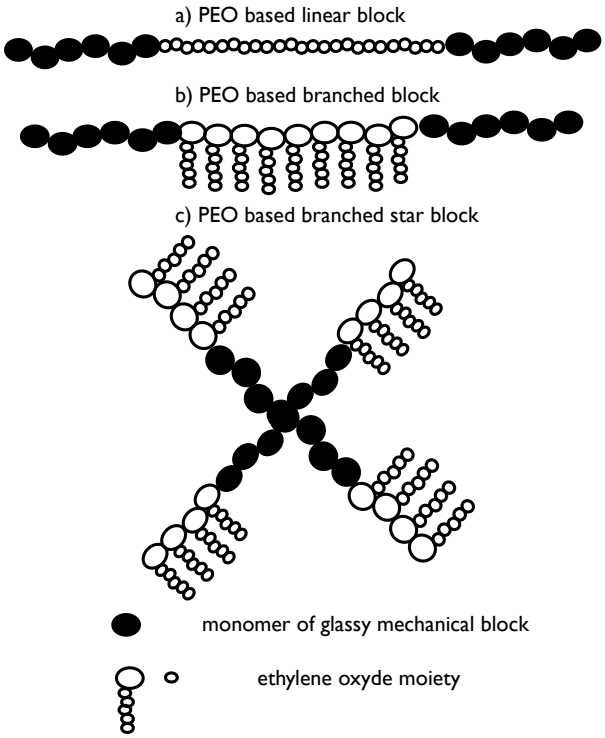


Figure 1: Architectures of SPE from linear or branched PEO

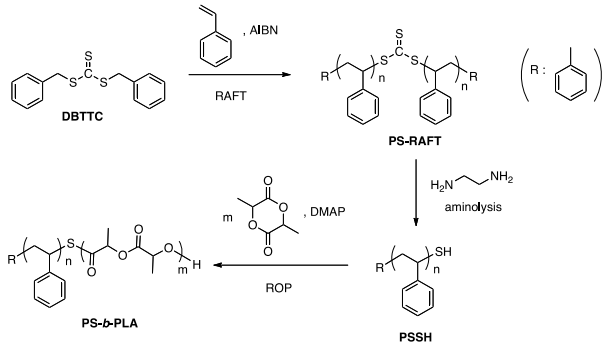
david.gle@univ-provence.fr

Polylactide (PLA) is one of the most studied polymers for biomedical applications and also as an alternative for petroleum based materials.[1,2] However, depending on the targeted applications, homoPLA can be brittle or ill-equiped to serve as a processable material.[3] To improve the mechanical properties, block copolymers have been studied and among the various potential architectures diblock copolymers with a PLA-based block synthesized via Ring Opening Polymerization (ROP) and a second block prepared via living/controlled radical polymerization (CRP) methods are an attractive option. Among these methods, Reversible Addition Fragmentation Chain Transfer (RAFT) is probably the most versatile due to the large range of functional monomers that can be polymerized.[4] To combine ROP and RAFT techniques, several main approaches exist. One of the most employed is based on a dual initiator, such as a RAFT agent bearing a functional group that is capable of initiating the ROP of lactides.[5] Alternative strategies have been developed as well, such as introducing the RAFT agent after the ROP[6] or combining silmultaneous RAFT and ROP to produce grafted copolymers.[7] However all those methods keep the RAFT agent intact either at the end or in the middle of the polymer chain, introducing potential problems with regard to block stability and/or toxicity.

The present work details our efforts in preparing diblock copolymers based on PLA and polystyrene (PS) or polyethylene (PE), where the two blocks are linked by a covalent sulfur bond. The key idea is to transform the dithioester/trithiocarbonate end group into a thiol function by aminolysis and to subsequently use it as the initiator of the ROP of lactide (see Scheme 1).



Scheme 1 Synthetic strategy for the synthesis of PS-*block*-PLA diblock copolymers

We initally present a model study employing styrylmercaptan as initiator for the ROP of lactide to prove the ability of thiols to ring-open the lactide in the presence of an organocatalyst. Subsequently, the synthesis of several PS-*block*-PLA copolymers with various PS/PLA length ratios is described.

The analyses of the polymeric material via multiple detector Size Exclusion Chromatography (SEC) and Liquid Chromatography under Critical Conditions (LCCC) as well as Diffusion Ordered NMR Spectroscopy (DOSY-NMR) evidences the formation of the desired block copolymer structures alongside residual macromercaptane and homopoly(lactide) in minor quantities. In addition, it was possible to prepare a thiol-capped poly(ethylene), which was subsequently employed to initiate the ROP of a lactide and to prepare a polyethylene-*block*-poly(lactide) copolymer, which formation was evidenced via NMR as well as SEC. The current study has demonstrated that it is indeed possible to employ RAFT derived macromercaptanes as initiating species in the organo-catalyzed ROP of lactides, thus providing an alternative platform for the generation of block copolymers with degradable and nondegradable strands.

urska.sebenik@fkkt.uni-lj.si

Introduction: In 1959, Hyde and Wehrly demonstrated a possibility of carrying out ring-opening polymerization of cyclosiloxanes in water emulsion[1]. Since then, anionic ring-opening polymerization (AROP) has been one of the most promising methods for preparing polysiloxane emulsions. D_4 (octamethylcycotetrasiloxane) has been the most widely used cyclosiloxane monomer in academic researches[1-8], patents[9-10] and in organosilicone industry.
In this work, batch AROP of D_4 in emulsion was investigated. Cationic and nonionic emulsifier were used. The concentration of emulsifiers was above their critical micelle concentration. Effects of emulsifier mixture concentration, nonionic/cationic emulsifier ratio and cationic emulsifier/initiator ratio on the kinetics and on the evolution of average molecular weight and distribution with time were studied and discussed[11].

Materials and Methods: Cationic emulsifier (hexadecyltrimethylammonium bromide - CTAB), nonionic emulsifier (secondary alcohol ethoxylate, Tergitol, Type 15-S-9), octamethylcyclotetrasiloxane (98%, Aldrich), KOH (p.a., Merck), deionized water.
Polysiloxane emulsions were synthesized isothermally at 80 °C in a 250 ml glass reactor equipped with a reflux condenser, a mechanical stirrer, a digital thermometer, and a nitrogen gas inlet. Monomer was added to the emulsifier solution and the pre-emulsion was stirred at 1000 rpm for 15 minutes. After 15 minutes, the mixture was heated and the stirring speed was lowered to 500 rpm. To initiate the polymerization KOH was added. The reactor content was sampled during the polymerization. To stop the polymerization HCl (0.5 M) was added to the withdrawn samples.
The conversion was determined by gravimetric analysis, by which the amount of monomer converted to large non-volatilizable polymeric chains was determined. Here, all volatile oligomeric cycles, which are formed during polymerization, were treated as monomer in conversion calculations. Average molecular weights were determined by gel permeation chromatography.

Results and Discussion: Monomer conversion and therefore polymerization rate increased with increasing overall emulsifiers' concentration, cationic/nonionic emulsifier ratio and cationic emulsifier/initiator ratio. KOH concentration affected polymerization kinetics only when the ratio KOH/CTAB was lower than equimolar ratio. Observations may be explained by polymerization mechanism proposed by Zhang[3] and De Gunzbourg[6]. During AROP in emulsion, different chemical reactions take place on the polymer particle surface and inside the particle. Main chemical reactions by which polymer is formed (initiation, propagation and termination) occur on the particle surface, where the cationic emulsifier is associated to the active centre (hydroxide anion). Therefore, it may be concluded that the polymerization rate is increased by increasing the specific particle/water interface and the number of active centres, which are defined also by the concentration of cationic emulsifier.
Average molecular weight and PDI increased with monomer conversion, what may be explained by polymer chain growth by successive polyaddition of D_4 and reversible termination at the particle surface and by chain growth by condensation reactions in the particle interior. By raising the amount of emulsifiers, the number of initiation sites increased what resulted in an increased number of polymer chains (N). Hence, at a given conversion, i.e. when an explicit part of monomer was consumed, the average length of chains was smaller while their number was larger. However, the initiation is not the only reaction that affects the N value. At higher conversions, condensation reactions become important as well. Each initiation reaction leads to the formation of one chain and each condensation reaction leads to the disappearance of one chain. Although the rate of N growth slowed down with time and conversion (N increased during the entire time (4 h) and conversion interval (up to 68%)), it may be concluded that initiation reactions prevailed over the condensation reactions during the period under investigation.

Kinetic Study of Aqueous Free- Radical Polymerization of 2-Acrylamido-2-methyl-1-propanesulfonic Acid via On-line ^{1}H NMR Technique

E. Nadim, H. Bouhendi, F. Ziaee, A. Nouri*

Iran Polymer and petrochemical Institute, P.O.BOX 14965/115, Tehran, Iran.

*Boouhendi@yahoo.com

Introduction

In recent years, Poly 2-acrylamido-2-methylpropanesulfonic acid, poly (AMPS), and its derivatives are often used as water- soluble polymers with various applications. Hence, according to the industrial application of poly AMPS, it is necessary to study its polymerization kinetic precisely to optimize the polymerization process and control characteristics of final product [1]. At this article, for the first time, the kinetic of AMPS polymerization in the presence of potassium persulfate in D_2O by ^{1}H NMR spectroscopy was investigated.

Materials and Methods

AMPS and potassium persulfate (KPS) were purchased from Fluka and Merck, respectively, Deuterium oxide (D_2O) as solvent was obtained from ARMAR Chemicals, Switzerland. H NMR experiments were carried out on a Bruker Avance 400 MHZ, Germany. At first a sample containing reaction mixture, solvent, monomer and initiator which was purged with nitrogen to remove dissolved air, was introduced into sample cavity and allowed to calibrate. Then, the sample tube was sent out. After setting the cavity at desired temperature, sample tube was inserted in to the sample chamber and the start time was recorded. The spectra were recorded at each 30-60 time interval up to high conversions (more than 75%).

Result and Discussions

Among different NMR techniques, ^{1}H was preferred over ^{13}C because of its greater sensitivity, higher rate of data collection and ability to use smaller diameter tubes, which helped maintaining isothermal conditions [2].

In order to estimate order of reaction the following equation was applied [2].

$$R_p = -\frac{d[M]}{dt} = \frac{d\Pi}{dt}[M_0] = k[M]^n[I]^p \qquad (1\text{-a})$$

or

$$R_p = k_0[M]^n[I]^p e^{\frac{E_a}{R}\frac{1}{T}} \qquad (1\text{-b})$$

Where R_p, [I], [M], [M_0] and E_a are polymerization rate, initiator and monomer concentrations, initial concentration of monomer, and activation energy respectively. In constant initial monomer content, slope of *-logR_p vs.-log [I]* shows the order of reaction with respect to the initiator concentration. Calculated amount of *p* was 0.48. *n* value determined by slope of *-logR_p vs.-log [M]* was 1.94. In a constant amount of monomer and initiator, slope and intercept of *-lnR_p vs.1/T* plot represent E_a and k_0, respectively. Calculated amount of E_a was 92.7kj/mol.K and k_0 determined by intercept of mentioned plot was 3.385×10^{13} mol.lit^{-1}.sec^{-1}.

As typical ^{1}H NMR spectra of a sample are illustrated in Figure 1.

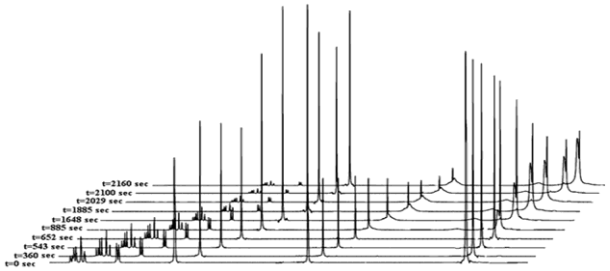

Figure 1: Typical ^{1}H NMR spectra at constant amount of initiator

Mechanistic study

The general rate of polymerization, with respect to usual assumption, is given by Equation (3);

$$R_p = k_p\left(\frac{2k_3}{k_t}\right)^{1/2}\left(\frac{K_c}{1+K_c[M]}\right)^{1/2}[S_2O_8^{-2}]^{1/2}[M]^{3/2} \qquad (3)$$

Order of reaction with respect to monomer from 1.5 to 1 would be described by above equation. But it is crucial to mention that for monomolecular termination, involving the reaction between the propagating radical and fragment of persulfate, order of reaction would reach to 2.

If R_{pm} represents polymerization rate by monomolecular termination (eq.4) and $\alpha = \frac{k_{tb}}{k_{tb}+k_{tm}}$ (in which k_{tb} and k_{tm} represent bimolecular and monomolecular termination constants respectively);

$$R_{pm} = k_p\left(\frac{K_c}{1+K_c}\right)\frac{2k_3}{k_{tb}}[M] \qquad (4)$$

Then R_p could be adjusted to Equation (5);

$$R_p = \omega[S_2O_8^{-2}]^{1/2}[M]^2\left\{\alpha\frac{1}{k_{tm}}\left(\frac{K_c}{1+K_c[M]}\frac{2k_3}{[S_2O_8^{-2}]}\right)^{1/2} + \left(\beta\left(\frac{1}{k_{tb}[M]}\right)^{1/2}\right)\right\} \qquad (5)$$

Where $\omega = (2k_3)^{1/2}k_p\left(\frac{K_c}{1+K_c[M]}\right)^{1/2}$ and $\beta = 1-\alpha$

Here, considering to monomer and initiator concentration and also initiation type, the power dependency of polymerization rate to monomer would change up to 2.

Conclusion

Determined order of reaction based on monomer and initiator resulted n=1.94 and p=0.49 with excellent deviations. Also, activation energy and k_0 over range of 35-47°C were determined and resulted E_a=92.7kj/mol.K and $k_0=3.385\times10^{13}$ mol. lit^{-1}.sec^{-1}.

Introduction: The problem of environment pollution has created an urgent need for the production of new biodegradable polymers. In addition, such materials have also found a wide variety of applications in the field of medicine, and aliphatic polyesters such as polylactide and polyglycolide are the state-of-the-art examples. Polyesters, however, suffer from weak mechanical strength and during their degradation the release of acidic products leads to a local acidic microenvironment due to bulk erosion, hindering cell growth and hence provoking inflammatory responses [**1**]. Polyesteramides (PEAs) include both ester and amide groups in the main polymer chain and thus combine the good mechanical and processing properties of technical polyamide with good biodegradability of aliphatic polyesters. At the same time, introduction of amide groups is also an approach to solve the problem of acidic degradation of polyesters due to surface erosion mechanism [**2-4**]. PEAs are mainly produced by batch synthesis, a well known example is the former commercial product from Bayer AG - BAK 1095 that is based on 1,4-butanediol, adipic acid and 1,6-aminohexanoic acid [**5**]. In literature the preparation of block and statistic polyesteramide on a twin-screw extruder from ε-caprolactam and ε-caprolactone was reported, however, it has never become an industrial process. In this work, we report a new reactive extrusion continuous process for the preparation of PEAs, which is based on the anionic ring opening polymerization of ε-caprolactam in the melt of commercially available polyester – polycaprolactone (PCL).

Materials and Methods: Sodium caprolactamate and hexamethylene-1,6-dicarbamoylcaprolactam were used as initiator and activator, respectively. The reactive extrusion was carried out on a twin-screw microcompounder (15 ml, DSM Xplore) combined with a mini injection molding machine (5 ml, DSM Xplore). The reaction conditions were optimized regarding the yield and molecular characteristics. The polymers synthesized in the microcompounder were stirred with water to remove the rest of monomer and to deactivate the initiator. The chemical composition of the synthesized PEAs was determined by means of elementary analysis. Differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) were employed to study the thermal behavior of the polymers. Size-exclusion chromatography (SEC) was performed using hexafluoroisopropanol with potassium trifluoro acetate (3 g/L) and toluene (2.5 mL/L) as eluent. The molecular weight was calculated against polymethyl methacrylate standards. The mechanical properties of PEAs were studied on a standard Zwick tensile tester (type Z010) using the specimens prepared on the mini injection molding machine.

Results and Discussion: PEAs of different chemical compositions were successfully prepared with almost quantitative yield. Monomodal molecular weight distribution was observed by SEC. The amide fragments were incorporated into the polyester backbone via the chain transfer reaction. Because of comparable melt viscosity before and after the polymerization reaction, the process design was significantly simplified. DSC curves of synthesized PEAs showed two melting and crystallization peaks upon heating and cooling, respectively. The position of these peaks is quite close to the phase transition temperatures of PCL and polycaprolactam, indicating the block structure of these PEAs. According to TGA measurement the PEAs exhibited a two-step degradation profile with weight losses occurring at lower temperature than both pure PCL and polycaprolactam. It was shown by tensile test that these polymers possessed quite good mechanical properties.

Conclusions: Block-structured PEAs were successfully prepared with almost quantitative yield by a new reactive extrusion continuous process that was based on anionic polymerization of ε-caprolactam in the PCL melt. The influence of initiator and activator concentrations as well as the ratio of two monomer units on the physico-chemical properties of synthesized PEAs was studied. Due to its simplicity this procedure can easily be up-scaled to an industrial process.

In this work, two types of hybrid nanocomposite samples were prepared, based on an addition of carbon coated cobalt (ccco) nanoparticles in a miscible blend of conducting Polyaniline (Pani) and polyurethane (Pu) matrix. The physical properties of the nanocomposites were studied in function of the doping rate and the mass fraction of polyaniline in the blend, from DC two microwave frequencies. Then two applications were treated; The first was the use of a polyaniline- polyurethane composite as an organic electronic ammonia sensor. The second application was relative to electromagnetic shielding in the microwave region.

The first nanocomposite was made with Pani in its insulating form (PaniEB) doped with Camphor Sulfonic Acid (CSA) and blended with Pu in solution. The doping transform the Pani from the insulating form (Pani EB) to a conductive form (PAni ES), and increase drastically the conductivity[1]. Pani-Pu composite showed a very low percolation threshold (<0.2%) with a maximum of conductivity of 10^4 S/m . Three doping rates were made : 10%, 25% and 50%; the latter correspond to the maximum of conductivity. Then we investigated the effect of doping rate on the reactivity of Pani-Pu composites with several concentrations of ammonia. The result showed that the reaction between ammonia and Pani-Pu composites depend on the doping rate. Moreover, the composite doped at 25% showed a detection threshold below 20ppb [Fig1].

The second nancomposite was obtained with the same components, adding magnetic carbon cobalt nanoparticles for EMI applications. We investgated the effect of doping and magnetic nanoparticles concentration (varies from 5 to 20%) on the electromagnetic properties (permitivity and permeability), shielding effectiveness (SE) and the absorption coefficient at microwave frequency [8-18GHz].

The results obtained showed a high shielding effectiveness (up to 80dB) and an absorption coefficient up to 10 dB [fig2]. The experience showed that we can adjust these characteristics by modifying the composition of the nanocomposite, to increase either the absorption (by increasing the magnetic charges concentration) or the reflexion (by increasing the Pani concentration).

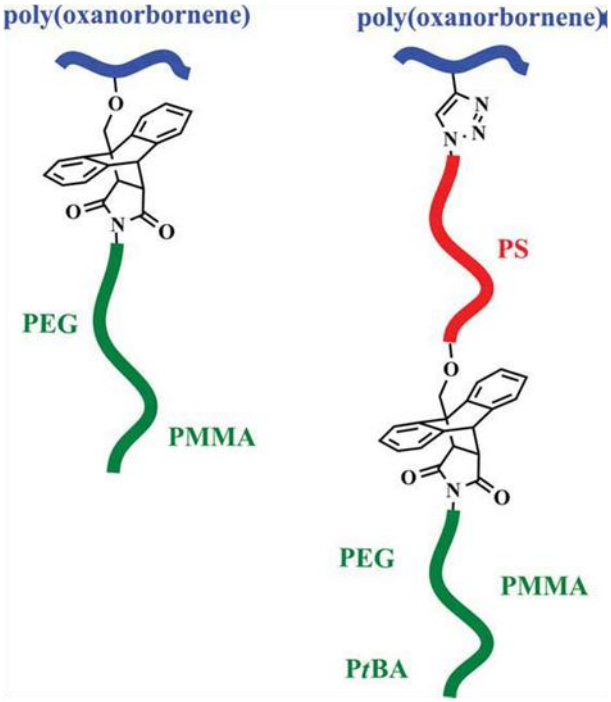
Istanbul Technical University

nesem_83@hotmail.com

Abstract

Anthracene-functionalized oxanorbornene monomer and oxanorbornenyl polystyrene (PS) with ω-anthracene end functionalized macromonomer were first polymerized via ring opening metathesis polymerization using the first-generation Grubbs' catalyst in dichloromethane at room temperature and then clicked with maleimide end-functionalized polymers, poly(ethylene glycol) (PEG)-MI, poly(methyl methacrylate) (PMMA)-MI, and poly(tert-butyl acrylate) (PtBA)-MI in a Diels–Alder reaction in toluene at 120^{0}C to create corresponding graft copolymers, poly(oxanorbornene)-g-PEG, poly(oxanorbornene)-g-PMMA, and graft block copolymers, poly(oxanorbornene)-g-(PS-b-PEG), poly(oxanorbornene)-g-(PS-b-PMMA), and poly(oxanorbornene)-g-(PS-b-PtBA), respectively. Diels–Alder click reaction efficiency for graft copolymerization was monitored by UV–vis spectroscopy. The dn/dc values of graft copolymers and graft block copolymers were experimentally obtained using a triple detection gel permeation chromatography and subsequently introduced to the software so as to give molecular weights, intrinsic viscosity ([g]) and hydrodynamic radius (Rh) values.



Branching Polyethylenimine Functionalized with Methylbenzimidazole: An Approach to Enhance Proton Conductivity via Multi-direction of Heterocycles

Autchara Pangon[1], *Kohji Tashiro*[2], *and Suwabun Chirachanchai*[1,3,*]

[1]The Petroleum and Petrochemical College, Chulalongkorn University, Soi Chula 12, Phyathai Road., Pathumwan, Bangkok 10330, Thailand

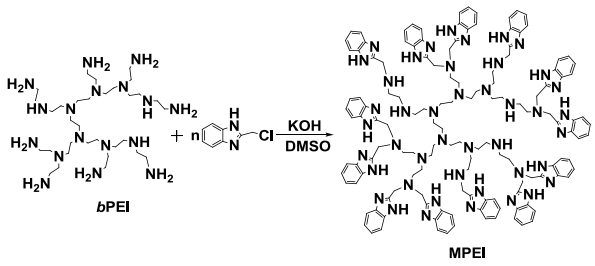
[3]Center for Petroleum and Petrochemicals, and Advanced Materials, Chulalongkorn University, Bangkok 10330, Thailand

e-mail: csuwabun@chula.ac.th

Heterocycles, for example imidazole, pyrazole, and benzimidazole have received much attention as proton conductive species in water-free polymer electrolyte membrane (PEM) for fuel cell due to their high thermal stability and amphoteric structure which can either donate or accept protons initiating proton transferring through hydrogen bond network.[1,2] The key point is to enhance the proton transfer efficiency of the heterocycles in the membrane. Up to the present, acid doped polybenzimidazole or blending imidazole derivatives, for example, have been reported.[3,4] The present work proposes the use of multi-benzimidazole branching to produce the proton transfer route in multi-direction in order to enhance the proton conductivity in PEM.

Polyethylenimine (PEI) is a flexible polymer which is available in linear and branch forms. Due to its high density and multi–direction of reactive amine functional groups of the branch PEI (*b*PEI) as compared with the linear one, *b*PEI was selected as a polymer core for functionalization with benzimidazoles as proton conductive molecules by a simple reaction of *b*PEI and 2-(chloromethyl)benzimidazole (CB) under basic condition as shown in Scheme.

Scheme



The MPEIs with a different degree of methylbenzimidazole substitution (DS) were prepared by varying the molar ratios of *b*PEI:CB. The polymer structure was proven by Fourier transform infrared spectroscopy (FTIR) Nuclear magnetic resonance (NMR) and elemental analysis. Edited-HSQC (Heteronuclear single quantum correlation) experiment was used to determine the proton and carbon connectivity. As shown in Figure, the peaks at F and G represent the methylene protons between benzimidazole and amine functional groups confirming the attachment of methylbenzimidazole on *b*PEI chain.

The modified MPEIs are appropriate for the use in high temperature PEM fuel cell due to their high thermal stability up to 280 °C as confirmed by TGA. The MPEIs showed a significant change in glass transition temperature (T_g) as observed from an increase of T_g along with an increase of DS. The hydrogen bond network and morphology changes related to temperature analyzed by temperature dependence FTIR and WAXD suggested the role of heterocycles and their favorable hydrogen bond for proton transfer efficiency.

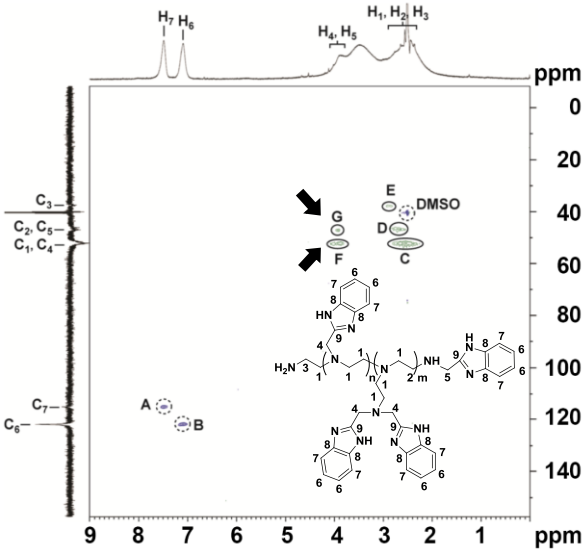


Figure Edited-HSQC spectrum of MPEI (solid line = negative phase peak, broken line = positive phase peak).

A systematic variation of benzimidazole units on the polymer chain conjugated on *b*PEI leads to an understanding of the structure-temperature-proton conductivity relationship and this will be clarified in the presentation.

Preparation and Characterization of Impregnated PVA/PSSA_MA/THS-PSA Membranes into Porous Polyethylene Membranes for Fuel Cell Applications

Chan Jong Park, Il Hyung Kim, Sung Pyo Kim, Hak Min Lee, Ji Won Rhim

Department of Chemical Engineering, Hannam University, 461-6 Jeonmin-dong, Yuseong-gu, Daejeon 305-811, Korea

jwrhim@gmail.com

In our laboratory, the poly(vinyl alcohol) (PVA) membranes, crosslinked with poly(styrene sulfonic acid-*co*-maleic acid) (PSSA_MA), was developed for fuel cell application[1]. 3-(trihydroxysilyl)-1- propanesulfonic acid(THS-PSA), which contains both the silica compound and the sulfonic acid group, was added into PVA/PSSA_MA membranes to enhance the proton conductivity and to reduce the methanol permeability simultaneously[2]. However, the resulting membranes of PVA/PSSA_MA/THS-PSA membranes showed very brittle when the PSSA_MA and THS-PSA contents were over 7 wt%. Then, to maintain the mechanical strength and the stability of the dimension at medium high temperatures, and also to enhance the proton conductivity, the impregnation methods were considered.

The PVA/PSSA_MA/THS-PSA was impregnated into porous polyethylene membranes. The contents of PSSA_MA over 10 wt% were possibly impregnated into PE membranes, and the dimensional stability was obtained through crosslinking.

This study focuses on the investigation of the impregnation of the poly(vinyl alcohol)(PVA) crosslinked with poly (styrene sulfonic acid-co-maleic acid)(PSSA-MA) to porous polyethylene membrane for the fuel cell application. In order to characterize the prepared membranes, the meaurements of the water content, contact angle, FT-IR spectra, thermal gravimetric analysis, ion exchange capacity, proton conductivity, methanol permeability and elastic modulus were carried out. The contents of PSSA_MA in the impregnated membranes could be increased up to 25% without the membrane brittleness which was the defect of the dense PVA/PSSA_MA membranes. The impregnated PVA/PSSA_MA(90:10) membrane exhibited a higher ion exchange capacity (1.2 meq./g dry membrane) than Nafion membrane (0.91 meq./g dry membrane). Through the elastic modulus measurement, the dimensional stability of the resulting membranes was expected to be increased higher than the dense membranes. The methanol crossover and water content were decreased even if the PSSA_MA content increased due to the reduction of the free volume.

The following figure shows the expected reaction scheme between PVA and PSSA_MA.

And the next figure describes the proton conductivities with increasing the PSSA_MA contents. The proton conductivity increases close to 0.02 S/cm at 25% PSSA_MA content.

Details will be discussed at the conference.

Dual 'Stimuli' Responsive Hydrogel: Effect of Ionizable Monomer on the Swelling Behavior

G. Roshan Deen[1], *Vivien Chua*[1] *and Xian Jun Loh*[2]

[1]Soft Materials Laboratory, Natural Sciences and Science Education, NIE, Nanyang Technological University, Singapore 637616.

[2]Institute of Materials Research and Engineering, Singapore 117602.

Introduction

In recent years, new research emphasis has been directed towards integrating multiple functions into a single polymeric material. Among the new advances in materials science are functional polymers with structural designs intended to produce a specific function. 'Stimuli' responsive polymers are polymeric materials which change their physical properties in response to external stimuli such as pH, temperature, electric field, illumination, pressure, magnetic field etc [1,2]. The potential responses to these stimuli can be changes in phase, shape, volume and optical properties. These interesting materials find applications in controlled drug delivery systems, skin care products, enzyme immobilizations, chemical sensors etc. When these polymers are chemically crosslinked using a suitable crosslinking agent, materials called hydrogels are obtained.

In this work, new hydrogels composed of *N*-isopropyl acrylamide (NIPAM) and *N*-acryloyl-*N*'-ethyl piperazine (AcrNEP) were prepared by free-radical solution polymerization at room temperature. The swelling behavior of the hydrogel and the effect of AcrNEP (a ionizable monomer) on the swelling was studied in detail.

Materials and Method

The monomer AcrNEP was synthesized by the method described earlier[3]. NIPAM (Aldrich), *N*,*N*'methylene bisacrylamide (MBA, Aldrich)), potassium persulfate (Aldrich), and *N,N,N',N'*-tetra methylene ethylene diamine (TEMED, Aldrich) were used as received. 1.0 M HCl and 1.0 M NaOH were used to prepare solutions of various pH (2-12).

Copolymer hydrogels of AcrNEP and NIPAM were synthesized by free-radical solution polymerization. Hydrogels containing various monomer feed ratios with a fixed crosslinker content of 2 wt% were prepared. The monomer feed ratios are summarized in Table 1. The chemical structure of the monomers and the crosslinker is shown in Figure 1.

Table 1 Monomer feed ratios used in the preparation of hydrogels.

Hydrogels	Feed compositions		Appearance after polymerization
	NIPAM (g)	AcrNEP (g)	
NA 90-10	0.9006	0.1098	Transparent soft solid
NA 70-30	0.7052	0.3382	Transparent soft solid
NA 50-50	0.5058	0.5106	Transparent soft solid
NA 20-80	0.2048	0.8083	Transparent soft solid

Silver nanoparticles were fabricated in the matrix of the hydrogel by the method of diffusion and *in-situ* chemical reduction.

Results and Discussion

All the hydrogels prepared in this showed excellent response to changes in pH. Figure 2 shows pH responsive character of the gels as function of AcrNEP content. The gels swell in acidic solution and de-swell in basic solution owing to protonation and de-protonation of the tertiary amine moiety of AcrNEP. The gels also exhibited temperature response and deswelled above the critical solution temperature of PNIPAM (32 °C).

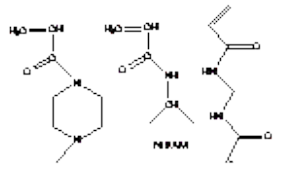

Figure 1. Chemical structure of

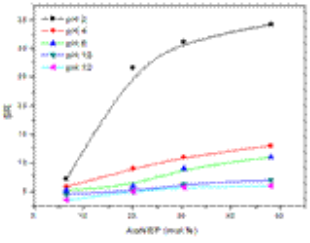

Figure 2. pH responsive swelling.

The presence of silver nanoparticles in the gel matrix was confirmed by UV-Vis spectrophotometry and scanning electron microscopy. A distinct absorption maximum was observed at a wavelength of 406 nm. The average size of the silver nanoparticles was around 50 nm. Water sorption of these gels followed non-Fickian behavior in acidic solution and Fickian behavior in basic solution. The penetration velocity of solvent (water) into the gel matrix increased with increasing ionic monomer in the hydrogel. Table 2 shows the water sorption parameters in solution of pH 2.

Table 2. Water sorption parameters.

Hydrogel	*n*	*k*	$D \times 10^8$ (cm^2 s^{-1})	$v \times 10^3$ (cm g^{-1})
NA 90-10	0.64	0.02	4.98	1.95
NA 70-30	0.67	0.03	6.63	2.06
NA 50-50	0.58	0.03	11.3	2.36
NA 20-80	0.49	0.07	13.8	2.76

Conclusions

A new type of pH and temperature responsive crosslinked hydrogel of NIPAM and AcrNEP was successfully synthesized. The presence of ionizable monomer played a vital role in tuning the pH responsive character of these gels. Swelling and de-swelling profile of the gels in solution of pH 2 and pH 12 showed a response time of about 60 min with good reversibility. Silver nanocrystals of size range 50 nm were fabricated in the matrix of these hydrogels.

Copolymerization of 2,2-Diallyl-1,1,3,3-tetraethylquanidiniumchloride with Maleic and Fumaric Acides

Gorbunova M.

Institute of Technical Chemistry, Ural Branch of Russian Academy of Sciences

mngorb@newmail.ru

A range of nitrogen-, phosphorous-containing allyl compounds for the synthesis of linear high molecular weight polymers via reaction of radical homo- and copolymerization to be carried out is rather narrow. Actually, among allyl monomers only quaternary salts of diallylammonium have found an application as monomers for the synthesis of polyfunctional polymers [1]. Moreover, the breadth of useful properties spectrum makes polymers based on them unique, so searching and studying of *N*-containing allyl monomers of new structural types is quite advisable. It is well known containing guanidine group compounds possess wide spectrum of antibacterial activity and use as medicine and fungicides [2]. That is why guanidine group introduction into high molecular compounds is undoubtedly of present interest.

Activity of 2,2-diallyl-1,1,3,3-tetraethylguanidiniumchloride (AGC) in reactions of radical copolymerization with maleic and fumaric acides has been studied. 2,2-Diallyl-1,1,3,3-tetraethylguanidiniumchloride was found to be copolymerized with fumaric acide in the conditions of free-radical initiation, the copolymers being characterized by statistical distribution of monomer units. AGC copolymerizes with maleic acid, the peculiarity of the system is a high tendency of the comonomer units toward alternation in the polymer chain (figure 1).

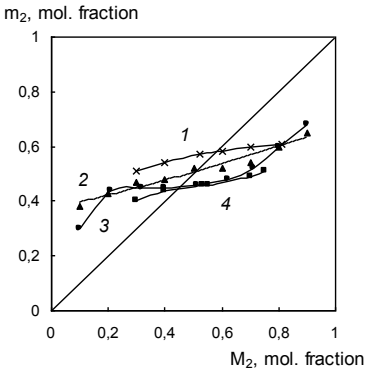

Figure 1. Dependance of composition of AGC copolymer with MA (M_2) on the monomer ratio at polymerization in methanol (*1*), in chloroform (*2*), in ethanol (*3*) and at bulk (*4*). $[M_1 + M_2] = 6$ mol/l, [AIBN] = 3 mass. %, T = 80°C.

AGC is less active if compared with maleic and fumaric acides. The rate of copolymerization of AGC with maleic and fumaric acides reduces with increasing molar fraction of acid in initial monomer mixture (figure 2).

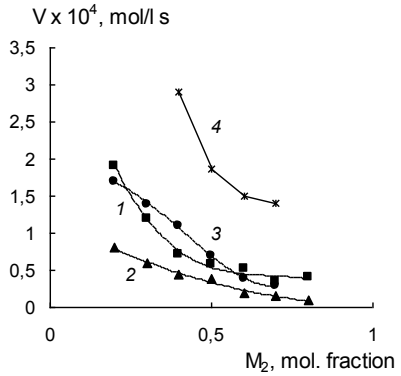

Figure 2. The rate of copolymerization of AGC with MA (M_2) vs. the monomer ratio. $[M_1 + M_2] = 6$ mol/l, $[M_1]/[M_2] = 0.5/0.5$, [AIBN] = 3 mass. %, T = 80°C. *1* – ethanol, *2* – methanol, *3* – chloroform, *4* – in bulk.

As a result of kinetic investigations at initial conversions it was determined that a usual for radical polymerization reaction half order with respect to initiator is observed indicating bimolecular mechanism of the growing chain failure, as well as deficiency of degradative chain transfer to the monomer intrinsical to allyl monomers.

The structure of the polymers obtained was identified by NMR ^{13}C. Analysis of the values of chemical shifts of the signals and their multiplets shows AGC to copolymerize with maleic and fumaric acides both double bonds participating.

The copolymers of AGC with maleic and fumaric acides are nontoxic, have a notable antibacterial activity and can be used for medicine aims.

Financial support by the Russian Foundation for Basic Reseach (grant № 09-03-00220) is gratefully acknowledged.

Influence of microcrystalline cellulose on thermal properties of polypropylene composite nonwovens

Katarzyna Bujnicka, Jolanta Kałużka

The Textile Research Institute Lodz, 5/15 Brzezińska Str., Poland

kbujnicka@iw.lodz.pl

Introduction

Properties of many polymers can be modified by adding other substances including the various nucleating agents[1]. The polypropylene is a cheap and very popular polymer. Nowadays when the public awareness and the concern for the environment is increasing the practical use of polypropylene is limited due to its chemical resistance and the slow degradation of products made of it. In order to increase susceptibility of polypropylene to degradation its degradable composites with natural additives are formed. Studies on the influence of these additives on hydrolytic and photolytic degradability of polypropylene composite nonwovens, showed that microcrystalline cellulose (3%wt) increases degradation capability (hydrolytic and photolytic)[2]. In this paper the influence of degradable microcrystalline cellulose on the thermal properties and crystalline structure of processed polypropylene composite nonwovens by melt-blown technique is presented.

Materials and Methods

The granulate polypropylene (melting flow index MFI = 1200 g/10min) its polypropylene matrix and polypropylene composite nonwovens with 1, 2 i 3 % wt of the microcrystalline cellulose have been tested. The average diameter of cellulose granule has been 20 µm (Sigma–Aldrich). The study has been carried out using differential scanning calorymetry (DSC). The thermal analysis measurement were performed using DSC 6220 Exstar SII Nano Technology by Haas. The samples of about 5 mg were heated to 260 °C in the aluminum melting-pots. The experiments were carried out in nitrogen atmosphere and the scans were obtained at 20°C/min. Thus, a melting endotherm of all samples with melting point (T_m) and melting enthalpy ($\Delta H_{exp\ (w)}$) was obtained. The thermal characteristics of polypropylene composite nonwovens for components in anisotropic and isotropic system was determinated. On the basis of the crystallization exotherm the crystallization temperature (T_c) of the polymer was calculated. The degree of crystallinity (X_c) of the each investigated sample was determinated based on DSC measurements using the by equation:

$$X_c = \frac{\Delta H}{\Delta H_m^0} \cdot 100\,\%$$

where: ΔH – actual melting enthalpy of nonwovens sample [J/g]; $\Delta H_m{}^0$ – theoretical value of enthalpy for 100 % crystalline polypropylene, for polypropylene $\Delta H_m{}^0$ = 209 J/g[3]. $\Delta H = \Delta H_{exp(w)}/w$; where: w- weight fraction of polypropylene; $\Delta H_{exp(w)}$ - melting enthalpy of polypropylene obtained graphically from the area of the endothermic peaks of the DSC thermograms.

Results and Discussion

The effect of adding cellulose on the degree of crystallinity and thermal properties of polypropylene composite nonwovens has been examined. The changes in melting point, melting enthalpy and crystallization temperature of polypropylene composite nonwovens were observed. The melting point of polymer in the composites decreases slightly and proportionally to the content of the degradable additives (Fig. 1).The similar trend was observed for isotropic system.

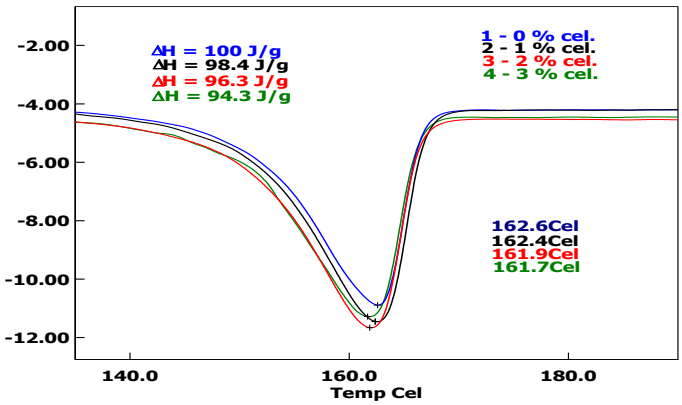

Fig.1 DSC thermograms – melting curves for anisotropic system: 1- 0 % wt of cellulose, 2 - 1 % wt of cellulose, 3- 2 % wt of cellulose, 4- 3 % wt of cellulose.
ΔH- actual melting enthalpy of nonwovens sample.

The cellulose used as biodegradable fillers in polypropylene composite nonwovens reduced homogeneity of the system and at the same time the melting enthalpy of polypropylene nonwovens sample was decreased. The minimal value of the melting enthalpy of 94,3 J/g was determined for nonwovens with 3 % wt of the microcrystalline cellulose. On the basis of the analysis of actual melting enthalpy (ΔH) of nonwovens samples, it was found that the degree of crystallinity of composites decreases proportionally with the cellulose content. The microcrystalline cellulose in polypropylene nonwovens did not form a nucleation center leading to a decrease of crystal growth in the crystallization process of the polymer. Cellulose has a hydrophilic character. Thus the hydrophobic polypropylene molecules are not adsorbed on the nucleation surface.

Conclusions

Addition of cellulose to the polypropylene nonwovens hinders the crystallization process of polymer. Low degree of crystallinity causes visible increased fragility and susceptibility of composite nonwovens. Thus, the biodegradable additive shows to enhance the degradability of new nonwovens.

Contact Polymerization of the Composition on the Basis of Acrylamide and Formaldehyde on Metal Surfaces

Lidia Kolzunova, Maxim Karpenko

Institute of Chemistry, Far Eastern Branch of Russian Academy of Sciences. Vladivostok. Russia

kolzunova@ich.dvo.ru

Introduction.

Recently, a substantial body of work has been performed on the search of polymerization compositions (PC) which would enable one to form, by means of the electropolymerization process, polymer films on electroconductive substrates. These films could, on one hand, find an independent application or, on the other hand, be used as special-purpose coatings. Among such PC one should mention as prospective the composition containing acrylamide (AA), N,N'-methylenebisacrylamide (MBAA), formaldehyde (F) and zinc chloride. The films produced on the basis of the above PC were suggested to use as protective and electrical insulating coatings or ultrafiltration and reverse-osmosis membranes [1]. For the monomer composition under study we revealed and recorded the post-polymerization effect by video microscopy and gravimetric methods. It was shown that principal reason of post-polymerization origin could be the phenomenon we found that consists in the fact that in the absence of external current regular zinc metal is capable to initiate polymerization in solutions of the same PC which was used for electropolymerization. Such a process would result in formation of a uniform polymer film. Since the formed polymer film, at least during the first minutes of synthesis, has a sufficiently high porosity, it allows low-molecular components participating in electropolymerization passing freely through the film to the zinc sub-layer (which was produced on a cathode during electrolysis process) and polymerize on it in accordance with the found effect in the absence of the external current source.

So the objective of this work was to study the process of initiating polymerization of acryl monomers by metal zinc and other metals under no-current conditions.

Results and Discussion.

Comparative studies of the kinetics of electropolymerization and zinc-initiated polymerization by the gravimetric method showed that zinc initiation is more efficient for this purpose. The course of the plots showing the dependence of the polymer deposit mass on time results from the fact that the formed polymer gradually seals the electrode surface which, thereafter, suppresses the supply of the electrolysis solution components to metal. As a result, the polymerization initiation process becomes attenuated. That is why it is impossible to grow a polymer film of a thickness more than 500-600 micrometers. It is clear from the above observations why post-polymerization does no prevail over electropolymerization, although the initiation by zinc is more efficient. It is evident that electropolymerization results in formation of sufficiently fine-porous film, so that subsequent polymer deposit mass growth is limited by the porous blockage in the same manner as at switched-on current.

Further studies were directed to revealing the mechanism of the polymerization initiation by zinc. We suggest that at zinc-initiation the formation of active particles inducing polymerization is the result of the zinc-acrylamide complex electroreduction. The point is, after putting the zinc rod into the polymerization composition under study it gains the potential about -(0.95-1.00) V. This value is sufficient to induce the reduction of the complex with formation of active particles and efficient electropolymerization. The cathode potential gradually decreases in the course of $[Zn^{2+}]$ increase. The polymerization rate (polymer product yield) is the higher when the higher is the potential).

It was established that it is possible to initiate polymerization not only by Zn, but also by other metals. The main criterion should consist in emerging of a sufficient (at least -(0.90-0.95 V) electrode potential in the PC under study. One could use, for example, Mg and Al, since both are more active that Zn. However, the polymer yield on Mg is too small because at excessively high potentials (E_{Mg} = -1.80 V) the rate of polymer deposition on the metal surface tends to drop, since the concentration of formed radicals increases resulting in their recombination with each other rather than initiation of regular polymerization. Besides, low polymer yield on the metal surface results from active gas emission due to water decomposition in the specified potential range and removal of polymer chains into bulk solution. Use of Al is characterized by its passivation in the polymer composition under study resulting in the fact that the potential value does not exceed -0.60 V, which is insufficient for discharge of the zinc-monomer complex with formation of active particles initiating polymerization. For low-active metals (Fe, Cu), whose electrode potentials are even lower, no polymer formation was observed as well.

Conclusion.

The previously unknown polymerization method based on initiating the film formation process by metal zinc (other active metals), which we developed for the polymerization composition on the basis of acrylamide, its derivatives and formaldehyde, can be competitive as compared to electropolymerization for the following reasons. On one hand, the method enables one to produce the same deposits as the latter one under technologically more advantageous no-current conditions. On the other hand, since polymerization proceeds on the metal surface in the absence of external current source, it becomes possible to produce, with using the suggested method, hollow polymer spheres, if the process is conducted on micro-powders of respective metals followed by their solution.

Synthesis and characterization of poly(L-lactic acid) nanocomposites with vermiculite of different modification

I. Aranburu, M.D. Fernández, M.J. Fernández

Department of Polymer Science and Technology, Faculty of Chemistry, University of the Basque Country, San Sebastian, Spain

ibai.aranburu@ehu.es

Polymer-layered silicate nanocomposites have received special attention in the recent years owing to their hybrid properties synergistically derived from two components when they are mixed intimately [1, 2]. The nanoscale incorporation of layered silicate materials in the polymer matrices is not straightforward and in most of the instances, surface modification of these materials is required to obtain organically modified silicates or clay which then is more compatible with the organic polymer matrices. The most widely used method is the treatment of the clays with quaternary ammonium salts, which allows the substitution of some metal ions present in the structures of the clay by quaternary ammonium ions with large organic groups. Another modification procedure includes the grafting of silanes containing a functional group, which can specially interact with the polymer matrix. Clay minerals have reactive hydroxyl groups at the surface and at the edge of the layers that can react with silanol (Si–OH) groups of the hydrolyzed silane to form siloxane (Si–O–Si) bonds.

Poly(L-lactide) (PLLA), one of the most popular and important biodegradable polymers, is a linear aliphatic thermoplastic polyester that exhibits excellent properties which are comparable to many petroleum-based plastics. Moreover, the properties of PLLA can be modified in a controlled manner through filling with inorganic nanoparticles. Nanocomposites can be synthesized by melt/solution blending and in-situ polymerization. The particular blending process which is used have a significant influence on the structure, and hence the properties of the nanocomposite.

The present study focuses on synthesis and characterization of different organically modified vermiculites (VMTs) and PLLA-modified VMT nanocomposites produced using melt compounding and solution blending. Three organoclays were prepared: OVMT, through the cationic exchange reaction of NaVMT with hexadecyltrimethyl-ammonium bromide (HDTMAB), VMTS and OVMTS by grafting glycidoxypropyltrimethoxysilane (GPMS) with the SiOH groups of VMT and OVMT respectively, to introduce epoxy functional groups on the silicate layers.

The organo-clays were characterized by ^{13}C and ^{29}Si solid-state nuclear magnetic resonance (NMR), X-ray diffraction (XRD), Fourier transform infrared spectros-copy (FTIR), high-resolution thermo-gravimetric analysis (HRTGA), and scanning electron microscopy (SEM). With the cation exchange of Na^+ for the cationic surfactant, expansion of the VMT layers takes place. Basal spacing value of OVMT indicates bilayer arrangement in the galery. The interlayer spacing of the VMT is the same as the VMTS, confirming that the grafting reaction occurs mainly outside the clay layers, onto the edge of clay platelets. HRTGA allows identification of two kinds of organic species on clay, physically and chemically adsorbed species, and demonstrates that the external-surface physically adsorbed surfactant can be removed after washing treatment, resulting in an increase in thermal stability and a slight decrease in the interlayer spacing of the resultant organoclays. OVMT and OVMTS display the lowest onset temperature decomposition compared with that of NaVMT, and VMTS due to the ammonium cation incorporation.

PLLA nanocomposites containing 2, 5 and 10 wt% of modified VMTs prepared by different procedures were characterized by XRD, HRTGA, and transmission electron microscopy (TEM). The PLLA/OVMT and PLLA/OVMTS nanocomposites increase the basal spacing value of modified VMTs. The increase in the interlayer spacing of the composites with OVMT and OVMTS, compared with that of the corresponding neat organoclay, indicates that intercalation of the PLLA chains inside the clay galleries occurs. The intensity of the peak related to the interlayer spacing value of the clay gradually increases with the mineral content rise, due to the increase of the diffracted X-rays by the additional intercalated oganoclay. The broadening of this peak is also observed due to partial disruption of parallel stacking or layer registry of the pristine organoclay, which reveals the existence of some exfoliated clay platelets. This intercalation/exfoliation coexistence is in agreement with the TEM data. The XRD reflections of the PLLA/VMTS material are close to that of VMTS, indicating that this sample is in fact a mixture of polymer and unintercalated clay particles. For the composites prepared from solution, the introduction of organophilic inorganic material improves the thermal stability of the polymer increasing the onset decomposition temperature, in oxidant atmosphere. The dispersed inorganic platelets assist the formation of a protective layer on the surface of the polymer, which acts as an insulator and a mass transport barrier retarding the decomposition rate of the polymer matrix. On the contrary, the melt prepared nanohybrids exhibit a lower thermal stability compared to PLLA and the solution cast ones, due to the polymer and surfactant degradation associated with melt processing.

Upon the Synthesis Possibilities of 2 - Hydroxyethyl Methacrylate Copolymer with a Comonomer with Spiroacetal Moiety

Aurica P.Chiriac, Loredana E. Nita, Manuela T. Nistor

"Petru Poni" Institute of Macromolecular Chemistry, Grigore Ghica Voda Alley No. 41-A, 700487 IASI, Romania

e-mail: achiriac1@yahoo.com

Introduction: The copolymerization processes between hydrophilic and hydrophobic monomers present interest in the design and synthesis of different compounds such as hydrogels and biocompatible materials. A large number of studies were devoted to the homopolymerization and copolymerization of 2-hydroxyethyl methacrylate (HEMA) owing to the multiple application fields of the poly(HEMA) and its copolymers. The incorporation of spiroacetal groups in the polymers structures improves the solubility and the adhesive properties. More than that, these polymers induce good oxidative and thermal stability, are good fiber formers, and films prepared from some of polymers that include this structural unit present good flexibility and tensile strength. These characteristics are attributed to the properties inherent into the spiroacetal ring: stiffness, which is higher than cycloaliphatic rings but lower than aromatic rings; interactions on ether oxygen such as hydrogen bonds or coordinate bonds with other functional groups, and bulkiness. The present study reports the synthesis of a copolymer based on HEMA and 3, 9-divinyl-2, 4, 8, 10-tetraoxaspiro(5.5) undecane (U) acquired through radical aqueous dispersion polymerization in the presence of AIBN.

Methods: The prepared dispersions were characterized from the viewpoint of the hydrodynamic radius, zeta potential and conductivity evolution during syntheses. The mean particle size and size distribution, as well as zeta potential and conductivity were also evaluated for the synthesized polymeric particles. The polymers compositions were confirmed by FTIR and ^{1}H-NMR spectra. Also, the thermal stability of the polymeric compounds was evaluated. SEM and AFM investigations of the polymer morphology are also presented.

Results and Discussion: The reactions taken into study refer to the heterogeneous free radical polymerization processes which involve the emulsification of a hydrophilic monomer (HEMA) and another hydrophobic (U) in water by an oil-in-water emulsifier (SLS), followed by the initiation reaction with an oil-soluble initiator (AIBN). In parallel with this variant of synthesis two other alternatives have been performed, respectively surfactant-free, but in the presence of protective colloid – cyclodextrin (CD) and poly(aspartic acid) (PAS) – which can prevent the interactive latex particles from coagulation. They may assure the colloidal stability via electrostatic stabilization mechanism or steric stabilization mechanism, or both. Also, the homopolymer poly(2-hydroxyethyl methacrylate) was prepared just to compare it with the synthesized copolymers. The presence of the comonomer positively affects the thermal behavior of the copolymer. As it was expected, the comonomer improves the overall thermal stability of the polymers. Also, the acquired type of network structure confers an increased thermal stabilization to the polymer. The inclusion of the oligosaccharides in the synthesis, like cyclodextrin, leads to the decrease of the initial decomposition temperature, because of the hydroxyl groups that are bordered outside of the ring. The same behavior is experienced for the other used dispersing agent, respectively PAS. This slight decrease of T_{onset} did not significant affect the system thermal stability, offset by the other improved properties conferred by achieving a network structure. SEM micrographs show that the polymers prepared with different stabilizers possess a distinct structure. The homopolymer seems to be with a lamellar structure instead of the copolymers that appear with an internal structure more homogeneous and dense.

Conclusions: The study presents the possibility to prepare a copolymer based on HEMA and 3, 9-divinyl-2, 4, 8, 10-tetraoxaspiro(5.5)undecane (U) through radical polymerization in the presence of AIBN, with a solid content of 10 wt.-% in the presence of a classic ionic surfactant – sodium lauryl sulfate (SLS) – and comparatively just using two variants of protective colloid: cyclodextrin and poly(aspartic acid). It is concluded on the proper critical micellar concentration for used surfactants, respectively attributing a mixed mode of particle nucleation (micellar and homogeneous nucleation) in case of synthesis with SLS and an entropic mechanism of stabilization with CD and PAS as stabilizers. The mean particle size and size distribution, as well as zeta potential and conductivity determination on the prepared polymeric particles attest: a relatively monodisperse distribution for the particle size; particles with negatively charged surfaces and copolymers conductivity prepared in the presence of PAS or CD increased by several orders against homopolymer. The thermal stability of the polymeric compounds was evaluated. As it was expected the comonomer improves the overall thermal stability of the polymers.

Taking into account the special effects which may be generated by both comonomers – network formation, biodegradability and biocompatibility, gel formation capacity, binding properties, amphilicity, good oxidative and thermal stability, good films formers, acid pH sensitivity – the interest in the development of these new polymeric structures with emphasis on theoretical aspects is thoroughly justified.

The Temperature Influence upon the Complexation Process between Poly(aspartic acid) and Poly (ethylene glycol)

Loredana E. Nita, Aurica P. Chiriac, Maria Bercea, Iordana Neamtu

"Petru Poni" Institute of Macromolecular Chemistry Grigore Ghica Vodă Alley No. 41 A, 700487, Iaşi ROMANIA

Introduction:

As it is well known, polymer blends, as physical mixtures between structurally different polymers that interact through secondary forces with no covalent bonding, constitute a useful approach for preparing materials with tailor made properties different from those of the constituent polymers. Blending polymers may result in reducing their basic cost, improving their processing, and maximizing their specific properties. Progressive elucidation of the effect of specific interactions on the miscibility in polymer blends has been one of the most noticeable achievements in the study of polymer blends in the last two decades.

In the present study the temperature influence on the formation of an interpolymer complex (IPC) based on poly(aspartic acid) (PAS) and poly(ethylene glycol) (PEG), it was investigated. The temperature influence during IPC formation was investigated onto the temperature range between 22^{o}C – 37^{o}C. The chosen domain of temperature corresponds to the storage temperature of the samples up to human body temperatures, owing to the final purpose the IPC utilization as biomaterials. The influence of the PEG molecular weight as well as the composition – the ratio between PAS and PEG – of the blends on the IPC formation was investigated. The directions of analysis have in view (1) to confirm the intervened interpolymer interactions based between others on the hydrogen-bonds evidenced by FT-IR spectroscopy, (2) to estimate through the dynamic viscosity the miscibility between PAS and PEG macromolecular chains and also, to find the best conditions in order to achieve the intermolecular complex related on the PAS/PEG domain of composition, temperature, and PEG molecular weight.

Materials and methods

Materials: Poly(aspartic acid) was synthesized in our laboratory through a reaction in two steps. The prepared homopolymer has the molecular weight of about 15,110 and the polydispersity index of 1.317. Poly(ethylene glycol)(PEG), Fluka Germany provenience, was used without further purification. PEG of four different molecular weights (Mw), respectively 2000 Da ([η] = 0.0935 dL/g), 4000 Da ([η] = 0.1211 dL/g), 10,000 Da ([η] = 0.2348 dL/g), and 35,000 Da ([η] = 0.5134 dL/g) (denoted in the present paper as PEG 2000, PEG 4000, PEG 10000 and PEG 35000) in order to cover several orders of weight extent was taken into study

IPC preparation: Briefly, the PAS/PEG complex was prepared by direct mixing the stock aqueous solutions of 1% concentration for 60 min, in the different PAS/PEG ratios (vol.%) respectively 0/100, 20/80, 50/50, 80/20 and 100/0. Thus, the total polymer concentration in the mixture was maintained constantly during each experiment. The solution of the polymer mixtures was then poured into Petri dishes and the films were obtained after drying at the room temperature.

Results and discussion

The importance of blending has increased in recent years because it has become a useful approach for preparing materials with tailor made properties different from those of the constituent polymers. The electrokinetic and rheological properties of the PAS/PEG blends are important parameters for the estimation of the behavior of blends under different conditions (temperatures and compositions). In the present paper, the influence of the temperature on the IPC formation was investigated in the temperature range of 22^{o}C to 37^{o}C. The observed behavior was discussed as a function of the molecular weight of PEG and the ratio between PAS and PEG during blends preparation. The intra-association (self-association) of the carboxyl groups in PAS and inter-association (intermolecular interactions) between PAS and PEG constituent components influence the frequency dependence of the dynamic moduli in the terminal region of the miscible blend systems investigated. Thus, the local polymer–polymer interactions by FT-IR spectroscopy, confirming hydrogen-bonding interactions, they were put into evidence. The miscibility and the polymer-polymer interactions were proved from the dynamic viscosity. Zeta potential and electrical conductivity of the blends were used to obtain the optimum conditions of temperature, PEG molecular weight and ratio between PAS and PEG, to have intermolecular complexes.

The corroborated data evidence the interpolymer complex formation using macromolecular compounds with closely molecular weights or the preparation of an interpolymer association with compact structure based on attractive forces between poly(aspartic acid) and poly(ethylene glycol) in the case of the compounds with different molecular weight.

Light-Driven Wettability Changes on a Photoresponsive Electrospun Mat

Menglin Chen[1] and Flemming Besenbacher[1,2]

[1]Interdisciplinary Nanoscience Center (iNANO), [2]Department of Physics and Astronomy (IFA), Aarhus University, DK-8000 Aarhus C, Denmark.

E-mail address: menglin@inano.au.dk

Functional surfaces with controllable wettabilities upon external stimulus have come to the forefront of research providing many new possibilities for biological and industrial applications.1 A particularly intriguing possibility is offered by light-responsive materials based on the photoisomerization of constituent molecules that undergoes a large conformational change between two states in response to the absorption of light at two different wavelengths,2 eg. *trans–cis* isomerisation of azobenzene chromophores.3

Electrospinning, a remarkably robust and versatile method for fabricating nanofibers, has become particularly powerful when its intrinsical nanoscale topography is combined with easy add-on functions. Herein we report the first study of light-responsive electrospun azobenzene modified polycaprolactone (PCL-azo) nanofibers (Figure 1).4 Surface chemistry of the nanofibers was probed with X-ray photoelectron spectroscopy (XPS) and Time-of-flight secondary ionmass spectrometry (ToF-SIMS). The light-responsive wettability of the fibers was subsequently investigated using contact angle (CA) measurements.

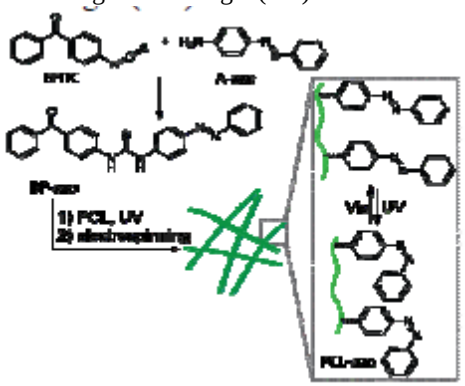

Figure 1. Schematic illustration of electrospinning of PCL-azo and the produced light-responsive nanofibers.

The conjugation of azobenzene with PCL was performed in a one-pot reaction (Figure 1). The heterobifunctional, photoactive crosslinker, BPITC, with isothiocyanate group reactive to aromatic amines and benzophenone species ready for C-H insertion in PCL upon UV illumination, was reacted with excess of A-azo first to form BP-azo and subsequently PCL. Thus the modified polymer PCL-azo having PCL as the linear main chains and BP-azo as the branch side chains was formed. XPS provides quantitative information of azobenzene present in the outer molecular layers, and BP-azo was proved to be successfully conjugated with PCL with nearly 90% yield in the one-pot reaction. ToF-SIMS was applied to identify the chemical species and to map their distribution on the surfaces of individual nanofibers with a depth resolution of 1–2 nm. The unique nominal m/z values from PCL main chains and BP-azo side chains were used to obtain chemical maps of the distribution of BP-zao side chains and PCL main chains on the fiber surfaces. (Figure 2)

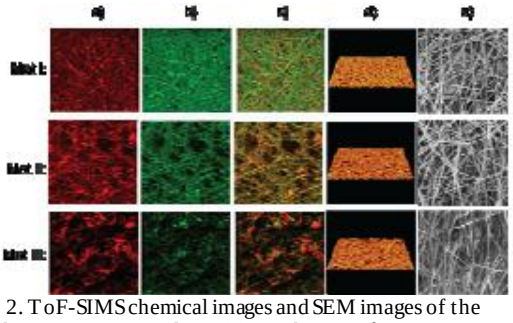

Figure 2. ToF-SIMS chemical images and SEM images of the nanofibrous mats I-III. Column (a): Azobenzene fragment ion images; column (b): PCL fragment ion images; column (c): Overlay images of column (a) and column (b); column (e): 3D images of total ions; column (e): SEM images. Area: 20μm • ~20μm.

The photo-responsibility of azobenzene is found to be retained in the electrospun fibers by water contact angle (CA) measurements. All the mats turned from hydrophobic to hydrophilic upon UV irradiation (365nm, I_{UV}=15 mWcm^{-2}, 1 h) and switched back upon visible light irradiation, where the Mat III showing the most significant changes. (Figure 3)

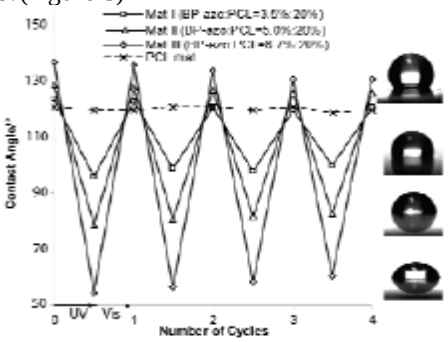

Figure 3. Reversible photo-response switching between hydrophobicity and hydrophilicity upon UV/vis irradiation.

The exhibited large, reversible and light-responsive wettability changes, arising from both the azobenzene functionalization and the roughness intrinsically offered by the electrospun nano/microscale hierarchical structures, allow us to control the properties and the function of the nanofibers with light, which open up for a lot of interesting and visionary applications in drug delivery, tissue engineering, sensors and optical storage.

Recently, studies which are made for the nanocomposite materials increase, since nanocomposite materials usually have better properties than composite materials containing micron or larger sized reinforcing materials. As can be seen from the literature, some nanomaterials such as carbon black, carbon nanotube, silica and clay have been widely studied and they have been used to make nanopolymer composite materials, which can be used for technical textile, aerospace, automotive industries and building, defence etc. Although some studies on cellulose nano whiskers (CNW) have been carried out in the last two decades, considerable effort has been devoted in recent years to the research and development of materials that utilize CNW, in order to reinforce different polymeric composites. Cellulose one of the most abundant natural polymers, has many advantages such as renewability, biodegradibility, nontoxicity, high specific strength and stiffness, low cost and also providing thermal stability, rigidity and strength to the polymer matrix.

Most of the previous studies were made on incorporation of hydrophilic CNW into polar polymer matrix solved with polar solvent (such as PVA solved with water) or into apolar polymer matrix solved with polar solvent such as DMF-Latex (1-6). From these studies, it has been seen that the CNW improved the thermal stability and mechanical properties of the composite materials. Due to the incompatibility with the hydrophilic CNW, it is necessary to develop new techniques to efficiently incorporate the CNW into the apolar polymer matrixes which is solved with apolar solvents.

The aim of the present study was to develop a nanocomposite materials made from apolar matrix solved with apolar solvent and hydrophilic CNW. For this purpose, one of the most widely used polyolefin polymer,polypropylene, was selected as a representative apolar matrix, since very few number of studies have been devoted to its reinforcement with CNW (7).

To compatibilize the hydrophilic CNW into apolar polymer matrix , Maleic Anhydrite grafted polymers such as MAH elastomer (Polystyrene-block-poly(ethyleneran-butylene)-block-polystyrene graft-maleic anhydride) were included into the formulations. The effects of the amount of CNW on the overall properties of the final polymeric nanocomposite product (especially thermal and mechanical properties) have been investigated.

lucia.escorial@uva.es

The use of polymeric membranes for gas separation in industrial applications is growing up in a very fast pace. Some of these applications are: CO_2/CH_4 separations in natural gas processing, CO_2 separations for enhanced oil recovery, alkene/alkane separations, etc. For polymers employed as gas separation membranes, high permeability and high selectivity are essential to minimize capital and operating costs. However, the separation performance at industrial operation conditions is compromised by plasticization-induced permselectivity losses. Plasticization is an increase in the diffusivity of a penetrant due to the facilitation of local polymer segmental motion caused by the presence of another penetrant molecule. [1][2]

In figure 1 the most typical behaviors experienced by passage of plasticizer gases as a function of pressure are shown. For type 3, permeability increases with pressure, but selectivity decreases significantly. For type 2, the most common behavior for glassy polymers, a minimum in the relationship between the permeability and the feed pressure (plasticization pressure) is observed; subsequently an increase in pressure produces an augment of permeability and a decrease of selectivity. For type 1, permeability decreases when pressure is high but selectivity is maintained. Therefore, the most interesting behavior for working with membranes at high pressure, would be the type 1.[3][4][5]

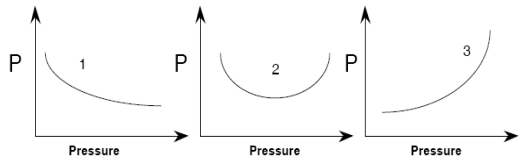

Figure 1

Our group is very interested on the development of plasticization-resistant polymer membranes using diverse approaches. Several methods to reduce the plasticization have been described but not too many are able to entirely remove it. In that way, some of these methods are physical and chemical crosslinking by heat treatment, chemical crosslinking by use of difunctional or polyfunctional compounds, or crosslinking by exposure to UV. However, most of the preceding crosslinking methods involve procedures difficult to apply in commercial membranes, increasing the cost or the manufacturing process. Also, some of them significantly reduce permeability.

Our group has demonstrated recently that some prefluoro polyimides, as 6FDA-6FpDA, with very high molecular weight, are more resistant against plasticization[6]. Thus, this study tries to figure out whether that result is universal and can be extended to other aromatic polyimides.

Thus, two polymers widely used in the industry, Matrimid® and P84®, Figure 2, along with other conveniently chosen ones, have been synthesized . After optimization of the polycondensation reaction, a methodical gas separation study at different feed pressures and temperatures has been carried out and results compared in order to establish relationships between Mw and properties.

Preliminary results denote that when the molecular weight of polymer reaches a threshold value, the plasticization is reduced and the capability to bear high pressures of real gases, as CO_2, is increased.

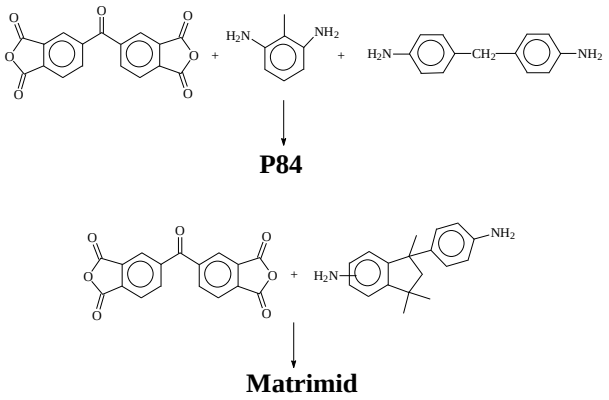

Figure 2

Results seems point out that in order to achieve materials with good capability to be employed in advanced industrial applications, a control of the molecular, in the sense of using high or very high molecular weight, should be considered.

Introduction

The use of polymer membranes for gas separation is increasing in the industry for a wide variety of applications. This technology is competing with consolidated operations such as pressure swing and cryogenic distillation. In this context, there is an increase need for gas separation processes involving the purification or removal of condensable and/or acid gases by economical and environment reasons. In order to develop a *state of the art* technology for these applications, new efforts have to be carried out in order to obtain materials with high rigidity, high and controlled fractional volume and extension of the separation through the time. In the last 5 years, two main approaches dealing with these requirements have been divulged on this topic. Thus, Budd developed the polymers with intrinsic microporosity (PIMs) that showed very high permeabilities even though their selectivity was rather low. Later, a new approach involving a thermally driven rearrangement of poly(*o*-acyloxyimide)s was developed by Park et al (2). By using this methodology, authors were able to make polymer membranes with outstanding gas separation properties (very high permeability and excellent permselectivity) for condensable gases as CO_2.

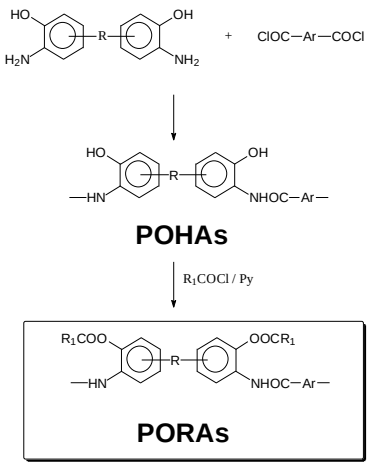

Figure 1. Synthesis of POHAs and PORAs

This work has been designed for the preparation of poly(*o*-acyloxyamide)s (PORAs) by reaction of bis-*o*-hydroxydianilines with diacid chlorides and subsequent derivatization of formed poly(*o*-hydroxyamide)s (POHAs). The ultimate target is attaining processable polymers with good gas productivity (Figure 1). Also, a thermal degradation study has been set out in detail in order to evaluate the ability of these systems to undergo thermal rearrangement processes to polybenzoxazoles.PORAs were characterized and evaluated as gas separation systems and their properties were compared both with POHAs and with related polyamides.

Results and Discussion

On using an *in situ* silylation methodology developed in our group (3), poly(*o*-hydroxyamide)s with very high molecular weight and good mechanical properties have been attained. These polyamides showed a weight loss at around 450 ºC, consistent with the formation of polybenzoxazoles. The $OOCR_1$ substituted polymers showed weight losses at lower temperature than those of their homologous POHAs. However, degradation processes were also observed.

All the polymers, regardless they were derivatized (PORAs) or not (POHAs), were amorphous.

Concerning gas separation properties, POHAs had low permeability and high selectivity, as it is usual for polymers with low FFV. However, derivatized polymers showed much better gas permeation properties. In particular, the polymers derivatized with pivaloyl chloride had a permeability-selectivity balance much better than other polymers widely used in the gas industry ($P(O_2) > 10$ barrer and $\alpha(O_2/N_2) > 4.5$).

PORAs underwent, for the polymer structures, an unavoidable degradation of the molecule during the conversion to PBOs. When the reaction was carried out using the classical method between acid chlorides and 2-aminophenol monomers, the presence of the *ortho*-hydroxy group lessened the reactivity of the amino group for monomers having electron-withdrawing groups.

Conclusions

A set of new polyamides having o-acyloxy groups has been developed. These polymers showed high film-forming ability and good gas separation properties. Relationships between substituted group size, gas permeability and X-ray diffraction patterns could be outlined. A theoretical and experimental study to figure out how these structures evolve to thermally rearranged materials (TR) was carried out. By means of this study, a relationship between groups attached to the aromatic rings, and ability to undergo a thermal rearrangement could be established.

Design of experiment - versatile tool for structure-property relationship investigations

Andrey Buryak Borealis Polyolefine GmbH,

Innovation & Technology, St.-Peter- Strasse 25, 4021 Linz, Austria

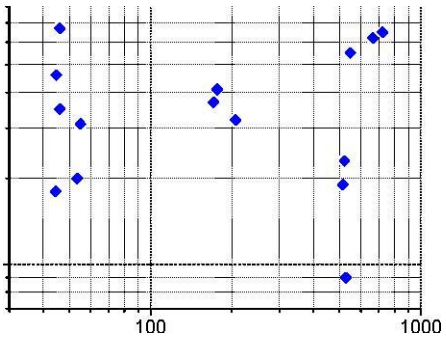
andrey.buryak@borealisgroup.com

Introduction: Even though the basic relationships between polymer structure and final application properties of polyethylene are already established in the literature [1-3], continuous material improvement is still ongoing. In this work a systematic investigation of structure-property relationships in bimodal polyethylene was carried out with the help of design of experiment. Applicability of the approach for the structure-property investigation studies and material optimization is discussed.

Materials and Methods: A series of bimodal polyethylene resins consisting of high and low molecular weight fractions were produced in a multistage polymerization process using a Ziegler-Natta catalyst. Four polymer design parameters were varied: 1st component melt flow rate, final melt flow rate, final resin density and the split between the two fractions.

Vertical: Final melt flow rate (5.0 kg), g/10 min
Horizontal: 1st component melt flow rate (2.16 kg), g/10 min

Tensile and impact (V-notched Charpy) properties of the produced resins were measured on specimens prepared

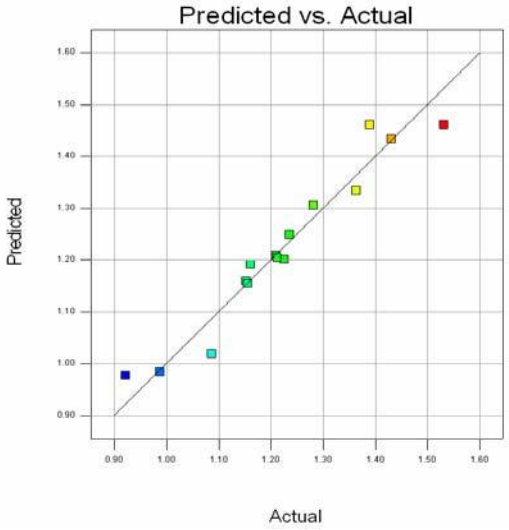


from compression moulded plates and correlated to the polymer design parameters.

Results and Discussion: The results of V-notched Charpy impact at 0°C can be reliably predicted from the polymer design variables (R^2 = 0.94) as can be seen from the graph below. The same is true for the impact measured at -20 °C. In both cases, high molecular weight of the first and the second components, higher amount of the high molecular weight component as well as lower final density were found to be favourable for high impact resistance.

An equally good model (R^2 = 0.94) was derived to predict the yield stress of the investigated bimodal HDPE resins. Along with the expected density influence, a statistically significant contribution from the final polymer melt flow rate was detected, indicating the influence of melt viscosity on the final crystallinity of compression moulded specimens.

Conclusions: The presented results show that design of experiment is a very convenient and versatile tool for systematic investigation of structure-property relationships in complex polymer systems. In a single series of experiments the influence of several polymer design parameters on the properties of interest can be evaluated



while minimizing the number of experiments and improving the efficiency of research work.

Synthesis and characterization of star-shaped conjugated systems with Triphenylamine core for photovoltaic applications

N. Metri, X. Sallenave, C. Plesse, L. Beouch, P.H. Aubert, G. Sini, F. Goubard, C. Chevrot

Laboratoire de Physicochimie des Polymères et Interfaces (LPPI), Cergy-Pontoise University. 5 mail Gay Lussac, 95031 Cergy-Pontoise Cedex, France

noura.metri@u-cergy.fr

The objective of this work concerns the synthesis and characterizations of novel conjugated organic molecules which were subsequently designed as hole-transporting materials in DSSCs based on TiO_2. These molecules must have the following properties: (i) a high hole mobility, (ii) an excellent pore-filling in TiO_2, and finally (iii) a weak trend to crystallization.

Currently, the reference molecule, Spiro-MeOTAD (2,2',7,7'-tetrakis-(N,N-di-p-methoxyphenyl-amine)-9.9'-SPIROBIFLUORENE) developed by Grätzel, has achieved photovoltaic conversion efficiencies around 5.1%.[1]

The approach developed in our laboratory involves the synthesis of five star-shaped molecules (**1-5**) with triphenylamine (TPA) core and Thieno[3,2-*b*]Thiophene (TTh) derivates which lead to amorphous materials with isotropic optical and charge carrier properties. We will present the synthesis methods used for these compounds and their thermal, optical and electrochemical characterization. Particular attention will be focused on determining the HOMO and LUMO energy levels of these new materials and their optical gap, which must remain high enough to limit any competition for absorption with the sensitizing dye. Finally, molecular engineering will be discussed in order to adjust ideally these properties for the photovoltaic application.

Functionalization of Polystyrene Surfaces

A. del Prado-Abellán, N. Briz, A. Gallardo, C. Elvira, H. Reinecke ICTP-CSIC, Madrid, Calle Juan de la Cierva, 3.

hreinecke@ictp.csic.es Introduction

One of the polymer most commonly used as a support for microessays is polystyrene (PS) due to its easy processability, low costs and, more importantly, its transparency. This work is focused on the controlled chemical modification of PS surface, creating thus functional groups for the insertion of molecules for the use in clinical essays or for separation of compounds. The functionalization of PS surfaces with SO2Cl groups, recently patented in our group, can be performed by a wet-chemical treatment in solution of concentrated chlorsulfonic acid at different times. The transparency of the modified surfaces is completely maintained upon this reaction. Being strong electrophiles the created functional groups are capable of reacting in a second step with nucleophiles such as amines, alcohol and thiols. The use of bifunctional nucleophiles allows binding of a huge number of different functional groups to the surface. These modifications where observed by spectroscopic techniques such as RAMAN and ATRIR. A concentration gradient on a nanometer scale of functional groups along the cross section of the polymer is formed. The aim of the present work is to study in more detail the distribution of these groups. Therefore, model compounds of well defined polymer-substrate systems have been prepared using a bottom-up approach.

Materials and methods

Monomer, p-vinylphenylsulfonyl chloride, was obtained using sodium p-vinylphenylsulfonate and thionyl chloride with catalytic amounts of DMF [1] (figure 1).

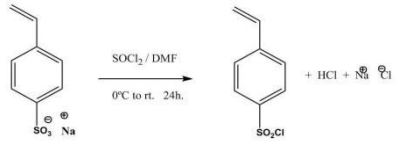

Figure 1: Synthesis of p-vinylphenylsulfonyl chloride.

The polymerization of this monomer was performed through radical polymerization in dissolution using the thermal initiator 2,2'-azobis-isobutyronitrile (AIBN) in toluene. Homopolymer and copolymers with different amounts of pure styrene were synthesized (figure 2).

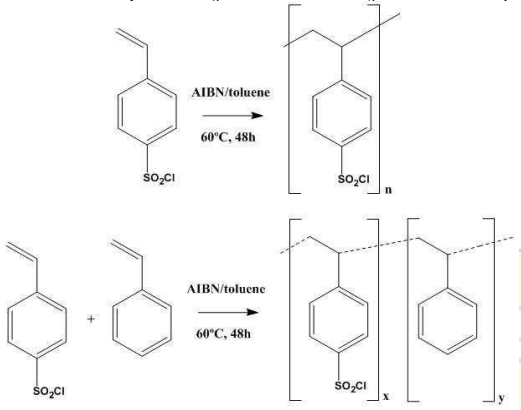

Figure 2: Polymerization in disolution of the modified monomer with and without comonomer.

Results and discussion

In order to establish a regular, structurally homogeneous surface with known number of chlorsulfonyl groups the most appropriate method is a bottom-up approach. In contrast to the chemical modification of PS by chlorosulfonic acid one starts here with a monomer (p-vinylphenylsulfonyl chloride) and obtains the corresponding polymer with the same functional group by radical polymerization. The obtained polymeric materials were studied by ATR-IR. Peaks at 1170 and 1370 cm^{-1} indicate the presence of SO2Cl units. In order to compare the ATR-IR spectra of homopolymer and copolymers of different compositions (figure 3), the spectra are normalized with respect to the signal at 1450 cm^{-1} that corresponds to C-H bonds of the polymeric chains and should not be affected by the substitutent in para position of the aromatic ring. After normalization one can correlate the intensity of the signals corresponding to SO2Cl groups to their quantity in the polymer. Comparing these IR spectra with those measured on PS surfaces functionalized by chemical modification with chlorosulfonic acid one can state an excellent concordance. This is an indication that the functionalization with SO2Cl takes place in a controlled and selective way without detectable side-reactions.

Conclusion

In this contribution a detailed characterization of the modified surfaces is given and possible applications of the modified surfaces are discussed.

Enhancing the Formation of the New Trigonal Polymorph in iPP-1-Pentene Copolymers

Ernesto Pérez, María L. Cerrada, Rosario Benavente and José M. Gómez-Elvira

Instituto de Ciencia y Tecnología de Polímeros (CSIC), Juan de la Cierva 3, 28006-Madrid (Spain) e-mail: mlcerrada@ictp.csic.es

Isotactic polypropylene, iPP, and its copolymers with other alpha-olefins are attracting an enormous interest, both industrially and academically, since a long time ago. One of the most striking reasons for the academic interest is the amazing polymorphism exhibited by these materials. Thus, depending on microstructural features, crystallization conditions and other factors like the use of specific nucleants, three different polymorphic modifications, α, β and γ, all sharing a three-fold conformation, have been reported [1,2]. Moreover, fast quenching of iPP leads to a phase of intermediate or mesomorphic order, which, on heating, undergoes a transformation into the α form.

In addition to those four modifications, a new trigonal form has been recently described [3-6] in the case of copolymers of iPP with high contents of 1hexene or 1-pentene as comonomers, named as δ form. In those reports, the new trigonal δ modification is the only one obtained for comonomer contents above around 14 mol-%, while variable proportions of it with the α modification were found in the comonomer range from around 8 to 13 mol-%. For these intermediate contents, it has been recently established [5] that the mesomorphic modification, as well as the α crystals, are competitors in the formation of the new trigonal modification.

One of the most interesting characteristics of those copolymers exhibiting the δ form is the surprisingly high degrees of crystallinity attained, reported to be on the order from around 25 to 40% for comonomer contents ranging from 15 to 30 mol-% of counits. The thermal history imposed to these samples is generally a cooling from the isotropic melt to room temperature, and the ageing at ambient conditions for long times (months).

With these considerations, a plausible question arises immediately: is it possible to enhance even more those unexpectedly high crystallinities? This is precisely the aim of the present communication, by imposing different crystallization conditions to a copolymer of iPP and 1-pentene.

The copolymerization of propylene and 1-pentene was carried out in toluene, with rac-dimethylsilylbis(1-indenyl)zirconium dichloride/MAO as the catalyst/co-catalyst system. This presentation deals with a copolymer, named as cPPe13, with the following characteristics: 1-pentene content in the copolymer:

13.0 mol-%, M_w: 103000 g/mol, M_n: 49900 g/mol, *mmmm* content: 90.3%.

Film samples of copolymer cPPe13 were obtained from the reactor powder by compression molding in a Collin press between hot plates, and subsequently cooled down to room temperature under two different thermal treatments: a relatively fast cooling between plates refrigerated with cold water after the melting of the material in the press (sample cPPe13Q, cooling rate around 80 °C/min), and a slow cooling at the inherent cooling rate of the press, after the power was switched off (sample cPPe13S, cooling rate around 1.5 °C/min).

A sample cast from hexane (cPPe13cast) and a specimen annealed at 65 °C (cPPe13ann65) were also prepared and analyzed.

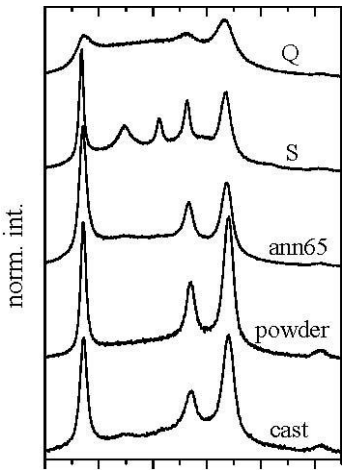

Fig. 1. Room-temperature X-ray diffractograms of the indicated specimens of copolymer cPPe13.

The X-ray diffraction results indicate a very interesting polymorphism in this copolymer, and, when crystallized from solution, amazingly high degrees of crystallinity are obtained, which can be as high as 65%, on the order of those ones obtained for iPP homopolymer.

Persistence of order in liquid crystalline copolymers

V. Rodríguez-Amor, J. P. Fernández-Blázquez, M. L. Cerrada, A. Bello and E. Pérez

Instituto de Ciencia y Tecnología de Polímeros (CSIC), Juan de la Cierva 3, 28006-Madrid (Spain)

e-mail: ernestop@ictp.csic.es

There has been in the last decades an intensive research dedicated to study the crystallization of liquid-crystalline (LC) copolyesters (1-3). In principle, the different chemical units of a random copolymer are not able to contribute fully to the three-dimensional periodicity of the crystal lattice (1), but yet they can crystallize by segregation and lateral matching of identical sequences. It can be anticipated that the tolerance of counits will be even easier for LC phases, due to their lower packing requirements.

For instance, in the SmA phase the molecules are arranged in layers so that their long axes are on average perpendicular to the layer planes, displaying one-dimensional (quasi) long-range order, but there is no translational periodicity in the planes of the layers or between the layers. This layering leads to a number of equally-spaced low-angle pseudo-Bragg peaks, although the tendency for layering is usually rather weak. The implication is that only the first one or two pseudo-Bragg peaks have observable intensity.

However, it has been reported (4) that the X-ray diffraction patterns of some polymeric SmA phases show more than one order of reflection from the layers, and that the first order is not necessarily the strongest.

Besides the introduction of flexible spacers, the copolymerization with non-mesogenic monomers is a widely used strategy in LC polymers in order to tailor the transition temperatures and the final properties (3,5).

This work presents the results about the persistence of order in main-chain LC copolyesters of bibenzoate (B) and terephthalate (T) units.

The copolymers and the homopolymers have been synthesized by melt transesterification of different proportion of diethyl *p,p'*-bibenzoate and dimethyl *p,p'*-terephthalate with diethylene glycol. The chemical composition of the sample was analyzed by ^{13}C-NMR spectroscopy, and the molecular weights were obtained by SEC. The results are the following:

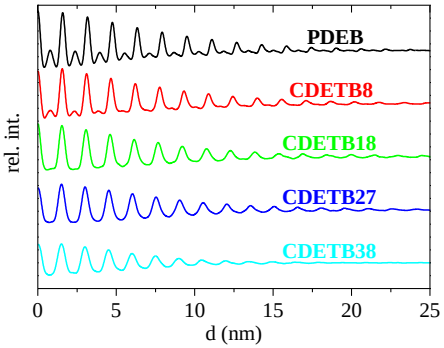
Sample	mol % T	M_n (g/mol)	M_w (g/mol)
PDEB	0	15800	31200
CDETB8	8	23700	45200
CDETB18	18	17800	33300
CDETB27	27	14800	28300
CDETB38	38	20100	41300
PDET	100	50400	156000

Variable temperature X-ray diffraction experiments were performed by employing synchrotron in beamline A2 at HASYLAB (Hamburg, Germany).

The X-ray diffractograms of these samples cooled from the melt to room temperature show a broad amorphous-like diffraction in the wide-angle region, and a narrow diffraction in the middle-angle region (and several orders), corresponding to the layer spacing. This layer spacing shifts slightly to higher angles (lower *d* values) as the T content increases.

But more interesting is the behavior of the intensity of these smectic layer orders. Thus, and contrary to the case of other reported polybibenzoates, up to 4 orders are observed for the homopolymer PDEB, and, interestingly, the second order is slightly more intense than the first one. For the copolymers, besides the slight change of the layer spacing, a more important variation is observed in the relative intensities of the different orders, the intensities of the higher orders decreasing very much with the T content in the copolymer.

By subtracting the corresponding amorphous-like broad diffraction, the different orders of the layer spacing can be isolated, and a kind of electron density profile has been obtained by appropriate Fourier transformation. These profiles are shown below:



It can be observed that the correlation length decreases slightly with the T content, and, more importantly, they display a pseudoperiodicity *d*/2 which is very evident in the homopolymer PDEB, but undergoes a continuous vanishing as the T content increase, in such a way that the profile for copolymer CDETB38 is close to the one arising from a single sinusoidal function.

In conclusion, the persistence of liquid-crystalline order is well evident in these copolymers.

INTRODUCTION: Preparation of new biocompatible materials for bone reconstruction has consistently gained interest in the last few decades. Wide ranges of materials were used as synthetic bone grafts. The design of osteoconductive behaviour is considered one of the most important characteristics of natural grafts, consisting especially in apatite-type content. The use of polymers for bone repair allows the synthesis of numerous biomaterials with specific structure and properties. Polymers are used in osseous applications due to their wide chemical composition, to their different mechanical behaviour and because the organic bone matrix are mainly formed by macromolecules [1]. In order to form apatite deposits in/on the implant, after implantation, polymer must contain negative chemical groups, in order to mimic the activity of bone proteins responsible for mineralization. The present research focuses on the preparation and characterization of 2-hydroxyethyl methacrylate (HEMA) and 2-acrylamido-2-methylpropane sulphonic acid copolymers as scaffolds for bone pathology.

MATERIALS AND METHODS: The polymeric matrices were synthesized by bulk radical polymerization using benzoyle peroxide as initiator and ethylene glycol dimethacrylate as cross-linking agent. Various increasing molar concentrations of AMPSA were used to obtain copolymer pellets (3 %, 5 %, 10 % molar content of AMPSA in feed). Polymerizations were conducted at 80 °C for 12 h. There were obtained polymeric pellets with flat shape and maximum surface, which were extracted in Soxhlet for 12 h with distilled water to remove any traces of the residual monomer that could negatively influence the in vitro assays. ATR-FTIR spectra of the copolymers were obtained at 20 °C and constant 40 % relative humidity. For mineralization tests, three samples of copolymer were incubated in synthetic body fluid (SBF1x, protocol of Professor Kokubo T.) at pH 7.45, adjusted with tris(hydroxy-methyl) aminomethane (Tris) and hydrochloric acid HCl, for 14 days, under sterile conditions, in containers with 50 mL of the incubation medium at 37 °C. The surface morphology after incubation was examined using scanning electron microscopy (SEM) coupled with energy dispersive X-rays spectroscopy (EDX). Polymers biocompatibility was verified by testing their in vitro cytotoxicity and viability on J774.2 cell line.

RESULTS AND DISCUSSION: Series of p(HEMA-co-AMPSA) copolymers with increasing molar concentrations of AMPSA were synthesized by bulk polymerization procedure. FTIR-ATR spectra showed absorbance wavelengths of the specific bonds which appeared in the polymers obtained (tertiary C atom at 1539.1 cm^{-1} from AMPSA), confirming the structure of the new materials (spectra not shown here). During incubation in SBF, several micro-cracks appeared on all polymeric surfaces. Scanning electronic microscopy (SEM) and energy dispersive X-rays (EDX) showed the presence of apatite deposits onto the surfaces of p(HEMA-co-AMPSA) copolymers incubated in SBF 1x. Best results were observed onto surface of p(HEMA-co-AMPSA) polymers with 10 and 15 % (molar) AMPSA (figure 1). This sustains the idea that negatively-charged sulphonic groups have a major influence upon the mineralization process of biomaterials. EDX spectra proved also the presence of nice HA crystals onto polymeric surfaces (Ca/P molar ratio of 1.68 and 1.7). The most promising polymers for mineralization potential having 5 and 10 % AMPSA molar content were then submitted to cytotoxicity and viability tests. Most of the cells retained their typical morphology of J774.2 cells with more and more extensions. A lot of cells could be evidenced at the polymer surface. Slightly toxic effects were noticed for polymers with 10 % AMPSA molar content in the feed. Probably the toxic limit concentration of AMPSA for the cells was achieved.

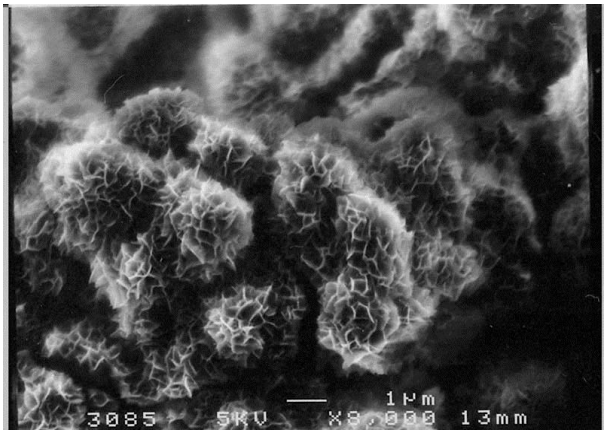

Fig.1. SEM microphotographs for p(HEMA-co-AMPSA) with 10 % AMPSA molar content in the feed incubated in SBF 1x

CONCLUSIONS: This research work offers an interesting perspective of the mineralization process of HEMA-based copolymers with sulphonic groups incubated in SBF 1x. Therefore, the new synthesized materials represent potential scaffolds for apatite crystal growth stimulation in bone tissue engineering.

Abstract

To modified rheological properties of drilling mud, preparation of appropriate hydrogels from Chitosan N-Isopropylacrylamide hydrogels by thermal and gamma radiation have been considered. In the thermal method, initiator and crosslinking agent have been used where gamma radiation process have been done in absence of any kind of initiator and crosslinking agents. Presented results illustrate that the gamma radiation method produced hydrogel with higher water swelling ratio. Rheological properties of modified hydrogel drilling fluid, such as apparent viscosity, plastic viscosity, gel strengthen, and yield point were investigated and compared with those of Cellulosemethylcarboxyl (CMC) and Xanthenes (XC) resins prepared drilling fluids which are widely used in drilling fluids. The hydrogel synthesized by gamma radiation showed improving rheological properties for drilling fluid comparing to CMC, XC, and thermally prepared hydrogel. Obtained results depict that increase in gamma radiation dose and monomer concentration which rendered high swelling hydrogels, were more suitable for improving drilling mud application. In other words, presented results demonstrate that whereas linear polymer effects on mud properties are more significant in polymer low concentration, prepared crosslinked hydrogel effects are more significant at high concentrations.

mypedram @gmail.com

Introduction: Recently, it has been observed that by incorporating filler particles into the matrix of talc reinforced polymeric composites, synergistic effects may be achieved in the form of higher modulus and reduced material costs, yet accompanied with decreased strength and impact toughness [1]. Such multicomponent hybrid composites based on poly (butylene terephtalate) (PBT) [2], acrylonitrile–butadiene–styrene copolymer (ABS) [3] and polypropylene (PP) [4] matrices have been studied. The aim of this work was to study the effect, on the mechanical properties, of the addition of second reinforcing filler such as mineral calcium carbonate (CC) or biomineralized calcium carbonate from eggshells (BCC) or a synthetic calcium silicate (SiCa) to the PP/talc composite.

Materials and Methods: The PP used was an isotactic homopolymer with melt flow index of 13 g/10 min, 230 °C, 2.16 Kg. The fillers used was: talc (TA) from Reverte with particle size d(50)=2.4 µm and surface area (SA) of 6.3 $m^2 g^{-1}$; CC from Reverte with d(50)=0.7 µm and SA of 9.1 $m^2 g^{-1}$; BCC with d(50)=8.4 µm and SA of 18.0 $m^2 g^{-1}$ and SiCa was kindly donated by professor T. Borrmann, Victoria University of Wellington, New Zeland with d(50)=12.0 µm and SA of 243.1 $m^2 g^{-1}$. The composites were prepared by melt mixing of the PP with one filler (reinforced composites) or a 1/1 mixture of fillers such as TA/CC or TA/BCC or TA/SiCa (hybrid composites). These composites were obtained by using a Brabender-Plasticorder batch mixer at a constant temperature of 190 °C during 15 minutes at a rotor speed of 75 rpm and under nitrogen atmosphere to prevent polymer oxidation. After the melt mixing, the tensile mechanical tests were performed according to the ASTM D 638-95.

Results and Discussion: Our study showed that the tensile modulus of PP/TA composites was improved by adding other inorganic fillers such as CC or BCC or SiCa. It was shown that the addition of any calcium-based inorganic reinforcements in PP/TA composites increased the stiffness according to the filler contents up to 20 wt.-%. On the other hand, the strength and toughness were decreased and the elongation at break is simultaneously reduced according the filler content. This effect could be attributed to the fact that reinforcing calcium based inorganic fillers strongly restrain the deformation of the polymer matrix as demonstrated in previous studies [5].

As shown in Figure 1, the enhancement of Young modulus of PP/TA reinforced composites compared with PP/calcium based inorganic filler composites and hybrid PP/TA reinforced composites depend on both compositions and surface areas of the filler. In particular, the BCC filler represent a new natural alternative reinforcing filler for PP and show a higher stiffness than the similar PP/CC composites. The better reinforcing effect of the BCC could be attributed to its higher surface area than the CC or talc filler. In the case of hybrid composites, it was observed that up to 50 wt.-% replacement of talc by CC or BCC or SiCa did not affect the Young modulus. This replacement of talc filler depend on the type and filler content and showed a higher modulus for PP/TA-BCC or PP/TA-SiCa hybrid composites than the PP/TA composite up to 20 wt.% of filler content. The addition of filler with higher surface area could promote a better dispersion of filler in the polymer matrix. Beside, a more phase homogeneity could be the explanation of this enhancement of the stiffness in the hybrid PP composites with TA-BCC or TA-SiCa fillers.

Conclusions: The mechanical properties of PP/talc composite could be improved by the addition of second micrometric filler based on calcium with higher surface area than talc.

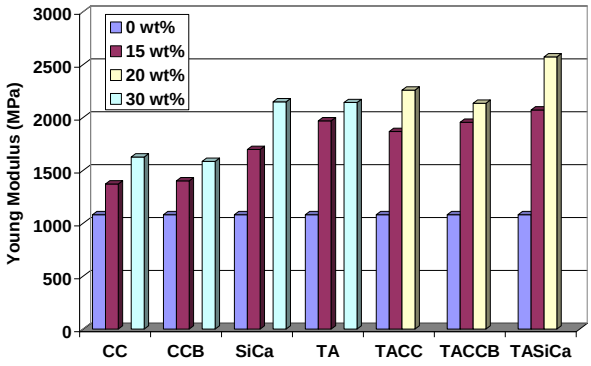

Figure 1. Young modulus of mineral filled composites: (CC =PP/CC; BCC = PP/BCC; SiCa = PP/SiCa; TA= PP/TA composites) and hybrid PP/talc (TACC= PP/TA-CC; TA-BCC=PP/TA-BCC; TASiCa=PP/TA-SiCa).

Introduction

Implants that serve as cell scaffolds and as drug delivery systems to prevent infections enable a faster healing of the tissues. This is particularly useful for the management of osteomyelitis, since the local administration of antimicrobials reduces adverse effects of the systemic treatment (1). Poly-ε-caprolactone (PCL) is a common component of biodegradable implants that erodes slowly due to its high hidrophobicity. Blending with other polymers may accelerate its degradation (2). On the other hand, injectable implants are attracting raising interest. Poloxamines (Tetronic®) are pH- and temperatureresponsive block copolymers that render *in situ* gelling solutions (3). The aim of this work was to prepare implants based on blends of PCL and poloxamines, applying hot melting without organic solvents, that are able to control the release of ciprofloxacin.

Materials and methods

Materials

Poloxamines Tetronic® 908, 1107, 1301 and 1307 were from BASF (New Milford, CT, USA). Ciprofloxacin was from Fagron (Spain) and PCL from Sigma-Aldrich (Mn 42500 Da, St. Louis MO, USA).

Preparation of implants by hot melting

Implants containing PCL and poloxamine in different ratios (0:1, 0.25:0.75, 0.50:0.50, 0.75:0.25, 1:0) and ciprofloxacin (10 mg/g) were obtained by melting at 80ºC under stirring. Then, implants were cooled in a water-ice bath and stored protected from light.

Ciprofloxacin release

Phosphate buffer pH 7.4 (10 ml) at 37ºC was added to test tubes containing the implants prepared at 80ºC. Ciprofloxacin release was monitored spectrophotometrically at 271 nm (Agilent 8453, Germany) while keeping the systems under oscillation movements (25 osc/min).

In vitro degradation assay

PCL:poloxamine implants were weighted and pretreated with NaOH 5M (10 ml) for 72 h at 20ºC. The medium was then replaced by phosphate buffer pH 7.4 (10 ml) at 37ºC. At prestablished times implants were removed, washed with water, dried for 12 h at 37ºC and weighted. Finally they were immersed again in phosphate buffer.

In vitro microbiological study

Staphylococcus aureus ATCC25923 was inoculated in Falcon® tubes containing Mueller-Hinton broth at a concentration of 3.2 x 106 CFU/ml. Implants, with and without drug, were incubated in this suspension at 37ºC for 24 h and the resistence of *S. aureus* to the drug was monitored by colony counts.

Results and discussion

Ciprofloxacin release

Implants containing solely PCL released ciprofloxacin very slowly; increasing the poloxamine ratio, the drug release rate accelerates.

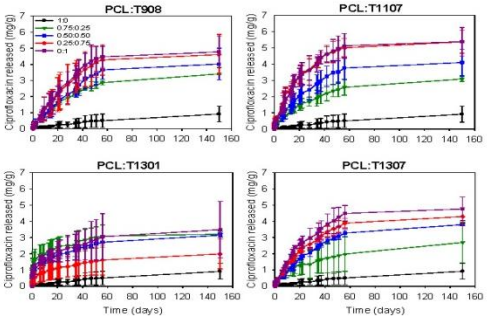

Figure 1. Ciprofloxacin release in phosphate buffer pH 7.4 from PCL:poloxamine implants prepared at 80ºC.

In vitro degradation assay

PCL implants eroded very slowly; as poloxamine content increases, erosion process turns faster.

In vitro microbiological study

In vitro microbiological assays confirmed the effectiveness of the implants with drug against *Staphylococcus aureus*. Although after 24 h some colonies could be observed in the test tubes, after 48 h bacterial growth was almost negligible.

Table 1. *Staphylococcus aureus* CFU/ml in Mueller-Hinton broth containing PCL:poloxamine implants with ciprofloxacin (10 mg/g).

Conclusions

PPCL:poloxamine implants can be easily obtained by hotmelting without using organic solvents. Drug releaseand erosion profiles can be tuned varying the ratio ofeach component in the blend composition.Microbiological tests indicate that the implants arepotentially useful for the osteomyelitis treatment.CL:poloxamine implants can be easily obtained by hot melting without using organic solvents..

Monomers *vs* Polymers of Cu(III) Corroles on Reduction of O_2

Jorge Vélez, *F. Isaacs*, *M. J. Aguirre*

Dpto. de Química de los Materiales, Facultad de Química y Biología, Universidad de Santiago de Chile, Casilla 40, Correo 33, Santiago, Chile.

Jorge.velez@usach.cl

Introduction:

Corroles, macrocycles belonging to the porphyrinic family (1,2), stabilize transition metals of in high and unusual oxidation states due to the contraction of the ring originated by the loss of one of the meso carbons. Metalocorroles are of special interest since there can achieve displacements of potential and valuable increases of current in the reaction of O_2 reduction (3) simulating enzymatical reactions of this type. In this work we present the characterization of two Cu(III) corroles (Fig. 1) and their behavior in the electrorreducción of O_2 in aqueous solutions at different values of pH.

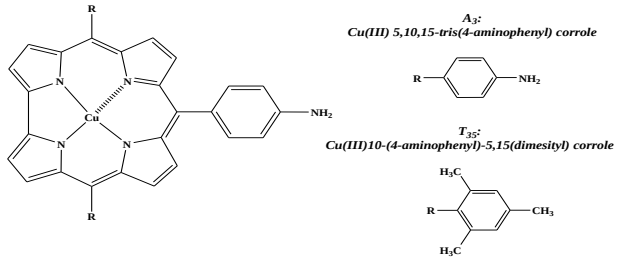

Fig.1. Structure of Cu(III) corroles studied.

Experimental

Glassy carbon electrodes were modified by evaporation of a drop and by electropolymerization of the corrolic solution in DMF. The electrochemical experiments were performed with CH-Instruments (Austin, TX, USA) Model 600B. A three-electrode system was used and consisted of a glassy carbon working electrode, a platinum wire counter electrode, and Ag/AgCl reference electrode. The activity of the modified electrodes for the oxygen reduction were performed in aqueous solutions at different pH values (3, 7 and 12) in N_2 athmosphere.

Results and Discussion

In the electrochemistry characterization of the corroles in DMF's solution (Fig. 2) three reversible waves are observed for the A_3 complex, whereas the complex T_{35} presented two reversible waves and a cathodic irreversible peak. The waves showed as II for both complexes centred to $E_{1/2}$ -0.22 and -0.12 V might correspond to the metallic couple Cu the (III)/ (II).

Knowledges

- Fondecyt 3100066

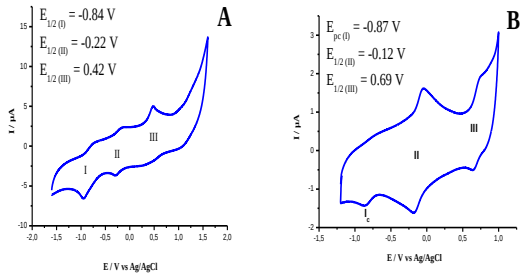

Fig. 2: Cyclic voltammograms of the corrolic solutions in DMF/TBAP 0.1M. 0.1 Vs-1, N2. A: Corrol A3, B: Corrol T35.

The electrocatalysis of O_2 reduction hows, in general, that the electropolymerized complexes on CV are more efficient for this reaction, and that of both compounds, which delivers better results to any pH turns out to be the one that possesses three aminophenyl groups in the periphery of the macrocycle, that is to say, the corrol A_3, having the starting wave for this reaction near to the -0.15 V.

In addition, at pH 3 for the complex A_3 (is observed a phenomenon that does not appreciate to any other value of pH worked. As much for the modification realized with drop as well as with electropolymer, there are seen two waves of reduction and one of oxidation. This gives a clear indication that the corrol A_3 in this way is capable of reducing O_2 to H_2O by four electrons.

Conclusions

- The characterization studies of this Cu corroles by NMR ^1H (not showed spectrum) indicate that in these complexes the dominant basal state is the diamagnetic Cu(III).
- In almost all the cases, the system A_3 showed to be more electrocatalytic in the O_2 reduction presenting the potential wave for this reaction near to -0.15 V.
- The number of electrons transferred in the O_2 reduction is four, indicating the reduction from O_2 to H_2O.

carmelo@polimeros.uson.mx

Introduction

Limitations such as fragility and impact resistance are some of the major problems associated with practical applications of conductive polyaniline. An effective method to overcome some of these problems is by preparing composite materials containing the intrinsically conductive polymer as filler dispersed in thermoplastic matrices [1].

Conducting polymers widely used as sensors are inherently rigid. An effective method to overcome this problem is by preparing composite materials containing the intrinsically conductive polymer as filler dispersed in elastomers such NBR. The preparation methods used has big influence on the electrical and mechanical properties of the composite material. Different blending methods has been studied with the objective of resolve this problems.

Materials and Methods

The fabrication technique is key component to optimizing the properties of the strain sensor. For this work composite material of acrylonitrile butadiene rubber (NBR) and polyaniline was prepared by in situ polymerization of aniline swollen in NBR film. The quantity of absorbed aniline was increased using an organic solvent to swell the NBR. The polymerization was carried out by immersing the swollen NBR films in a solution of copper(II) perchlorate hexahydrate. The resulting films were characterized by SEM, DTA, electrical conductivity, surface resistivity, and mechanical properties with the aim to use as a mechanical stress sensor.

Results and Discussion

Some indication of the high-temperature miscibility of PANI with NBR in their blends may also be gained from the onset temperatures [2]. We measured the thermal properties of the composites using a Perkin Elmer DTA-7. Only small shifts in the onset temperature of the major exotherm are observed indicating that the miscibility is limited in this blend at room temperature.

Uniaxial stress-strain measurements were performed on a universal testing machine. The mechanical properties of the NBR are affected by blending with PANI mainly decreasing the ultimate elongation at break. However composites with the highest content of polyaniline have enough elasticity (199 %) to be used as elastomeric sensor.

The electrical conductivities of composite films were measured by the standard two-point probe method with the electrodes in a sandwich configuration and also by evaluating the surface resistance in one side of the film.

We found that composites have surface conductivity but also have a bulk conductivity indicating presence of polyaniline inside the elastomer not only over the surface like many composites prepared with similar methods of in situ polymerization.

Some samples were subjected to repeated stress-strain cycles in a Universal Testing Machine and the change in electrical resistance was measured. Two electrodes were settled on the grips of a mechanical universal testing machine to measure the change in electrical resistance of the sample during a strain-stress testing. A cycle of elongation at a rate of 44 mm / min was carried out and a graph of the resistance of the sample during the test was obtained.

Repeated cycles displayed a similar behavior showing that the sample could have a use as deformation sensor.

Conclusions

A reversible dependence of electrical resistance at stretch has been only observed in case of nano-size conductive particles [3] while a irreversible tenso-resistive effect is obtained in micro-size particles.

Our results suggest that PANI distribution in NBR matrix plays an important role in tenso-resistive behavior. A stress sensor is proposed using this composite material

Ultra-thin Electronic Nanocomposites of Carbon Nanotubes and Self Assembled Block Copolymers

Cheolmin Park, *Jinwoo Sung*, *Yeon Sik Choi*, *Sung Hwan Cho*

Department of Materials Science and Engineering, Yonsei University, Seoul, Korea

e-mail: cmpark@yonsei.ac.kr

Introduction

The nanostructures of block copolymers are of great importance due to their capability of fabricating nanocomposites with the functional materials such as quantum dots and single-wall carbon nanotubes (SWNTs). In this presentation, our current efforts will be discussed to develop ultra-thin electronic composite sheets of networked SWNTs self-assembled with various types of block copolymers such as amphiphilic and conjugated block copolymers which have versatile potential applications of low electric resistance sheets for transparent electrodes,[1] semi-conducting channel layers for organic transistors[2] and bipolar hole-electron carrier channel network for high performance electro-luminescence devices.

Results and discussion

The versatile application of the electronic composite sheets is mainly attributed to (1) the efficient dispersion of SWNTs with a conjugated block copolymer, poly(styrene-*block*-paraphenylene) (PS-*b*-PPP), in solution, (2) the control of the number of nanotubes by centrifugation, and (3) the individually networked deposition of SWNTs embedded in the conjugated block copolymer on the target substrate by spin coating as shown in Figure 1.

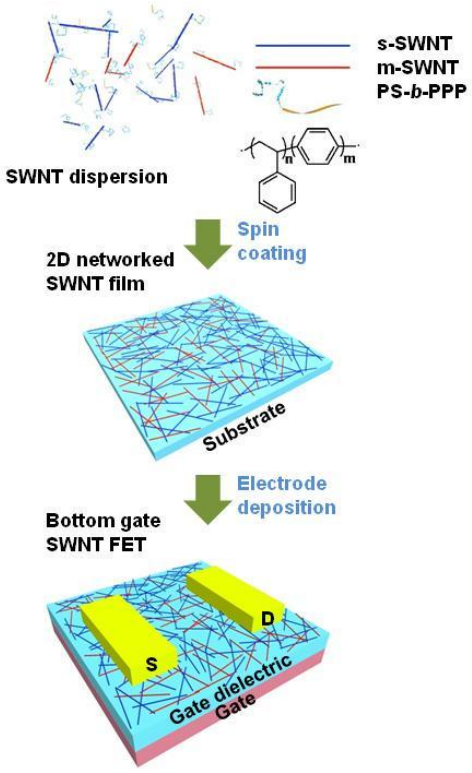

Figure 1. Schematic of field effect transistors fabricated with SWNTs/block copolymer nanocomposites

The individually deposited SWNTs are also visualized in under-focused phase contrast in TEM as shown in Figure 2. A single nanotube is apparent with the characteristic granular domains of approximately 7 nm in diameter in the inset of Figure 2.

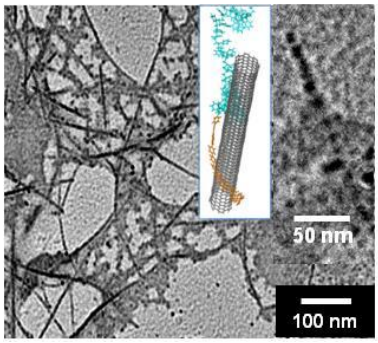

Figure 2. TEM micrograph of a SWNTs/PS-b-PPP nanocomposite

A highly reliable bottom gate/top contact field effect transistor with a networked composite film was realized with a specific range of tube density and a high on/off current ratio of approximately 10^5 which resulted from the Schottky barriers evolved between the individual m- and s-SWNTs in the network.

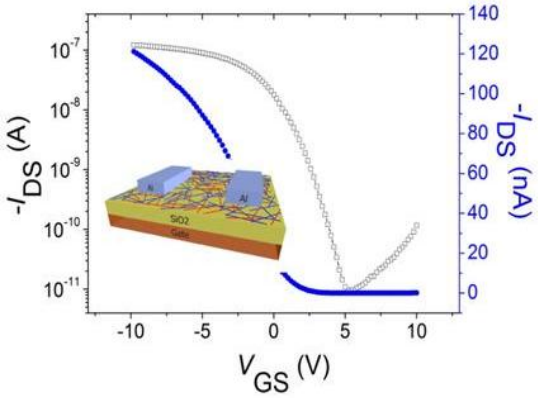

Figure 3. Transfer characteristics of SWNT transistor with Al contact and SiO_2, insulator.

Furthermore, the fabricated electronic nanocomposites are highly transparent, flexible, and chemically robust and thus, they can be conveniently micro and nano-patterned by nanoimprinting techniques.

Polymer Electrolyte Membranes Based on Poly(phenylene ether)s with Pendant Perfluoroalkyl Sulfonic Acids

Kazuhiro Nakabayashi, Tomoya Higashihara, and Mitsuru Ueda

Department of Organic and Polymeric Materials, Tokyo Institute of Technology, 2-12-1-H120, O-okayama, Meguro-ku, Tokyo 152-8552, Japan

ueda.m.ad@m.titech.ac.jp

Development of polymer electrolyte membranes (PEMs) based on aromatic polymers have been investigated over the past decades to realize alternatives of sulfonated perfluoropolymers (e.g., Nafion® and Flemion®). For example, PEMs based on sulfonated multiblock copolymers have been widely studied as the promising polymer architecture for high-performance PEMs.[1] Recently, the introduction of perfluroalkyl sulfonic acids into aromatic polymers also demonstrated drastic improvement of proton conductivity due to its high acidity (pK_a~ –6).[2] Thus, as well as sulfonated multiblock copolymers, this approach can be a promising way to improve performances of aromatic PEMs.

Hence, in this work, novel poly(phenylene ether)s containing pendant perfluoroalkyl sulfonic acids with ion exchange capacity (IEC) of 1.17–1.83 mequiv/g (**4a–5a**) were synthesized by the aromatic nucleophilic substitution reaction of a perfluoro monomer (decafluorobiphenyl or hexafluorobenzene) with 2,5-bis(4'-iodophenyl)hydroquinone, followed by the Ullman coupling reaction with potassium 1,1,2,2,-tetrafluoro-2-(1,1,2,2-tetrafluoro-2-iodoethoxy)ethanesulfonate (**PTES**). These poly(phenylene ether)s consist of the rigid polymer backbones with the high fluorine content and the flexible perfluoroalkyl sulfonic acid side chains, that is, the structure mimics that of the sulfonated perfluoropolymers (Figure 1). Their IEC values could be readily controlled by changing the equivalent of **PTES** in the Ullman coupling reaction. The structure of polymers was confirmed by ^{1}H and ^{19}F NMR spectra.

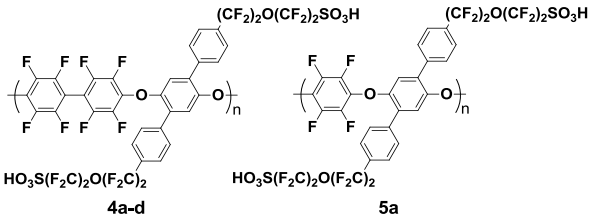

Figure 1. Structure of **4a–5a**.

The **4a–5a** membranes prepared by solution casting showed significantly low water uptake (19.3–28.0 wt %) and excellent dimensional stability even in the hydrated state, which were due to the strong hydrophobicity of the polymers (i.e., the high fluorine content). Besides, the high oxidative stability against hot Fenton's reagent (3% H_2O_2 aqueous solution containing 2 ppm $FeSO_4$ at 80 °C) was achieved. Humidity dependence of water uptake was evaluated in the **4a–5a** membranes at 80 °C. The **4a** and **4b** membranes with IEC = 1.17 and 1.38 mequiv/g showed low water uptake comparable to the Nafion 117 membrane in a whole range of relative humidity. The **5a** membrane with IEC = 1.83 mequiv/g showed the highest water uptake (24.0, 20.1, 12.6, and 8.8 wt % at 95, 80, 50, and 30% RH, respectively), which corresponded to λ (the number of water molecules per a sulfonic acid) = 7.3, 6.1, 3.8, and 2.7, respectively. These λ values are as high as those of the Nafion 117 membranes. Figure 2 shows humidity dependence of proton conductivity of the **4a–5a** membranes at 80 °C. All membranes show high proton conductivity comparable to the Nafion 117 membrane at 95% RH. The proton conductivity of the **4a–d** membranes, however, decreases rapidly with decreasing relative humidity from 95 to 30% RH. On the other hand, the **5a** membrane with IEC = 1.83 mequiv/g maintains high proton conductivity comparable to the Nafion 117 membrane to 30% RH. The high λ values of the **5a** membrane should contribute to high proton conductivity. As for sulfonated aromatic polymers with the same IEC values, high proton conductivity like the **5a** membrane has never been achieved, which obviously indicates that the high acidity of perfluoroalkyl sulfonic acids contributes to drastic improvement of proton conductivity.

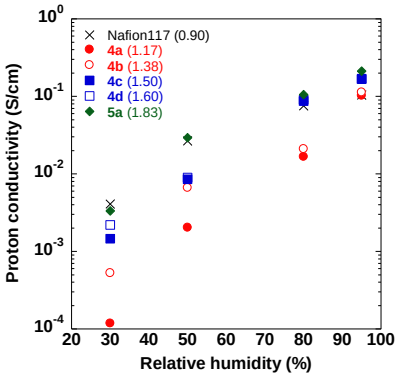

Figure 2. Humidity dependence of proton conductivity of **4a–5a** and Nafion 117 membranes at 80 °C.

In summary, novel poly(phenylene ether)s containing pendant perfluoroalkyl sulfonic acid with IEC = 1.17–1.83 mequiv/g (**4a–5a**) were successfully synthesized. All membranes showed high dimensional and oxidative stability. Among them, the **5a** membrane with IEC = 1.83 mequiv/g accomplished high proton conductivity comparable to the Nafion 117 membrane in the range of 30–95% RH, which resulted from the strong acidity of perfluoroalkyl sulfonic acids.

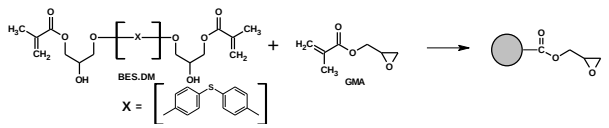
Introduction

In recent years, copolymers based on GMA have attracted increasing interest. The attention focused on these copolymers is largely due to the ability of pendent epoxide groups to enter into a large number of chemical modifications of the initial polymer. Copolymers based on GMA have been used as supports for enzymes and as sorbents for chromatography, they can also be used in removing metal ions (eg. mercuric ions) or even as biomaterials [1-2]. Immobilization on polymers is most important in the industrial application of enzymes, which as immobilized biocatalysts offer unique advantages in terms of better process control, increased stability etc.[3]

Materials and Methods

Copolymers containing glycidyl methacrylate and bis[4(2-hydroxy-3-methacryloyloxypropoxy)phenyl]-sulfide (BES.DM) were obtained in a suspension-emulsion copolymerization procedure [4]. The initiator AIBN (1 wt %) was dissolved in monomers, and then the mixture was diluted with a mixed solvent (toluene/decan-1-ol) taken in different proportions. Different concentrations of toluene in the mixture with decan-1-ol were used to qualify the effect of the diluent character on the microsphere properties. The dispersion medium was prepared through the dissolution of 1 wt% bis(2-ethylhexyl)sulfosuccinate sodium salt (DAC, BP) in deionized water, and it was used in a 1/5 (w/w) ratio according to the organic phase. The reaction mixture was stirred at 600 rpm for 18 h at 80 ^{o}C.

After cooling a purification procedure was applied to remove the diluents and unreacted monomers from the products. The obtained copolymers were washed with distilled water, filtered off, dried and then extracted in a Soxhlet apparatus by different solvents. Microscopic examination showed that in most cases particles of perfectly spherical shapes with diameters in the range 5-30 µm were obtained. Uniform particles (5-15µm) used in further studies. Chemical structure of the obtained copolymers was confirmed by spectroscopic method.



Scheme of copolymerization

The selected copolymers were modified with some amines in the epoxide ring opening reaction. 10 g of selected microspheres were placed together with diethylenetriamine (DETA) or triethylenetetramine (TETA) (10 excess to epoxide groups) and 200 mL of toluene. The whole content was heated over a water bath at 80^{o}C for 24 h. Their FTIR and elemental analyses were carried out. Next, the obtained microspheres were tested as matrices in immobilization proceses of selected enzymes.

Results and Discussion

New copolymers of different degrees of crosslinking obtained from glycidyl methacrylate (GMA) and bis[4(2-hydroxy-3-methacryloyloxypropoxy)phenyl]-sulfide (BES.DM) as crosslinkers were obtained according to reaction shown in Scheme 1 [5]. The obtained copolymers have different number of epoxy groups ranging from 0.73 to 2.79 mmol/g. The closest epoxy groups numbers to theoretical values are characteristic for microspheres containing 1:1 and 1:2 (mol%) GMA:BES.DM.

The monomers were used for the synthesis of porous microspheres in the presence of pore-forming diluents, decan-1-ol and toluene. Influence of diluents composition on their structures was studied. Porous structure of the obtained microspheres in dry (from nitrogen adsorption-desorption measurements) states, their thermal properties (thermogravimetric analysis), and swelling characteristics in 10 solvents of different chemical nature were examined.

A selected microspheres with hanging epoxide groups are tested in reactions with biological active compound (e.g enzymatic proteins) to develop effective procedures for the immobilization of selected enzymes in these media.

Conclusions

Synthesis, copolymerization, and properties of the new copolymers of bis[4(2-hydroxy-3-methacryloyloxy-propoxy)phenyl]sulfide (BES.DM) and glycidyl methacrylate (GMA) of different cross-linking degree in the form of microspheres are presented. Thermal resistance of the studied copolymers increased with increase of BES.M concentration. Swelling characteristics and the epoxide content around 0.73 - 2.79 mmol of epoxy groups per gram make these copolymers very interesting for their chemical modification.

Abstract Body: Cross-linked Copolymer of Acrylamide (AM) and 2-acrylamido-2-methyl-1-propane sulfonaic acid (AMPS) were prepared via thermally initiated free – radical precipitation polymerization in an organic solvent. 1-6 Hexa diol di acrylate And 2,2 azobis isobutyronitrile were used as cross-linker and initiator respectively. The effect of (HDDA) concentration on different features of sample(i.e., spectral characteristics, glass transition temperature, equilibrium swelling, gel content rheological properties) was investigated. The Flory-Rehner equation and rubber elasticity theory were used to discuss the network structure of polymer. Apparent and rotational viscosities were used to determine the optimal cross-linker concentration. The sample maximum with value of viscosity was obtained using 0.9 mmol/L of the cross-linker. In addition the m and n parameter of Ostwald equation were investigated as well

A feasible route to disperse bacterial cellulose nanowhiskers in polymers by melt compounding of interest in packaging applications and physical characterization of the optimized nanocomposites

Martinez-Sanz Marta, Lopez-Rubio Amparo And Lagaron Jose Maria

Novel materials and nanotechnology group, iata, csic, apdo. Correos 73, 46100 burjassot, spain

E-mail: lagaron@iata.csic.es

Abstract Body:

The present work reports on the development and physical characterization of novel nanocomposite materials obtained through melt compounding consisting of an EVOH matrix reinforced with bacterial cellulose nanowhiskers (BCNW). Cellulose-based fillers are in general very difficult to disperse via melt blending processing routes and hence most of the existing studies relate to composites obtained by solvent casting. With the overall aim of enhancing the nanofiller dispersion in melt compounding processes, several methodologies have been developed and optimized for the efficient incorporation of bacterial cellulose nanowhiskers and in general of cellulose nanowhiskers into polymeric matrixes (1).

Bacterial cellulose was selected as the reinforcing agent due to its structure and unique properties, such as high crystallinity, high degree of purity, low density and biocompatibility. Furthermore, while plant cellulose is associated with other kinds of natural biopolymers like lignin and hemicellulose, bacterial cellulose is obtained with a high degree of purity. These outstanding properties have made bacterial cellulose an interesting filler to reinforce nanocomposite polymeric and biopolymeric materials (2-5).

Highly crystalline bacterial cellulose nanowhiskers (BCNW) were first incorporated into an EVOH carrier by means of both high voltage spinning and solution precipitation in liquid nitrogen and, subsequently, melt-mixed with the pure EVOH matrix, generating diluted nanocomposite compression moulded films with a final concentration of 2 wt.-% BCNW (6). The morphology of these materials was studied by optical microscopy with polarized light, TEM and cryo-SEM, revealing a significant improvement in the dispersion of BCNW through the developed methods as compared to direct melt-mixing of the freeze-dried material with the polymeric matrix. Furthermore, for the precipitation method, it was possible to incorporate up to 4 wt.-% BCNW without significant aggregation of the nanoreinforcement.

While the direct addition of freeze-dried BCNW had a negative effect on the water permeability and mechanical properties of the material, reductions of more that 50% in water permeability and increased elastic modulus and tensile strength were measured for the nanocomposites with enhanced dispersion.

Thus, a full morphological and physical properties characterization of the optimized nanocomposites were carried out relating their particular structure to specific properties relevant to the high barrier application in packaging.

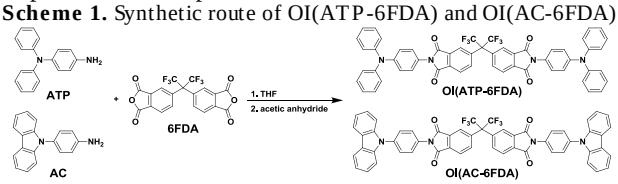
Introduction

Memory devices based on organic materials have been receiving interests because of simplicity in device structure, good scalability, low-cost potential, and low-power operation compared to silicon-based memories[1]. From the molecular designing point of view, donor (D)-acceptor (A) structure is known to be very important for the expression of memory characteristics[2, 3]. In this study, we report the synthesis and memory characteristics of two novel oligoimides (OIs) with D-A-D structure, which were derived from 4,4'-(hexafluoroisopropylidene)diphthalic anhydride (6FDA) and 4-aminotriphenylamine (ATP), or *N*-(4-aminophenyl)carbazole (AC), respectively. In addition a novel A-D-A type OI derived from 4,4'-diaminotriphenylamine (DATP) and 4-(trifluoromethyl)phthalic anhydride (3FA), is also reported. The role of D and A moiety and their sequence in memory characteristics were investigated.

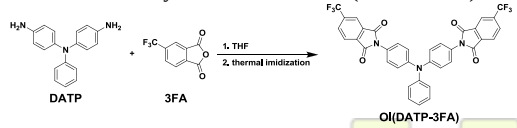
Results and discussion

Synthesis of OIs. OI (ATP-6FDA) and OI(AC-6FDA) were synthesized by the condensation reaction of amines (ATP or AC) with dianhydride (6FDA), followed by chemical imidization as shown in scheme 1. On the other hand, OI(DATP-3FA) was obtained from DATP and 3FA via thermal imidization due to its high solubility (Scheme 2). The desired structures of the three OIs were confirmed by ^{1}H NMR, ^{13}C NMR, IR, and elemental analysis. All the OIs were readily soluble in common organic solvents which might be originated from the introduction of hexafluoroisopropyl or trifluoromethyl units. In addition, it was possible to prepare a smooth thin film by vacuum evaporation and deposition.

Scheme 1. Synthetic route of OI(ATP-6FDA) and OI(AC-6FDA)



Scheme 2. Synthetic route of OI(DATP-3FA)



Thermal, optical, and electrochemical properties of OIs. The thermal, optical and electrochemical properties were evaluated by using TGA, UV-vis spectroscopy, and CV. These data are summarized in Table 1. All OIs showed excellent thermal stability such as high 5% weight loss temperature ($T_{d5\%}$) over 380 ˚C, which are expected to meet the requirement of heat resistance in electronics industry. The optical band gaps (E_g^{opt}) of OI(ATP-6FDA), OI(AC-6FDA), and OI(DATP-3FA) were 3.28, 3.51, 3.11 eV, respectively. The largest band gap of OI(AC-6FDA) indicates that this OI takes the most twisted conformation of the three.

Table 1. Thermal, optical, and electrochemical properties of OIs

	$T_{d5\%}$ (˚C)	E_g^{opt} (eV)	HOMO (eV)	LUMO (eV)
OI(ATP-6FDA)	459	3.28	-5.21	-2.10
OI(AC-6FDA)	526	3.51	-5.53	-2.02
OI(DATP-3FA)	381	3.11	-5.32	-2.21

Memory properties. The memory effects of the OIs were demonstrated by the current-voltage (I-V) characteristics of an ITO/OI/Al sandwich device. Thin films of OIs were deposited onto ITO. Figure 1 shows the representative memory properties of OI(ATP-6FDA). OI(ATP-6FDA) shows non-volatile negative differential resistance (NDR) behavior with a threshold voltage around 4 V and a high ON/OFF ratio in the range of 10^3~10^4 (Figure 1(a)). Also, OI(ATP-6FDA) exhibits good response to the write-read-erase-read (WRER) voltage bias more over than 30 cycles (Figure 1(b)). These results indicate that OI(ATP-6FDA) has the potential for being the alternative material of current memory devices.

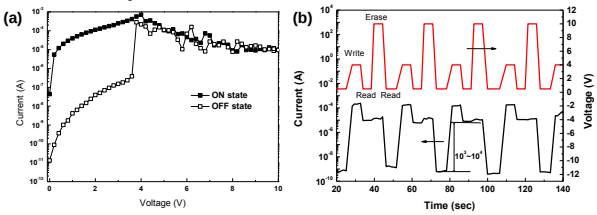


Figure 1. (a) I-V characteristic and (b) current response of OI(ATP-6FDA)

Conclusions

New three OIs containing D and A units in the arrangement of D-A-D or A-D-A were designed and synthesized in order to investigate the role of D and A moiety and their sequence in memory characteristics. All OIs showed high thermal stability. OI(ATP-6FDA) showed NDR behavior with a high ON/OFF ratio. The memory properties of other OIs will be further investigated.

Introduction

Polymers are a class of materials which are very used in the biomedical field. However, their applications are limited by the bacterial infection phenomenon which is a very serious problem. Indeed, approximately 65 % of the hospital infections are related to implants and biomedical materials. This phenomenon is responsible of big economic cost and of significant mortality.[1,2] To prevent this problem, several strategies were proposed, especially the impregnation of the biomaterial with antibiotics. Unfortunately, this strategy can not be used for long times and would exhibit appearance of resistance phenomena. On the other hand, the grafting of bioactive polymers on biomaterial surfaces is considered as a very recent strategy and a promising solution. [2,3]

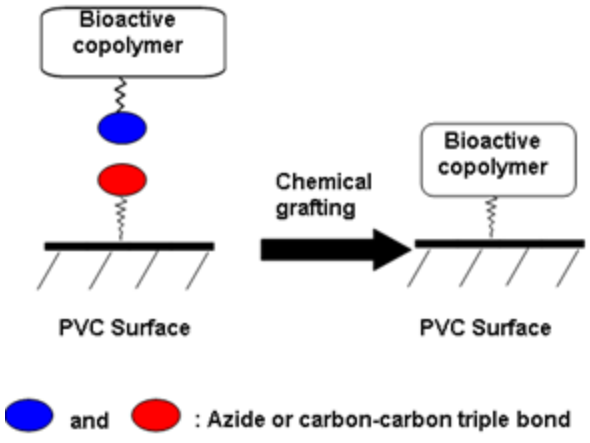
The major challenge in the conception of a new antibacterial biomaterial consists in finding the chemical structure which gives the widest spectrum activity towards microorganisms and a maximum time durability of this activity.

Materials and methods

Reagents: PVC (sigma-Aldrich), NaN3, propargyl amine, PVBC.

Characterizations: NMR, FTIR-ATR (diamond), fluorimetry, Size Exclusion Chromatography (SEC), AFM, XPS, TGA, DSC, contact angle measurements.

Results and discussions



Scheme 1. chemical grafting of antibacterial polymers on PVC surfaces.

eral
h is
The chemical pathway consisted on click addition between azide groups and carbon-carbon triple bond. PVC surfaces as well as a serial of antibacterial copolymers bearing these two anchorage groups were successfully prepared and characterized.

Two strategies in terms of antibacterial properties were envisaged, namely the bactericidal and the anti-adhesive (bacteriophobe) ones.

In the case of the bactericidal strategy, copolymers bearing various bactericidal groups (quaternary ammoniums, guanidinium…) and chemical backbones (polystyrene, polymethacrylate…) were synthesized and characterized by spectroscopic techniques. The thermal properties of these copolymers were assessed by TGA and DSC, which particularly showed a decrease of thermal stability and increase of Tg after quaternization of tertiary amines. The copolymers were then chemically grafted onto PVC surface by click addition for which the operating conditions were optimized. The surface density of the quaternary ammoniums was quantified by colorimetric titration using fluorimetry.[4] This study showed densities higher than 10^{14} charge/cm^2 which is characteristic of bactericidal surfaces. Surface energy as well as surface hydrophilicity were assessed by contact angle measurements in static and dynamic modes, using different liquids especially water. This study mainly showed an increase of surface hydrophilicity and energy after copolymers grafting. Besides, the influence of the chemical grafting on the thermo-mechanical properties of the PVC material was also studied. No significant changes were observed. AFM study showed changes of topography.

Finally, preliminary study using epifluorescence microscopy (LIVE and DEAD test) and zone of inhibition experiment showed bactericidal properties of the PVC surfaces against Pseudomonas aeruginosa and staphylococcus aureus. The anti-adhesive strategy is under investigations.

Conclusion

In this work, antibacterial copolymers were successfully grafted on PVC surfaces by click addition.

Sensory Coumarin-Containing Polymers

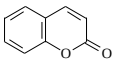
S. Vallejos, P. Estévez, H. El Kaoutit, M. Trigo, F. Serna, F. García, J.L. Peña, J.M. García

Departamento de Química, Facultad de Ciencias, Universidad de Burgos, 09001 Burgos, Spain

svallejos@ubu.es

Introduction

Coumarins establish a family of dyes (Scheme 1), which are applicable in different fields of science and technology.



coumarin (2*H*-chromen-2-one)

Scheme 1

They exhibit strong fluorescence in the UV and VIS region, which makes them suitable to use as a colorants, dye laser media and as nonlinear optical chromophores. In medicine coumarin derivatives are used as anticoagulants, as a fluorescent indicators for the physiological pH region and as fluorescent probes to determine the rigidity and fluidity of living cells and its surrounding medium. Coumarins and its derivatives has been a subject of considerable interest in numerous fields.

Due to the interesting properties associated with coumarins, we are studying the fluorescence enhancing or quenching phenomenon and chromogenic behaviour of coumarin-derivatives containing polymers upon interaction with different chemicals. Regarding this point, we are applying our previously developed technique to put these organic molecules in water solution by incorporating as comonomers in water soluble polymers. Furthermorne, the incorporation as comonomers in bulk polymerization to give crosslinked hydrophilic dense films, gave rise to handle sensory materials to be uses as naked eye cromogenic sensor

Materials.

We follow conventional organic reactions, starting with the commercial 2*H*-chromen-2-one (coumarin), to prepare the chemosensory coumarin-containing motifs (see monomers structure on Scheme 2). The solution radical copolymerization of the sensory monomers with a set comonomers renders water soluble polymers (Scheme 2) with the sensory comonomer in a molar ration lower than 5%, and, preferably lower than 2%. In the same vein, the bulk copolymerization of the comonomers using a cross-linking agent, e.g., 1,2-ethanedioldimethacrylate, gives hydrophilic dense membranes with gel behavior (water swelling percentage ranging 50-200%). The membranes as easily handle materials, with good mechanical properties, even after water or organic-solvents swelling.

The membrane will be used to prepare naked eye sensory strips for the detection of different chemicals. As an illustrative example, Figure 1 depicts the chromegenic sensing of cyanide in water using one of our previously prepared sensory membranes.**¡Error! Marcador no definido.** The water soluble polymers will be use to characterize the observed sensing phenomena, from a chemical and physical viewpoint. The chemosensing phenomena may arise from feeble reversible interactions (binding site-signalling and displacement approach) or from irreversible chemical reactions (chemodosimiter approcach).

High Performance Gas Separation Membranes with Aging and Plasticization Resistance

Alberto Tena[1], *Ángel E. Lozano*[1,2], *Ángel Marcos-Fernández*[1,2], *Jose G de la Campa*[1,2], *Javier de Abajo*[1,2], *Laura Palacio*[1], *Pedro Prádanos*[1], *Antonio Hernández*[1]

albtena@ictp.csic.es

There is a commanding economical and social need of improving the gas purification of mixtures including carbon dioxide as a component. The separation of this gas can be carried out by diverse methods including chemical absorption, pressure swing sorption, PSA, carbon molecular sieves and so on. However, these systems suffer from diverse limitations.

It is well known that many polymeric compounds show excellent processability, good mechanical properties and high thermal stability, and that some aromatic polymers and polyheterocycles having high fractional free volume are excellent candidates for gas separation applications. However, polymer membranes have some limitations when they are applied in industry, since their separation productivity (balance between permeability and selectivity) is not preserved when the feeding pressure is high or when the process involves a gas able to interact with the polymer matrix [1]. Thus, many polymers show a minimum in the perrmeabilty *vs* applied pressure plot. This pressure is named the plasticization pressure and denotes the maximum pressure at which the material can be employed throughout the operative (industrial) life. In addition, when the polymeric materials reach the plasticization point, there is a drastic decrease in selectivity lessening the ability of the membrane to discriminate a mixture of gases in their components [2].

The need of new materials with a lower capability of undergoing plasticization processes has moved to investigate new ways of making polymeric materials. Our approach includes the use of polymers with good separation properties having very high molecular weight. Specifically, polyimide **6FDA-6FpDA** has been used (Figure 1), which features outstanding gas separation for various pairs of gases when the supply pressure is low [3].

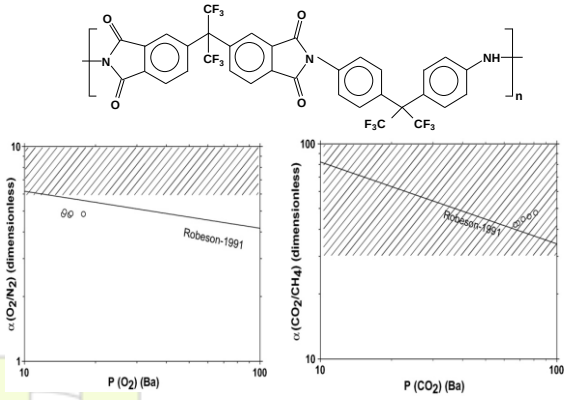

Figure 1. Structural unit and gas separation properties of 6FDA-6FpDA

Properly, on using a specific method of synthesis, polymers of high or very high molecular weights have been obtained in a controlled way [4]. These polymers, that were cast on films and evaluated for CO_2 and other gases at different pressures, showed a dazzling ability to resist plasticization (Figure 2).

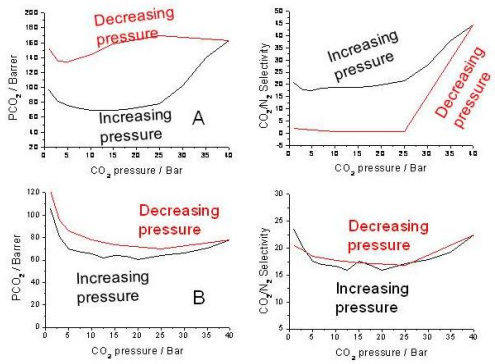

Figure 2. Variation of CO_2 permeability and CO_2/N_2 selectivity with the supply pressure to samples heated at 180ºC (A) and T above to Tg (B)

For industrial applications, this behavior must be constant over time.

In this paper, we also present a study of how permeability and selectivity for a 6FDA-6FpDA membrane evolves, at a constant pressure, as a function of exposure time.

Results permit to state that very high molecular weight combined with a thermal treatment can prevent both the plasticization and the aging processes.

Up to date, no many references have narrated that behavior. Thus, only chemical treatments, as crosslinking, and use of IPNs systems have been efficiently employed to decrease the plasticization.

Aknowledgements

We are indebted to the Spanish Junta de Castilla y León for the financing of this work through the GR-18 Excelence Group Action and to the Ministry of Science and Innovation in Spain for their economic support (projects MAT2007-62392/MAT and MAT2008-00619/MAT). A. Tena thanks CSIC for a predoctoral JAE fellowship received to carry out this work.

Introduction

In the last decades, a huge research effort has been employed to prepare polymer membranes for gas separations that improve the well-established trade-off between permeability (gas flux) and selectivity (separation capacity), also known as Robeson's upper bound [1]. Aromatic fluorine-containing polyimides, mainly those having the group hexafluoroisopropylidene, are some of the most attractive and promising gas-separation materials. They do not only present a favorable balance of gas permeability and selectivity but also excellent thermal, chemical and mechanical properties.

Recent research in this subject [2, 3] has shown that the simultaneous increase in main chain rigidity (strongly hindered ring rotation) and fractional free volume, FFV, (low packing density) provides polyimides with high permeability and good selectivity.

This work shows the synthesis of a series of polyimides derived from the twisted, non-coplanar diamine 1,4-bis(4-amino-2-trifluoromethylphenoxy)2,5-di-*tert*-butyl benzene (CF_3TBAPB). The effect of trifluoromethyl (CF_3) groups on the transport properties has been studied by comparing with analogous polyimides without CF_3 moieties (TBAPB) [2].

Materials and Methods

A series of polyimides was synthesized from diamine CF_3TBAPB and three commercial dianhydrides following the classical one-step polyimidation methods. The structures are shown in Fig.1. Polyimides were obtained by both thermal **(H)** and chemical **(C)** imidization of the polyamic acid precursor. The chemical structure of polyimides was confirmed by conventional techniques such as ^{1}H-NMR, ^{13}C-NMR and FTIR.

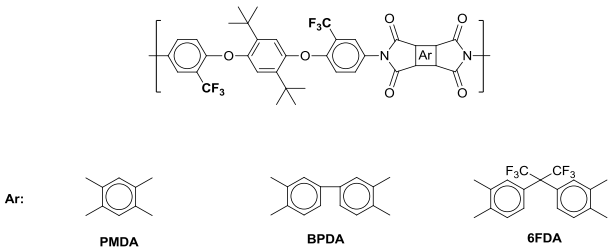

Fig.1. Chemical structure of polyimides

Polymer films were heated above their glass transition temperature, Tg, under a nitrogen atmosphere to strip off the residual solvent. Structural characterization of films was performed by WAXS. FFV was calculated from density data obtained by a buoyancy method [2].

Thermal stability and Tg, were determined by TGA and DSC, respectively.

Pure gas permeability coefficients (P) were determined by using a barometric permeation method at 30 °C and 3 bar pressure. Ideal selectivity for two pure gases was defined as $\alpha(A/B) = P_A/P_B$. For permeation experiments, O_2, N_2, CH_4 and CO_2 were used.

Results and Discussion

All polyimides showed high thermal stability, with decomposition temperatures above 480 °C, and Tgs higher than 270 °C. The reaction of diamine CF_3TBAPB with rigid dianhydrides yielded polyimides with much higher FFV than the analogous TBAPB series.

The performance of these membranes for gas pair CO_2/CH_4 is shown in Fig. 2. In general, the new polyimides exhibited higher permeability to specific gases, with good selectivity, than those analogous without CF_3 groups.

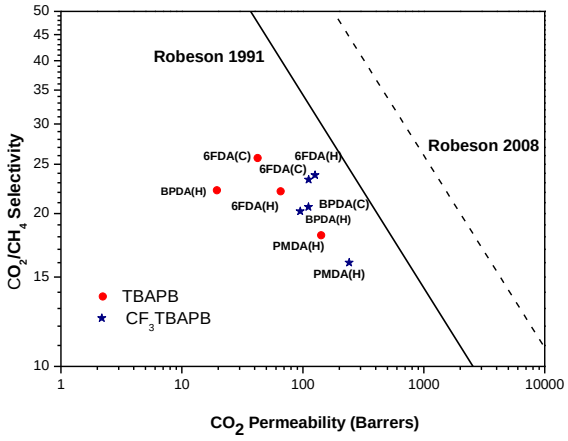

Fig.2 CO_2/CH_4 Selectivity versus CO_2 Permeability

No clear relationships between membrane properties and imidization method were found.

Conclusions

Novel polyimides having high FFV and high molecular chain rigidity have been obtained by a right combination of CF_3 and *tert*-butyl pendent groups on a diamine moiety. These fluorinated polyimides showed an excellent balance for gas separation, particularly for O_2/N_2 and CO_2/CH_4.

Direct Patterning of Regioregular Poly(3-hexylthiophene)

Yuta Saito, *Tomoya Higashihara*, *Mitsuru Ueda*

Department of Organic and Polymeric materials, Tokyo Institute of Technology

ueda.m.ad@m.titech.ac.jp

Introduction. Recently, semiconducting π-conjugated polymers (πCPs) have become the subject of great interest in electronic device application such as organic solar cells and organic thin film transistors (OFETs). Semiconducting πCPs should be simple, low cost and large area patternable to simplify the fabrication of the electronic devices. Although the patterning processes of πCPs by ink-jet printing and microcontact printing methods have been reported, their processability and resolution are still not enough for the practical device fabrications. [1] Thus, micro-fabrication of πCPs by photolithography method, which allows using conventional equipments for semiconductor manufacturing, has recently been reported. [2] However, complicated synthetic routes are required for obtaining such materials and those are not favorable in terms of environmental and industrial issues.

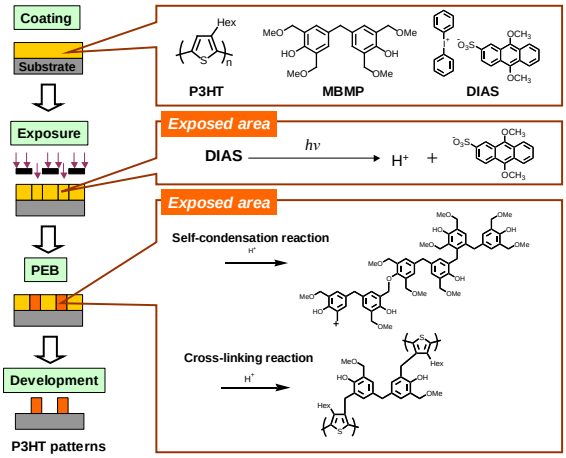
Previously, we reported the simple photolithographic patterning method of poly(3-hexylthiophene) (P3HT), which is a representative πCP. [3] However, the head-to-tail (H-T) regioregularity of P3HT used as a matrix polymer was only 85 %, and it may result in low OFET properties because of low crystallinity and less chain packing.

Here, we report a simple patterning process of H-T regioregular P3HT (rr-P3HT) with a regioregularity of 95 %. The photosensitive rr-P3HT was prepared by combining 4,4'-methylenebis [2,6-bis(methoxymethyl) phenol] (MBMP) as a cross-linker and diphenylidonium 9,10-dimethoxyanthracene-2-sulfonate (DIAS) as a photoacid generator.

Materials and Methods. rr-P3HT and MBMP were synthesized according to a previous report. [4,5] Other reagents and solvents were used as received.

Photolithographic properties of rr-P3HT resists were evaluated as following methods. rr-P3HT was dissolved in 1,1,2,2-tetrachloroethane, followed by addition of MBMP and DIAS. The 100 nm thickness of polymer films were obtained by spin-casting from the solution on a silicon wafer. These films were pre-baked at 80 °C for 1 min, and then exposed by non-filtered ultra-high pressure mercury lamp, followed by post-exposure baking (PEB) at temperature (120-170 °C) for 1 min. The dissolution rate (Å/sec) of the film was determined from the changes in the film thickness before and after development with chloroform.

Results and Discussion. In this patterning process, the PEB temperature is crucial because the diffusion of photo-generated acids from PAG after UV exposure is an important key factor (Scheme 1). Thus, the effect of the PEB temperature on the dissolution rate in chloroform was investigated. Very high dissolution contrast was obtained at a PEB temperature between 140 and 170 °C. This result indicates that the cross-linking reaction is promoted effectively under these PEB conditions.



Scheme 1. Patterning process of P3HT resist

The loading weight contents of MBMP and DIAS were optimized for the dissolution rate. It is expected that MBMP and DIAS may inhibit carrier transportation in the semiconductive layer of OFETs, so the amounts of MBMP and DIAS should be minimized. Large dissolution contrast between exposed and unexposed area was obtained in the case of 5 wt% MBMP and DIAS loadings.

Based on these preliminary optimization studies, optical images of the contact-printed pattern were obtained using the P3HT resist consisting of rr-P3HT (90 wt%), MBMP (5wt%), and DIAS (5 wt%) (Figure 2). A clear negative pattern was successfully obtained with 15 μm features on a 100 nm thick film.

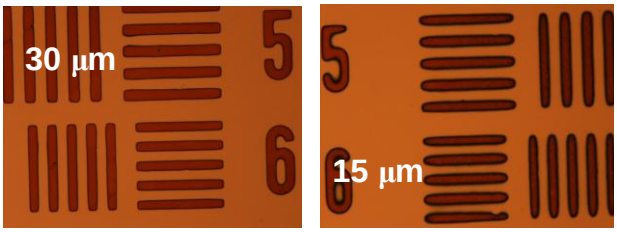


Figure 2. Optical images of the patterned P3HT resist

Conclusion. A simple patterning method of rr-P3HT by photolithography has been developed. A clear 15 μm lines were fabricated on a film containing rr-P3HT, MBMP, and DIAS. OFET using this patterned rr-P3HT is expected to show high transistor properties.

smolina@ictp.csic.es

Introduction

In recent years, water consumption has exponentially increased due to the global population growth, so that the development of different technologies for obtaining and optimizing its use is essential.

Although evaporation processes are still used considerably, ultrafiltration, nanofiltration and reverse osmosis membrane processes are predominantly used at present in the purification and desalination of water. For this reason, the research and development on novel polymer materials is important to fabricate membranes more permeable, more selective and more durable [1].

Biofouling is one of the most important problems in these technologies because it causes the flow through the membrane to decrease significantly with time and gives way to shorter lifetime. Biofouling could be minimized by periodical washing with aggressive chemical products, which on turn can degrade the polymeric membranes. This problem can be solved by using hydrophilic polymers because it has been found that microorganisms and biological substances are weakly adsorbed on hydrophilic membranes [2].

The aim of the present work has been to prepare novel aromatic polyamides with improved hydrophilicity, and the fabrication of asymmetric porous membranes from them. The approach chosen to achieve this target has been to incorporate highly hydrophilic groups, such as sulfonyl, phenolic, amide and oxyethylene within the same polymer. This modification is justified by the results of a previous work, where it has been possible to confirm the great ability of PEG to absorb water [3].

Materials and Methods

Polyamides shown in Figure 1 were synthesized by partial or total nucleophilic substitution with Cl-PEG on the phenolic starting polymer. The chemical structure and modification degree of modified polyamides were confirmed by conventional techniques such as ^{1}H-NMR, ^{13}C-NMR and FTIR, and they were characterized by GPC, contact angle, TGA, DSC, and X-ray diffraction.

Asymmetric porous membranes were prepared by the conventional method of phase inversion using DMF as solvent and water as coagulation medium. Then, they were evaluated as ultrafiltration membranes at laboratory scale (P=3 bar).

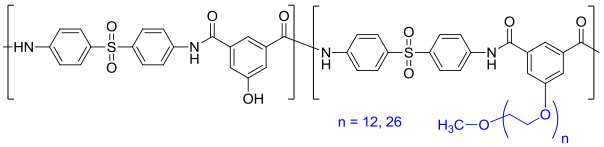

Figure 1. PEG containing aromatic polyamides

Results and Discussion

Hydrophilicity of the novel polymers were investigated first by contact angle measurements. It was observed that the greater the content of PEG the higher the contact angle, what indicated higher hydrophilicity. The membranes were then characterized by their molecular weight cut-off as a function of pore size and distribution.

The introduction of PEG chains allowed increasing membrane permeability respect to the unmodified polyamide and commercial polyamides. Thus, on increasing the modification degree and the length of PEG side chains the water uptake increased and the water flux became higher.

Therefore, a lower biofouling is to be expected in the modified polymeric membranes and works are at present being carried out to evaluate this improvement.

Conclusions

Aromatic polyisophthalamides bearing free –OH groups can be conveniently modified by incorporating PEG side chains by a nucleophilic displacement reaction. The hydrophilicity of these novel materials can be tuned by controlling the molecular weight of PEG and the modification degree. Higher hydrophilicity should give way to higher biofouling resistance, which would allow a longer lifetime of membranes.

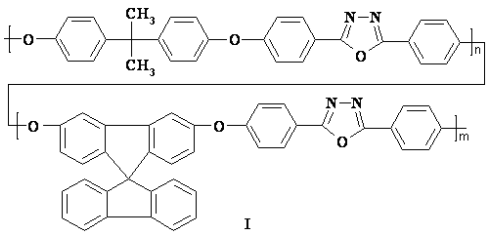
airineia@icmpp.ro

Introduction: Poly(1,3,4-oxadiazole)s and their derivatives have been widely utilized in electronic devices as electron-transporting and hole-blocking materials or in obtaining polymer light-emitting diodes and photovoltaic cells [1, 2]. Copolymerization with solubility-enhanching units, such as fluorene or phenolphthalein led to materials with improving properties and solubility [3, 4].

Materials and Methods: Copolymers Ia-e were prepared using reported procedures [3,4]. Ultraviolet-visible and fluorescence spectra were recorded on an Analytik Jena SPECORD 200 spectrophotometer and PerkinElmer LS55 luminescence spectrometer using 10 mm quartz cells.

Results and Discussion: Aromatic copolyethers containing 1,3,4-oxadiazole rings **Ia-e** were obtained by nucleophilic substitution polymerization technique of 2,5-bis(p-fluorophenyl)-1,3,4-oxadiazole with 9,9-bis(4-hydroxylphenyl)fluorene or a mixture of latter in different amounts with 4,4'-isopropylidenediphenol [1,4]. Their properties were investigated by electronic absorption and photoluminescence spectroscopy. The copolymers in dimethyl sulfoxide (DMSO) solution emitted in the range of 360-370 nm depending on the copolymer structure. The emission band can be assigned to the oxadiazole moiety.



I

Ia: n=1, m=0; **Ib**: n=0.75, m=0.25; **Ic**: n=m=0.5; **Id**: n=0.25, m=0.75; **Ie**: n=0, m=1

The sensing capability of copolymers **Ia-e** to different nitroaromatic compounds such as nitrobenzene (NB), picric acid (PA), 1,3-dinitrobenzene (1,3- DNB), 2,4-dinitrotoluene (2,4-DNT), 2,6-dinitrotoluene (2,6-DNT) or fluoride ion was analyzed in $9 \cdot 10^{-4}$ M DMSO solutions. These nitroderivatives were chosen because they are structurally similar to well-known explosive 2,4,6-trinitrotoluene. Upon addition of picric acid as quencher, the emission intensity of **Ib** decreased dramatically with a blue shift of the emission maximum and a fluorescence quenching up to almost 30-fold (Fig. 1). In contrast, only about 4-fold decrease of fluorescence intensity was found for **Ia** or **Id** using 2,6-DNT as quencher. The Stern-Volmer plots of copolymers **Ia-e** were linear at low concentrations of nitroaromatics but deviated from linearity for higher concentrations of quencher, showing a positive curvature. The Stern-Volmer constants for **Id** estimated from the initial linear parts of S-V curves are 54160, 5540, 6870 and 5360 M^{-1} for PA, DNB, 2,4-DNT, 2,6-DNT, respectively. The K_{SV} data suggest that picric acid is the most efficient quencher, followed by 2,4-DNT and 1,3-DNB.

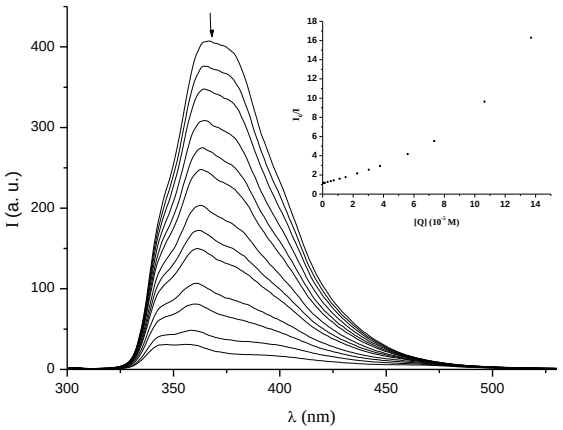


Fig. 1. Fluorescence spectra of **Ic** in DMSO upon addition of picric acid, excitation wavelength 298 nm. Stern-Volmer plot is shown as inset

The influence of the solution on the spectral characteristics of copoly(1,3,4-oxadiazole-ether)s was studied in solvents having different polarities. The emission intensity decreased from a highly polar solvent to a less polar one. However, the solvatochromic effect on the electronic absorption bands (λ_{max}) was less significantly for copolymers **Ia-e**.

Conclusion: Oxadiazole copolymers exhibit good fluorescence-emitting ability especially the polymers containing fluorene units and their emission can be efficiently quenched on the addition of nitroaromatic compounds.

The problem of low photochemical stability of organic dyes in polymeric media leads to the search for new optically transparent polymers for dye lasers. Their use contributes to the miniaturization of lasers and lower their costs.

In the course of research the mesoporous polymers based on polyether (PEG), 2,4-toluene diisocyanate (TDI) and octamethylcyclotetrasiloxane (D4) were synthesized. The formation of mesopores occurs as a result of microphase separation. The detection of cavities in the polymer was the premise for the study of polyurethanesiloxsane polymers as the polymer backbone for the organic dyes introduction. The introduction of xanthene dye Rhodamine 6G into polymer system was carried out by its adsorption from the solution in ethanol in the pores of the polymer.

The range of transparency of polyurethanesiloxsane samples was determined by the spectral method. It was established that in the case of doping polymers with Rhodamine 6G, the absorption band characteristic for this dye appears in the electronic absorption spectrum.

Fluorescence intensity for various samples correlates with the value of the optical density at the excitation wavelength. The bands have average half-width equal to 60 nm. Fluorescence intensity, as well as in the case of the electronic absorption spectrum, is maximal for the samples obtained at molar ratio [PEG]: [TDI]: [D4] = 1:15:15, [PEG]: [TDI]: [D4] = 1:10:20 and [PEG]: [TDI]: [D4] = 1:10:15.

It was found that when polymer obtained with the high content of 2,4-toluene diisocyanate organic dye (Rhodamine 6G) being doped, the line of stimulated luminescence spectrum narrows tenfold. The operational life of the sample on the basis of [PEG]: [TDI]: [D4] = 1:15:30 was more than 10,000 laser pulses at the pump power density 27 MW/cm2. For this sample, there was the smallest half-width of the lasing spectrum at excitation power density of 23.3 MW/cm^2 (Figure 1)

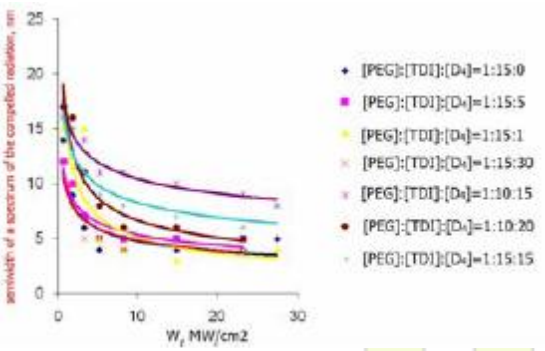

Fig. 1. Dependence of semiwidth of a spectrum of the compelled radiation of Rhodamine 6G (5•10-3 mol/l) from intensity of excitation IAG-Nd3 + the laser (532 nm).

(Fig.

The normalised spectra of laser generation and fluorescence of Rhodamine 6G in polymer are presented [PEG]:[TDI]:[D4] =1:15:30. For this sample the least semiwidth of a spectrum of generation was observed at excitation power density 23.3 MW/cm^2 (Fig. 2).

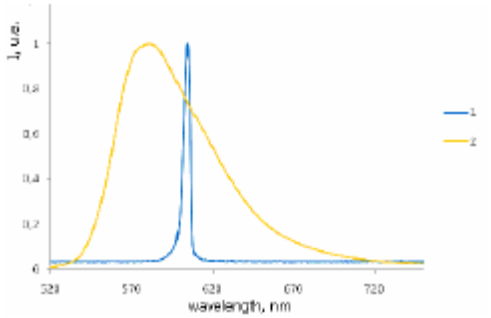

Fig. 2. Spectra of the spontaneous and compelled radiation of Rhodamine 6G in the sample [PEG]:[TDI]:[D4] =1:15:30 (excitation power density 23.3 MW/cm^2): 1 – a spectrum of the compelled radiation, 2 – a fluorescence spectrum.

It was established that the photostability of rhodamine 6G molecules largely depends on the content of dimethylsiloxsane component in the polymer (Fig. 3).

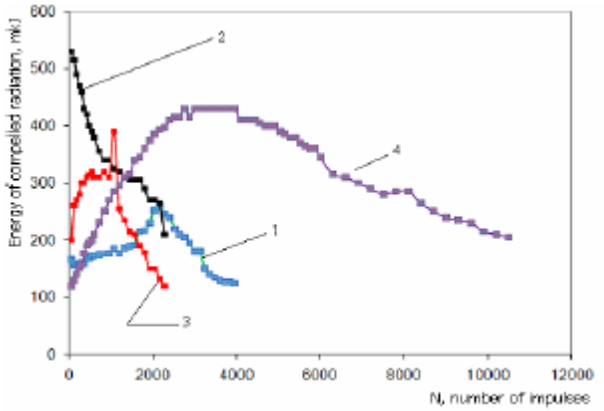

Fig. 3. Photostability of polymeric matrixes, doped by Rhodamine 6G (5•10-3 mol/l) at energy of an impulse a rating 30 mJ
1 - [PEG]:[TDI]:[D4] =1:15:0,
2 - [PEG]:[TDI]:[D4] =1:15:5,
3 - [PEG]:[TDI]:[D4] =1:15:10,
4 - [PEG]:[TDI]:[D4] =1:15:30

The photostability of the polymer obtained at high content of dimethylsiloxsane component increases more than threefold.

Acrylates Block Copolymers with N-trityl-L-serine methyl ester and Pyrene Prepared by ATRP

E.C. Buruiana, V. Podasca, T. Buruiana

Petru Poni Institute of Macromolecular Chemistry, 41 A Gr. Ghica Voda Alley, 700487, Iasi, Romania

e-mail: emilbur@icmpp.ro

In recent years, the strategy for designing and producing synthetic polymers containing appropriate amino acids has attracted a great interest because these materials can display novel and improved properties (e.g. biodegradation, biocompatibility, chirality, etc). Most of the prior work has been focused on the production of polypeptides [1], polyesters polyamides, and polysulfides having (L-) glutamate, lysine, proline, tyrosine or cysteine units in their backbone,which are intended for applications in the pharmaceutical field, molecular separations, tissue engineering,. microchips or stimuli-responsive materials. For achieving such functional polymers with controlled molar mass, narrow molecular weight distribution, and well-defined architecture, new synthesis methodologies were used, like ring-opening polymerization, atom transfer radical polymerization [2,3], reversible additionfragmentation chain and transfer polymerization. Within the family of amino acids-based copolymers, our group has been reported data concerning the oligoconjugates based on dipeptide and poly(3-hydroxybutyrates)[4], or poly(N-acryloyl chloride) functionalized with (S)-phenylalanine and pyrene units [5] obtained by classical procedures (anionic ring opening polymerization, radical polymerization, grafting).

The objective of the present work is to investigate the preparation of novel acrylates diblock copolymers with Ntrityl-L-serine methyl ester and Pyrene derivative used as initiator in atom transfer radical polymerization (ATRP). Furthermore, the presence of luminescent fluorophore, covalently linked on the end of polymer backbone, could be exploited for development of optically active and photo luminescent polymers, suitable for applications in biomedicine, biology, analytic techniques, and optical devices.

Materials and Methods

Metyl methacrylate (MMA); CuBr; 1-**(**Bromoacetyl**)**-pyrene, N,N,N',N",N"-Pentamethyldiethylenetriamine (PMDETA), 1,4-Dioxan, N-Trityl-L-serine methyl ester and 2-Methacryloyloxyethyl isocyanate were purchased from Aldrich. As polymerization method, ATRP was used for preparing diblock copolymer.

Results and Discussion

First, methacryloyloxyethylcarbamoyloxy-N, trityl serine methyl ester **(MTS)** was synthesized and characterized to be used as co-monomer for the preparation of diblock copolymer. The polymerization of this monomer was initiated of a macroinitiator based on acetyl pyrene- and bromine-terminated poly(methylmethacrylate). The structure of the resulting copolymer is given in Figure 1.

The spectral analysis ($_1$H NMR, FTIR, UV/vis) confirmed the structure of block copolymer, and GPC measurements showed that the molecular weight of this polymer was about 13610 (polidispersity index: 1.1), in agreement with NMR data. In the UV spectrum, both macroinitiator and block copolymer presented absorption bands at 310 and 348 nm, due to π-π*transition of the pyrene ring., while in the fluorescence spectrum they emits at 389 nm, 410 nm and 432 nm, all corresponding to the pyrene monomer fluorescence.

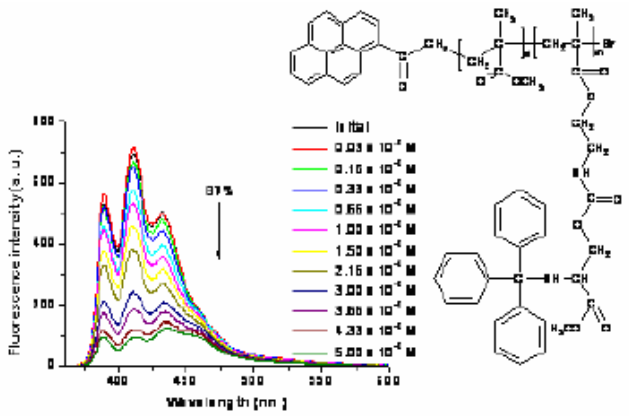

Figure 1. Structure of diblock copolymer based on MMA and MTS, and its photobehavior by the addition of TCNQ in DMF solution.

Quenching experiments were performed in the presence of various aromatic nitroderivatives and amines, KI, tetracyanoquinodimethane (TCNQ), the minimum concentration detected being 3x10 $^{-7}$ M/L for the latter.

Conclusions

In conclusion, the formation of diblock copolymer of **(MMA)**$_{40}$–b-**(MTS)**$_{18}$ containing pyrene molecule on the end of macromolecular chain was investigated using ATRP, the results obtained by the fluorescence study suggesting possible applications as chemosensors.

Introduction

Nowadays, there is a considerable interest focused on the concept of using light in the development of multifunctional materials with novel or improved properties targeting a wide range of applications. Acrylates, methacrylates and urethane (di)methacrylates with controlled design and functionality are among the most investigated structures, because the resulting crosslinked materials find applications in various fields such as coatings, adhesive, microlithography, dental materials tissue engineering, orthopedic surgery, drug delivery systems, and many others [1]. For the majority practical purposes UV photocurable resins consist of a combination of multifunctional acrylates (mono-, di-, tri-) that form very complex polymeric networks. One of the goals of polymer science is to understand the nature and the state of the formed polymer in its application, for which is useful knowing and correlating the structure, properties and kinetics of a given process that take place in such materials.

For modern applications of some biomaterials, the chemistry of hybrid nanocomposites has also been explored to establish if the structural order within the material can be controlled on nanometer/submicron scale. In particular, the dispersion of nanosized inorganic particles into a polymer matrix open the possibility of generating new types of nanostructured materials (nanodevices) with designed surface and structural properties, which can be used in physical, biological, biomedical, and pharmaceutical applications [2]. Thus, the incorporation of inorganic particles like silica [3], hydroxyapatite [4] or nanometer silver particles [5] in some photopolymerizable monomers led to materials for applications in catalysis, drug and wound dressing, optical information storage, surface-enhanced Raman scattering, and others.

In this study, we synthesized a series of multifunctionalized urethane dimethacrylates to be further used for preparing of hybrid nanocomposites, where the impact of nanosized silver particles on the properties and morphology of the final crosslinked nanomaterials by UV-irradiation, is discussed.

Materials and Methods

Poly(dimethyl siloxane) (M_n = 5600), PEG (Mn = 1000), L-tartaric acid (TA), isophorone diisocyanate (IPDI), 2-hydroxyethyl methacrylate (HEMA) were purchased from Sigma Aldrich Chemical Co. and used without further purification. The initiators used were Irgacure 651 and Irgacure 819 (from Sigma-Aldrich Chemical Co.).

Results and Discussion

A series of photopolymerizable urethane dimethacrylates with different functionalities (eg. siloxane, carboxylic groups, etc) incorporating a small quantity of silver nanoparticles (1-2.5 wt.%) were subjected to photopolymerization experiments using suitable photoinitiators. In tandem, hybrid composites with nanosilver particles were also prepared by in situ procedure. ^{1}H NMR and FTIR spectroscopies confirmed the structure of the urethane dimethacrylates. Subsequently, the progress of photopolymerization of these monomers under UV irradiation was investigated by FTIR spectroscopy and photoDSC with respect to conversion and polymerization rate using Irgacure as an initiator. Combined analyses of UV spectroscopy and scanning electron microscopy (TEM) confirmed the existence of nanosized silver uniformly distributed in the polymer matrix (Fig. 1). Other specific properties of the synthesized hybrid nanocomposites will be presented, too.

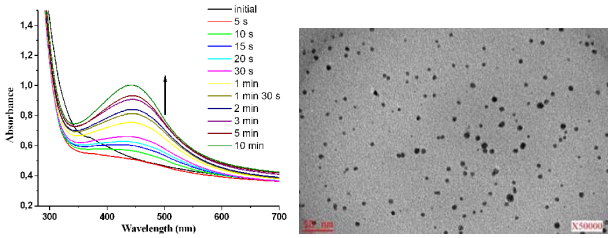

Figure 1. UV spectrum of the hybrid composite and TEM bright field image of the silver nanoparticles (2.5 wt.%) dispersed into a polymer matrix after UV irradiation.

Conclusions

In summary, we have described novel hybrid materials composed of polymeric networks formed by photopolymerization of various urethane dimethacrylates and silver nanoparticles (1-2.5 wt.%) incorporated before UV curing or by in situ synthesis. The UV-curing behaviour of all monomers with respect to conversion and polymerization rate showed that there are small differences in function of structural and compositional factors.

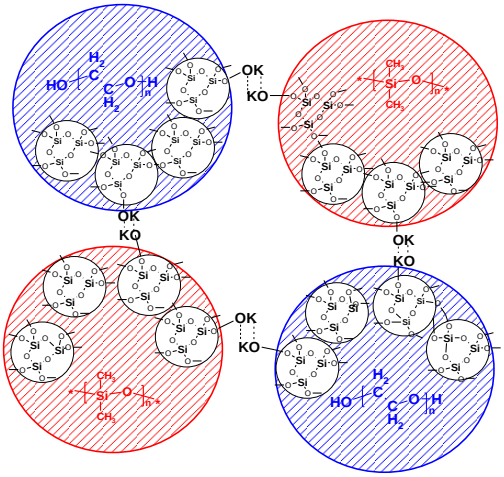
Organic-Inorganic Gels for Heterochain Polymers Modification

[1]Gumerova O.R., [2]Davletbaev R.S.

[1]Kazan State Technological University, Kazan, Russia
[2]Kazan State Technical University, Kazan, Russia

olese4ka85@mail.ru

The synthesis of organic-inorganic gels based on the tetraethoxysilane and thermodynamically incompatible olygomers - oligooxyethylene glycol and oligodimethyl siloxane - is worked out.
The experimental research was aimed at overcoming incompatibility of inorganic and organic components, that is the main problem of obtaining materials based on the sol-gel technology.
The estimation of probability of cross-link density formation showed that as a result of tetraethoxysilane hydrolysis and following polycondensation the fractal clusters of silica are formed in the bulk of the oligomer matrix. Silica network in the bulk of oligomer is formed by orientation of fractal interconnected clusters as well as interfacial formation of associates of potassium-siloxanolate groups. Owing to the associates lability silica gel is spread in polymer melts or reactive oligomers with the subsequent forming of silica network in the bulk of polymeric matrix:



The silica fractal clusters were researched as nanostructure forming modifiers of polymers based on aromatic isocyanates in order to improve their performance properties. It was determined that gel did not interreact with isocyanate groups and produced no catalytic effect on the reaction of isocyanate groups with hydroxyl ones.
It was established that the modification of heterochain polymers on the base of aromatic isocyanates by organo-inorganic gels led to the formation of additional intermolecular interactions. As a result the significant increase of tensile strength and Young's modulus in the area of very low concentrations was observed. This effect is evident in Fig. 1.

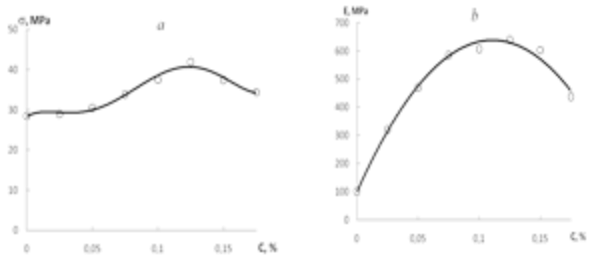


Fig. 1 Tensile strength (*a*) and Young's modulus (*b*) as functions of concentration organic-inorganic gel in heterochain polymer

It was shown that the structural modification of block-copolymers based on polyethers, aromatic isocyanates and organocyclosiloxanes by gel led to the enhancement of microphase separation and adsorption ability of polymer, caused by interfacial formation of mesopores. Temperature dependence of dielectric loss tangent is shown below in Fig. 2 for the polymer, modified with organic-inorganic gel in amount of 0.01 mass %.

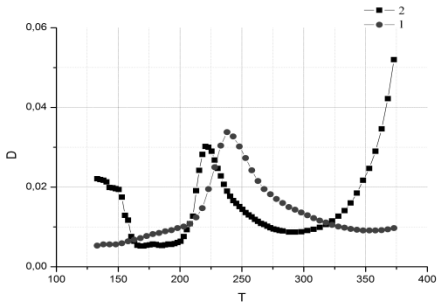

Fig. 2 Temperature dependence of dielectric loss tangent for the polymers: 1 – unmodified, 2 – modified

The addition of organic-inorganic gel into the polymer matrix resulted in significant changes in surface relief that was obtained with the help of atomic-force microscopy.
It was determined that the modification of heterochain polymers by organic-inorganic gels caused the formation of additional intermolecular interactions. Consequently the significant increase of physical-mechanical properties in the area of very low concentrations was observed.
Temperature dependence of dielectric loss tangent and atomic-force microscopy results showed the significant effect of the organic-inorganic gel modification on the microphase separation process.

Novel Polymetacrylamides Containing a Triazole Moiety. Application to the Extraction/Elimination of Metal Cations from Aqueous Media

M. Trigo, A. Gómez, P. Estévez, S. Vallejos, H. El Kaoutit, F. Serna, F. García, J.L. de la Peña, J.M. García

Departamento de Química, Facultad de Ciencias, Universidad de Burgos, 09001 Burgos, Spain

mtl0005@alu.ubu.es

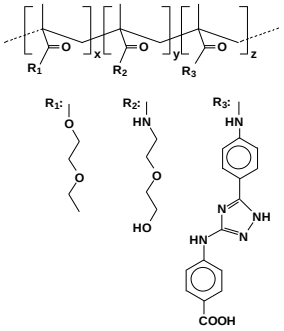
Introduction

The properties and characteristics of the triazole heterocycle are expected to be retained by the polymer containing it. In this regard, the triazole derivatives are well-known binding sites for metals, and can be used for the removal of cations as well as sensing and molecular recognition.[1-4]

Due to the general interest of the elimination of environmentally polluting metals, we describe the synthesis of a metacrylamide monomer containing a triazole moiety and the preparation of related novel polymethacrylamides with this aim.

Materials

Three different copolymers (**I**, **II** and **III**) were prepared by radical copolymerization of mixtures of the three different co-monomers (Scheme 1, Table 1) using ethylene glycol dimethacrylate as cross-linking agent (**II** and **III**) and AIBN as a radical thermal initiator.



Scheme 1. Chemical structure of copolymers

Table 1. Materials

Copolymer	Appearance	$R_1(x)^a$	$R_2(y)^a$	$R_3(z)^a$	CLA [b]	WSP [c]
I	Powder-lineal water soluble	-	95	5	-	-
II	Powder - crosslinked	-	95	5	5	-
III	Film-crosslinked	29.7	69.3	1	1	167

[a] Molar composition ratio of the monomers. [b] Cross-linking agent (1,2-ethanedioldimethacrylate) molar percentage [c] Water-swelling percentage: weight percentage of water uptake by the films upon soaking until equilibrium, in pure water.

Cation elimination/extraction and recognition

Cross-linked copolymethacrylamide **II** was employed as a solid extraction phase. In order to study the influence of the electron environment in triazol moiety on extraction effectiveness, cross-linked copolymer **II** and polymethacrylamide **I** were treated to deprotonate carboxylic acid moiety.

Cation extraction experiments of several cations from aqueous solution using copolymethacrylamide **II** and deprotonated methacylamide **II** as extractant phase show that the best results in terms of extraction percentage, distribution coefficient and selectivity are obtained with Pb^{II}, Hg^{II} and Ag^{I}, reaching extraction percentages between 90 and 97%.

A cation sensing ability of the membrane **II** towards cation Fe^{III} was observed in extraction experiments, changing from colorless to reddish upon soaking in aqueous solution. In contrast, the polymer remained completely silent in the presence of the other cations tested.

The colorimetric cation sensing ability of film **III** was studied by UV-visible spectrometry (Figure 1), resulting in a gradual increment of the absorbance of the 455 nm band with the Fe^{III} concentration.

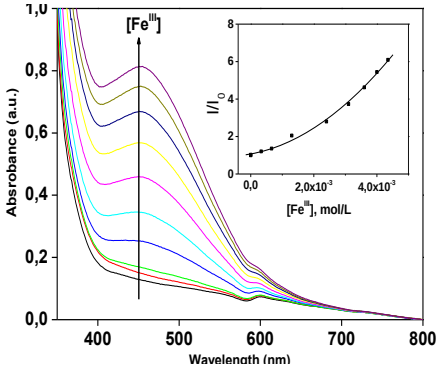


Figure 1. UV/Vis titration curve of film **III** with Fe^{III} in water (inset: I/I_0 vs. Fe^{III} concentration at 455 nm).

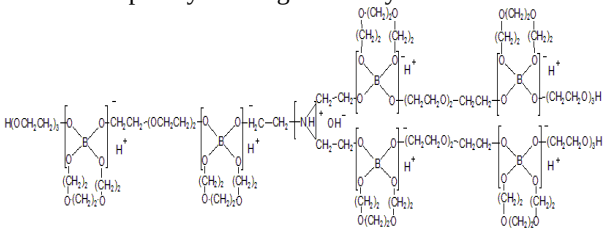
emelina_oy@mail.ru

One of the promising directions in polymer chemistry is synthesis of polymers with fire resistance and high strength. Preparation of strong and heat-resistant polymer materials is achieved by adding into the polymer matrix such elements as boron, silicon, fluorine, etc.

Use limitation of organoboron polymers is primarily caused by their hydrolytic instability. The hydrolytically stable esters of boric acid are performed by creating steric hindrance around the boron atom.

It was determined by the method of NMR ^{1}H-spectroscopy that intermolecular complexes are formed in boric acid ethers with the participation of borate anions and tertiary amines. Viscosimetric analysis of sterically hindered esters of boric acid indicated the presence of intermolecular ionic complex interactions as well. The data of infrared spectroscopy and titration analysis on the consumption of hydroxyl groups indicated that all the initial reagents had reacted completely forming sterically hindered ether.



The sterically hindered esters of boric acid were produced by di- and trisubstituted glycol. The structure of esters of boric acid suggests the presence in his part of the terminal hydroxyl groups able to interact with isocyanate groups.

Polyurethanes derived from sterically hindered esters of boric acid, have high physical and mechanical properties.

Thermal properties of organoboron polymers were studied using thermogravimetric analysis. It was established that the beginning of thermal oxidative degradation observed in the range from 240 to 311°C and a maximum speed of thermal oxidative degradation was achieved at temperatures of 351 to 412°C depending on the percentage of boron (Fig. 1, 2).

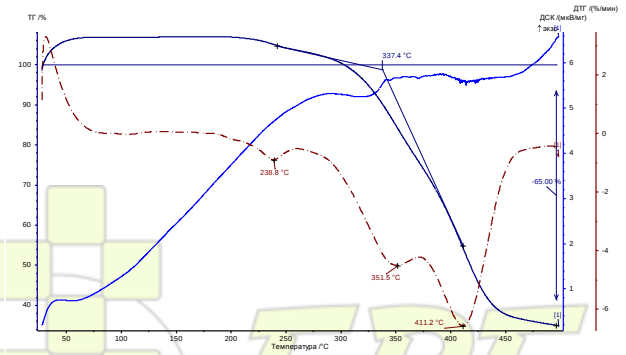


Fig. 1 Curves of differential thermal analysis for polymer obtained on the basis of sterically hindered ester of boric acid (5.0% boron)

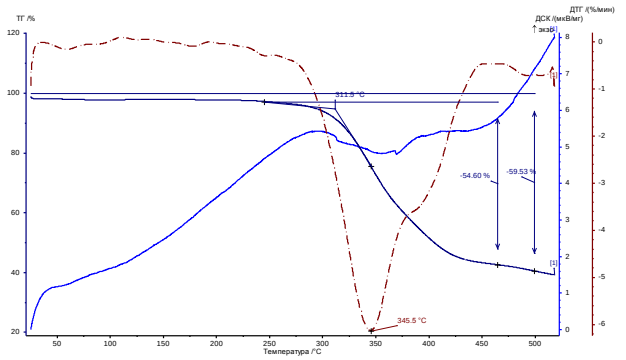

Fig. 2 Curves of differential thermal analysis for polymer obtained on the basis of sterically hindered ester of boric acid (7.5% boron)

The data of infrared spectroscopy, NMR ^{1}H-spectroscopy and viscosimetric analysis showed the presence of intermolecular ionic complex interactions in sterically hindered esters of boric acid. The contribution of organoboron part in the polymers caused increasing their thermal stability and physical and mechanical properties.

Epoxy Polymers for Medical Applications. In vitro Biological Properties

2Institute of Nuclear and Energy Research, University of São Paulo, Brazil.

e-mail; fili@unifei.edu.br

Introduction

Today, polymers represent the most important and largest family of materials being used in medical technology. Applications of polymers in medicine and surgery include temporary, permanent devices and complex devices simulating the physiological function.

In the literature there are some studies related to epoxy formulations for orthopedic and dental applications. Many studies have examined the cytotoxicity *in vitro* of epoxy networks[1-2] as well as their monomers precursors.[3-4] However, to our knowledge, only one work has been undertaken about the blood compatibility of epoxies materials.[5] The requirement of materials to medical applications varies markedly according to the application being considered. One of the major problems encountered in medical applications is blood compatibility since many of these devices either handle blood directly or come into contact with blood in subcutaneous or implantable devices. The purpose of the present study was to examine the blood compatibility and cytotoxicity properties of four epoxyamines networks.

Materials and Methods

The epoxy prepolymer used was a diglycidyl ether of bisphenol-A (DGEBA; DER 331 from Dow Chemicals, Brazil), with an epoxide equivalent weigh 187 g eq.$^{-1}$.

The aliphatic amines used were triethylenetetramine (TETA; DEH 24 from Dow Chemical, Brazil), diethylenetriamine (DETA), 1-(2-aminoethyl)piperazine (AEP) and isophorone diamine (IPD) from Aldrich, Brazil (99 % purity). The epoxy polymers were prepared using stoichiometric amounts (ratio epoxy to amino-hydrogen, e/a = 1). The cure schedule chosen for each formulation were optimized by previous calorimetric studies in order to obtain the cured-fully networks.[6] In this work, the *in vitro* blood compatibility of the epoxy networks was studied by four *in vitro* bioassays: protein adsorption, blood platelet adhesion, thrombus formation and cytotoxicity. The cytotoxicity was evaluated against Chinese hamster ovary (CHO) cells, ATCC CHO k1 (American Type Culture Collection, ATCC). Details of all tests using in this work were previously published.[5]

Results and Discussion

For the epoxy materials surfaces studied in this work was observed a higher human albumin adsorption when compared to the human fibrinogen adsorption suggesting a nonthrombogenic behavior for these surfaces. The results about platelet adhesion and thrombus formation indicated that DGEBA-IPD and DGEBA-AEP epoxy networks exhibits better hemocompatible behavior. It is well known that the biocompatibility is certainly controlled by the cellular activity at the interface of the synthetic material. The cytotoxicity level of epoxy specimens was relatively low for all materials studied (Fig. 1). The materials revealed no signs of cytotoxicity to Chinese hamster ovary cells, showing a satisfactory cytocompatibility.

For this reason it is possible to consider that the epoxy polymers studied are biocompatible materials.

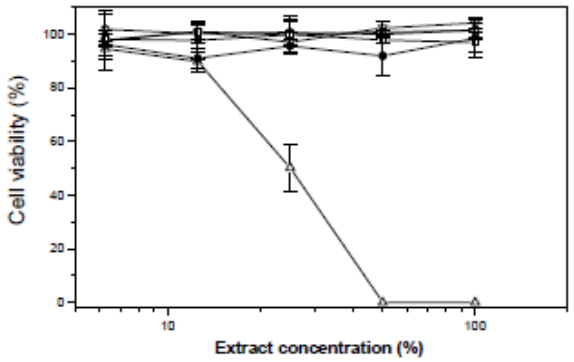

Fig. 1 Cytotoxicity of the DGEBA-DETA (□), DGEBA-TETA (■), DGEBA-AEP (●) and DGEBA IPD (○) epoxy networks extracts, negative control (UHMWPE) (∇), and positive control (phenol) (Δ) against Chinese hamster ovary cells.

Conclusions

The protein adsorption assays onto polymeric surfaces showed that the epoxy polymers adsorbed more human albumin than human fibrinogen. The results about platelet adhesion and thrombus formation indicated that DGEBA-IPD and DGEBA-AEP epoxy networks exhibits better hemocompatibility. The cytotoxicity results indicate that every studied epoxies materials are biocompatible with Chinese hamster ovary cells.

Studies of these materials using animal models, drug release and adhesion assays using bone-titanium joints for use as orthopedic cement are currently being investigated in our laboratories and the results will be reported elsewhere.

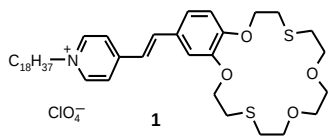
Introduction

Design and preparation of the ultrathin films based on crown-containing dyes is currently one of the most interesting and rapidly developing areas of research at the "junction" of polymers and colloids, physical-organic and biological chemistry, bio- and nanotechnology [1]. The properties of a new class of photochromic materials synthesized at the Photochemistry Center of the Russian Academy of Sciences [2], such as crown-containing dyes, have recently become the subject of intense studies. The presence of a crown ether fragment in the dyes facilitates their selective bonding to metal cations. Spectral measurements taken in organic and water-organic media have shown cation influences on the physico-chemical properties of the sensor molecule [2]. There are three functional parts in the structure of the amphiphilic pyridinium benzodithia-18-crown-6 dye (**1**) (Figure 1): an ion-selective part of the dithia-containing macrocycle, a photosensitive benzo-C=C-pyridinium part, and a lipid-like hydrophobic "tail" (C18).

Figure 1. The structure of the amphiphilic pyridinium benzodithia-18-crown-6 dye (**1**).



1

Materials and Methods

The polymer films with the dye **1** (total thickness of 10 μm) were prepared by modified spreading technique on the medical glass substrate from 10% polymer solutions in chloroform. The spectra of the polymer-dye films were recorded in the range 300–800 nm using absorption and fluorescence spectrophotometers. The absorbance of the polymer films without dye was below 300 nm. The influence of heavy cations on these films was studied using 10^{-3}, 10^{-4}, 10^{-5} and 10^{-6} M $Hg(ClO_4)_2$ or $AgClO_4$ aqueous solutions. The spectra of the dye-polymer films in all cases showed a strong band with an absorption maximum at 400–450 nm, which was assigned to the dye *trans*-form according to published data on the pure dye in some organic solvents [2].

Results and Discussion

Applying various salts to the polymer-dye film, it was possible to directly obtain changes in the dye **1** spectral parameters (the wavelength maximum and its shift). For example, the absorption wavelength maximum for the polymer-dye film based on poly(vinyl chloride) (PVC) was at 419 nm and absorption intensity about 0.160 arbitrary units. The maximal shifts of absorption on about −26 nm for the polymer-dye film were found in the case of 10^{-3} M $Hg(ClO_4)_2$ aqueous solutions. There were no linear dependences between salt concentration in solution and the wavelength shift for the absorption maximum in the case of $Hg(ClO_4)_2$. The same polymer-dye films were used for detection of silver cations in aqueous solutions and showed better results. The maximal shifts of absorption on about −25 nm for the polymer-dye film were found in the case of 10^{-3} M $AgClO_4$ aqueous solution (Table 1).

Table 1. The wavelength for the absorption maximum (nm) for the polymer-dye film based on PVC before (λ_0) and after (λ) treatment with $AgClO_4$ solutions.

Ag^+ M	λ_0, nm	λ, nm	$\Delta\lambda$, nm
10^{-3}	419 ± 1	394 ± 1	−25
10^{-4}	419 ± 1	405 ± 1	−14
10^{-5}	419 ± 1	412 ± 1	−7
10^{-6}	419 ± 1	418 ± 1	−1

Linear dependence between salt concentration in solution and the wavelength shift for the absorption maximum was found in the case of $AgClO_4$ solutions which could be promising for the quantitative detection of the silver cations in aqueous solutions.

The fluorescence wavelength maximum for the polymer-dye film based on PVC was at 502 nm and fluorescence intensity about 450 arbitrary units. The maximal shifts of fluorescence on about −15 nm for the polymer-dye film were found in the case of 10^{-3} M $Hg(ClO_4)_2$ aqueous solutions. It is important to underline the almost linear dependence between salt concentration in solution and the wavelength shift for the fluorescence maximum in the case of $Hg(ClO_4)_2$ **solutions. This could be promising for the quantitative detection of the mercury cations in aqueous solutions. On the other hand, the maximal shifts of fluorescence on about** −19 nm for the polymer-dye film were found in the case of 10^{-3} M $AgClO_4$ aqueous solutions.

Conclusions

Thus, the wavelength shift for the absorption maximum in the case of $AgClO_4$ solutions and wavelength shift for the fluorescence maximum in the case of $Hg(ClO_4)_2$ indicated the most promising materials for novel optical chemosensor for quantitative detection of the silver and mercury cations in aqueous solutions that is important for environmental monitoring.

Gradient in Viscoelastic Properties of Polymers to Control Adhesion

François Tanguy[1], Ralph Even[2], Isabelle Uhl[2], Anke Lindner[3], Costantino Creton[1]

francois.tanguy@espci.fr

In order to obtain polymers showing good adhesive properties, materials having both a liquid-like behavior (to create easily a molecular contact and dissipate energy upon debonding) and an elastic behavior (to resist shear forces) are necessary.
Efficient bonding to rougher low energy surfaces requires however a low elastic modulus and a high degree of viscoelasticity. Such a very soft adhesive will then possess a low resistance to stress during debonding. We believe that an innovative solution to this problem is to create a gradient in the viscoelastic properties of the adhesive to obtain a more dissipative behavior near the adhesive/adherend interface and a more elastic behavior in the bulk. Multi-layer materials can offer these properties. Bi-layer adhesives have already been studied and show some interesting properties [1].

Materials and Methods:

We focus here on model acrylate polymers (PolyBA-co-AA) prepared by emulsion polymerization for applications as Pressure Sensitive Adhesives (PSA).
Different molecular weights (Mw) and architectures were studied. All polymers were nearly linear and uncrosslinked with a relatively high average Mw (300k-1570k).
In order to create a gradient in viscoelasticity through the thickness, multi-layer materials were made, using the different latexes at our disposal. Thin films of homogeneous polymers were dried with a final thickness of 25µm. Once prepared, films with different properties were assembled to obtain multi-layer materials. In order to ensure good adhesion between the layers, the films were subsequently annealed at 80°C under load for 10 hours.
Probe-tack tests were carried out on these films on glass slides. The analysis of the stress – strain curves and real-time movies obtained through this experiment provide the information to evaluate the adhesive properties of the sample [2].
Adhesive properties were completed with detailed rheological characterizations. The linear viscoelastic properties and the large strain properties of the films were measured in the standard parallel plate shear geometry, and in the uniaxial extensional geometry.

Results and Discussions:

Bi-layer adhesives show interesting synergetic properties lying in between the properties of homogeneous layers of the two materials. Adding a viscous layer to an elastic backing layer, leads for example to a slightly increased adhesion, especially on a polyethylene substrate. Due to the elastic backbone, an interfacial debonding is obtained, with a higher level of dissipation at the interface due to the viscous layer.
Note that the viscoelastic properties of the two layers have to be relatively close: if the layers are too different, only the softer viscous layer is deformed, resulting in a cohesive debonding.

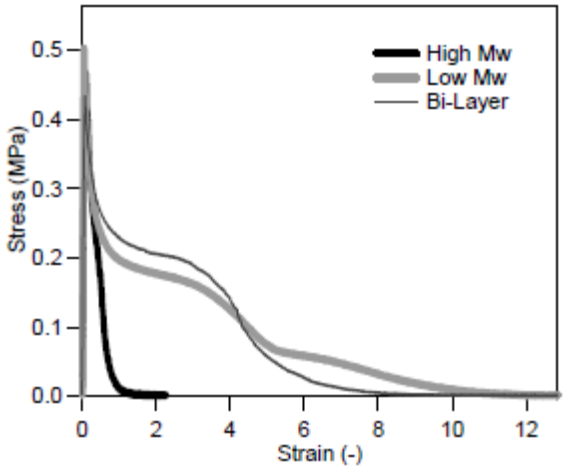

Fig. 1: Tack curves for homogeneous materials (thick lines) and bi-layers (thin line); Vdeb = 10 µm/s

When changing the thickness of the two layers, we observed a strong variation of the overall adhesive properties. This can be explained by the formation and growth of fibrils inside the material, sensitive to the thickness of the viscous layer and to the position of the interface.

Conclusions:

We have successfully prepared multi-layer adhesives from acrylic polymers made from model latexes. We have shown that their adhesive properties are enhanced compared to homogeneous adhesives, especially on polyolefins. Thickness and viscoelastic properties of each layer are two important parameters and need to be finely tuned.

Comparative Study for Tin and Zinc Catalysts for Lactide Polymerization

Jakub Wojtaszak, Jolanta Ejfler, Izabela Czeluśniak

Faculty of Chemistry, Wroclaw University, 14 F. Joliot-Curie 50-383 Wroclaw, Poland

DRWHO@eto.wchuwr.pl

Introduction:

In recent years, there has been increasing interest in biodegradable and bioassimilable polylactide (PLA) due to their pharmaceutical and biomedical applications. The low-molecular-weight PLA has been recently proposed as materials in drug delivery systems.[1] With those type of applications, it is critical that polymers decomposition profile has to be precisely matched to the needs of the application. In practice, PLA is prepared industrially via the ring-opening polymerization (ROP) of L-lactide (LA) using bis(2-ethylhexanoate)tin(II), $Sn(Oct)_2$.[2] This initiator is widely used in preparing of various graft and block copolymers starting from any hydroxyl derivatives as co-initiators and using cyclic esters as monomers.[3]

Much interest have been devoted also to zinc complexes as potential nontoxic catalysts. Recently, the zinc initiator/alcohol system has been demonstrated high activity in ROP of LA and allow for better control of the polymerization, as in the case of $Sn(Oct)_2$.[4] Among known Zn complexes the zinc initiators with aminophenolate ligands have been found as excellent initiators for LA polymerization in the presence of alcohol as co-initiator.[5]

The aim of this study was to compare the widely used $Sn(Oct)_2$ catalyst with $[Zn(\eta^2\text{-}L^2)_2]$ initiator (L= N-[methyl(2-hydroxy-3,5-di-tert-butylphenyl)]-N-methyl-N-(1,3-dioxolan-2-yl-methyl) for synthesis of low-molecular PLA with acetylene end-group.

Materials and Methods:

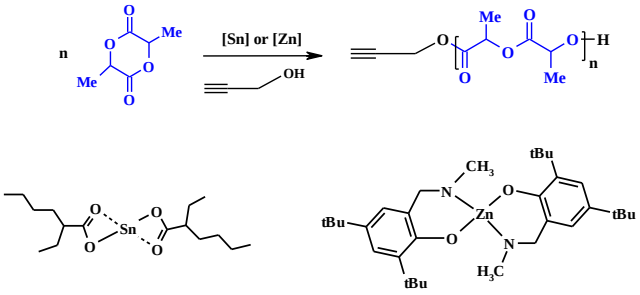
The polymerizations were carried out under nitrogen using the conventional vacuum/nitrogen line or glove-box techniques. NMR spectra were recorded using a Bruker AMX-300 and 500 spectrometers. Gel Permeation Chromatography (GPC) data were obtained using a Viscotek GPC max equipped with a refractive index detector Viscotek VE 3580 and 2x 300 mm Shodex GPC 6 µm KF-802.5 columns. Tetrahydrofuran (THF) was used as the eluent at a flow rate of 1.0 mL/min at 30°C. Polystyrene standards were used for calibration.

Results and Discussion:

The low-molecular-weight PLA polymers terminated with an acetylene group were synthesized by ROP of LA in the presence of $Sn(Oct)_2$ and $[Zn(\eta^2\text{-}L^2)_2]$ initiator and propargyl alcohol as co-initiator (Scheme 1). The degree of LA polymerization (DP) value was calculated from the LA-to-alcohol-to-complex ratio and from ^1H NMR spectra. For presented polymers, theoretical DP was in good agreement only in the case of using Zn initiator. Generally, the tin initiator gave higher DP value than calculated. Moreover, the polydispersity indexes of PLA were higher than those observable for Zn complex.

In order to confirm the structure of synthesized PLA the ^1H NMR spectra have been analyzed. The main evidence for present of the propynyl end-group is the chemical shift of methylene protons of propynyl group attached to polymer chain, observable in spectra of PLA synthesized using both initiators. However, ROP of LA by Zn initiator gave polymer with higher tacticity.

The ROP of LA by both initiators was carried out in NMR probe. In the case of Sn initiator, beside ROP of LA



Scheme 1

reaction LA estrification occured giving propynyllactyllactace as side product.

Conclusion:

The presented results lead to the conclusion, that in the ROP of LA initiated by $Sn(Oct)_2$ esters of LA formed besides PLA. In order to obtain desired product, PLA or LA ester, the initiator-to-alcohol-to-LA molecular ratio must be precisely selected.

Magnesium Catalysts Design for Ring-Opening Polymerization of Lactides

Jolanta Ejfler, Slawomir Szafert, Krzysztof Mierzwicki, Piotr Sobota

Department of Chemstry, University of Wrocław, 14 F. Joliot-Curie, 50-383 Wrocław, Poland

e-mail: je@wchuwr.pl

Introduction

Polylactide (PLA) is the most prominent examples among the biodegradable polymers due to its wide application in biomedical and pharmaceutical fields.

Although many developed strategies for the preparation of PLAs, the most effective remains ring-opening polymerization (ROP) initiated by metal alkoxides and among them candidates of primary importance are monomeric complexes with nontoxic and essential for life metals such as magnesium. Up to now only few examples of magnesium compounds that are active as initiators in ROP of cyclic esters have a structure proven by X-ray analysis, which is highly desirable to design well-defined "single-site" initiators. Herein, we report the preparation and the detailed structural discussion of a series of homoleptic magnesium complexes with aryloxo and aminaphenolate ligands.

Results of the compounds' activity in ROP of lactides are also reported.

Results and Discussion

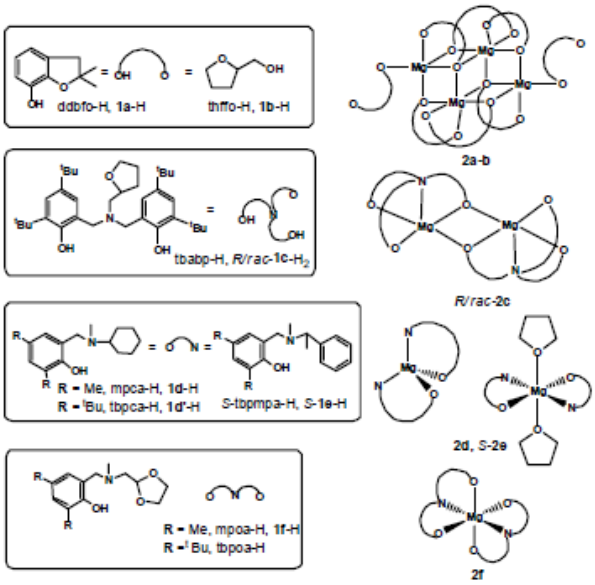
For the synthesis of magnesium compounds we utilized variety of oxo ligands including commercially available 2,3-dihydro-2,2-dimethyl-7-benzofuran alcohol (ddbfo-H; **1a**-H) and tetrahydrofurfuryl alcohol (thffo-H; **1b**-H) as well as aminaphenolate ligands: tbabp-H (**1c**-H_2), tbpca-H (**1d**-H), tbpmpa-H (S-**1e**-H) and tbpoa-H (**1f**-H), obtained by route previously reported by our group (Scheme 1).1

The reactions of not sterically demanding bidentate **1a**-H or **1b**-H with $MgBu_2$ yield tetranuclear compounds $[Mg(ddbfo)_2]_4$ (**2a**) and $[Mg(thffo)_2]_4$ (**2b**) with open dicubane geometry. Higher dentate or more bulky bidentate ligands like the chiral and racemic amino-*bis*-phenolate ligands *R*-**1c**-H_2 and *rac*-**1c**-H_2 form much less aggregated structures, the dimeric magnesium complexes $[Mg(R\text{-bpthfa})]_2$ (*R*-**2c**) and $[Mg(rac\text{-bpthfa})]_2$ (*rac*-**2c**) as presented in Scheme 1.

The aminophenolate bidentate ligands **1d**-H and *S*-**1e**-H appear to be well suited for the synthesis of monomeric tetrahedral magnesium compounds $[Mg(tbpca)_2]$ (**2d**) and $[Mg(tbpmpa)_2]$ (*S*-**2e**). The hemilabile **1f**-H ligand in the reaction with $MgBu_2$ gave six-coordinate complex $[Mg(tbpoa)_2]$. **2f**. The structures of all magnesium complexes were confirmed by NMR spectroscopy as well as X-ray study.

Lactide Polymerization

The monomeric hexacoordinated magnesium **2f** proved to initiate polymerization L-LA (**2f**/L-LA = 1/50) in high conversion within 30 min to afford PLA with moderate Mw = 8600 and PDI = 1.12. In this case, the NMR end group analysis of isolated PLA indicated the presence of hydroxyl and aminophenolate ester end groups. Monomeric tetrahedral compounds **2d** and *S*-**2f** were next tested.



Scheme 1. The magnesium compounds with aryloxo and aminaphenolate ligands.

Although they both showed no activity they become extremely active when external donor was added as described in Table 1. All of the initiator systems exhibit molecular weights in close agreement with calculated values and narrow PDI characteristic for well controlled living propagation.

Table 1. Polymerization of L-LA with initiators (I) **2d**, *S*-**2e**, **2d**/BnOH, *S*-**2e**/BnOH

(I)	[I]:[L-LA]: BnOH	t min	$10^{-3}M_n$[b]	$10^{-3}M_n$[c]	C %	PDI[c]
2d	1/100/0	5d	-	-	-	-
2d	1/50/1	1	6.88	7.02	96	1.09
2d	1/100/1	5	15.58	13.37	92	1.10
S-2e	1/100/0	5d	-	-	-	-
S-2e	1/50/1	1	7.20	6.59	90	1.02
S-2e	1/100/1	10	14.82	13.80	95	1.08

General polymerization conditions: solvent toluene (10 mL), T = 25 °C, [I] = 0.025; a conversion determined by 1H NMR spectroscopy; b determined by GPC, PDI calibrated with polystyrene standards.

Conclusion

We have synthesized and characterized new magnesium aryloxides. The results clearly support the adventage of monomeric magnesium species over polynuclear analogos in lactide polymerization. The dynamic behavior in solution involve by hemilabile aminophenolate ligands may be an important factor for catalytic applications.

hamidkat2000@yahoo.fr

Introduction

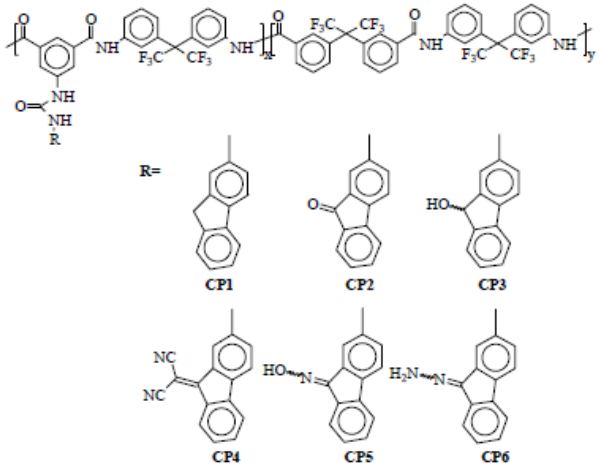
Due to the outstanding mechanical properties of aromatic polyamides (aramids), we have used the aramid backbone to prepare advanced functional materials. Thus, we have synthesized chemically modified copolyamide consisting of 90% of structural units of poly(*m*-phenylene isophthalamide) (NOMEX®) and 10% of structural units containing pendant fluorene derivatives. Following this strategy, the excellent mechanical and thermal properties of NOMEX® were maintained, and the materials gave rise to creasable films or dense membranes to be used as colorimetric or fluorescence sensory materials.1 Moreover, a 10% mole content of the structural units with the urea binding site and fluorescent fluorene group is especially adequate for measuring changes in the fluorescence behavior upon interaction with analytes and, sufficient for giving rise to perceptible ‘‘naked eye’’ colorimetric variations.

Results and discussion

The copolymer **CP1** was firstly prepared and then chemically modified to render copolymers **CP2** to **CP6** (Scheme 1).[2] These modifications were carried out following orthogonal and high yielding reactions and were previously studied using model compounds. This synthetic approach has proven to be a really adequate strategy to prepare new functional soft materials. The reaction conditions were optimized with the model compounds and then applied to the polymers. These model compounds were also used to study the chromogenic and fluorogenic behaviour of the polymers in solution, supposing that each model mimics the behaviour of its corresponding polymer, but with a defined molecular weight and higher solubility.[3,4]

Chromogenic and fluorescence behavior

As previously outlined, the chromogenic and fluorescentbehaviors of high-performance polymers are key properties for many novel applications, such as for chromogenic and fluorogenic sensing materials or for hybrid LUCO/LED emitting devices. The copolymers (Scheme 1) give rise to fluorescent and colored solutions in organic solvents. Upon addition of different anions, a fluorogenic and chromogenic response is observed, as depicted for CP2 in Figures 1 and 2. Thus, the addition of CO3 2- gives rise to a selective color change and to the fluorescence quenching.



Scheme 1. Chemical structure and codes of the modified copolyamides.

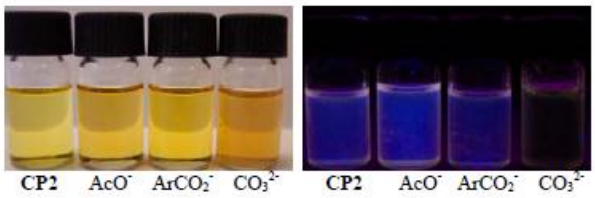


Figure 1. Chromogenic (left) and fluorescence (right) images of solutions of copolyamide **CP1**, **CP2**, **CP3**, **CP4**, **CP5** and **CP6** (from left to right) in DMSO (8x10-3M). The anions have a concentration of 2x10-2M. The right photograph was taken under irradiation with UV (365nm).

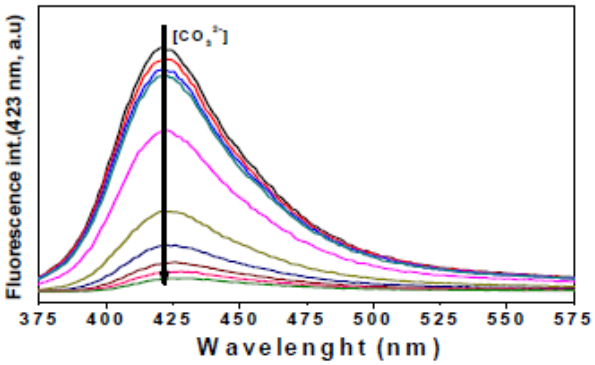

Figure 2. Fluorescence titration curves of a DMSO solution of the copolyamide **CP2** with potassium carbonate (fluorescence intensity at 423 nm).

Study Of Surface Energy Of Polypropylene Films Treated By Corona At A Ambient Temperature And Above.

H. C. de Sena1 and J. S. C. Campos1

1DTP, FEQ, State University of Campinas, Campinas, SP, Brazil

hildosena@feq.unicamp.br

Introduction: This work examines the critical surface tension and the surface free energy of polypropylene films (PP) under three different conditions: corona treatment at room temperature, corona treatment above ambient temperature and without treatment. The objective is to modify the surface of PP films raising the surface free energy and evaluate the temperature influence on the surface energy of these films.

Materials and Methods: The material was PP isotactic produced by the Policast company with 28µm average thickness. Corona's generator geometry is point-plan type with 5000 volts potential between the electrodes [1]. The critical surface tension and the surface free energy of PP films were obtained by measuring the contact angle between a drop of deposited liquid on the PP surface against the parameters of corona treatment time (2s to 90s) and the distance between the electrodes (5mm). Films previously cleaned with ethanol were used to determine the contact angle without corona treatment, then treated with corona discharge at room temperature (25°C) and above (55°C). Measurements of contact angle were carried out with a Tantey Model CAM-MICRO goniometer under the sessile drop method at 23°C (3°C) in water, glycerol, formamide, diiodomethane and ethylene glycol. To determine the critical surface tension of the PP films in different treatments Zisman's approach was performed [2]. The surface free energy of the polymer is analyzed using the alternative formulation of equation of state (EQS) propose by Kwok and Neumann [3], the Wu and VCG (van Oss, Good and Chaudhury) approach derived from Young equation [4-7]. The form of EQS used in this work is as follows:

$$0 = -\gamma_{LV}(1+\cos\theta) + 2\sqrt{\gamma_{SV}\gamma_{LV}}\,(1-\beta_1(\gamma_{SV}-\gamma_{LV})^2) \qquad (1)$$

Where:

β is a constant which equals 1,057x10^{-4} (m/mN)^2.

Results and Discussion: The surface free energy values of PP films calculated from Zisman's approach, EQS, Wu and VCG approach are given in Table 1 and Fig. 1.

Table 1. The surface free energy (γ_{SV}) values reproduced from different approaches and treatments.

Approach	γ_{SV} (mN/m)		
	Without corona [a]	Corona at 25°C (2°C)	Corona at 55°C (2°C)
Zisman's	34,62	39,56	40,31
EQS	33,45	45,87	45,46
Wu [b]	42,23	62,63	61,35
VCG [b]	36,87	48,14	47,38

[a] Films previously cleaned with ethanol were used to determine the contact angle without corona treatment.

[b] Mean of the surface free energy of PP films treated with corona discharge above 10s of treatment.

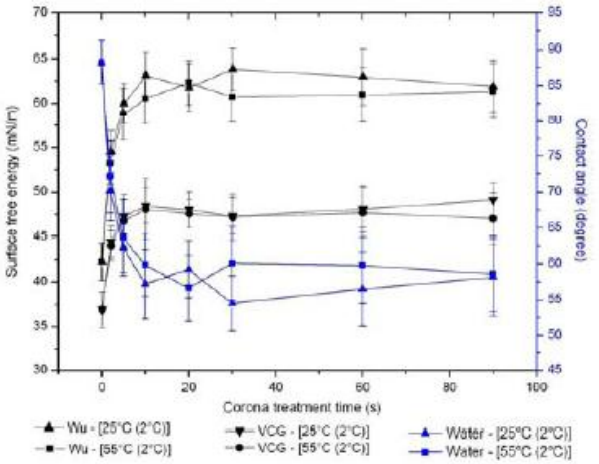

Fig. 1. Contact angle and γ_{SV} values of PP films determinate by Wu and VCG approach.

Conclusions: The results shows significant influence of corona treatment in order to increase the surface energy of PP films by decreasing the contact angle value between the sample and drop of water. Films treated by corona at room temperature and above ambient temperature did not show significant differences in the values of critical surface tension as well as for surface free energy.

Keywords: Polypropylene, Corona treatment, Critical surface tension, Surface free energy.

Background and New Opportunities with the Aromatic Thermosetting Copolyesters

Zeba Parkar and James Economy

Department of Materials Science and Engineering, University of Illinois, Urbana Champaign

jeconomy@illinois.edu

Work on aromatic thermosetting copolyesters (ATSP) was first announced via the issuance of a U.S. Patent (1995)[1] which describes the synthesis and properties of this novel family of polymers. In the present paper we provide a very brief review of the development of linear polyesters from 1881-1995. We then discuss our more recent work on ATSP. Finally, we consider four distinct areas of opportunity for commercial utility of the ATSP currently under development in our group, namely 1) a matrix for high performace composites, 2) a coating to achieve very high flame resistance, 3) design of outstanding ablation materials and 4) coatings which display outstanding wear resistant surfaces.

Early Work on the Aromatic Copolyesters: This work may represent some of the earliest published research in the field of polymers. In 1882, Klepl[2] reported the thermal polymerization of phydroxybenzoic acid (PHBA) to form a p-oxybenzid along with the dimer and trimer of the PHBA polymer. Schiff[3] reported on forming a similar polymer by reacting the acid chloride of PHBA with itself. In 1909 Emil Fischer[4] published a paper confirming Klepl's preparation of the dimer and trimer one year before Ostwald proposed his colloidal theory as an alternate interpretation for the nature of polymers. It wasn't until 1930 when the colloid interpretation was put to rest by Staudinger.

The next report on this family of materials was in 1959 when Gilkey and Caldwell[5] published a paper in which they reported that the homopolymer of p-acetoxy benzoic acid was unstable at 350°C producing a sublimate as a byproduct. We began our work in 1962 and by the spring of 1963 we had successfully prepared the homopolymer of PHBA which indeed was stable in air at 350°C. The Ekkcel or Xydar copolymer consisted of PHBA and BPT (bisphenol terephthalate) (molar ration 2:1 respectively) and was designed originally to melt at temperatures of 400°C. It could be extruded to temperatures above 400°C but under high shear conditions tended to fibrillate. One of the unique features of these aromatic copolyesters is their ability to undergo ordering and randomization reaction on heating at temperatures of 350°C and above.

Commercial Development of the Aromatic Copolyester of PHBA: In 1971 we announced the availability of the PHBA homopolymer[6] as a coating made by plasma spray for use primarily as an abradable seal in aircraft engines. This market in the ensuing years grew to a highly profitable $25 million per year by the early 1980's but began to fall off by the year 2004. In the case of the melt processable copolyester a 25 million lb/year plant was built by the late 1970's by Dart-Kraft to manufacture this polymer for use in high temperature kitchenware. This market has ceased in the USA but appears to continue in Europe. Work on a Kevlar-like fiber based on the aromatic polyesters has not been pursued even though it would have significant advantages over Kevlar including an LOI of 0.40 compared to 0.28 for Kevlar, very low moisture uptake compared to Kevlar and a much lower cost of manufacture. These fibers are melt spun compared to the need for H_2SO_4 as a spinning solvent for Kevlar.

ATSP: Thermosetting copolyesters of trimesic acid, acetoxybenzoic acid, isophthalic acid and hydroquinone diacetate have been prepared[7] and shown to display a number of important features with obvious commercial potential in the area of 1) ablative shields, 2) high temperature carbon reinforced composites,[8] 3) flame resistant coatings, and 4) highly wear resistant coatings. Progress in each of these four topics will be reviewed in this presentation. In addition, a number of key advantages of this novel system will be described including 1) Ease of consolidating molded structure to greatly reduce porosity by carrying out high temperature Interchain Transesterification Reactions (ITR) 2) Taking advantage of the liquid crystalline nature of the ATSP to match the negative CTE of the carbon fiber reinforcement 3) The unique flame resistance (LOI ~ 0.4) to greatly enhance the flame resistance of a wide variety of textiles 4) preparing ultra-low wear blends of ATSP/Teflon (1:1)[9].

From the above, it should be fairly evident that the ATSP resin will in the near future achieve significant commercial success.

Effect of Acrylic Copolymer Dispersants Bearing Epoxy Groups on Dielectric Properties of Carbon Black-filled Epoxy System

Bui Thanh Son, Jin-Young Bae

Department of Polymer Science and Engineering, Sungkyunkwan University, Suwon-si, Gyunggi-do 440-746, Republic of Korea

e-mail b521@skku.edu

Introduction

Material requirements for the commercial applications of embedded capacitor dielectrics include high dielectric constant (K) and low dielectric loss. Much effort has been made to achieve high-k and low-loss at low temperature by thin film deposition, anodization, sol-gel process, and polymer thick film composites. For the polymer thick-film methods, many attempts have been tried to increase the dielectric constant of polymers by employing conductive fillers such as carbon black for percolative high-k polymer composites. However, high dielectric loss (usually >100%) of carbon black-polymer composites was obtained due to the imperfect passivation of carbon black leading to the current leakage through carbon black near the percolation threshold. In this study, good dispersion (and passivation) of carbon black particles in polymer matrix is considered as a very effective way to lower dielectric loss.

Materials and Methods

Preparation of [carbon black/acrylic dispersant/epoxy] composites : A representative example of [carbon black/acrylic dispersant/epoxy] composites was prepared by mixing carbon black, acrylic dispersant, 3,4-epoxycyclohexylmethyl-3,4-epoxycyclohexanecarboxylate, hexahydro-4-methylphthalic anhydride, 1-methylimidazole in the presence of ethyl acetate solvent. The whole mixture was stirred using a high-speed homogenizer (3 min) and ultrasonicated (3 min), respectively. The process was repeated three times. Then, the solvent was removed using a rotary evaporator under a reduced pressure. The resulting carbon black-epoxy paste was used to form a dielectric which was coated onto a copper clad substrate with a single edge blade. Then the sample was cured at 160-190 ^{o}C for 2 hr in the furnace.

Results and Discussion

In this study, we describe the use of copolymeric dispersants with an acrylic backbone and epoxy side groups for formulating [carbon black/epoxy] composites. Six epoxy-containing acrylic copolymer dispersants were prepared from hexyl methacrylate (HMA), poly(ethylene glycol) ethyl ether methacrylate (PEGMA) and glycidyl methacrylate (GMA) via a group transfer polymerization (GTP) technique. The epoxy-containing acrylic copolymer of the highest concentration of PEGMA showed the desirable passivation effect on carbon black, and was found to lower the viscosity of [carbon black/epoxy] paste, leading to well-cured composite after heat treatment. The thick composite film prepared by employing the [carbon black/epoxy/acrylic dispersant] paste was built up on a Cu plate by a screen printing process followed by thermal curing. The dielectric properties of 3.1 vol. % carbon black-filled epoxy showed us high-k (Dk 4900) and rather low dissipation factor (Df 29%) @ 1 MHz.

In conclusion, the passivation of conducting CB by acrylic copolymer dispersants bearing epoxy groups was employed in order to make it possible to maintain the low dielectric loss (Df) which is normally increased by the current leakage through conducting CB. Well-defined acrylic copolymer dispersants synthesized by GTP method were incorporated into the epoxy matrix for controlling CB dispersion/ passivation. Among various dispersants, Dispersant 1 (HMA/PEGMA/GMA 1/1/1) with proper amounts of hydrophilic and hydrophobic moieties gives the best CB passivation effect with low viscosity in epoxy paste and high K/low loss in epoxy film

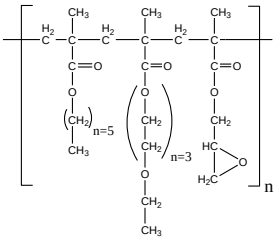

Figure 1. The typical structure of acrylic copolymer dispersants bearing epoxy groups

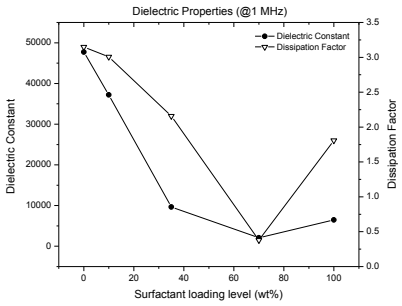

Figure 2. Dielectric properties of carbon black (3.1 vol%)-filled epoxy composite as a function of dispersant loading.

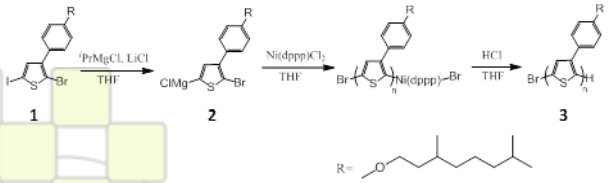
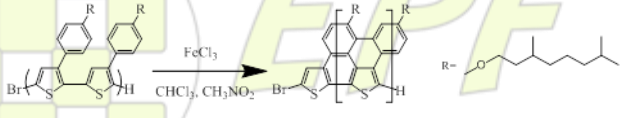
Introduction. Graphenes have garnered significant attention because of their unique electronic properties, such as massless Dirac fermion behavior, half-integer quantum Hall effect, and high-carrier mobility (μ=10^5 cm^2/(Vs) or higher).[1,2] Graphene-based nanostructures are recognized as promising building blocks for an alternative to silicon-based mesostructures in future electronic nanodevices. Several methods have so far been reported to produce graphene sheets based on exfoliation or chemical oxidation of graphite or heat treatment of silicon carbide.[3] Recently, Müllen and co-workers reported the synthesis of linear two-dimensional graphene nanoribbons by the oxidation of polyphenylenes having phenyl side chains synthesized via Suzuki-Miyaura coupling.[4] They first succeeded in controlling the width of graphene nanoribbons. However, polydispersity indicies (PDIs) of graphene nanoribbons have not been controlled yet because the polyphenylene derivative was synthesized via conventional polycondensation. In this report, we report the synthesis of novel graphited polythiophene via oxidantion of polythiophene derivatives with low PDIs, which were obtained by the Grignard metathesis (GRIM) polymerization.[5,6]

Materials and Methods. The synthetic routes of polythiophene derivative are depicted in Scheme 1. The monomer, 2-bromo-5-chloromagnesio-3-(4'-(3",7"-dimethyloctoxy)phenyl)thiophene (**2**), was prepared by the stoichiometric Grignard exchange reaction of **1** with ^{i}PrMgCl at 0 °C for 30 min in the presence of LiCl in THF. (1,3-Bis(diphenylphosphino)propane)nickel(II) dichloride was then added and polymerization was carried out at room temperature for 1 h. The reaction was quenched with 5N-HCl aq. to generate poly (3-(4'-(3",7"-dimethyloctoxy)phenyl)thiophene) (P3PhT(**3**))(M_n 8900, PDI 1.05). Intramolecular Scholl reaction of the P3PhT was performed subsequently with $FeCl_3$ as an oxidative reagent at room temperature. P3PhT was dissolved in $CHCl_3$ under argon and a solution of $FeCl_3$ in CH_3NO_2 was added. The resulting solution was stirred for 72 h. The reaction was quenched with methanol and conc. HCl aq. to obtain graphited polythiophene of **4**. The synthetic route of **4** is shown in Scheme 2.



Scheme 1. Synthetic routes of P3PhT (3)



Scheme 2. Synthetic route of graphited polythiophene (4).

Results and Discussion.
The comparison of the ^{1}H-NMR spectra and UV-vis spectra of **3** and **4** is shown in Figure 1 and 2, respectively. In Figure 1, the signals of aromatic protons in **4** at 6.8-7.2 ppm slightly diminish after the oxidative reaction.

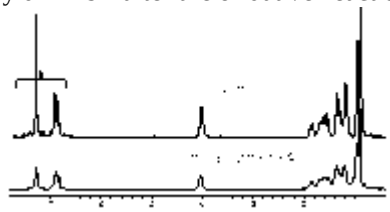


Figure 1. 1H-NMR spectra of 3 and 4.

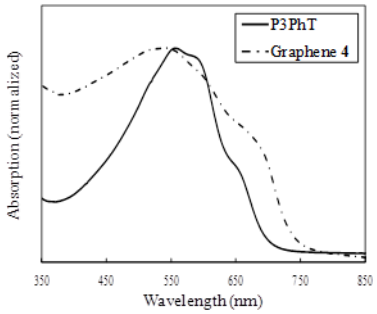

Figure 2. UV-vis spectra of 3 and 4 in the films.

Moreover, the UV-vis spetrum of **4** (λ_{onset} = 738 nm) shows a red shift by 50 nm compared to that of the precursor **3** (λ_{onset} = 696 nm) in the film state.
These results suggest that the intramolecular oxidation of **3** partially proceeds to result in more planer conformation.

Conclusions. Novel graphited polythiophene via oxidation of polythiophene derivatives could be synthesized. ^{1}H-NMR spectra and UV-vis spectra supported the formation of the partial graphited structures.

Synthesis and Characterization of Thianthrene-based Poly(phenylene sulfide)s with Very High Refractive Index over 1.8

Yasuo Suzuki, Kimiya Murakami, Shinji Ando, Tomoya Higashihara, Mitsuru Ueda

Department of Organic and Polymeric Materials, Tokyo Institute of Technology

ueda.m.ad@m.titech.ac.jp

Introduction

In recent years, high refractive index polymers have been developed for various optoelectronic applications.[1] Especially, in polymeric microlens for CMOS image sensors, very high refractive index (high-*n*) exceeding 1.7 or even 1.8, is frequently desired, even though typical refractive indices of conventional polymers are in the range of 1.30–1.65. The general approach to enhance refractive index in polymers is the introduction of substituents with high molar refraction or low molar volume, such as heavy halogens, sulfurs, and metal atoms, according to the Lorentz-Lorenz equation.

Poly(phenylene sulfide) (PPS) is one of the most promising high-*n* polymers because of its high sulfur content and well-packed structure. In a previous report, thianthrene-based PPS (TPPS) **1** and **3** were prepared from 2,7-difluorothianthrene (DFT) and 4,4'-thiobisbenzenethiol (TBBT) or sodium sulfide, respectively. However, TPPS **1** was poorly soluble and TPPS **3** was insoluble in organic solvents, and the reported refractive index of TPPS **1** (1.692 at 633 nm) was unexpectedly low despite of its high sulfur content.[2]

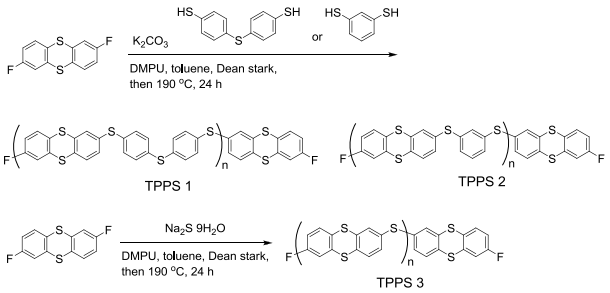
We report herein the synthesis of TPPSs with low to moderate molecular weights (MWs) to endow the solubility. These TPPSs were prepared from DFT and dithiols, including TBBT, *m*-benzenedithiol (*m*BDT), or sodium sulfide nonahydrate, by aromatic nucleophilic substitution reactions. Their refractive indices were extremely high, reaching 1.8020, which is the highest value in reported organic polymers with high transparency in the visible region.

Results and Discussions

The TPPSs were prepared by the polycondensation of DFT with dithiols, such as TBBT, *m*BDT, and sodium sulfide nonahydrate (**Scheme**). To increase the solubility of TPPSs, the molecular weights ($M_{n\ calc}$) were controlled by changing the molar ratios of monomers. TTPSs **1** and **2** ($M_{n\ calc}$=10,000) were soluble in *N*,*N*'-dimethylpropyleneurea (DMPU), 1,1,2,2-tetrachloroethane (TCE), and *N*-methylpyrrolidone (NMP), but insoluble in *N*,*N*-dimethylformamide (DMF), dimethylsulfoxide (DMSO), and $CHCl_3$ at room temperature. On the other hand, TPPS **3** with the most rigid structure among them was least soluble except for that with $M_{n\ calc}$=5,000 which was only soluble in DMPU.

Thermal stability of the TPPSs was evaluated with thermogravimetry (TG) and differential scanning calorimetry (DSC) (Table). All the TPPSs obviously exhibit good thermal stabilities without significant weight loss up to approximately 400 °C. The 5% weight loss temperatures ($T_{5\%}$) are higher than 430 °C. The T_g values are in the range of 143-147 °C, based on the DSC measurement. These results indicate that TPPSs have suitable thermal properties for optical materials.

Films of TPPS **1** ($M_{n\ calc}$=10,000), **2** ($M_{n\ calc}$=10,000), and **3** ($M_{n\ calc}$=5,000) were prepared by spin-casting from their TCE or DMPU solutions followed by heating up to 250 °C to remove the solvent. All films are tough and flexible enough to evaluate optical properties despite their low-to-moderate MWs. All TPPS films show good transparency in the visible region, and the transmittances of TPPSs **1**, **2**, and **3** at 400 nm are 93, 64, and 84%, respectively. The refractive indices of TPPSs were measured at 633 nm with a prism coupler (**Table**). The refractive index of TPPS **1** was reported as 1.692, which is too low judging from its sulfur content (34.65 wt%). In contrast, all TPPS films with low-to-moderate-MWs exhibit very high-*n* in the range of 1.7856-1.8020, which are in the highest class of organic polymers without inorganic components. To our best knowledge, this is the first report of a wholly colorless and transparent in the visible region with refractive indices over 1.80. Moreover, the very low in-plane/out-of-plane birefringences (Δn) of the TPPS films ranging from 0.0033 to 0.0039 is suitable for optoelectronic applications (**Table**).



Scheme. Synthesis of TPPSs.

Table. Thermal and optical properties of TPPSs.

TPPS	Sc[a] (wt%)[a]	$T_{5\%}$ (°C)	T_g (°C)	$T_{400\ nm}$ (%)	Δn[b]	n_{av}[c]
1	34.65	471	143	93	0.0037	1.7856
2	36.18	438	142	69	0.0039	1.7966
3	39.04	430	145	84	0.0033	1.8020

[a]Sulfur content. [b]Birefringence. [c]Average refractive index: $n_{av} = [(2n_{TE}^2 + n_{TM}^2)/3]^{1/2}$.

Conclusions

The TPPSs with low to moderate MWs were prepared by the polycondensation of DFT with TBBT, *m*BDT, or sodium sulfide nonahydrate showed relatively high solubility, high transparency in the visible region, and high thermal stability. Furthermore, these polymers exhibited very high refractive indices of 1.7856–1.8020 at 633 nm while maintaining low birefringence values.

Polymers, which are produced by emulsion polymerization technique, are called latexes. These latexes have been largely used in adhesive, paint, paper coating and textile industries. In latexes, surfactants are used with different aims but besides they can cause some undesirable problems like formation of foam. Particularly, in processing of paper coating adhesives, foam, especially micro foam, which is tiny, often invisible bubbles, suspended to give rise to undesirable viscosity increases and cause various surface deformations. It can be regarded as the most troublesome to accomplish in processing because it is harder to recognize and eliminate. In order to eliminate these unfavorable problem, anti-foaming agents need to be used whether in synthesis or after synthesis.

In this study, PPG-b-PDMS-b-PPG tri block copolymers, having different molecular weights, were synthesized as anti-foaming agents in order to eliminate micro foams in fast process of paper coating of acrylic based latexes. PPG-b-PDMS-b-PPG tri block copolymers were synthesized by polycondensation reaction of a Cl terminated PDMS and PPG with different molecular weights. Surface tension of tri-block copolymers were determined by Du Nouy tensiometer. Foamability was analysed by Ross-Miles test method and foam characteristics were observed under Leica DMR microscope.

Synthesis of water-soluble Polyamide Dendrimers for DNA Sensors

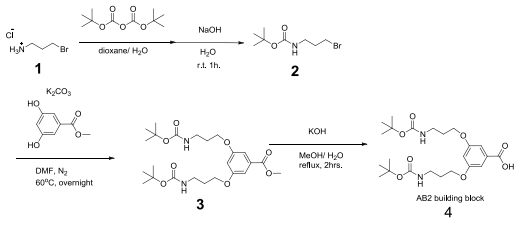
Introduction

Recently, water-soluble conjugated polymers have received much attention because of their potential utilities in the field of sensitive chemical and biological sansors.[1] Especially, it was shown that water-soluble dendronized conjugated polymers could be strong candidates because they possess high quantum yield in water due to hydrophilic dendron segment effectively preventing the aggregation of conjugated polymer.[2] However, the synthesis of dendronized polymers requires multi step procedures via grafting-onto or macromonomer approaches. In this work, we synthesized simpler water-soluble polyamide G1, G2 and G3 dendrimers, which had a pyrene unit as a fluorescence group and ammonium periphery. DNA sensing behavior of the dendrimers would be investigated using UV-Vis absorption and Emission spectra.

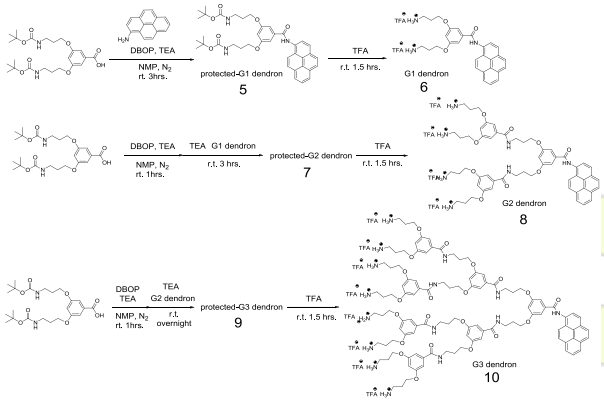
Results and discussion

Synthesis of AB2 building blocks Scheme 1 shows the synthesis of AB2 building blocks. **2** was synthesized according to a previous paper.[3] 3,5-Dihydroxy benzoate was reacted with **2** under the presence of K_2CO_3 to obtain protected AB2 building block (**3**). AB2 building block (**4**) was obtained by the hydrolysis of the methyl ester group of **3**.[4]



Scheme 1 Synthesis of AB2 building blocks

Synthesis of Dendrimers The dendrimers were grown from 1-aminopyrene by a divergent approach using diphenyl (2,3-dihydro-2-thioxo-3-benzoxazolyl) phosphonate (DBOP) as condensing agent.[5] Coupling reactions for the synthesis of protected-dendrimers (**5, 7, 9**) were conducted by a two-step method[6] consisting of (1) activation of carboxylic acids of AB2 building blocks by DBOP to generate an active amide and (2) condensation of the active amide with 1-aminopyrene, G1 or G2 dendrimers. *tert*-Butyl carbamate group of protected-G1, G2 and G3 dendrimers (**6, 8, 10**) were deprotected using trifluoroacetic acid to obtain cationic charged dendrimers. (Scheme 2) All products were characterized by IR and ^{1}H-NMR spectroscopy, and the MALDI-TOF MS spectrum of dendrimers and only showed signals attributed to the presumable MSs .



Scheme 2 Synthesis of polyamide dendrimers.

DNA sensing behavior of dendrimers The interactions between DNA and G1 dendrimers were investigated by the changes of G1 dendrons UV-Vis absorption and emission spectra. As shown in Figure 1a, UV absorptions of G1 dendrimers are red-shifted by adding DNA. Decrease in the emission of G1 dendrons upon adding DNA is also observed in Figure 1b. Because the maxima and shapes of emission spectra do not change and no new peaks appear, possible mechanism for the quenching of cationic G1 dendron is attributed to its aggregation near the negatively charged DNA, leading to self-quenching.

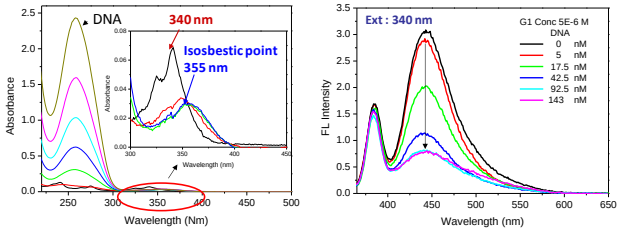


Figure 1 Absorption (a) and Emission (b) spectra of G1 dendrons in the presence of DNA in aqueous solution.

Summary

Cationic water soluble dendrimers that contain a fluorescence molecule pyrene at the core were successfully synthesized via divergent method using DBOP as the condensing agent. UV absorption and emission spectra of G1 dendron showed the DNA sensing behavior. DNA sensing behavior of G2 and G3 dendriers is now under investigation.

Shape memory polymers (SMPs) are one type of smart materials, and have found tremendous applications in space exploration, engineering, and recently in medical devices [1,2,3] owing to their superior properties of large deformation, light weight, low density, low cost and easy processing etc [4]. Most commercially available SMPUs have a high elastic strength and high glass transitional temperatures, higher than the human body temperature, therefore are not particularly suitable for medical device applications. SMPs with a relatively low elastic strength and a near-body transitional temperature are desirable for medical devices such as the laser-activated cork screw surgical tool [5] and the SMP-based bandages [6]. Therefore it would be useful to develop low T_g and low elastic strength pure SMPs for medical applications, and further modifications can be made to change these SMPs into ones which can be activated by other mechanisms such as light by adding nanoparticles. In this research, different polyols and hard segments (MDI and IPDI at different molar ratios) were used to synthesize polyurethane-based SMPs (SMPUs) with tailored and controllable properties suitable medical device applications.

Various polyurethane-based shape memory polymers (SMPUs) were synthesized using five types of polyols (poly(caprolactone) (PCL), poly(ethylene adipate) 2200 (PEA), polyether-type polyols of poly(ethylene glycol) (PMTG), and two polyester-type polyols of poly(butylene adipate) (PBA) and (PBA-U)) as soft segments and two different diisocyanates: isophorone diisocyanate (IPDI) and 4,4′-diphenylmethane diisocyanate (MDI) as hard segments. The effects of the concentration of the diisocyanates, and polyols on material properties such as crystallinity, transition temperature, shape memory effect and tensile strength were investigated.

X-ray characterization revealed only polyol soft segments have crystalline structure, mixture of hard segments with polyols do not introduce additional crystalline structure but reduce the crystallinity of the polyols. The crystallinity of the SMPUs increases with IPDI content. The result showed that high concentration IPDI in polymers may prevent or restrict the reaction and crosslink between polyol and diisocyanate, and a large amount of soft polyol and diisocyanate hard segments may co-exist as separated "macrophases", not good for the formation of high quality SMPUs, in agreement with the shape memory effect obtained.

SMPUs with a maximum strain over ~1000%, recovery rate up to ~98%, fixity up to ~90% and near body transitional temperatures of 35~45°C were obtained that are suitable for the development of SMPU-based medical devices. The SME properties are summarized in table. A high content of MDI hard segment results in SMPUs with better shape memory effect, increase in IPDI content leads to deterioration of shape memory effect: reduced maximum strains and stress recovery rates, but increased shape fixity. The results indicate that high concentration IPDI prevents or restricts chemical reaction and crosslinks between polyols and hard segments, leading to large phase separation and coexistence of soft and hard segments in macrophases.

Amphiphilic Multiarm Star Block Copolymer via Diels-Alder Click Reaction

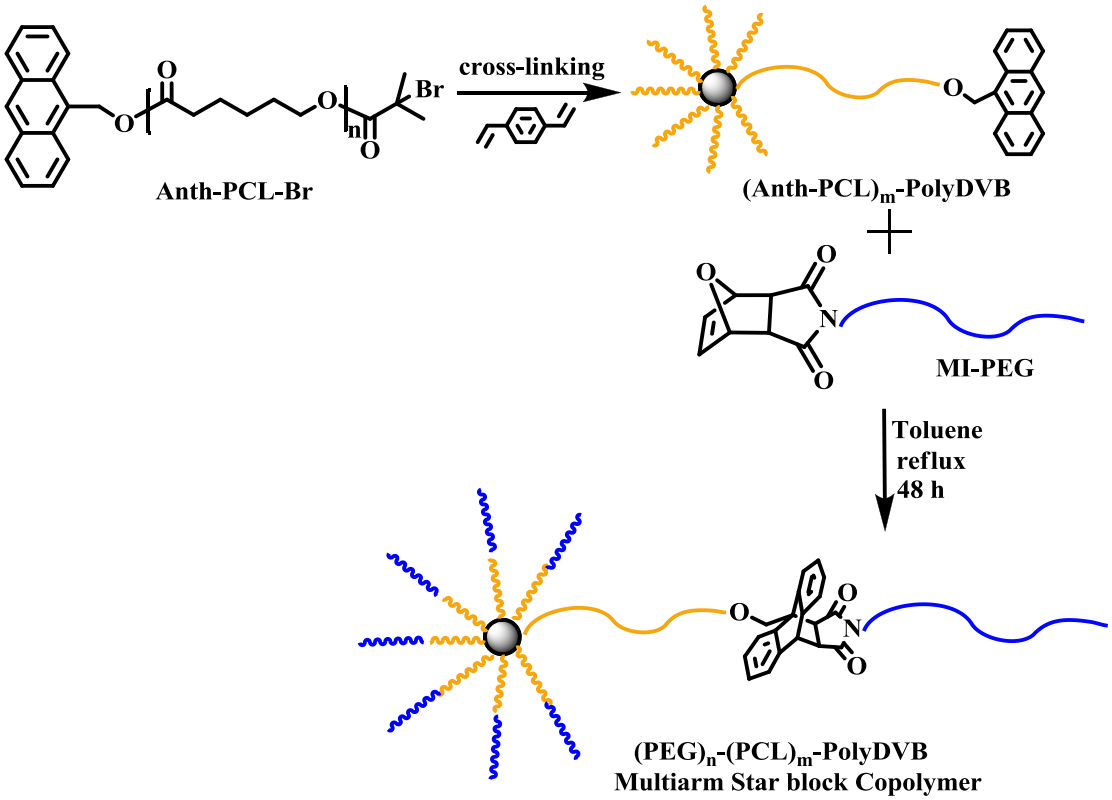
Nese Çakır, Aydan Dag, Hakan Durmaz, Gurkan Hizal, Umit Tunca

Istanbul Technical University

cbu_nese_87@hotmail.com

Abstract

Multiarm star block copolymer: poly(caprolactone)$_m$-poly(divinylbenzene)-poly(ethylene glycol)$_n$,(PEG)$_n$ -PCL)$_m$-polyDVB, was successfully prepared via a combination of cross-linking and Diels-Alder click reaction based on "arm-first" methodology. For this purpose, multiarm star polymer with anthracene functionality as reactive periphery groups was prepared by a cross-linking reaction of divinyl benzene using α-anthracene end functionalized polycaprolactone (Anth-PCL) as a macroinitiator. Thus, obtained multiarm star polymer was then reacted with furan protected maleimide-end functionalized polymer: MI-PEG at reflux temperature of toluene for 48 h resulting in the corresponding multiarm star block copolymer via Diels-Alder click reaction. The multiarm star and multiarm star block copolymer was characterized by using ^{1}H NMR, SEC, Viscotek triple detection SEC (TD-SEC) and UV.



Synthesis and Characterization of Biodegradable Polyester Resins

Stefan Theiler, *Helmut Keul*[*], *Martin Möller*[*]

Institute for Technical and Macromolecular Chemistry, RWTH Aachen University and DWI an der RWTH Aachen e.V./Pauwelsstr. 8, D-52056 Aachen, Germany

E-mail: keul@dwi.rwth-aachen.de

Introduction: Chemical approach towards biodegra-dable polyester resins via Michael addition is presented. Star-shaped poly(caprolactone)s were prepared by means of chemically catalyzed ring-opening polymerization of ε-caprolactone with a multifunctional initiator followed by end capping with acrylate. Polyesters with pendant double bonds were used to form novel polyester resins by means of Michael addition using several polyether diamines as crosslinking agents (Figure 1). Variation of crosslinking agent, crosslinking density and the composition of the star-shaped functional poly(caprolactone) allows the adjustment of the resins hydrophilicity, thermal and mechanical properties.

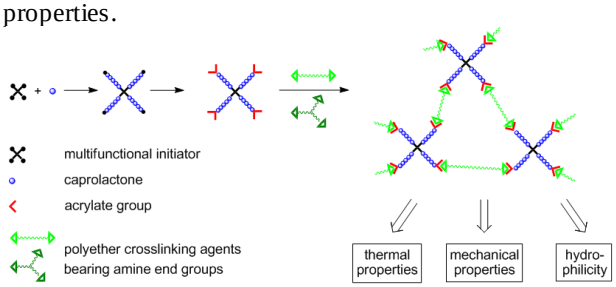


Figure 1. Biodegradable polyester resins: synthesis of star-shaped poly(caprolactone) and crosslinking with polyether crosslinking agents bearing amine end groups.

Materials and Methods. Star-shaped functional poly(ε-caprolactone)s (**1a-f**) used in this work were synthesized according to [1]. Characteristics of the prepolymers are shown in Table 1.

Table 1. Functional prepolymers: degree of functionalization, NMR and SEC analysis.

	Prepolymer	DF[a] %	$M_{n,NMR}$[b] g·mol^{-1}	$M_{n,SEC}$[c] g·mol^{-1}	M_w/M_n[c]
1a	s6PCL5-A[d]	99	3900	7400	1.23
1b	s4PCL5-A	93	2700	4300	1.42
1c	s4PCL10-A	95	4600	9000	1.40
1d	s4PCL20-A	90	9700	19400	1.23
1e	s4PCL50-A	94	23300	40200	1.13
1f	s4PCL100-A	100	46200	70600	1.11

[a] Degree of functionalization determined by NMR. [b] Number average molecular weight (M_n) determined by NMR. [c] M_n and molecular weight distribution (M_w/M_n) determined by SEC (PMMA standards). [d] s6PCL5-A indicates: star-shaped PCL with 6 arms and 5 CL repeating units per arm.

For the preparation of biodegradable polyester resins star-shaped acrylate functionalized poly(ε-capro-lactone)s (**1a-f**) and a crosslinking agent (ratio of acrylate to amine groups: 1:0.25 to 1:1.50) were dissolved in dichloromethane. The mixture was kept at room temperature in a stream of dry air until the solvent was evaporated (for ~30 min), followed by heating in an oven at 55 °C for 15 h.

Results and Discussion. Biodegradable polyester resins of all poly(caprolactone) prepolymers have been prepared with amino-telechelic poly(tetrahydrofuran), Jeffamines (PEO/PPO di-/triamines) and PEG diamines of different molecular weights as crosslinking agents. Determination of converted C,C-double bonds by means of Raman spectroscopy proves that the degree of crosslinking can be adjusted by the ratio of acrylate to amine groups in the feed (for acrylate:amine >1). At a molar ratio of 1:1 all C,C-double bonds were converted. Resins prepared with a ratio of acrylate:amine <1exhibit free amino groups which can be used for biofunction-alization.

Hydrophilicity of the polyester/polyether resins can be adjusted by using different crosslinking agents. Crosslinking with amino-telechelic poly(tetrahydro-furan) results in hydrophobic resins, while crosslinking with PEG diamines results in hydrophilic resins.

Thermal properties of the resins were investigated by means of DSC. Increasing crosslinking density results in a decrease of melting temperature and enthalpy. Using prepolymers with increasing CL chain length (**1a** to **1f**) and a 1:1 molar ratio of acrylate to amine groups, melting temperature and enthalpy increase.

Tensile strength of the resins was measured according to the ISO 37 norm. Resins with high crosslinking density show elastic behavior while resins with low crosslinking density show viscoelastic behavior. Increasing the CL chain length in the prepolymer results in resins with higher E moduli, Yield and breaking stress.

Conclusions. Starting from poly(ε-caprolactone), prepolymers biodegradable resins were prepared using amino terminated polyethers as crosslinking agents. Crosslinking density can be tuned by the ratio of prepolymer to crosslinking agent in the feed as well as by the composition of both components. Hydrophilicity, mechanical and thermal properties of these polyester/polyether resins can be adjusted in a wide range. The biodegradable polyester resins are promising candidates in biomedical applications, for example in the development of vascular prostheses.

Introduction

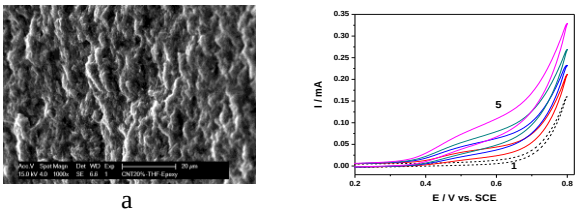
Carbon nanotubes (CNTs) have become the subject of intense investigation since their discovery [1]. Such considerable interest reflects the unique behavior of CNTs, including their remarkable electrical, chemical, mechanical and structural properties. Numerous advantages of CNTs as electrode materials have been attested for analysis of diversified chemicals of food quality, clinical and environmental interest [2,3].

Materials and Methods

Multiwall carbon nanotubes (MWCNTs) with a 90% purity, synthesized by catalytic carbon vapor deposition (CCVD) were provided by Nanocyl™ NC7000. The epoxy resin Araldite®LY5052 and the curing agent Aradur®5052 were produced by Hunstman Corporation. The MWCNTs and all the reagents were used as received. Different contents of MWCNTs (in the range between 0.1% and 30% wt.) were used to obtain composite electrodes using two-roll mill procedure (TRM). The dispersion and morphology of MWCNTs- epoxy composite- electrodes were characterized using different microscopic techniques, i.e., dynamic light scattering (DLS), atomic force microscopy (AFM), and scanning electron microscopy (SEM). Also, the electrical conductivities of these composites were investigated by DC conductivity measurements. The electroactive surface areas of the composite electrodes were determined through the electrochemical characterization using the classical potassium ferricyanide ($K_3[Fe(CN)_6]$ method. Cyclic voltammetry (CV), differential-pulsed voltammetry (DPV), square-wave voltammetry (SWV) and chronoamperometry (CA) techniques were applied to determine the electroanalytical performance of the electrode in order to detect salicylic acid (SA), which was chosen as model for the pharmaceutical compounds.

Results and Disscussion

Figure 1.a shows the SEM image of the composite electrode containing 20 %, wt. MWCNT (MWCNT20) with good dispersion of CNTs in the polymer matrix, forming a three-dimensional network.
The electrochemical characterization revealed a higher electroactive surface area of the MWCNT20 electrode, which was selected as optimum for further detection experiments. In figure 1.b the CVs of MWCNT20 composite electrode in the presence of SA are presented to characterize its electrochemical behavior in alkaline medium.



a b

Fig.1a- SEM image of MWCNT20 electrode; b- CVs of MWCNT20- electrode recorded in 0.1 M NaOH supporting electrolyte (1) with addition of: 1, 2, 3, 5mM SA (2-5). Scan rate: 50mVs^{-1}.

The good results regarding the electroanalytical parameters of the detection were achieved using CV, DPV, SWV and CA techniques. Additionally, the detection measurements were performed for the determination of acetyl salicylic acid (ASA) from real pharmaceutical samples (aspirin tablets). The obtained results are promising for practical application in drug testing.

Conclusions

The composite electrode containing 20 %, wt. MWCNT (MWCNT20) was selected as optimum for the detection experiments based on the correlation between morphology, electrical conductivity and electrochemical behavior.
The MWCNT20 composite electrode exhibited useful features as environmentally friendly sensor for the electrochemical determination of SA and ASA with respect to its mechanical resistance, very low cost, simple preparation and easy renewal of the active electrode surface.

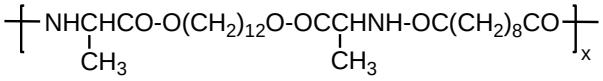
Electrospun nanofibers of a biodegradable poly(ester amide). Scaffolds loaded with antimicrobial agents.

Alfonso Rodríguez-Galán, Manuel Roa, Angélica Diaz, Jordi Puiggalí, Luis Javier del Valle

Dpt. Chemical Engineering. Universitat Politècnica de Catalunya. Av. Diagonal 647. 08028-Barcelona. Spain

alfonso.rodriguez-galan@upc.edu

Introduction. Biomedical applications such as preparation of scaffolds used for tissue engineering and drug delivery, have become one of the most interesting topics in the electrospinning field. The most used materials correspond to polyesters, polyamides and polyurethanes. However, only a few papers have been published reporting the elaboration of poly(esteramide)s (PEAs) nanofibers.
PADAS is a regular and biodegradable poly(ester amide) based on 1,12-dodecanodiol, L-alanine, and sebacic acid obtained by interfacial polymerization. Due to its biodegradable nature, it can be used like biomaterial that suppors and favours the cellular growth.



Chemical structure of PADAS

In this study, ultrafine PEA fibers containing antimicrobial compounds were prepared by electrospinning of a PADAS solution with small amounts of silver nitrate ($AgNO_3$) or Chlorhexidine.

Results and Discussion. Regular and homogeneous PADAS fibers could be obtained from hexafluoroisopropanol (HFIP) solutions at concentrations ranging between 1-10% (Figure 1). Experiments performed with other solvents rendered irregularly shaped fibers or mixtures of fibers and beads.

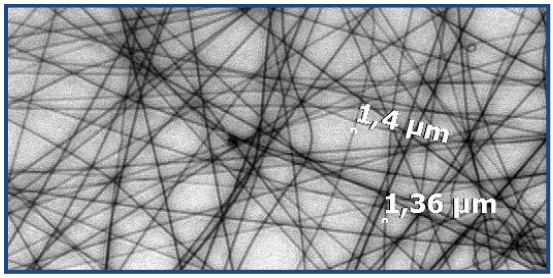


Figure 1. Optical micrograph of PADAS fibers electrospun from a 10% HFIP solution.

Fibers containing antimicrobial agents such as $AgNO_3$ or Chlorhexidine diacetate could be prepared from a 10% PEA/HFIP solutions. Because low solubility of the salt in HFIP, fibers with $AgNO_3$ were prepared from drug/polymer ratios of 0.001-0.24% while Chlorhexidine containing fibers were obtained at concentration of 0.3-4.2%.
The morphologies of the ultrafine PADAS fibers were observed on a scanning electron microscope after gold coating (Figure 2). The average diameters were determined by analyzing SEM micrographs with an image analysis program.

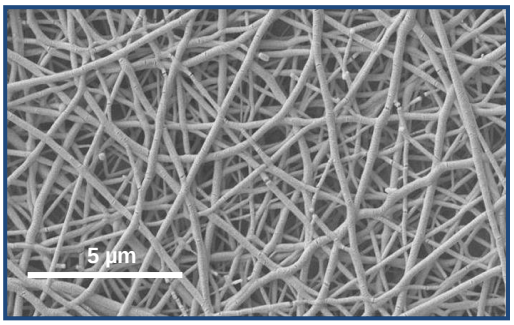

Figure 2. SEM image of ultrafine electrospun PEA fibers from 10 % PADAS/HFIP solution containing 0.16% of $AgNO_3$.

Our results showed that the diameter of fibers containing $AgNO_3$ decreased dramatically: when the conductivity of a polymer solution is increased by adding a salt, the diameter of the resultant fibers is significantly reduced.
Antibacterial activity of scaffolds made from nanofibers containing silver nitrate or Clorhexidine have been evaluated against Gram positive and negative bacteria. Fibers with silver salt are more effective than Chlorhexidine fibers inhibing the growing of both kinds of bacteria.

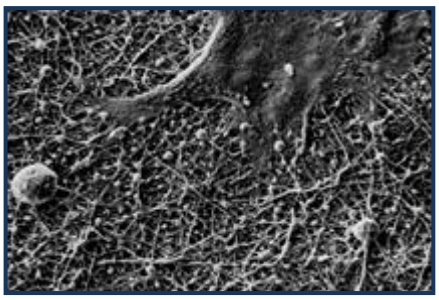

Figure 3. SEM image of Hep-2 cells on PADAS fibers.

The capability of scaffolds made from antimicrobial PADAS fibers to support cell attachment and proliferation was also evaluated (Figure 3).

Conclusions. Fibers of PADAS with diameters of 500-2000 nm can be prepared by electrospinning of 1-10% solution in HFIP. nanofibers with antimicrobial activity against *E. coli* and *M. luteus* are obtained when $AgNO_3$ or Chlorhexidine are added to the PEA/HFIP solutions,. These nanofibers are biocompatible with epithelial Hep-2 and MDCK cells.

Introduction: The encapsulation of titanium dioxide nano-powder has been attempted by a modified emulsion/dispersion polymerization using wall materials composed of methyl methacrylate (MMA), ethylene glycol dimethacrylate (EGDMA) and methacrylic acid (MAA). The nano hybrid composite particles diameters of 0.2um - 10um have received much interest in a wide range of industrial fields, such as diagnosis, electronics, toner, and dispersion stability properties. Moreover, inorganic core/organic shell hybrid composite particles may provide better electrical, optical and thermal properties and extend their range of industrial application. Encapsulation of inorganic particles by a polymer shell provides better mechanical properties such as strength, shape, and chemical resistance. Above all, the enhancement in dispersion stability of hybrid composite particle is most significant characteristics of inorganic core/polymer shell composite particles.

Materials and Methods

Using monomers took Methyl methacrylate (MMA, purity 99%), methacrylic acid (MAA), crosslinking agent used to Ethylene glycol dimethacrylate (EGDMA), Methyl alcohol (MeOH, SAMCHUN chemical), 2,2'-azobis(2-methylpropionitrile) (AIBN), and polyvinylpyrrolidone (PVP, Mw=55,000/360,000 g/mol) (Sigma Aldrich Co. Ltd.) were chemically pure grade and purified by reduce pressure distillation. Titanium dioxide (TiO_2) nano particles are offered from TRONOX™ (TR-HP-2). The TiO2 used in this study are a rutile crystal structure, hydrophilic surface property, below to 1.0um size. In the first step, 0.2% (w/v) of PVP was dissolved in a methanol in a 500ml customizing three necks round bottomed flask equipped with a ultra-sonicator, a thermometer, a reflux condenser, and a nitrogen gas inlet and outlet. TiO2 nano-particles were dispersed in the mixture of MMA and EGDMA by 15min ultra-sonication at room temperature. The TiO2 dispersion in the monomer mixture was done by ultra-sonication, mixture was poured into 0.2% (w/v) of PVP methanol solution and emulsified with ultra-sonication 15min again. Then a solution of AIBN was added into reactor. The vibrating power was changed from 50% to 40%. Then the flask was immersed into a 65◦C oil bath under a nitrogen atmosphere. In the second step, MAA was added slowly into the reactor to incorporate the composite particle surface. After adding the MAA, the reactions were carried out for 4 h at the same temperature. Cooling to room temperature terminated the reaction. After termination process ended, deionized water was added to the produced hybrid composite particle mixture for clean, didn't reaction monomers, and it was isolated from the mixture by centrifugation. Hybrid composite particles were washed with deionized water several times. Finally, the particles were drying at 60◦C in a convection vacuum oven.

Results and Discussion

The effect of sonication can be clearly shown in terms of the particle size. In Figure 1(RTMA; without sonication, UTMA and UHTMA; with sonication), the particle size results are summarized, showing that if sonication step is added during the polymerization, the particle size much reduced compared with that without sonication.

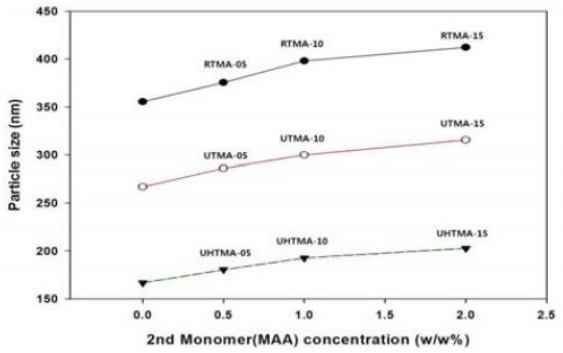

Fig.1 Particle size analysis by DLS.

Conclusions

In the current experiment, it has been attempted that the conventional emulsion/dispersion polymerization is modified to ensure the stability of nano-particle during the encapsulation process as well as the efficient encapsulation. With an aid of ultra-sonification it is found that the very thin wall is formed around the surface of titanium dioxide nano-particles and that the majority of the encapsulated particles contain single titanium dioxide particle.

Authors Instructions:

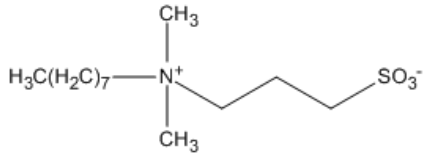
This study focus on modified proton exchange membrane, Nafion 212, which hope enhance conductivity simultaneously decrease AC impedance by immersed sulfobetaine-type surfactants as N-Octyl-N,N-Dimethyl-3-Ammonio-1-Propanesulfonate (DAPS).

Introduction

This study surfactant as N-Octyl-N,N-Dimethyl -3-Ammonio-1-Propanesulfonate ($C_{13}H_{29}NO_3S$) is a zwitterionic surfactant that having a head group containing both a negatively charged chemical moiety and a positively charged chemical moiety. That can provide an improved stabilization mechanism than an ionic-type surfactant [1] simultaneously structure have SO^{-3} group can help proton conduction. There is not had any research to study the sulfobetaine-type surfactants as DAPS applied for Nafion 212 on PEMFC. Therefore, this investigate is very important.

Materials and Methods

The materials of investigation were include proton exchange membrane as Nafion 212 (thickness is 0.05mm), surfactant as N-Octyl-N,N-Dimethyl-3-Ammonio-1-Propanesulfonate ($C_{13}H_{29}NO_3S$) which chemical structure as



The experimentation that Nafion 212 (size is 5*5cm) was soke into 3% DAPS surfactant for 1,3,6 and 24hrs then dry on oven. It was employ AC impedance apparatus to analyze the property of membrane.

Results and Discussion

The Warburg impedance [2] was impedance of electrolyte (bulk resistance, Rb) as Nafion 212/ DAPS for ionic move. The which impedance of electric charge to transfer (charge transfer resistance, Rct) which was electric charge to transfer need reaction activation energy and parallel connection with capacitance (C) as shown in Figure 2 that can calculate conductivity of Nafion 212/ DAPS from σ=L/(Rb*A)

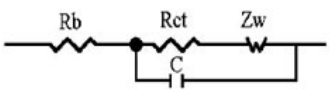


Figure 1 Simulate impedance of equivalent circuit.

Nafion 212 immersed into 3% DAPS surfactant for 1,3,6 and 24hrs that can obtain AC impedance as shown in Figure 2. The Rct had smallest when Nafion 212 immersed into 3% DAPS surfactant for 24hrs whcih mens electric charge to transfer need smaller reaction activation energy.

As Nafion 212 immersed 3% DAPS surfactant for 3hrs which had highest conductivity as shown in Figure 2.

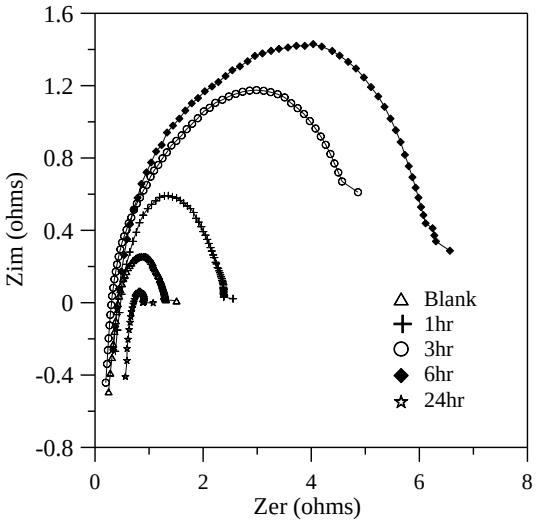

Figure 1 AC impedance of Nafion 212 immersed 3% DAPS surfactant on different time.

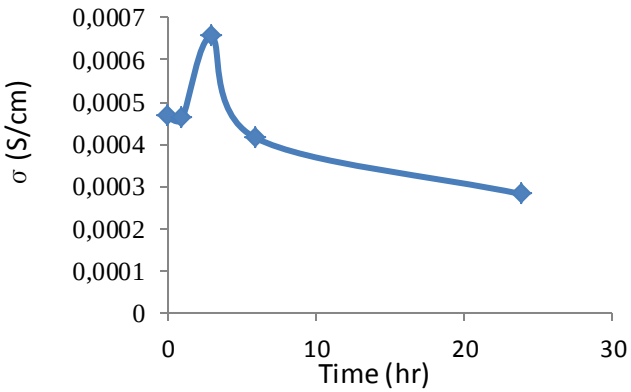

Figure 2 Conductivity of Nafion 212 immersed into 3% DAPS surfactant on different time.

Conclusions

Nafion 212 immersed into 3% DAPS surfactant for 24hrs whcih need smaller reaction activation energy but immersed 3hrs on 3% DAPS surfactant which had highest conductivity

1.0 Introduction :

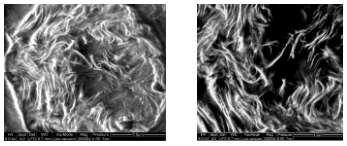
Electronic conducting polymers are difficult to be synthesized because it involves meticuluos procedures and requires several chemicals. Other alternative is to radiate any polymers to form *trans*-vinylene (C=C) group [1]. Therefore, the conductivity of these irradiated conducting polymers is expected to occur through the delocalization of electrons of the conjugated bonds structure along the polymer chain [2]. In this study two types of polyethylene i.e. HDPE and LDPE were chosen to investigate how the different in the chain arrangement of the polyethelenes may affect the overall structure the polymers upon radiation hence their electrical properties. Furthermore, conjugated bonds are expected to be easily formed after irradiation due to their simple and straight polymer chains structure. There are several studies on irradiated HDPE [1] and LDPE [3] that had been done. However, most studies concentrated on the mechanical and thermal properties of these irradiated polyethylene. To date, there are no studies on electrical properties of HDPE and LDPE that have been reported.

2.0 Materials and Methods:

Both HDPE and LDPE sheets were prepared by compression moulding technique. The sheets were then Irradiated using electron beam accelerator, EPS-3000 at 100 to 800 kGy of irradiation dose with 2 MeV and 10 mA. The morphology of these irradiated HDPE and LDPE sheets were observed under FESEM, Quanta 200 F. The changes in the structure of both irradiated sheets were analyzed using ATR–FTIR Perkin Elmer Spectrum One FTIR spectrophotometer in the frequency range of 4000 – 400 cm^{-1}. The thermal properties of both samples were studied using TGA Pyris 1 and DSC Q200. The type of HDPE and LDPE semiconductor were carried out by hot-point probe measurement and the band gap energy for both irradiated samples were determined from the UV spectra obtained from Perkin Elmer Lambda 800 UV-vis spectrophotometer.

3.0 Results and Discussion:

Interestingly, it was found that LDPE was able to withstand higher irradiation dose up to 800 kGy without showing any degradation as compared to HDPE that started to degrade at 700 kGy. Both sheets became harder after irradiation due to the formation of interchain crosslinking in their polymer structures. This has been confirmed from their respective TGA and DSC analysis in which their decomposition and melting temperatures were higher than in their un-irradiated systems. The formation of crosslinking in these irradiated HDPE and LDPE system were further confirmed from the formation of interpenetrating structures which were observed from their electron micrographs (Figure 1). From the hot-point probe measurement, both irradiated HDPE and LDPE were *p*-type semiconductors. The presence of charge carriers in these systems were due to the delocalization of electrons from the conjugated C=C bonds that were formed in these irradiated systems. The formation of these conjugated C=C bonds in these irradiated HDPE and LDPE systems has been confirmed from their FTIR analysis in which the C=C bonds of *trans*-vinylene and *end*-vinyl were detected at 965 cm^{-1} and 888 cm^{-1} respectively. However, it was found that irradiated HDPE system exhibited higher concentration of conjugated bonds than LDPE due to the closer chain arrangement in the HDPE system that in turn enhance the electrons delocalization along the HDPE chain hence giving lower band gap energy of 2.75 eV compared to LDPE which was 3.97 eV. Interestingly, it was found that the band gap of irradiated HDPE was lower than the polyphenylene [4] and silicon carbide [5] semiconductor.



(a) (b)

Figure 1: FESEM micrographs for (a) HDPE and (b) LDPE sheets at 600 kGy of irradiation dose.

4.0 Conclusions

A p-type irradiated HDPE and LDPE semiconductor with band gap energy of 2.75 eV and 3.97 eV respectively can be obtained by Electron Beam irradiation

5.0 Acknowlegements

This study was funded by Fundamental Research Grant Scheme awarded by the Ministry of higher Education Malaysia.

Introduction

Thermal conductivity is a crucial material property in novel plastic based products with embedded electronics containing dissipative components. Another application example is present small housing for transformers and battery chargers. Typically construction of these products doesn't include heat sinks. The dominating route for heat transport out from the product is radiation; usually forced convection is not applied. Although minimization of energy consumption in these small systems is an unconditional necessity local hot spots may be harmful and/or cause material degradation and structural defects. High temperatures are uncomfortable for skin contact and long term high local thermal expansion cause effects like delamination, etc. Today there exist commercial compounds with conductivity 5 - 10 W/Km, and many of them are electrically conductive. Such needs of mass production as low cost, excellent processability, high impact properties, etc, set needs of new heat conductive plastic compounds.

A lot of tomorrow's products with embedded electronics are based on injection molding technology, and a potential method to manufacture these smart products is in-mould labeling method where electronics is transferred by films containing this functionality. Both technologies, films and injection molding, require excellent processing properties of plastics.

Heat conductivity in composites is a complicated issue. Novel nanofillers are promising candidates to create high conductive materials, for example heat conductivity of CNT may be 3 - 6 kW/Km when the typical value of neat polymer is about 0.2 W/Km. Phonons plays the major role in heat transfer in plastics, but in some cases contribution of radiation may be essential. The crucial issue in heat conductive compounds is energy transfer over filler-matrix interface.

Modern numerical tools allow us to simulate heat transfer in realistic applications. These methods give us a strong support to study new constructions and material properties.

Simulation

According our simulation of some constructions in plastic embedded electronics with dissipative elements, careful constructions may allow using materials with quite low heat conductivity, typically 1 - 2 W/Km may allow to avoid undesired high temperatures in hot spots. Increased heat conductivity expands the area with higher temperature, but the maximum temperatures fall down to such values which are less harmful, i.e values with "comfortable" skin contact and without risk of chemical degradation of plastic material.

These results give a motivation to develop compounds characterized with good processability and mechanical properties, with moderate heat conductivity and with reasonable price.

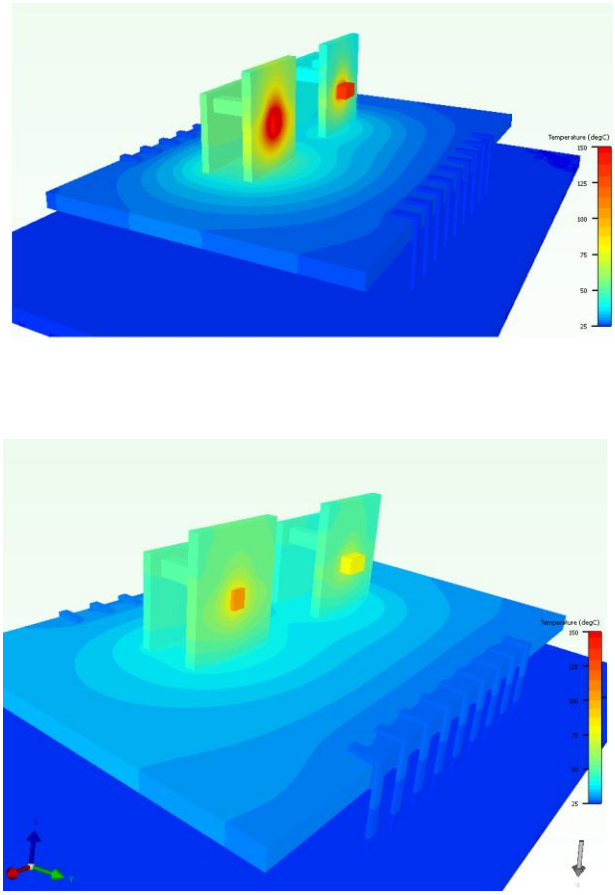

Figure: Simulation examples of an optoelectronic component with two hot spots. The thermal conductivities of materials are 0.27 W/Km (above) and 2 W/Km (below).

Experimental work

Polypropylene is used as a matrix material for composites. Different type of carbon base and mineral fillers in micro and nano scale were used.

Conclusions

To construct (non-conductive) plastic compounds with moderate thermal conductivity (1 - 2 W/Km) is a challenging topic. The requirement of good mechanical properties limits filler loadings, especially cases were fillers have strong reinforcing effects, a good example is CNT. Many mineral particles allow high loading levels. A route toward desired goal is hybrid systems with (at least) two different types of fillers.

Modification of Polysulfones by Click Chemistry: Amphiphilic Graft Copolymers and Their Protein Adsorption and Cell Adhesion Properties[1]

Lokman Torun,[1] Gorkem Yilmaz,[2] Hojjat Toiserkani,[2] Dilek Odaci Demirkol,[3] Serhan Sakarya,[4] Suna timur,[3] Yusuf Yagci[2]

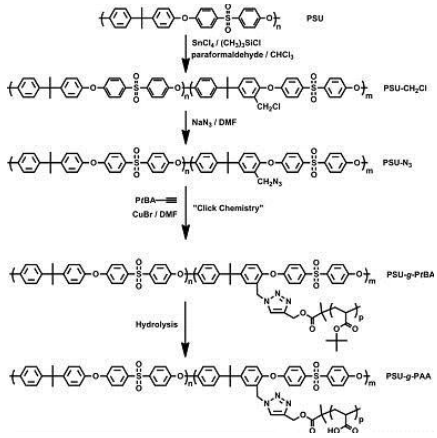
Lokman.torun@mam.gov.tr

As part of our continuous interest in developing synthetic methods for the preparation and modification of various macromolecular structures, we present modification of polysulfunes (PSUs) by modular approach to yield amphiphilic graft copolymers. For this purpose, PSU was first chloromethylated using paraformaldehyde in the presence of $SnCl_4$ and $(CH_3)_3SiCl$. Subsequent azidation in the usual manner produced PSUs with side chain azide functions. Parallel to this, α-alkynefunctionalized poly(tert-butylacrylate) (alkyne-PtBA) was synthesized by ATRP. Then, alkyne-PtBA was successfully clicked to the PSU main chain. At the final stage, the ester groups were hydrolyzed in the acidic media to give polyacrylic polyacrylic acid-grafted polysulfone (PSU-g-PAA) (Scheme 1). The final structure was confirmed by H NMR, IR, UV-Vis and GPC.



Scheme 1.

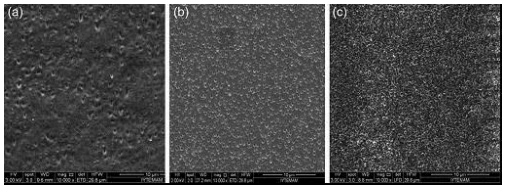


Figure 1 SEM images of PSU (a), PSU-g-PtBA (b) and PSU-g-PAA (c) membranes (magnification is10,000).

Protein adsorption experiments were carried out on the membranes with BSA. When the membranes were treated with 0.5 mg BSA, relative protein amounts on PSU, PSU-g-PtBA, and PSU-g-PAA were found to be as 41, 46, and 30%, respectively. As correlated with the contact angle measurements, the highest adsorption amount was observed for the most hydrophobic PSU-g-PtBA. After 24 h incubation, microscopic images of Caco-2 cells (as the model of eukaryotic cells) adhered on to the PSU (b) and PSU-g-PtBA (c), and PSU-g-PAA (d) membrane covered on the tissue culture plates (Figure 2). Prokaryotic cell adherence to the membranes was investigated by using both S. aureus and E. coli. Aureus cells were counted to be adhered than E. coli cells. The grafting of hydrophilic PAA on the PSU intensively decreases the adhesion of S. aureus cells. Hence, almost twofold reduction in the cell amount on the PSU-g-PAA surface was observed /Figure 3).

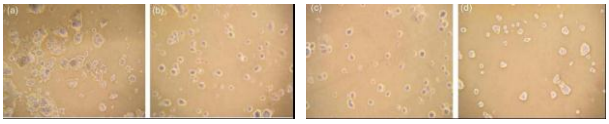

Figure 2. Microscopic images of Caco-2 cells adhered on the tissue plate for negative control (a), PSU (b), PSU-g-PtBA (c), and PSU-g-PAA (d) membranes

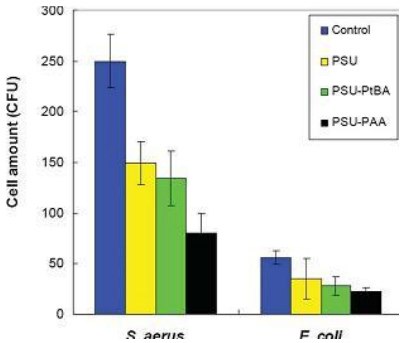

Figure 3. Amount of adhered bacteria on the PSU membranes.

In conclusion, this work demonstrated that click chemistry can efficiently be used for the synthesis of amphiphilic graft copolymers of PSUs. The strategy of combining controlled living polymerization and click chemistry methods provides fair control on the hydrophilic characteristics to be introduced to the PSU precursor. The obtained polyacrylic acidgrafted PSU displayed increased hydrophillicity characteristics, which reduced their protein fouling and cell adhesion properties with respect to the unmodified PSU precursor.

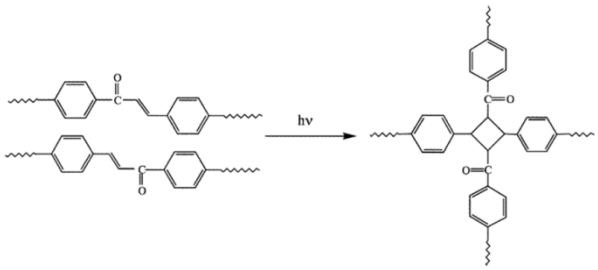
UV curable coatings have gained more and more attention and are expected to substitute the conventional solvent-based coatings, because of their superior properties and processing advantages such as excellent chemical resistance, solvent-free technology, ultrafast polymerization, and good weathering characteristics.[1] Among the oligomers used for UV-curable coatings, polyurethane acrylate (PUA) oligomers have gained more and more attention and speedy development due to a wide range of excellent application properties, such as high impact and tensile strength, abrasion resistance and toughness combined with excellent resistance to chemicals and solvents.[2]

Photosensitive polymers with photocrosslinkable groups are used in a wide variety of applications in the field of macro- and microlithography, printing, liquid crystalline display, nonlinear optical materials , holographic head-up-display, integrated circuit technology, photocurable coatings, photoconductors, energy exchange materials, etc. Among the various photocrosslinkable groups, chalcone group containing α,β-unsaturated carbonyl unit has attracted particular attention due to its excellent photoreactivity at UV absorption wavelength.[3]



In this work, novel UV curable chalcone modified urethane acrylates (UA-C) containing isophorone diisocyanate and polyethyleneglycol segments were synthesized and employed in UV curable formulations. Crosslinking behaviour and film properties were investigated.

Introduction: Heavy metal ions contamination causes a serious environmental problem because of their increased discharge, toxic nature and other adverse effects on receiving waters [1]. The presence of Cu (II) ions in water is also a problem. Excessive intake of copper results in an accumulation in the liver [2-3] and become toxic to humans, causing cancer etc [4]. Therefore, there is a need to develop technologies that can remove excessive copper ions found in water [5]. The conventional methods for the removal of dyes and heavy metals from wastewater include coagulation and flocculation, oxidation or ozonation, membrane separation, and adsorption [6]. Among all the treatments proposed, adsorption is one of the more popular methods for the removal of pollutants. This process is preferred because of treating industrial effluents and it is a useful tool for protecting the environment [7]. The adsorbents may be of mineral, organic or biological origin. Activated carbons [8, 9], zeolites [10, 11], clays [12, 13], silica beads [14], biomass [15] and polymeric materials [16] are significant examples.Recently, the use of natural polymers such as cellulose, starch, chitosan, alginate has received great attention due to their biodegradability [17]. Chitosan is non-toxic, hydrophilic, biocompatible, biodegradable and anti-bacterial, which has led to various applications in different industries [18]. Chitosan is a β-(1,4)-linked polysaccharide of Dglucosamine derived from chitin, and it is a major component of the shells of crustacean organisms [19]. It is possible to significantly improve adsorption properties of chitosan by physical or chemical modification. Chemical modifications may include: chemical cross-linking (to increase polymer stability in acidic solutions), or grafting of new functional groups (to increase the adsorption sites) [20].

In this study, we studied the preparation of itaconic acid and crotonic acid grafted crosslinked-chitosan beads and their potential use as an adsorbent for removal of Cu(II) ions from aqueous solutions.

Materials and Methods: Chitosan-*g*-poly(itaconic acid) (Ch-g-IA) crosslinked beads and chitosan-*g*poly(crotonic acid) (Ch-g-CA) crosslinked beads were synthesized in two sequential steps. In the first step, chitosan beads were prepared by phase-inversion technique and then were crosslinked with epichlorohydrin under alkaline condition. In the second step, the graft copolymerization of itaconic acid or crotonic acid onto the chitosan beads was initiated by ammonium persulfate (APS) under nitrogen atmosphere.

Results and Discussion: Grafted chitosan beads were characterized by FT-IR analysis and grafting percentage determination. Grafting percentages values of Ch-g-IA and Ch-g-CA beads were determined as 18 % and 9 %, respectively. Then, their adsorption capacities were investigated in case of their usage in removal of Cu (II) from aqueous solutions. Adsorption capacities were determined as 0.25 and 0.3 mmol of Cu(II) per gram of croslinked chitosan beads for Ch-g-CA and Ch-g-IA, respectively. In addition, Cu (II) ions adsorbed on Chg- IA and Ch-g-CA crosslinked beads were regenerated effectively by 1 M HNO3 solution. The adsorption capacity of the recycled beads can still be maintained acceptable level at the 5th cycle. Grafted chitosan beads can be effective adsorbents for removal of Cu(II) ions from aqueous solution.

Conclusions: Grafted chitosan beads can be effective adsorbents for removal of Cu(II) ions from aqueous solution.

Keywords: Chitosan bead; Itaconic acid; Crotonic acid; Adsorption; Copper

Effect of Glass Fiber and Glass Beads Content on Mechanical and Tribological Properties of Polyamide-6

A Mimaroglu, MSc, PhD and H. Unal, Msc, PhD

mimarog@sakarya.edu.tr, unal@sakarya.edu.tr

In this experimental study, two mineral fillers were selected on the basis of their shape and size which was spherical glass beads and fibrous glass fiber fillers. These fillers are added to polyamide-6 to produce composite materials with improved mechanical properties at lower production cost. Composites of polyamide-6 reinforced with glass beads and glass fibers were prepared in a twin-screw extruder, followed by injection moulding. The tensile, Izod, flexural and tribological properties of the injection moulded composites were investigated. Tensile measurements showed that the tensile strength and modulus of the composites increased with increasing filler content. The impact strength and elongation at break decreases with the increase in filler ratio. The results of single components were as aspected. The best mechanical properties were attained by the simultaneous use of two fillers. In addition, the content of glass beads partial replacement of glass fiber with glass beads resulted in reduced coefficient of friction and wearing rate of the materials.

The Influence of Nature of Nickel Complexes and Halide-Containing Initiators on the Polymerization of Vinyl Monomers

Natalya Valetova, Galina Malysheva, Ilya Ilitchev, and Dmitry Grishin

Research Institute of Chemistry, Lobachevsky State University of Nizhny Novgorod
Gagarin Ave. 23/5, Nizhny Novgorod, 603950, Russia

e-mail: nata-bor-2005@mail.ru

Introduction. Application of metal complexes for regulation of elementary stages of polymerization is one of the most developing area in synthetic chemistry of polymers.

Materials and Methods. $NiBr_2(PPh_3)_2$ was prepared according to literature [1] from $NiBr_2*3H_2O$ and triphenylphosphine in butanol-1 while 2,2'-bipy$NiBr_2$ was synthesized by mixing of the THF solutions of $NiBr_2$ and 2,2'-bipy at 50^0C [2]. Zinc dust activation was carried out by Clemmensen method [3]. The reaction was as follows: zinc dust, a nickel complex, a halide initiator and a monomer were charged into an ampoule with a magnetic stirring bar. The mixture was heated at 65^0C for 5h, after that the ampoule was opened and the mixture was poured into excess hexane.

Results and Discussion. The catalytic systems based on bis(triphenylphosphine)- or (1,2-diphenylphosphinoethane) nickel dibromide and iodobenzene with zinc dust were reported [4-6] to initiate polymerization of styrene and methyl methacrylate (MMA). Developing this area and searching new effective chain regulators, we study the activity of the catalytic system $NiBr_2(PPh_3)_2$/Zn/PhI in the polymerization of butyl acrylate (BA) and butyl methacrylate (BMA) as well as in the copolymerization of BMA with styrene. In addition, the influence of ligand structure in the nickel complex and that of organic halide initiators was estimated in MMA polymerization. It was established that polymerization of BMA in the presence of the $NiBr_2(PPh_3)_2$/Zn/C_6H_5I catalytic system results in the polymer with the yield about 80%. On the contrary to conventional radical polymerization, BMA reacts more actively than BA in this case. The study of dependence of styrene-BMA copolymer composition on the content of monomer mixture indicates that this catalytic system exerts no influence both the copolymer composition and the relative ratio of monomers r_{st}=0.68 and r_{BMA}=0.31. In the case of conventional radical copolymerization of BMA and styrene in the presence of AIBN the relative ratios of monomers are r_{st}=0.67 и r_{BMA}=0.34.

It was found that the presence of strong electronoaccepting groups in *para*-position of aromatic initiator – bromobenzene in the polymerization of MMA catalysed by $NiBr_2(PPh_3)_2$/Zn results in considerable growth in the yield of polymers compared with reaction in the presence of bromobenzene itself or other arylbromides containing electronodonating groups in the aromatic ring when the yield of polymers does not exceed 9 % in 5 h. For instance, PMMA was prepared with *para*-bromobenzonitrile or *para*-bromoacetophenone in the yield of 99 and 51 % in 17 and 36.5 h, respectively. MMA polymerization proceeded with phenyl iodine reaches 83 % polymer yield in 7 h [5]. The structure of initiators exerts a considerable influence of the yield of polymers: it grows in the row PhI<$(CH_3)_2C(Br)C(O)OC_2H_5$<$C_6H_5CH_2Cl$<$CHCl_3$. The structure of ligands attached to nickel atom is also crucial for the reaction. It was found that the use of 2,2'-bipy$NiBr_2$ catalyst results in higher yield of polymer than that of 4,4'-bipy$NiBr_2$ but lower yield than $NiBr_2(PPh_3)_2$.

Conversion smoothly grows with time of reaction in the polymerization of BMA and MMA catalyzed by $NiBr_2(PPh_3)_2$ and 2,2'-bipy$NiBr_2$, respectively. The number-average molecular weight of polymers also gradually increases with conversion. The MWD curves shift towards high molecular weight region. These features are characteristic of «living» radical polymerization.

Conclusions. The structure of both organic halide acting as initiator and the nickel complex influences the yield and molecular weight parameters of the polymers obtained. The most active nickel complex involving in the catalytic system was found to be $NiBr_2(PPh_3)_2$. P-bromobenzonitrile as aryl bromide shows the most initiating activity in MMA polymerization while the most active alkyl halide under similar conditions was found to be $CHCl_3$. The polymerization of vinyl monomers catalyzed by the system derived from these compounds proceeds via the controlled regime up to yield of 99%.

First Linear-Soluble Poly (*p*-phenylenemethylene) via Boron Ester of Benzyl Alcohol

Deniz Gunes, Yusuf Yagci, Niyazi Bicak

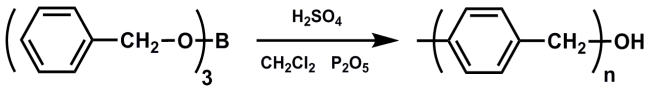
Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

denizsun@gmail.com

Introduction: Poly(phenylene alkylene)s consisting of alkyl bridged phenyl rings are chemically inert and heat resistant polymers with low dielectric constant, high solvent resistance and good barrier properties.[1] Among those, poly (*p*-xylene) has found great interest as coating material. Structurally similar polymer, poly(*p*-phenylenemethylene) (PPM) has also found attention since the first report of Friedel and Crafts on the reaction of benzyl chloride with aluminum chloride in 1885.[2] Various Friedel-Crafts catalysts have been studied for polymerization of a wide variety of benzyl derivatives including benzyl halides, benzyl alcohol and benzyl ethers. However, all those attempts were failed in preparing soluble and linear PPM due to side reactions via *ortho* position of the phenyl ring.

Herein, we present the first report for the synthesis of entirely soluble PPM starting from boron ester of benzyl alcohol (tribenzylborate) (TBB) by an acid-catalyzed polymerization.

Result and Discussion: The structure of the polymer was confirmed by both ^{1}H and ^{13}C NMR analysis. The ^{1}H NMR spectrum of the isolated polymer represents a quite simple pattern in which intense singlets appearing at 7.1 and 3.8 ppm associated with aromatic and methylene protons respectively were noted. The ^{13}C NMR spectrum of the polymer shows aromatic carbon signals around 128 ppm and aliphatic carbon signal at 39-41 ppm, whereas the signal of the methylol carbon at the chain end is invisible. Another weak signal centered at 138 ppm must be due to aromatic quaternary carbons of the phenyl rings.



Notably, TGA analysis revealed reasonably high decomposition temperature (540 °C). It is important to note that TGA curve represents a single and sharp decomposition, suggesting one type of connection between the repeating units in the polymer. In view of the simplicity of the TGA pattern, the multiple peaks in the ^{13}C NMR spectrum of the polymer can hardly be ascribed to ortho and para isomerism.

DSC traces of the polymers showed no glassy transition within the 0-300°C temperature range. This must be due to absence of side chains in the polymer structure.

Interestingly, the XRD patterns of the polymers disclosed a completely amorphous structure.

The dielectric spectrum of the polymer presented in shows that, ε^{0} (real part of the dielectric constant) is extremely small (1.8 to 1.9) in the 10 kHz to 13 MHz range and almost independent of frequency, indicating the absence of polar or ionic groups in the polymer structure.

It is important to note that THF solutions of the light-yellow polymers exhibit green-yellow fluorescence, which is visually observable. A broad fluorescence emission band with a maximum at 422 nm is observed by excitation at 370 nm of wavelength. The broad and intense absorption band in the 320-410 nm range is associated with benzenoid transition of the polymer and implies reasonable UV filtering effect of the polymer.

Conclusion: Acid-catalyzed reaction of TBB at room temperature results in the formation of poly(1,4-phenylene methylene) with the molecular weight in the range of Mn = 1000-8600 Da.[4] The polymerization proceeds via carbocationic mechanism, with first-order kinetics with respect to TBB and 0.7th order with respect to proton concentration. The resulting amorphous polymers that consist of the ^{1}HNMR and ^{13}CNMR spectral analysis evidencing 1,4-phenylene methylene repeating units show high thermal stability (polymer degradation temperature: 540 °C) and very low dielectric constant ($\varepsilon^{'}$ = 1.8 to 1.9), as in the case for poly(para-xylene) and related poly(phenylene alkylene)s.

Block-Brush Copolymers via Romp and Sequential Double Click Reaction Strategy

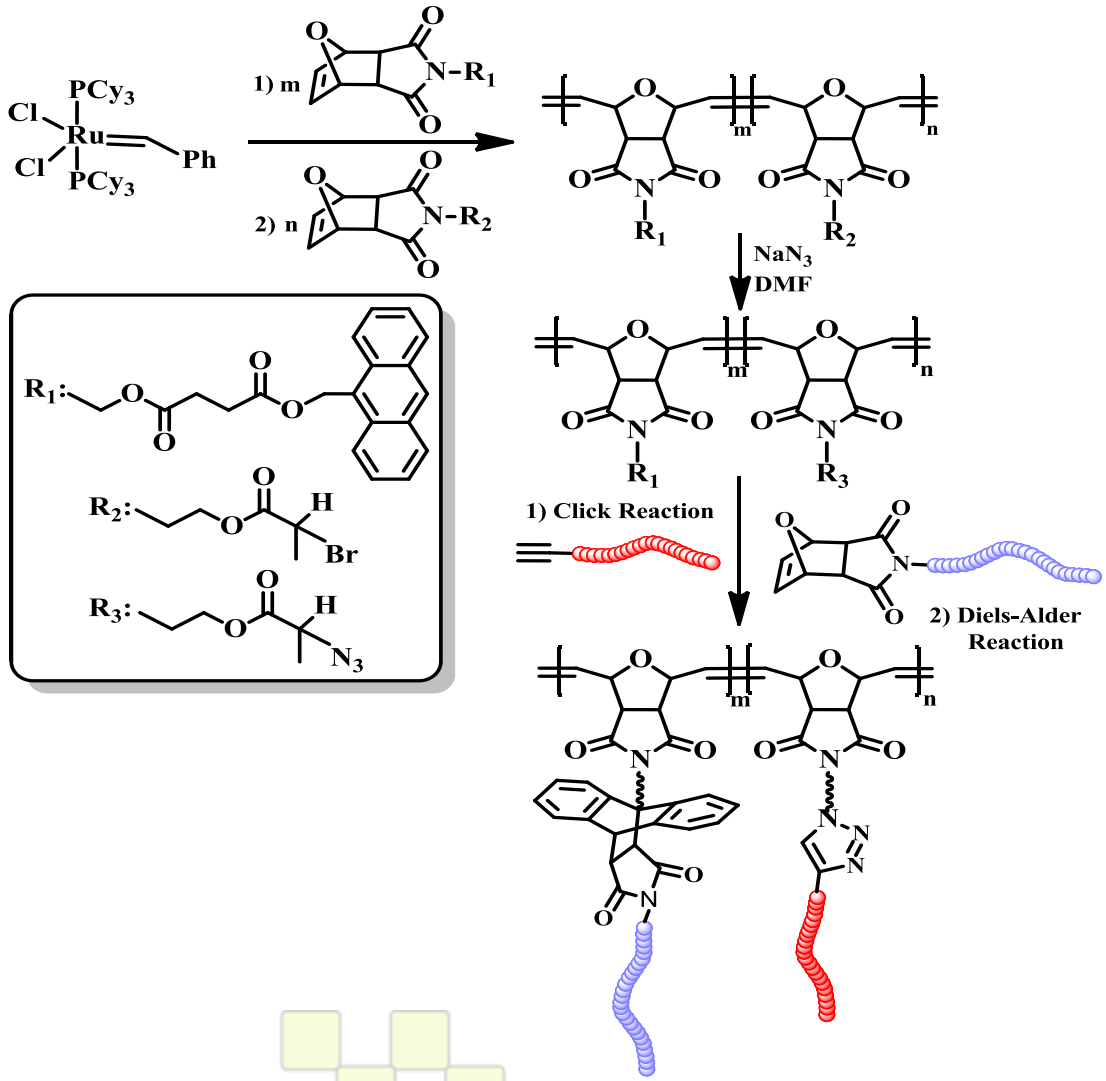
Hatice Sahin, Aydan Dag, Hakan Durmaz, Gurkan Hizal, Umit Tunca

Istanbul Technical University

haticesahin85@hotmail.com

Abstract

We report an efficient way, sequential double click reactions, for the preparation of brush copolymers with AB block-brush architectures containing polyoxanorbornene (poly(ONB)) backbone and poly(ε-caprolactone) (PCL), poly(methyl methacrylate) (PMMA) or poly(*tert*-butyl acrylate) (P*t*BA) side chains: poly(ONB-*g*-PMMA)-*b*-poly(ONB-*g*-PCL) and poly(ONB-*g*-P*t*BA)-*b*-poly(ONB-*g*-PCL). The living ROMP affords the synthesis of well-defined poly(ONB-anthracene)$_{20}$-*b*-poly(ONB-azide)$_5$ block copolymer with anthryl and azide pendant groups. Subsequently, well-defined linear alkyne end-functionalized PCL (PCL-alkyne), maleimide end-functionalized PMMA (PMMA-MI) and P*t*BA-MI were introduced onto the block copolymer via sequential azide-alkyne and Diels-Alder click reactions, thus yielding block-brush copolymers. The molecular weight of block-brush copolymers was measured via triple detection GPC (TD-GPC) introducing the experimentally calculated dn/dc values to the software



New mixed matrix composite membranes made from polymers able to undergo thermal rearrangement processes. Gas separation study.

laurap@termo.uva.es

Polymer membranes have served as a key element in many useful scientific and technological fields such as water purification, sensors, fuel cells and gas and vapor separation. Gases are among the most important commercial products, and their separation and purification have a high economical and environmental impact. In this regard, there is a growing interest in the development of novel polymeric materials with improved performance to be used as permselective membranes in the separation of gas and vapor mixtures.

Aromatic polyimides (PIs) have been traditionally considered to be efficient separation materials due to their good permeability and high selectivity for gas separation. They offer excellent thermal and mechanical properties, as well as good chemical resistance. Aromatic polymers interconnected with heterocycling rings, such as polybenzoxazoles (PBOs), possess superior thermal and chemical properties due to their rigid-rod structure having high-torsional energy barriers between two individual phenyleneheterocyclic rings. This restricted freedom of movement could lead to large differences in the mobility of penetrants according to their sizes, and, hence, to high gas selectivities.

Unfortunately, it is very difficult to dissolve PBOs in common solvents for membrane preparation. This fabrication challenge makes very difficult to report permeation and separation data for these materials.

To avoid the solubility drawback, Mathias et al. proposed a new and simple synthetic method using thermal conversion in solid state of *o*-hydroxyl-containing polyimides to polybenzoxazoles (PBOs) through a thermal treatment (TR method)[1].

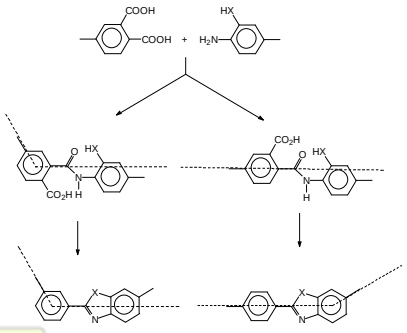

Fig. 1: Thermal transposition from *o*-OH-PI to PBO

Also, it is known that poly(*o*-hydroxyamide)s are able to evolve to PBOs under thermal treatments at temperatures near 350°C[2].

Thus, the thermal rearrangement (TR) method has been recently applied to aromatic polyamides (PAs) and poliimides (PIs) containing *o*-positioned functional groups (e.g. –OH, and –SH), producing materials with impressive permeation and selectivity values[3].

On the other hand, mixed matrix composite, MMC, membranes offer the potential of combining an easy processability and improved gas separation properties for many combination of polymer and particles. In this way, when the composite is well designed, the presence of inorganic or activated carbon particles in a polymer matrix may lead to increments of permeability and also to improvements of permselectivity what permits to exceed the gas productivity trade-off [4,5].

Here, a work dealing with new mixed matrix composite membrane having activated carbon particles and polymer matrix poly(*o*-hydroxyamide)s is presented. These MMCs-PAs have been characterized and their gas separation properties evaluated. Also, the membranes have undergone thermal treatments at temperatures higher than 350 °C, in order to achieve MMC-PBOs. Carbon load and temperature treatment have been optimized in order to achieve the best gas separation properties.

Finally, preliminary results using as polymer matrix poly(o-hydroxyimide)s and other inorganic particles have been accomplished.

Introduction

Unsaturated polyesters produced by polycondensation of saturated and unsaturated dicarboxylic acids with glycols have been introduced firstly by Vorlander in 1984 [1], and developed by Carlton Ellis with addition of liquid monomer such as styrene to unsaturated polyesters [2]. Unsaturated polyester resins are used in composites, sheet production, surface coatings and moulding processes.

Plasticizers are usually used to improve the thermomechanical quality of materials such as reducing the glass transition temperature. It is well known that plasticizer can act as a diluent by reducing the viscosity for polymerization process.

When unsaturated polyesters are cross-linked with a vinylic reactive monomer, such as styrene it is obtained very rigid, thermal and chemical resistant, film forming materials and coatings. Cross-linking process can be carried out via thermal or photoinitiation by using suitable catalyst and initiator pairs. Both of these ways have typical advantages and drawbacks but photocuring process is more preferable than thermalcuring process because of possessing control ability on the curing kinetics. Various parameters such as type of photoinitiator [3], light intensity [4], photoinitiator concentration [5], temperature and monomer functionality affect the kinetic reaction in the course of the photocuring.

Although several researchers have studied the effect of plasticizer type and amount on the polymerization kinetics, the kinetics of their photopolymerization have not been studied widely.

Materials and Methods

In this study, commercially available unsaturated polyester resins were cured with one component Type II initiator, namely 2-Mercaptothioxanthone (TX-SH) and different type and amounts of plasticizers (Dioctyl phthalate and Trioctyl Trimellilate) were added to the formulations and the effect of plasticizers on the curing kinetic of polyester resins were studied by Photo-DSC technique.

The values of curing kinetic parameters such as, the time (t_{max}) to reach the maximum value of the rate of polymerization (Rp_{max}) and final conversion (C_s) presented considerably variations depending on the effects of types and amounts of plasticizer.

Keywords: photopolymerization, curing kinetics, unsaturated polyester resin, plasticizer

Introduction

Nowadays, especially in the developed world, there has been a great interest the use of recycled resources for different industrial applications due to its positive effect on the environment. From a general perspective, there is a marked tendency to increase the use of recycled materials, as a result of government regulations or due to increasing public concern for a pollution-free environment. In general, lubricating greases are highly structured colloidal dispersions, consisting of a thickener dispersed in mineral or synthetic oil. In recent years, increasing attention has been directed towards polymers or biopolymers to development new thickener agents with suitable properties to substitute traditional thickeners [1, 2]. Some thermoplastics polymers exhibit the ability for swelling and gel formation in organic media and therefore they serve as the dispersion medium of greases. The overall objective of this work was to study the influence of plastic waste concentration on the rheological properties and microstructure of polymer based lubricating greases. With this aim, viscous and linear viscoelastic measurements, as well as morphological analysis and differential scanning calorimetry tests, have been performed on the samples.

Experimental

Materials

A naphthenic oil (SR-10) from crude distillation, kindly provided by Verkol Lubricantes (Spain), and waste polymer supplied in pellets by Eslava Plasticos, S.A (Spain) was used as the gelling agent.

Manufacture of lubricating greases

Processing of lubricating greases was performed in an open vessel, by stirring with an IKA RW-20 mixer (Germany) with a four-blade propeller to disperse the gelling agent. Batches of 600 g were processed for 60 min at 170 ºC and rotational speed of 150 rpm. Then, the solution was cooled down to room temperature in order to induce gelification. Cooling was carried placing the solution on steel sheet having the sample a thickness of 3-5 mm. A final homogenization treatment (rotational speed: 4000 rpm; homogenisation time: 5 min), using a rotor-stator turbine (Ultra Turrax T-50, Ika, Staufen, Germany), was applied at room temperature. Waste polymer contents in the blends were 4, 6.5, 9, 11.5 and 14 % (w/w).

Results

Figure 1 shows the mechanical spectra, in the linear viscoelasticity range of polymer based greases as a function of waste polymer concentration. As can be observed, the linear viscoelasticity response is qualitatively similar for all the greases studied and also to that found with other commercial lubricating greases [3].The evolution of the storage and loss moduli with frequency for these lubricating greases (higher values of the storage modulus and a minimum in the loss modulus at intermediate frequencies) is characteristic of polymeric systems with physical entanglements [4]. As can be observed in Figure 1a, a significant increase in both SAOS functions, and a shift of the minimum in G'' to higher frequencies, are noticed when increase waste polymer concentration. The above-mentioned increase in both linear viscoelasticity functions is similar in the low frequency range and, consequently, the relative elastic characteristics of these gel-like dispersions are not significantly affected, as can be observed in Figure 1b where the loss tangent (G''/G') is plotted versus frequency. In this sense, formulations containing high waste polymer concentration show minimum loss tangent values at large frequencies.

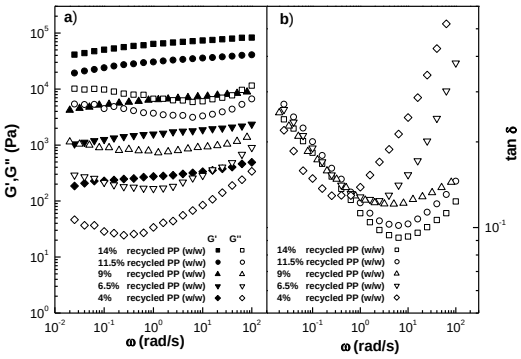

Figure 1. Frequency dependence of the storage and loss moduli (a) and tan δ (b) at 25ºC.

Conclusions

From the result obtained, it can be deduced that this waste polymer can be potentially used as an effective thickener agent for lubricating greases. The evolution of the linear viscoelasticity functions with frequency is qualitatively similar to that found for traditional lithium lubricating grease. It is observed that lubricating greases based on waste plastic show enhanced of viscoelastic modulis with respect to traditional lithium lubricating greases, which may represent an important advantage. In general, the studied formulations in polymer-based greases show lower mechanical stability tendency, mainly at lower plastic waste content, than traditional lubricating greases.

Introduction

Polymer composites with cellulose fibers (with micro or nano size) are developed with the aim of substituting for glass-fiber-containing composites in some important applications like biomedicine, cosmetics, packaging industry, automotive, construction and other industrial fields [1-2]. Nano-scale cellulose fibers production and application in composite materials is a relatively new research field and has gained increasing attention in the past two decades [3-4]. Two directions could be detected: research studies which explore the development of nano-bio-plastics as fully biodegradable nanocomposites and studies aimed at dispersing cellulose nanofibers in non-biodegradable, petroleum derived polymers.

The main goal of this work is to employ different ultrasonic conditions in order to isolate nanofibers from microcrystalline cellulose (MCC) and to evaluate their influence on the thermal behavior of poly(vinyl alcohol) (PVA). PVA was chosen as a matrix because of the expected interaction of its hydroxyl groups with the hydrophilic surfaces of the cellulose nanofibers, leading to strong hydrogen bonding.

Materials and Methods

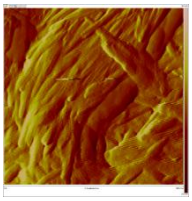
PVA 120-99, 1200 polymerization degree and 99% hydrolysis degree, was used as a matrix. Cellulose nanofibers were obtained from microcrystalline cellulose (MCC) using high power ultrasound technique, different power and time of sonication. Nanofibers isolated by applying different ultrasonication conditions were characterized by atomic force microscopy. AFM images were captured in tapping mode by a MultiMode 8 atomic force microscope equipped with a Nanoscope V converter from Bruker.

The obtained cellulose fibers (NF), 5wt. % were used as reinforcements in a poly(vinyl alcohol) (PVA) matrix. The thermal properties of PVA/NF cellulose fibers nanocomposite films were determined and compared with the thermal behavior of cellulose microfibrils (MF) containing PVA.

Differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) were performed on a SDT Q600 V20.9 from TA Instruments under helium flow (100 mL/min). The samples were dried for 24 h at 40 ^{o}C before characterization and were tested from the ambient temperature to 600 ^{o}C at a heating rate of 10^{o}C/min.

Results and Discussion

Several differences were observed in AFM images regarding the size and the aspect ratio of the nanofibers obtained in different ultrasonic conditions. When increased power and time of ultrasonication were used, the thickness of nanofibers decreased from an average of 50 nm to almost 20 nm. An AFM image (500 nm x 500 nm) of NF cellulose fibers obtained by ultrasonication is shown in the figure below.



No significant changes for glass transition temperature (T_g) and melting point (T_m) of PVA composites with reference to neat PVA were observed in DSC diagrams of PVA/NF composites, only a slight increase in crystallinity was noted. In case of PVA/MF composites a significant decrease of both T_g and cristallinity was revealed by DSC. The stronger interactions between cellulose fiber surface and adjacent PVA chains in case of smaller size fibers and the influence of water were proposed to explain these results. TGA and DSC results pointed out that most of the water present in PVA composites was bound water, with a limited lubrication effect.

Thermogravimetric analysis (TGA) was used to investigate the effect of cellulose fibers on the thermal stability of the composites. Slightly higher onset degradation temperatures were obtained for PVA/NF composites in comparison to neat PVA, showing an increase of the thermal stability caused by the addition of cellulose nanofibers. No changes were detected in case of PVA/MF composites.

Conclusions

Nanofibers with valuable properties can be obtained using the method of ultrasonication. In contrast to common cellulose fibers with micrometer size, cellulose nanofibers can enhance the thermal stability of PVA.

Department of Chemical Engineering, University of Castilla-La Mancha
Avda. Camilo José Cela, s/n, E-13004 Ciudad Real, SPAIN

marialuz.sanchez@uclm.es

Abstract

Textile industry shows a growing interest into the functionalization of textiles for innovative commercial applications. The emerging technologies based on microencapsulation are able to confer new properties and add value to the textiles that were not possible or cost-effective using other processes.

A thermoregulatory fabric is an intelligent textile that has the property of offering suitable response to changes in external conditions or to external and environmental stimuli. The level of thermal wellbeing depends on the heat exchange between the human body and the environment that surrounds it, many efforts have been devoted to induce a thermo-regulating effect into textiles. When the external temperature is higher than the material melting point, it produces a freshness sensation. However, when the external temperature is lower than material melting point it produces a warmness sensation. This behaviour is due to the presence of microcapsules containing phase change materials (PCM).

To apply these PCM microcapsules to fabrics, their thermal activity must work in a range of skin temperature and be harmless to the skin. When the body is at its normal temperature there are certain temperature ranges common to certain parts of the body. The core of the body, or the abdominal area, and the head normally maintain an average skin temperature higher than that associated with other areas of the body. Generally, the overall average comfortable skin temperature is 33.3ºC, and if this cannot be maintained, a person begins to feel uncomfortable.

In this study, polystyrene microcapsules containing phase change materials were synthesized by suspension like polymerization process. Thermal properties, surface morphology and structural stability of the PCM microcapsules were investigated using differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), environmental scanning electron microscopy (ESEM) and infrared thermography (IR) techniques. The intactness of PCM microcapsules can be maintained up to approximately 135ºC according to TGA and DSC analyses. In addition, the fixation of microcapsules into textile substrate by means coating technique was tested. Different coating products, mass ratio of microcapsules to coating binder and different textile substrate were studied in order to get thermal comfort in fabrics. Furthermore, a comparison was made of the thermal insulating effect of the thermo-regulating textiles according to the used textile substrate.

PCM microcapsules were successfully incorporated into the textiles by using TEXPRINT ECOSOFT N10® and WST SUPERMOR® as polymeric binders without modifying the original properties of textile (Figure 1).

Microcapsules were successfully fixed into seven fabric substrates for different textile applications by a coating technique. Results also indicated that the presence of microcapsules containing Rubitherm® RT31 produces a significant thermal insulation effect during a cold to warm transition or vice versa (20-45ºC), as can be seen in Figure 2. Thus, this kind of microcapsules can be used to obtain textiles with comfort-related properties.

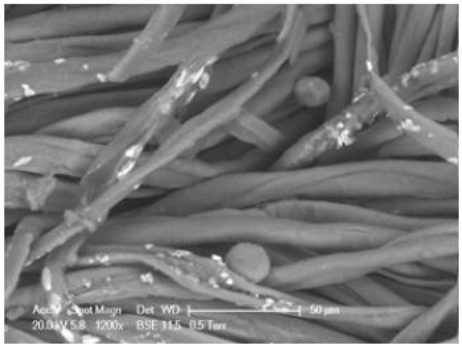

Figure 1. ESEM micrographs of a thermo-regulating textile.

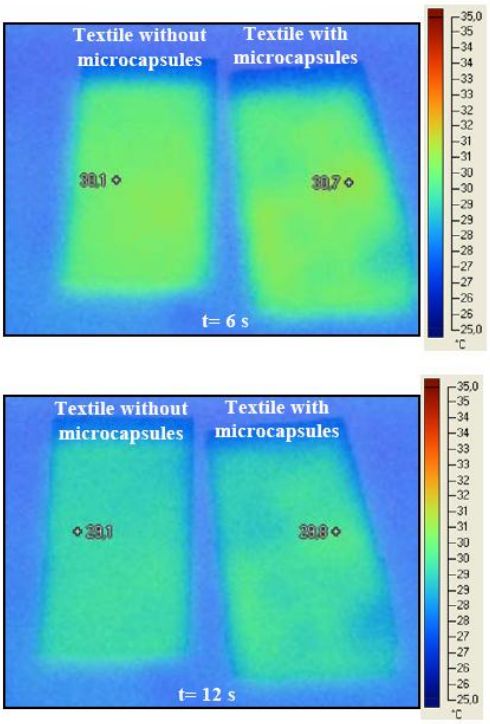

Figure 2. Infrared camera images of coated textile with and without PCM microcapsules at different times.

Removal of crystal violet from aqueous solution by thermosensitive hydrogels: Investigation the effect of hydrophilic comonomer amount

Introduction: Residual synthetic dyes are the major contributors to color in wastewaters generated from textile and dye manufacturing industries [1]. Because of this reason, the removal of color from industrial effluents becomes environmentally important [2]. Synthetic dyes usually have a complex aromatic molecular structure and exhibit considerable structural diversity [3-4], which make them more stable and more difficult to biodegrade [5-7]. The conventional methods for the removal of dyes from wastewater include coagulation and flocculation, oxidation or osonation, membrane separation, and adsorption [8]. Among several chemical and physical methods, adsorption process is one of the most effective methods to remove dyes from wastewater [2]. Many kinds of adsorbents have been developed for various applications [9, 10]. Some low-cost materials have also been directly used as sorbents, such as chitosan, zeolites, clay, fly ash, coal, natural oxides, industrial wastes for dye adsorption [11].

Hydrogels are three-dimensional cross-linked polymeric structures which are able to swell in aqueous environments [12]. Some hydrogels are stimuli sensitive; they exhibit significant changes in their swelling and mechanical properties in response to changes in pH, ionic strength, or temperature of the external environment [13-14]. The best known temperature sensitive polymeric network is poly(N-isopropylacrylamide) [15-16] and has a lower critical solution temperature (LCST) at about 32°C [17]. Therefore, N-isopropylacrylamide monomer takes a wide and important place in synthesis of thermosensitive hydrogels [18-20].

The aim of this work is investigating the usage of p(N-isopropylacrylamide-co-itaconic acid) p(NIPAm-co-IA) temperature sensitive hydrogels for removal of cationic dye (crystal violet) from aqueous solutions. For this purpose, N-isopropylacrylamide was copolymerized with various amounts of sodium salt of itaconic acid in the presence of crosslinking agent N,N methylenebisacrylamide to obtain temperature sensitive hydrogels. The chemical structure, swelling and deswelling properties of these hydrogels were investigated. In addition, their adsorption properties (ie. adsorption capacities, kinetics, isotherms) were investigated in case of their usage in removal of crystal violet (CV) solution.

Materials and Methods: Monomers (NIPAAm and IA (10% wt.)) and the crosslinking agent (NMBA) (1% molar ratio of the total mixture) were dissolved in deionized water in glass tubes. The required amounts of PPS and PBS were added. The solution was purged with nitrogen gas for 30 min. to eliminate dissolved oxygen in the system. The polymerization reactions were carried out for 24 h at 10°C. At the end of the polymerization, the hydrogels were washed 1 L fresh water four times to remove any unreacted monomers and initiators. Then the hydrogels were dried under vacuum at 50°C during 24 hours for using dye adsorption experiments.

Dye adsorption experiments were carried out in 100 mL beaker flasks containing 50 mL of synthetic dye solution at room temperature. Hydrogel (0.05 g) was added to the CV solution (500 mg/L) for the determination of adsorption capacity. After desire treatment period (1., 3., 5., 7., 24., 48. and 96. hours) the residual dye concentration in the solution was determined colorimetrically with a spectrometer by the measurement of absorbance at the maximum absorption wavelength (590 nm for CV). All of the experiments were done at their natural pH value of dye solutions and were carried out in triplicate. The adsorption capacities (mg dye/g hydrogel) of hydrogels were calculated using the following equation:

$$q_e = (C_o - C_e)V/m$$

where q_e (mg/g) is the adsorbed amount of dye per gram hydrogel, C_o and C_e are the initial solution concentration (mg/L) and equilibrium concentration (mg/L), respectively; V is the volume of the solution; and m is the amount of the hydrogel used (g).

Results and Discussion: According to adsorbed dye amounts, the adsorption capacities of hydrogels, having different hydrophilic comonomer amount, were found in the range of 75 - 100 mg dye/g hydrogel. In addition, the results indicated that the pseudo-second-order kinetic model fitted better than the data obtained from pseudo-first-order model for the adsorption of CV on to hydrogels. Furthermore, according to effect of the initial dye concentration findings, it is concluded that, Freundlich isotherm explains the adsorption better than Langmuir isotherm.

Conclusions: The results showed that the synthesized hydrogel can be used as an adsorbent for important applications for removal of cationic dyes from wastewater.

Introduction

The development of polymeric materials of medical use to posses prolonged and adjustable therapeutic effect is an actual and perspective direction in modern Macromolecular Chemistry. Natural polysaccharides and their derivatives, in particular the products of etherification of polysaccharides by phosphoric acid are of considerable interest among polymer mediums. Dextran phosphates are known to be referred to low-toxic substances that possess immunomodulatory activity, biodegradability and can be obtained in the form of stable viscous solutions and hydrogels [1,2]. In this work the samples of water-soluble dextran phosphates using melt H_3PO_4: $(NH_2)_2CO$ were obtained and the influence of the etherification reaction conditions on the functional composition and yield of the zol-fraction was studied.

Materials and Methods

The parent polymer was dextran with molecular weight $6 \cdot 10^4$ Da. Phosphorylation reaction of dextran was carried out in the melt H_3PO_4: $(NH_2)_2CO$ in the temperature range 100 - 135°C [3].The regularities of the etherification reaction of dextran, depending on composition of the mix, temperature and pressure of the reaction zone (0,15-1,0 bar) were studied. Chemical composition and physical and chemical properties of the reaction products were evaluated by IR spectroscopy, ^{31}P-nuclear magnetic resonance (NMR), Scanning Electron Microscopy, elemental analysis, viscometry, High-performance liquid chromatography and potentiometric titration.

Results and Discussion

Materials with the degree of substitution by phosphate (DS_P) and carbamate groups (DS_N) 0,27-0,69 and 0,13-0,48 respectively and zol-fraction of 23,5-100 % yield were obtained. The dextran phosphates were established to be mono-and dibasic mono-and diphosphates, which percentage depends on the system conditions.

It was shown, that increasing the quantity of phosphorous acid leads to the increase in DS_P and the decrease in the zol-fraction due to the formation of additional crosslinks in the structure of the modified polysaccharide. The decrease in urea content increases the yield of the zol-fraction of dextran phosphates, since with the decreasing of pH of the mixture the degree of degradation of macromolecules increases, as well as the formation of monobased phosphates is predominant. With the growth of the reaction temperature the medium molecular weight of the reaction products significantly increased and their solubility was sharply reduced. The yield of zol-fraction was established to decrease as the pressure of the system reduced.

SEM data showed structural changes of polysaccharide in consequence of the modification. Granules of dextran phosphates was shown to be broken into unhomogeneous pieces with loose and porous structure.

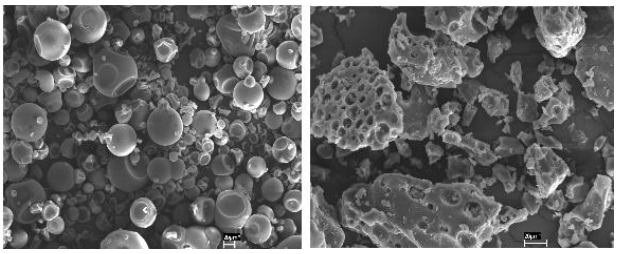

Figure 1 Electronic microphotos of initial (I) and modified dextrans (II) with DS_P = 0,67, DS_N = 0,20.

Conclusion

Thus, during the research optimum conditions for the obtaining of the stable viscous solutions of dextran phosphates, having large exchange capacity that allows to use them as polymers- mediums for drugs have been defined. The possibility of application of phosphate-dextran as a medium of anticancer drug, in particular, α-2b-interferon was established.

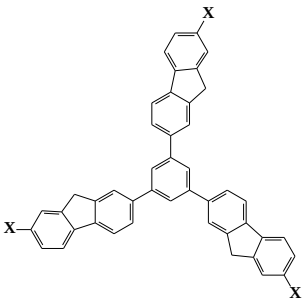
New Branched oligophenylenefluorenes for luminescent applications

Irina A. Khotina, Alexey I. Kovalev, Alexey V.Shapovalov, Natalia S. Kushakova

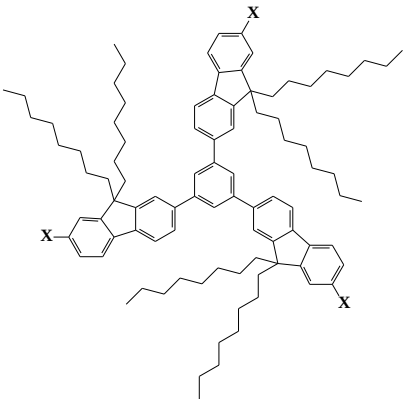
A. N. Nesmeyanov Institute of Organoelement Compounds RAS

khotina@ineis.ac.ru

Fluorenylene dendrimers - 1,3,5-tri (2-fluorenyl) benzene and 1,3,5-tri [2 - (9,9-dioctylfluorenyl)] benzene, which are model compounds for the branched oligophenylenefluorenes, synthesized by the cyclocondensation of unsubstituted and dioctylsubstituted acetylfluorenes respectively.



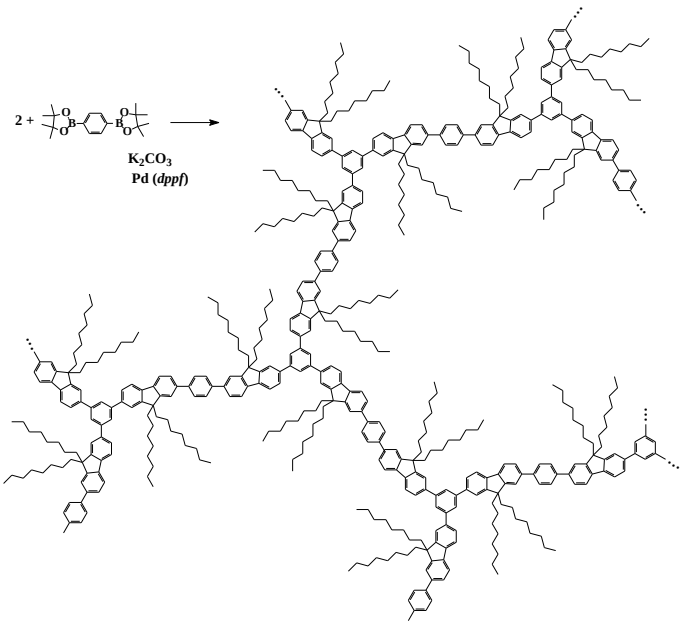
1

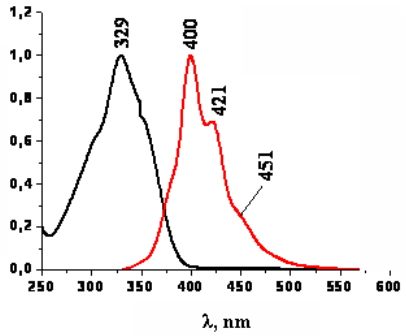


2

X = H, Br

Joint polycondensation of phenyl-bis-pinacoldiborate with tribromoarylenes in the presence of Pd complex in Suzuki reaction “A3 + B2” type led to the synthesis of branched oligophenylenefluorenes. The absorption and fluorescence spectra of model compounds and oligophenylenefluorenes recorded in solutions and interpreted. It was shown that the synthesized branched oligomers did not have the aggregation of fragments, which distinguishes them from known linear fluorescent polymers.





Comparative analysis of the fluorescence spectra of model compounds and oligofluorenes shows that the latter are more structural. A bathochromic shift of the main fluorescence bands at 25 nm and 35 nm and an increase in Stokes shift also observed. This, despite the great length of phenylene chains in the oligomer molecules, in comparison with similar chains in model compounds, may be associated with a decrease in the effective length of conjugation, the violation of planarity, such as occurs in hexaphenyl compared with terphenyl.

Synthesis, Morphological Characterization and Antimicrobial Application of Nanostructured Membranes of Cellulose Acetate

Introduction

The electrospinning process is very attractive due to its low cost methodology and easily adaptable to industrial scale production of nanofibers, especially biomaterials, in a simple and repetitive method[1]. Cellulose acetate (CA) is an amorphous, nontoxic and odorless polymer most commercialized currently and soluble in various solvents[2]. The development of anti-septic[3], biocompatible and nanostructured membranes of CA, by electrospun method, with the incorporation of silver nanoparticles is an interesting option. This new materials are very promising in the helth area, because of its low cost compared to options available today.

Materials and Methods

The AgNPs were synthesized in a aqueous media by chemical reduction of $AgNO_3$ using $NaBH_4$ as reducing agent and sodium citrate as stabilizer. The nanometric dimension of the silver particles was monitored by UV–vis and confirmed through Transmission Electron Microscopy (TEM). Cellulose acetate (CA) membranes nanostructured, with AgNPs, were successfully prepared via electrospinning of CA in DMAc/Acetone/Water (32%/63%/5%) solvent mixture, and characterized using FEG and SEM microscopy. The antimicrobial action of the CA film impregnated with AgNPs was evaluated by the use of both *Gram* positive microorganisms, *Staphylococcus aureus* (*S. aureus*) ATCC 29213 and *Staphylococcus epidermides* (*S. epidermides*) ATCC 12228.

Results and Discussion

The Figure 1 shows the UV-vis spectrum of Ag nanoparticles sinthesized in aqueous medium.

The Figure 2a shows the images of SEM and 2b of FEG, for cellulose acetate nanoestructured membranes with Ag nanoparticles.

Microbiological analysis confirmed the antimicrobial activity of the films by the inhibition of bacterial growth for *S.epidermides* and for *S. aureus*.

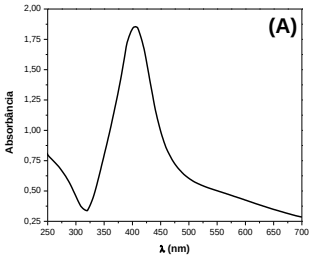

Figure 1- UV-vis spectrum to Ag nanoparticles sinthesized in aqueous medium

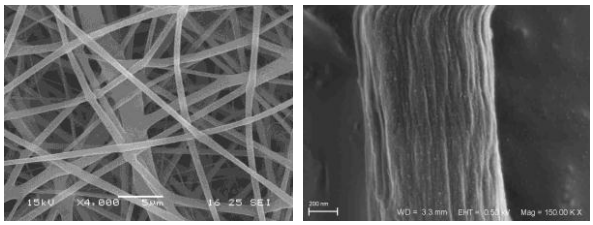

(a) (b)

Figure 2 – Images for cellulose acetate nanoestructured membranes with Ag nanoparticles, from:
(a)SEM (b) FEG

Conclusions

The silver nanoparticles impregnated in the cellulose acetate nanoestructures membranes, confer anti septic properties to this new material.

Introduction

World have to find out new solutions to facing problems such as depletion of fossil fuel reserves, global warming and pollution of our planet. An alternative energy resource must overcome these problems and it must be renewable, economical and convenient for many applications.Proton Exchange Membrane Fuel Cell (PEMFC) is very promising new energy resource for humankind. PEMFCs have important advantages such as high energy conversion, environment friendly, low emission values in contrast to conventional fossil energy resources. Polymeric Proton Exchange Membranes are most important components of Fuel Cells. These membranes account for proton transfer and separation anod and cathode. Perfluorinated ionomers as Proton Exchange Membrane have been used for long times in Fuel Cells, recently new alternative structures have appeared in this area. Especially high performance polymers have outshined the other alternatives because of their resistance to application conditions and easily modification ability for membrane form. Sulfonated and/or phosphonated high performance polymers such as polysulfones, polyetherketones, polyimides, polyphenylenes have taken place in membrane applications.

Polysulfones (PSU) can dissolve many solvents and have high glass transition temperature, high thermal stability, good mechanical properties, and excellent resistance to hydrolysis and oxidation. Their outstanding properties have resulted several important advantages in Proton Exchange Membrane researches.

Polydimethylsiloxane (PDMS) has extremely low T_g (-125 °C) so PDMS is most flexible chain molecules known. PDMS has not only high thermal and chemical stability but also poor mechanical properties and high gas permeability.

Copolymerization of flexible, durable and mechanically poor PDMS blocks with relatively brittle, durable and mechanically good PSU blocks can improve drawbacks of each blocks.

Sythesis and properties of PSU-PDMS multiblock copolymers have been reported by many researches [1-5]. These multiblock copolymers exhibit multi-phase separation and high thermal and hidrolitic stability. Altough PSU-PDMS multiblock copolymers are suitable for Fuel Cell conditions (thermal and chemical stability etc.), they were not examined in this purpose by researchers.

Materials and Methods

In this study, firstly it is synthesized α,ω-difunctional telechelic polysulfone oligomers using 4,4'-dichlorodiphenyl sulfone (DCDPS) and different dihydroxyl compounds.

Commercially available α,ω-difunctional telechelic polydimethylsiloxane oligomers containing different functional end groups with different molecular weight were copolymerized with α,ω-difunctional telechelic polysulfone oligomers.

Multiblock PSU-PDMS copolymers were modified via electrofilic substation way in mild sulfonation reactions in order to obtain Proton Exchange Membranes.

Obtained Proton Exchange Membranes were characterized by ATR FT-IR, NMR, GPC and performance tests.

Keywords: polydimethylsiloxane, polysulfone, telechelic oligomer, multiblock copolymer, sulfonation, proton exchange membrane.

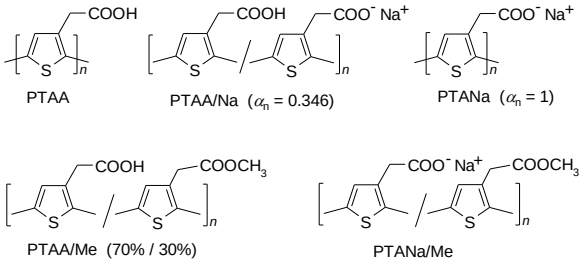
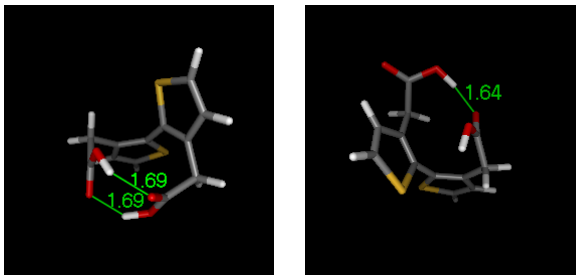
vohlidal@natur.cuni.cz

Background & Methods: Unlike the structure and the ionic equilibria, the thermodynamic and transport properties of aqueous solutions of conjugated polyelectrolytes including PTAA are little known. Our work aims to partly fill this gap by examining the transport of ions in aqueous solutions of partially (34.6 %) neutralized regio-irregular PTAA (PTAA/Na). Aqueous solutions of PTAA/Na were carefully purified by dialysis. The conductivity of these solutions has been studied as a function of the concentration of ionized groups and temperature. The conductivity data were complemented by determination of the macropolyion constituent transport numbers at 25 °C using the indirect moving boundary method; coloring of PTAA anions enables easy monitoring the boundary movement, as well as easy determination of the polymer concentration in a solution. Combination of these results allowed us to estimate the fraction of so-called "free" counterions in the system. In addition, we studied the UV/vis spectra of PTAA/Na, PTANa and PTANa/Me to obtain new information on the solution behavior of PTAA derivatives. These results are extensively compared with the UV/vis data obtained by others groups and completed with the DFT calculations aimed at estimation of the preferred conformations of PTAA chains and electronic transitions in the chains.



Results & Discussion: The transference numbers of PTAA/Na macropolyion constituent, T_p, showed only a small dependence on the polymer concentration. The fraction of "free" sodium counterions, *f*, obtained from the measured T_p and molar conductivity increased as the polymer concentration decreased. This behavior strongly contrasts with that of highly charged strong polyelectrolytes such as DNA or poly(styrenesulfonic acid) and its salts, for which *f* is a decreasing function of the solution dilution, which indicates an increase in the counterion-macropolyion association in highly diluted solutions. On the contrary, PTAA/Na obeys the concentration dependence observed typically for dilute solutions of spherical macropolyions and cylindrical oligopolyions.

The observed qualitative identity of the UV/vis spectra taken from a DMF solution and from a film of PTAA showed that π-stacking of thiophene rings in bulk PTAA does not occur, which strongly contradicts with the behavior currently observed for majority of polythiophenes. Strong intramolecular non-covalent interactions via hydrogen bond stabilizing distorted conformations of PTAA chains are proposed to be the main reason for this exceptional behavior, as well as for the slowness of conformational relaxations of PTAA/Na chains in solutions.



We demonstrated the validity of the Lambert-Beer law for PTANa and PTAA/Na but the non-validity of this law for PTANa/Me aqueous solutions; the latter system was instead found to exhibit an isosbetic point at 402 nm. This can be explained by the aggregation of the polymer chains due to the presence (ca. 1/3) of non-hydrolyzed ester groups in the chains. On the other hand, we did not observe any isosbestic point during acidobasic titrations of PTAA/Na solutions though two such points have been reported by another research group. Only continuous shifts of the absorption bands without their crossing have been observed during the latter titrations.

We have summarized and critically evaluated discrepancies between published spectroscopic data and those obtained in this work, as well as among the data on PTAA-based systems available in the literature. These discrepancies can be partly ascribed to certain differences in the chemical structure of the samples studied by various groups and partly to the history of the studied polymer solutions (owing to the slowness of conformational relaxation of PTAA/Na chains).

Conclusions: The main output of the present work is the first characterization of the transport properties of a weak anionic conjugated polyelectrolyte: partially neutralized PTAA. The second output is new knowledge on the unusual spectroscopic behavior of PTAA forms and the rational lying behind it.

klemen.burja@helios.si

The water-born resins in ecologically acceptable coatings represent advantageous materials in comparison to previously used solvent-born resins. Among the most widely used water-born dispersions are the polyacrylic ones. Since one of desired properties is the ability of the coating to repel water, the aim of our work was to elucidate the effect of the type of methacrylic ester side chain on hydrophobicity of polyacrylic dispersion.

For this reason we prepared acrylic dispersions of different chemical composition by a two step emulsion polymerisation.[1-3] The methacrylic part of the polymer was varied using methacrylic esters of different hydrophobicity, *i.e.*, methyl methacrylate, *n*-butyl methacrylate, *t*-butyl methacrylate, 2-ethylhexyl methacrylate and isobornyl methacrylate. In addition, acrylic acid monomer, which is used as a *co*-stabilizer for acrylic water dispersions, was replaced by two other type of monomers, *i.e.*, 2-hydroxyethyl methacrylate and maleic acid. The molar ratio between monomers, surfactant and initiator used in emulsion polymerization was in all cases constant. We evaluated various physical and chemical properties of the synthesized acrylic dispersions and their dried films, such as particle size distribution, molecular weight, rheology, glass transition temperature and surface tension.

Synthesis and self-assembly of block copolymers bearing *o*-nitrobenzyl side groups

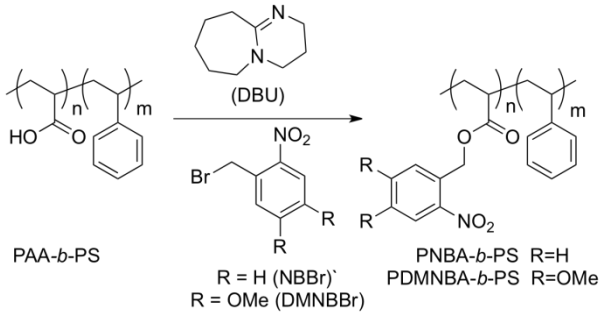
Olivier Bertrand, Jean-Marc Schumers, Charles-André Fustin and Jean-François Gohy

Université chatholique de Louvain, Institut de la matière condensée et des nanoscience/Bio et Soft Matter

olivier.bertrand@uclouvain.be

In the past decade, block copolymers have proved themselves to be powerful tools for preparing a wild range of nanostructured materials, either in the solid phase (thin films) [1-2] or in solution (micelles) [3-4] since they are able to self-assemble at the nanoscale into well-ordered morphologies. Moreover, the family of stimuli responsive block copolymers shows great potential for application in diverse fields due to their ability to change their properties when submitted to a stimulus (pH, temperature, light irradiation) [4]. Among all the existing stimuli light is particularly interesting [5] since it can be localized in time and space, it can be triggered from outside of the system, and it does not require particular reagents which limit byproducts.

We report on block copolymers containing *o*-nitrobenzyl photocleavable side groups. They are interesting precursors to trigger micellization by light. The block copolymers are composed of a polystyrene (PS) block and a poly(nitrobenzyl acrylate) or poly(dimethoxynitrobenzyl acrylate) block bearing photocleavable side-groups (PNBA-*b*-PS and PDMNBA-*b*-PS). The synthetic strategy consists in preparing block copolymer precursors by Atom Transfer Radical Polymerization (ATRP), and grafting the desired *o*-nitrobenzyl derivative in a post-modification step (**Scheme 1**)



Scheme 1: synthesis strategy.

The copolymers will be used for light induced micellization. Starting from the copolymer dissolved in a non selective solvent like chloroform, a UV irradiation will be performed to cleave the *o*-nitrobenzyl moieties and generate COOH groups. Since the poly(acrylic acid) (PAA) block thus formed is insoluble in the solvent used, it will aggregate leading to the formation of micelles with a PAA core and a PS corona (**Figure 1**).

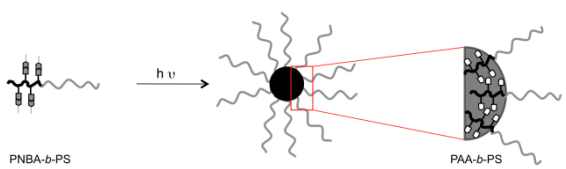


Figure 1 : light induce micellization.

Zinc Metal as Catalyst for Direct Grafting of Vinyl Acetate from PVC

Gokhan Cankaya, *Niyazi Bicak*

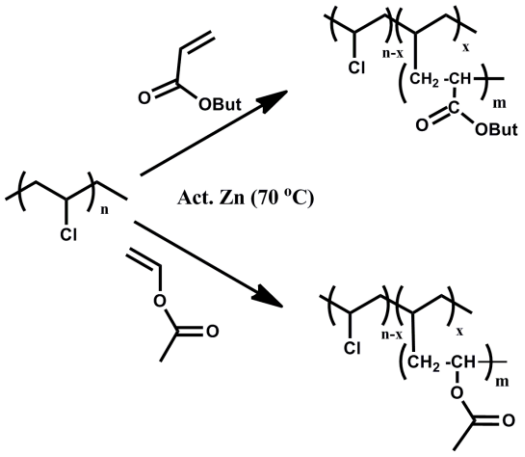
cankayagok@gmail.com

Istanbul Technical University Department of Chemistry, Maslak 34469 Istanbul-Turkey

Introduction: Modification of PVC by grafting is desirable to attain materials with tunable mechanical properties. The earlier methods of PVC modification by grafting from approach are based on radiation grafting and photoiniferter techniques. ATRP has also been used in combination with telechelic approach for grafting of PVC. In the following works Percec *et. al*[1] and our group[2] demonstrated graft copolymerization of some acrylic monomers by ATRP method from labile chlorines of PVC. This process allows control of the grafting degree; however color of the graft copolymer is important drawback.

More recently we have developed activated zinc powder-alkyl halide initiation system for controlled/living polymerization of vinyl monomers, including vinyl acetate. In this presentation, this method was extented to prepare for graft copolymerization from chlorine atoms of PVC. Overall process is stirring monomer solution of PVC with activated zinc catalyst at 70 ^{0}C.

Result and Discussion



Scheme-1: Grafting of PVC with BA and VAc by Zn catalyst

Zinc activated grafting from approach was applied for the vinyl monomers, vinyl acetate and butyl acrylate. The ^{1}HNMR spectrum of the PVC-*g*-PVAc in fig-1 shows a sharp singlet at around 4.9 ppm, which arises from CH-O bond of Vac and 3.6 ppm corresponding CH-Cl bond implying unreacted chlorine groups of PVC.

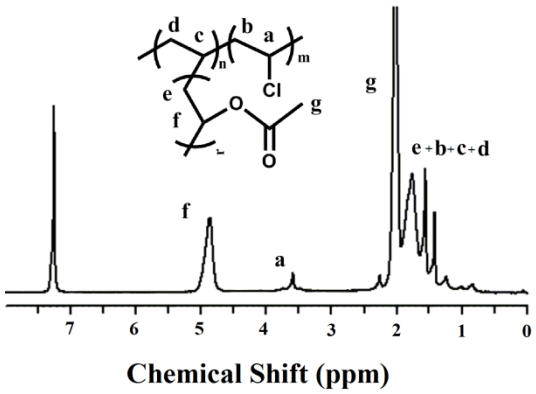


Figure 1: ^{1}HNMR spectrum of grafting of PVC with VAc by Zn catalyst

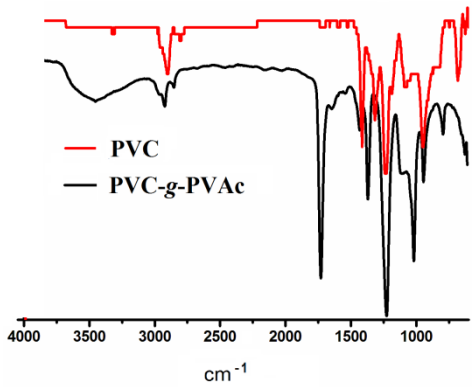

Figure 2: FT-IR spectrum of grafting of PVC with Vac by Zn catalyst

FT-IR spectrum of the graft copolymer is well agreement the NMR spectrum. Apart from the PVC, carbonyl groups of the grafted polymer appeas at 1731 cm^{-1} as seen in fig-2.

Conclusion: The results showed that the process allows direct grafting of PVC and high graft yields (up to 1400 %) are attained within reasonable periods.

Development of Stimuli-Responsive Polymers for Liposome Based Drug Delivery Systems

P. Alves, J.F. Coelho, M.H. Gil, P.N. Simoes

Department of Chemical Engineering, University of Coimbra, Pólo II, Phinhal de Marrocos, Coimbra 3030-790, Portugal

palves@eq.uc.pt

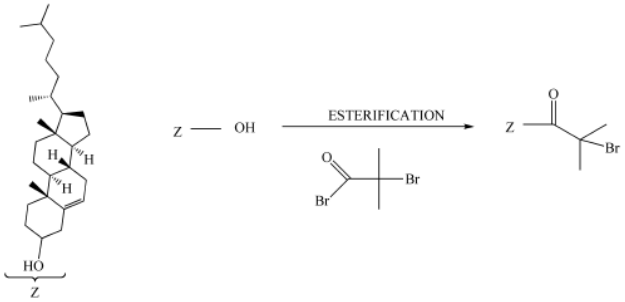
Introduction:

Liposomes are self-assembled vesicles that consist of an aqueous core domain entrapped by a lipid bilayer. They are attractive materials for drug delivery systems (DDS) due to their biocompatibility, non-immunogenicity, non-toxicity and ability to entrap both hydrophilic and hydrophobic compounds [1,2]. Despite the promising capabilities as DDS, liposomes have shown low transfection efficiency and low stability in the systemic circulation. To overcome these problems, functional polymers are being attached to the liposomes by means of a hydrophobic anchor, forming polymer-caged liposomes (PCL). This strategy also allows the preparation of PCL that can respond to environmental stimuli (pH and temperature), enhancing their usefulness as DDS.

The development of new polymers to be used in PLC is crucial in these systems. This work reports the tailored synthesis of macromolecules based on a LRP method, more specifically a metal catalyzed method, known as Single Electron Transfer (SET). This strategy presents several advantages over other methods, such as mild work conditions, fast kinetics and very high tolerance to different functionalities. It is a well established method and provides an effective tool for synthesizing advanced polymer materials with different architectures, topologies, compositions, and high degree of control over polymer microstructure.

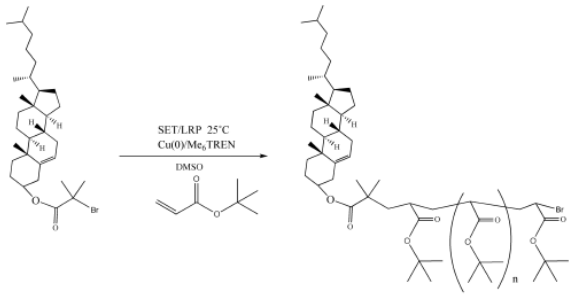
Methods

In the present work, cholesterol (CHO) was used to anchor the polymer into liposome. The synthesis started with the esterification of the OH-end group of Cholesterol with bromocarboxylic acids, yielding an initiator structure, shown in scheme 1.



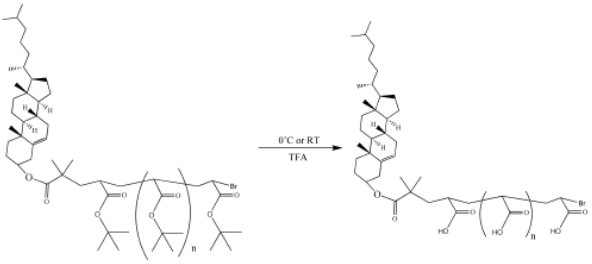
Scheme 1: Representation of cholesterol esterification.

This previously obtained CHO initiator with the terminal bromide was then used for the SET/LRP of tert-butyl acrylate (tBA) with Cu(0) and tris[2-(dimethylamino)ethyl]amine (Me6-TREN) in dimethylsulfoxide (DMSO) at 30ºC [3, 4]. The schematic reaction of this procedure is presented in scheme 2.



Scheme 2: Representation of the SET/LRP reaction.

The tBA units of CHO-PtBA were then deprotected with trifluoroacetic acid (TFA) to form CHO-PAA [5] (scheme 3).



Scheme 3: Representation of the hydrolyses of tBA to acrylic acid.

Results

The synthesized polymers were completely characterized by H-NMR, FTIR, DMTA, mDSC, TGA and multiSEC. The behavior of the complexes liposome/polymer regarding polymers with different characteristics was investigated towards its application in DDS.

Rapid Removal of Copper from ATRP Mixtures by Chemical Reduction with Wetted Zinc Powder

Fatma Canturk, Bunyamin Karagoz, Niyazi Bicak

Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

fatoshh@gmail.com

Introduction: Copper mediated ATRP is an excellent controlled/living polymerization technique that allows creating various polymer architectures.[1] despite its peculiarities ATRP has not found application in mass production of polymers. This is due to color of the polymer products arising from the copper residues.
The use copper catalysts anchored to solid supports has been considered as useful for recovery and reuse the catalyst. The copper complexes physically adsorbed on silica supports were determined to be effective in preparing copper-free polymers at the end of the polymerization. However, heterogeneity of the process does not allow attaining narrow molecular weight distributions. The Schiff base ligand covalently linked to silica support[2] was reported to give copper-free polymers with relatively high polydispersities (PDI: 1.4-1.6). Shen group[3] and other groups introduced various amine ligands covalently attached to solid supports to attain better control of the molecular weights. Copper complexes immobilized on Janda gel resin was determined to give colorless polymers[4]. However, the resulting polymers showed broad polydispersities. Post purification after the polymerization was consired as useful to avoid loss of control of the chain growth.Despite those endovours in obtaining copper free polymers with low polydispersities is still a chalanging problem and needs further development.

Herein, we describe a quick method of the copper removal from ATRP mixtures, based on chemical reduction with zinc powder.

Result and Discussion: It was demonstrated that, simple mixing of an ATRP mixture with wetted zinc powder (i.e. 0.3 g per mmol copper) together with small amounts of silica gel as seeding material yields colorless solutions and the elemental copper precipitated at the bottom, in less than 5 min.

$$CuBr_2 \cdot L + Zn(0) \longrightarrow Cu(0) + ZnBr_2 \cdot L$$

Scheme 1: Chemical reduction of the copper complex by zero-valent zinc.

Table 1: Ligand and solvent effects on the chemical reduction of copper by zinc powder in ATRP solution.

Run	*[Zn] /[Cu] (mol/mol)*	*Ligand*	*Contact time for decolorization*
1	5	HTETA	3.5 min
2	5	PMDETA	1.3 min
3	5	Bipyridyl	2.7 min

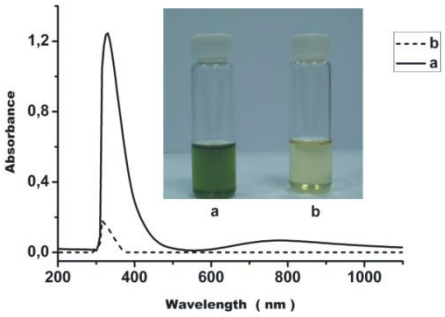

Figure 1: UV-Visible spectrum of ATRP solution of PMMA in toluene (diluted 1/ 250), before (a) and after (b) copper removal by zinc powder.

AAS and UV spectra of the filtered polymer solution showed no any trace of copper (Fig-1).

The polymer (PMMA) (Mn:12400) isolated from clear ATRP solution obtained by short contact with zinc powder was determined to be "still living" as confirmed by chain extension with styrene yielding block copolymer, PMMA-*b*-PS (Mn:15800) (Fig-2).

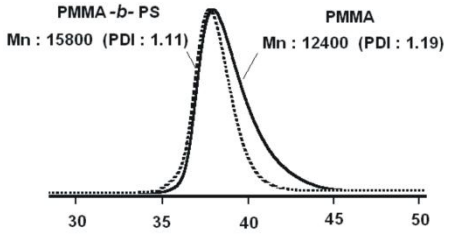

Figure 2: GPC trace of PMMA and PMMA-*b*-PS .

Prolonged stirring with zinc powder (*i.e.* 24 h) however, yields non-living polymer, due to reductive dehalogenation of the end-groups. Reduction of the bromoalkyl end-groups can be accelerated by adding few mL acetic acid and completed within 2 h.

Conclusion: Treatment of ATRP solutions by zinc powder provides rapid removal of the copper complex and the terminal halide groups remain unaffected.

Solid Supported Benzoquinone as a Click Component for Facile Immobilization of Amino Acids and Proteins

Kubra Yuksel, Gokhan Cankaya, Okan Sirkecioglu, Niyazi Bicak

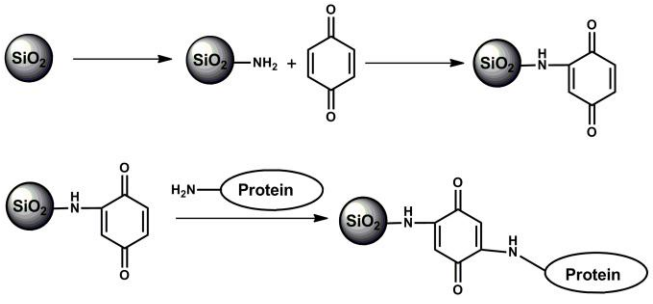
Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

yksel_kbra86@hotmail.com

Introduction: The term "click chemistry" has been coined by K. B. Sharples in order to define nearly quantitative reactions providing easy connection of two reagents having highly reactive groups. To date, the Cu(I)-catalyzed 1,3-dipolar cycloaddition of alkynes to azides, yielding triazole connection has been one of the most popular click reaction. This reaction proceeds in various media including aqueous solutions[1]. Another popular click reaction is Diels-Alder reaction based on cyclization of diene and dienophile at ambient temperatures[2].Altough other click reactions such as reaction of epoxides with amines or carboxylic acids are already being used extensively industry, this chemistry is less common in academia.Herein, we describe a forgotten compound, benzoquinone as a click component due to its exceptional michael addition capability. Benzoquinone is unique member of quinones having reversible redox behavior and a very reactive Michael acceptor for amines, thiols and hydrocyanic acid etc. This chemical behavior has been exploited in designing heat stable polymers and redox-active materials. In this work, we have studied preparation of solid supported benzoquinone for easy immobilization of proteins and amino acids.

Result and Discussion:

In this study, surfaces of micron size silica spheres were modified with 3-trimethoxy silyl 1-amino propane (Scheme-1).



Scheme-1: Solid Michael receptor for amines, amino acids and thiol functional polymers.

TGA and acid titration methods revealed an amine content of 1.2 mmol per gram. The resulting material was reacted with benzoquinone in methanol solution.

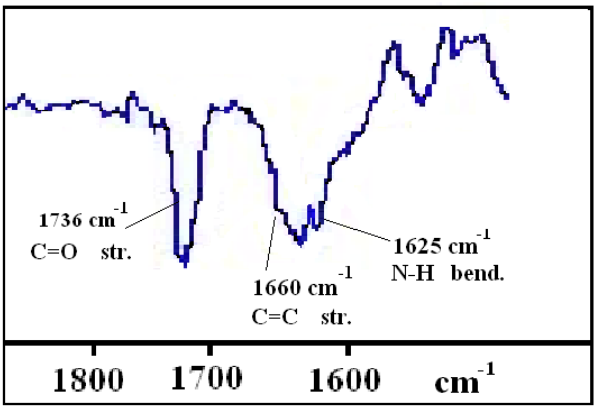


Figure-1: FT-IR spectrum of quinone functional silica microspheres.

FT-IR spectrum of this material showed (Fig-1) characteristic vibration bands of carbonyl groups of the quinone moiety at 1736 cm^{-1}. Stretching vibration of carbon-carbon double bands appeared at 1660 cm^{-1}. Another typical band, N-H bending vibration was observed at 1625 cm^{-1}, indicating incorporation of benzoquinone into the structure.

The resulting material was employed as efficient Michael acceptor for immobilization of amine functional compounds such as amino acids and proteins.

Two amino acids (glycine and alanine) were introduced to quinine functional surface of the silica microspheres in methanol solution using calcium hypochloride as oxidant.

The structures of the materials obtained in each step were confirmed by FT-IR andTGA analyses.

The results showed that addition of amino acids takes place in high yields which approches to the benzoquinone density of the microspheres. Ovalbumine was also studied for the surface modification in similar conditions.

Conclusion: The click chemistry with surface bound benzoquinone moieties is useful to generate amino acid functional micro beads. Although we have not studied yet, such materials might be used as chiral stationary phase for separation of amino acids and proteins.

Preparation and characterization of a polyetherimide/polyaniline composite

Evandro M. Alexandrino[1], *Maria I. Felisberti*[2]

Chemistry Institute, University of Campinas (UNICAMP), P.O. Box 6121, Zip Code 13083-970, Campinas - SP, Brazil

[1]evaalexandrino@iqm.unicamp.br, [2]misabel@iqm.unicamp.br

Introduction

Polyaniline (PAni) is one of the most interesting conductive polymers due to its excellent environmental stability, easy and cheap chemical synthesis and interesting electrical and electrochemical properties in the emeraldine form. On the other hand, it shows poor mechanical properties and processability. In the last three decades, since the work from MacDiarmid *et al.*[1], the combination of polyaniline with thermoplastics, elastomers and thermosetting polymers as composites and blends has been widely studied. However, the preparation of polymer composites with high thermal performance thermoplastic has been less explored due to the lower thermal stability of polyaniline in the doped state with usual dopants like HCl. Among the methods to improve the thermal stability of PAni, the use of organic acids with high molecular weight such as camphorsulfonic acid (CSA), dodecyl benzene sulfonic acid (DBSA) and *p*-toluene sulfonic acid (TSA) showed interesting results[2].

Polyetherimide (PEI) is an amorphous high thermal performance thermoplastic, with good mechanical and chemical resistance. In this work, a composite using polyetherimide as the matrix and doped polyaniline with *p*-toluene sulfonic acid as polymer filler was prepared by extrusion process, and their morphological, structural, mechanical and thermal properties were determined.

Materials and methods

Aniline (Vetec, 99%) was distilled under vacuum before use. Ammonium persulfate (Synth, 98%), HCl (Synth) and NaCl (Synth, 99,5%) were used without further purification. The polyetherimide (trade name Ultem®1001) was obtained from SABIC Innovative Plastics.

Polyaniline was synthesized by chemical oxidation, through the addition of a solution 3M $(NH_4)_2S_2O_8$/1M HCl/3M NaCl to a solution 0,4M aniline/1M HCl/3M NaCl, dropwise and under vigorous stirring. This reaction was kept between -10ºC and 0ºC. The green solid (PAni/HCl) was washed with a H_2O:EtOH solution (5:2 v/v) and dried under vacuum for 36h. The PAni/HCl was undoped by stirring in a NH_4OH 1M solution for 24h, washed and dried again, and then was doped with *p*-toluene sulfonic acid (PAni/TSA) by stirring in a TSA 1M solution for 24h. The composite with 10% of PAni/TSA were prepared in a double screw mini compounder at 330ºC and injection molded under pressure of 8 bar and temperature of 330ºC in bars for tensile tests according with ASTM D1708.

Samples were thermal characterized by TGA (Seiko EXSTAR6000 TG/DTA 6200 at 10ºCmin^{-1}) under oxidative atmosphere and DSC (TA Instruments 2910 at 10ºCmin^{-1}) under N_2 atmosphere. Structural characterization was made by FTIR (Bomem MB series B-100 from 4000 cm^{-1} to 400cm^{-1}) and morphological characterization was obtained by SEM (JEOL JSM6360-LV 10kV). The tensile test was realized in a EMIC DL 200 apparatus.

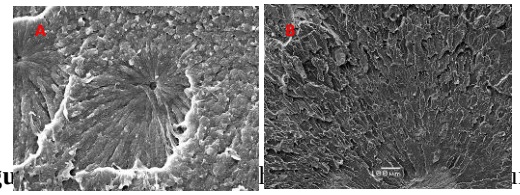
Results and discussion

The FTIR spectra of the synthesized polyanilines show the main absorptions of polyaniline in the emeraldine form. The ratio between "quinoid ring" (1580 cm^{-1}) and the "benzoid ring" (1460 cm^{-1}), confirms the emeraldine state in the obtained polyanilines[3].

TGA analysis shows that Pani/TSA presented a higher stability in comparison to PAni/HCl. The T_{10} (10% weight loss temperature) for PAni/TSA is approximately 310°C. The PEI-PAni/TSA composite with 10% of polyaniline shows T_{10} at 532°C, near the value for pure PEI. The differential thermogravimetric analysis (DTG) shows acceleration in the second loss event. DSC analysis of the composite shows no alteration in the T_g value in relation to the pure polyetherimide.

The tensile test shows a significant decrease (38%) of the tensile stress for the composite comparing to the value obtained for the polyetherimide. However, the value obtained for the composite is in the same range of the one of pure polycarbonate.

The polyaniline morphology shows the characteristic globular aggregates, which were related to the high superficial tension. The composite presented agglomerates of polyaniline throughout the polyetherimide matrix, with a good adhesion in the interfacial region. The micrographs of the fracture resulting from tensile test suggest different fracture mechanism for PEI and its composites (Figure 1).



Figuures: (A) pure PEI; (B) PEI-PAni/TSA

Conclusion

Composites of PEI and PAni/TSA showed a decrease of the mechanical properties, probably due to the presence of aggregates of polyaniline. The SEM micrographs show a good interfacial adhesion and suggest changes in the fracture mechanisms.

Cationic Homo and Copolymerization of Indene and Other Olefins

Fábio José B. Brum[*], *Maria Madalena C. Forte, Felipe N. Laux*

Federal University of Rio Grande do Sul (UFRGS)/LAPOL/Engineering School, Brazil
[*]P.O. Box 15010 – Porto Alegre, 91501-970 /RS/Brazil – fjbrum@yahoo.com.br

Monomers such as indene (Ind), styrene (St) and limonene (Lim) can be polymerized by acid catalysis (1). Papers published in the last two decades have described the polymerization of indene at low temperatures using catalyst type Friedel-Crafts (2). The number-average molecular weight (Mn) of polymers produced by cationic polymerization depends on the type and amount of catalyst. The type or reaction mechanism varie according to the catalytic system employed (3). In this study, the effect of the comonomer type on the number-average molecular weight (M_n) and glass transition temperature (T_g) of the indene copolymers, using $AlCl_3$ as catalyst, were evaluated. The indene (Ind) cationic homo and copolymerization with styrene (St) and limonene (Lim) were performed at -20 °C under N_2 atmosphere. The resulting polymers were characterized by infrared (FTIR) and gel permeation chromatography (SEC). The Tg of the polymers was determined by calorimetry (DSC). The molar ratio monomers/catalyst of 100 was the same for all polymerization reactions.

Table 1 shows the reaction conversion, M_n, polydispersity (M_w/M_n) and T_g of the polyindene (Pind), polystyrene and polylimonene obtained. The indene polymerization conversion was higher than those with the other monomers. Lim present very low reactivity with $AlCl_3$ catalyst and thus the lowest conversion degree. As expected, the PInd presented the highest M_n (33,000 g mol) and it was obtained only oligomeres of limonene (M_n<500 g/mol). Although the styrene polymerization presented the highest reaction conversion the PS M_n was around 2,500 g/mol. The polymers polydispersity was quite different and that of PS was very anomalous, possibly due to a competition between initiation and termination reactions (3). The Pind T_g was approximately 207 ° C due to the chain stiffness, since the PInd has a semi-ladder structure. The limonene oligomer presented solidification temperature at around -7 ºC due to its very low M_n.

Table 1. Monomers homopolymerization* conversion and product characteristics

Polymer	Pind	PS	PLim
Conversion (%)	80.59	92.48	7.23
M_n (g/mol)	$33x10^3$	$2.5x10^3$	478
M_w/M_n	2.1	13.8	1.5
Tg (°C)	207	99	-7

*$AlCl_3$ = 2.42 x 10^{-3} mol; [Ind] = 1.95 mol/L; [St] = 2.15 mol/L; [Lim] = 1.71 mol/L T = -20°C; t = 5h.

Figure 1 shows the M_n, M_w/M_n and T_g values of Ind-co-St copolymers as function of the comonomer relative composition in the medium. The St caused a significant decrease in the copolymer M_n since it play as chain transfer agent through beta-elimination reaction. An increase in the Lim content up to 40% increased the M_w/M_n of the Ind-co-St copolymers due mainly to the M_n decrease. The Tg values of the copolymers stood between the homopolymers' Tg values according to the comonomer content.

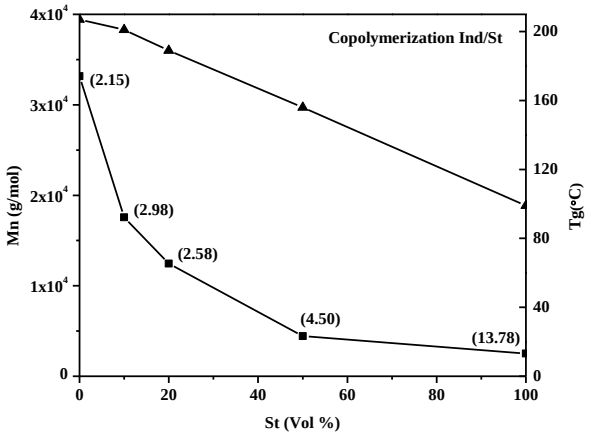

Figure 1. Mn and Tg of the Ind-St copolymers as function of St content (Tab.1).

Figure 2 shows the M_n, M_w/M_n and T_g values of indene-limonene (Ind-co-Lim) and styrene-limonene (St-co-Lim) copolymers as function of the relative composition in the reaction medium. The Lim caused a significant decrease in the M_n of the Ind-co-Lim copolymer since it play as chain transfer agent through beta-elimination reaction. The copolymer M_w/M_n values varied from 2 and 3. On the other hand, content until 20% of Lim increased the St-co-Lim copolymer M_n. The M_w/M_n of the St-co-Lim copolymers decreased as lower the copolymer M_n value.

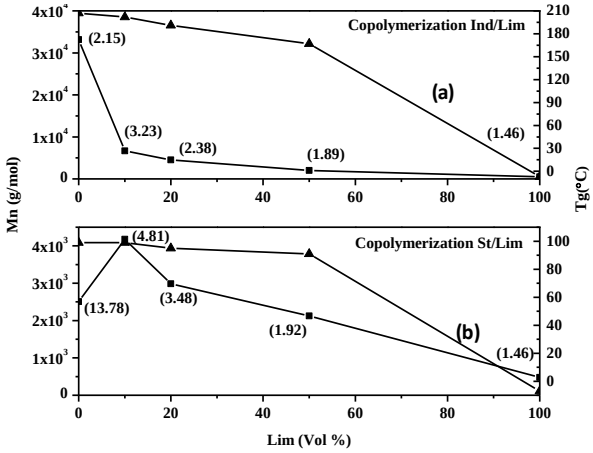

Figure 2. M_n (M_w/M_n) and T_g of the Ind-co-Lim (a) and St-co-Lim (b) copolymers in function of the St content.

St and Lim depressed significantly the M_n and have the same effect on the T_g of the Ind copolymers. This may be related to a higher effect of St and Lim as a chain transfer agent than Ind.

Poly(ethylene imine) Tedhered Microspheres for Selective Extraction of Aldehydes from Organic Mixtures

Baris Gure, Deniz Gunes, Bunyamin Karagoz, Niyazi Bicak

Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

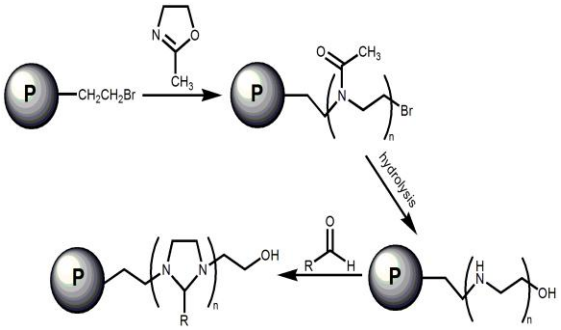
gurebaris@gmail.com

Introduction: Selective separation of organic compounds by solid supported trapping agents is of importance due to its advantages over traditional separation-purification techniques such as distillation, fractional crystallization, derivatization, precipitation etc. Common techniques of aldehyde separation from organic mixtures need extreme care, due to their easy oxidation by air oxygen. Derivatization of aldehydes by bisulfite addition and hydrazone formation is mostly applicable in lab-scale processes, but not in industrial processes. Years ago, Wanzlick *et.al*. described dianilino ethane as efficient and selective reagent for selective extraction of aldehydes by forming pyrrolidine ring[1]. In the following works, diethylene triamine (DETA) and triethylenetetramine (TETA) immobilized to ST-DVB resin was demonstrated to be efficient and selective sorbent for removal of aldehydes from organic solutions, by our group[2].

In the present work, 1,2-diaminoethane-aldehyde chemistry was extended to poly(ethylene imine) (PEI) surface brushes tethered to crosslinked PBEMA microspheres prepared by suspension polymerization of 2-bromoethylmethacrylate, methyl methacrylate and ethyleneglycoldimethacrylate[3].

Result and Discussion: PBEMA was fabricated by SIP of 2-methyl-2-oxazoline from bromoethyl groups originating from BEMA co-monomer involved. (Scheme-1)

Polyoxazoline grafts so generated (62-133 %) generated were then converted to PEI by acid and base hydrolysis respectively (Scheme-1).



Scheme 1: Schematic illustration of grafting, hydrolysis and aldehyde separation.

The resulting PEI brushes were employed in extraction of various aldehydes from methanolic solutions. Experiments revealed that, aldehyde uptake capacities found (1.5-2.1 mmol.g^{-1}) were almost equal to the theoretical capacity (by assuming two nitrogen per aldehyde molecule). The aldehydes loaded were easily leached out by acid treatment and the resin material was recovered.

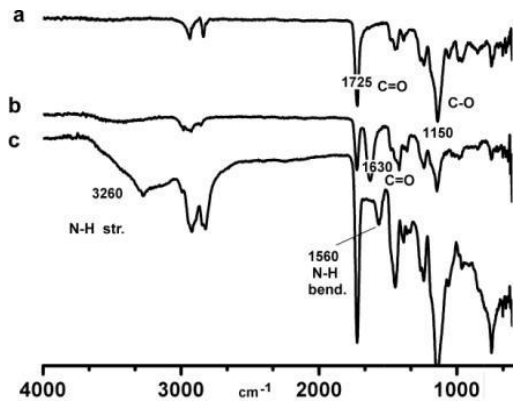


Figure 1: FT-IR spectrum of the a) BEMA beads b) Oxazoline grafted PBEMA and c) PEI grafted PBEMA

Table 1: Trapping capacities of PEI grafted PBEMA

Aldehyde	Capacity (mmolg^{-1})	Capacity after the regenaration (mmolg^{-1})
Benzaldehyde	2.2	2.0
Acetaldehyde	7.1	6.8
4-Hydroxy Benzaldehyde	2.26	2.1
Salicylaldehyde	4.52	4.1
Phtaldialdehyde	-	-

Conclusion: PEI brushes tethered to crosslinked PBEMA beads showed reasonably high trapping capacities for aromatic and aliphatic aldehydes. This material demonstrated to be approximately same results after the regeneration. Consequently, the resins described are cost effective sorbents for the removal and recovery of aromatic aldehydes from various mixtures.

Sulfonated Polystyrene Brushes Tethered to PS-DVB Microspheres as New Generation of Ion Exchange Polymers

Ozlem Ozer, Ahmet Ince, Niyazi Bicak

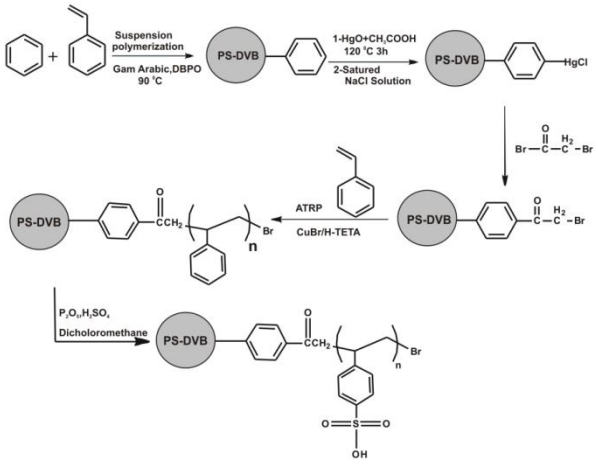
Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

ozlem.ozer86@hotmail.com

Introduction: Ion exchange resins are densely crosslinked macroreticular or macroporous polymers bearing ionic functional groups, readily capable of forming salts with metal ions in aqueous solutions. These materials have found extensive uses for large-scale producing of deionized water, which is of interest for processing of industrial and manucipal waters.

Advents of living polymerization techniques, such as ATRP, RAFT and NMP have made it possible to create new sophisticated polymer architectures. These techniques have enable also surface initiated polymerization (SIP) on inorganic or insoluble organic supports. There appear tremendous reports aimed at generating various functional polymer brushes on solid supports. These functional brushes may confer compatibility, selective binding of different organic species or biomolecules.

It was considered that, flexibility and partial mobility of the graft chains may provide rapid interaction of the functional groups located on these chains. Insoluble supports possessing ion exchange groups are expected to have rapid exchange of metal ions. One important limitation in their preparation is connection of the linear polymer brushes with solid support with hydrolytically stable linkages.



Result and Discussion: Ongoing studies in our lab we have developed a method for linking of surface brushes with various supports by hydrolytically stable bonds.

Taking advantage of this chemistry, in the present work surfaces of PS-DVB(10 %) microspheres[1] were decorated with linear PS brushes in high yields (540 %). Subsquent sulfonation of the brushes yielded sulfonic acid functional (4.1mmolg^{-1}) hairy beads (Scheme-1). The resulting material was demonstrated to have fast and high ion exchange capacities for metal ions in water.[2]

Metal ion	Theoretical capacity[1] (mmolg^{-1})	Capacity of the acid form (mmolg^{-1})	Capacity of the sodium form (mmolg^{-1})
Ca(II)	2.05	3.7±0.2	3.6±0.1
Mg(II)	2.05	0.9±0.1	1.8±0.1
Mn(II)	2.05	0.6±0.1	1.9±0.1
Fe(III)	2.05	1.1±0.2	1.2±0.1

(1) By assuming two sulfonic acid group per divalent metal ion.

It was found that the capacities of sodium form are equal or slightly higher than those of the acid form of the resin.

Conclusion: The sulfonated PS brushes tethered to solid PS-DVB microspheres showed high exchange capacities for the metal ions studied. The capacities approach to theoritical capacity when used as sodium form. Regenerability and recovery of this material is similar to those of commercial ion exchange polymers. Since the grafting degree is a adjustable parameter any desired capacity of resin material can be attained by the SIP methodology described.

Butyl Sulfonium Sulfate as Cationic Initiator for Synthesis of Poly(cyclohexeneoxide)-*b*- Poly(2-methyl-2-oxazoline) Copolymers

Ceren Elci, Okan Sirkecioglu, Niyazi Bicak

Istanbul Technical University, Department of Chemistry, Maslak 34469 Istanbul, Turkey

cerenelci@gmail.com

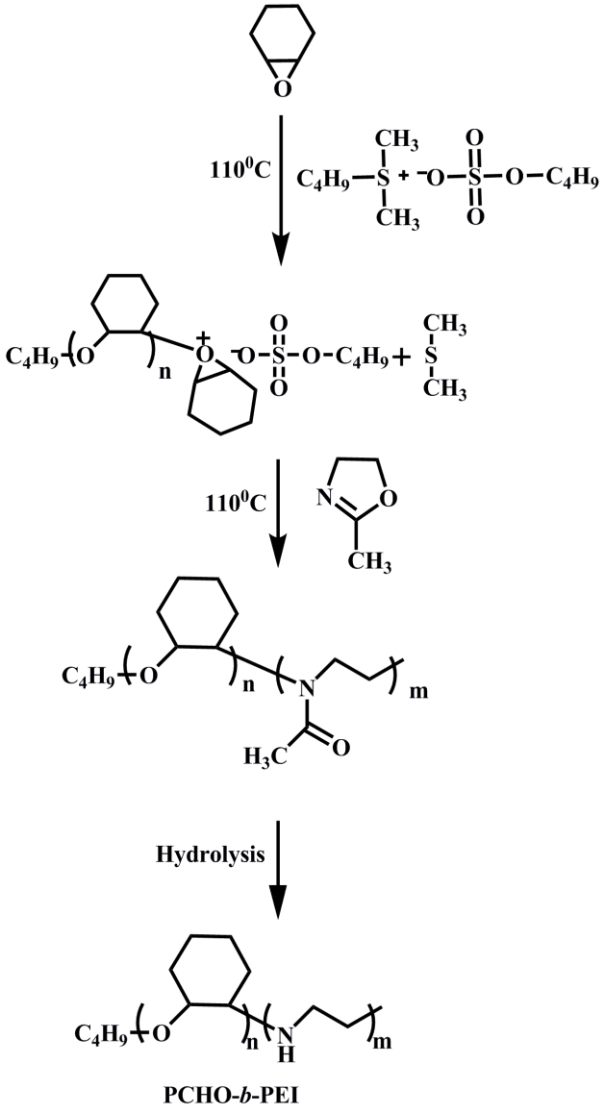
Introduction: Synthesis of block copolymers derived from the monomers polymerizing by different mechanisms is difficult to achieve. End-group transformation of the first block is one of the most common routes to attain such block structures. Various end-group transformation methods, cationic to radical, anionic to radical or radical to ionic have been developed for preparing block copolymers[1-2].

In this work, we have studied synthesis of poly(cyclohexeneoxide)-*b*-poly(2-methyl-2-oxazoline) (PCHO-*b*-POXA) copolymers using sulfonium sulfate as single initiator. Although, both monomers are polymerizable by cationic-ring-opening (CROP) mechanism, there is no living cationic initiation system initiating polymerization of both monomers.

Result and Discussion:

In this study a room temperature ionic liquid (butyl dimethyl sulfonium butyl sulfate) derived from dibutyl sulfate and dimethyl sulfide was demonstrated to be efficient "latent initiator" for CROP of cyclohexeneoxide (CHO) above 110 °C. Although the polymerization of CHO is slow, appreciable yields are attained within 24 h (72 %). Polymerization of the oxazoline monomer at the same temperature from sulfonate end-groups of PCHO simply gave well-defined block copolymers, poly(cyclohexeneoxide)-*block*-Poly(N-acetyl ethyleneimine). Subsequent hydrolysis of the second block yielded a chelating amphiphilic block copolymer, PCHO-*b*-PEI in good purities[3].
The structures of the polymer were confirmed by ^{1}H NMR, FT-IR, GPC analyses.

Conclusion: The initiator system described provides an easy access to amphiphilic block copolymer, (PCHO-*b*-POXA). Apparent advantage of this procedure is formation of the amphiphilic block copolymer without necessity of end group modification Having easy modification capability of the imino group, the resulting block copolymer might be of interest in diverse applications, i.e. construction of metal or metal oxide nanocomposites with unusual physicochemical behaviors.



PCHO-*b*-PEI

Modeling of precipitation co-polymerization of water-soluble polymers in organic solvent

Rosario Mazarro, Paolo Arosio, Giuseppe Storti, Massimo Morbidelli

Institute for Chemical and Bioengineering, ETH Zurich, Wolfgang-Pauli-Str. 10, 8093 Zurich, Switzerland

rosario.mazarro@chem.ethz.ch

Introduction: Several water-soluble polymers are industrially produced by solution polymerization. This operating mode is typically limiting the quality of the final product, in particular in terms of maximum molecular weight. In order to explore the potential of a heterogeneous process, the reaction can be carried out in organic solvent. Precipitation polymerization is generically defined as a heterogeneous polymerization in which the produced polymer is insoluble in the reaction medium.[1,2] Both the initiator and monomer are soluble in the solvent and the reaction starts as a homogeneous polymerization in the continuous phase. With the proceeding of the reaction, the polymer chains grow and precipitate thus nucleating a second, dispersed phase. Since monomer and initiator are soluble also in the newly formed, polymer-rich phase, from this point on - in terms of conversion, after a few percents - the reaction can occur in both phases. Since the difference in reactivity between the two phases can be significant, the properties of the final product can be largely different depending upon the reaction locus. Therefore, the identification of the specific contribution of each reaction locus is crucial for proper understanding and design of the process.

The aim of this work is to combine experimental and modelling activities to elucidate the main mechanisms regulating the product quality of the precipitation co-polymerization of two different systems, namely, the co-polymerization of vinylimidazole and vinylpyrrolidone in butylacetate, and the one of acrylic acid and vinylpyrrolidone in a mixture of ethyl acetate and cyclohexane.

Materials and Methods: Several reactions have been performed in well stirred, isothermal, glass reactor while changing operating parameters such as monomer mixture composition, monomer mixture holdup, initiator amount, stirring rate, presence of stabilizer, and temperature. Conversion and co-polymer composition have been measured by gravimetry and gas chromatography; the molecular weight distribution (MWD) by gel permeation chromatography; and the particle size distribution (PSD) by light scattering.

Results: A comprehensive model of the system has been developed based on the previous literature for homo-polymerization processes.[3,4] Two phases are considered: the continuous, solvent-rich, and the dispersed, polymer-rich phase. A simple kinetic scheme, typical of free radical polymerization, is considered in each phase, in order to account for the heterogeneous nature of the system. Notably, the diffusion of active chains from the continuous to the dispersed phase is accounted for. Finally, the model includes the population balance equations for active and dead polymer in order to describe the complete molecular weight distribution of the final product.

Even though the parameter evaluation problem was especially difficult due to the lack of values from the literature, the final model predictions in terms of kinetics, co-polymer composition and MWD are quite satisfactory (Figure 1).

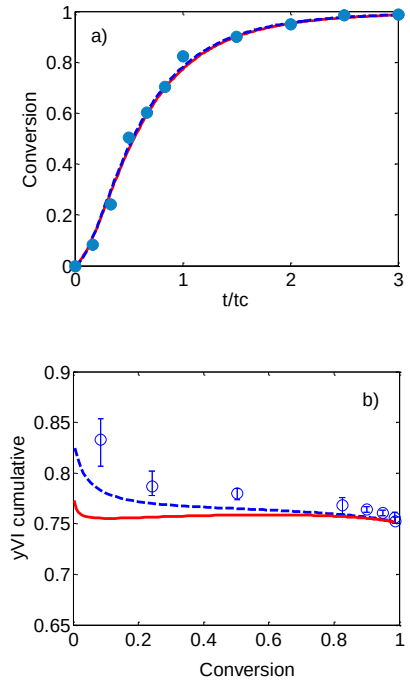

Figure 1. Conversion versus time (a) and cumulative composition versus conversion (b) for the co-polymerization of vinylimidazole and vinylpyrrolidone (75/25) in butylacetate. Symbols: experimental data. Line: model simulations in the two limiting cases: completed transport of the active chains from the continuous to the dispersed phase (—) and no transport (--).

Two completed different systems have been analyzed. In the co-polymerization of vinylimidazole and vinylpyrrolidone in butylacetate, the reaction is going on in two fully segregated phases, being the mass transport of active chains negligible. This way, the final polymer is a mixture of two types of macromolecules, each one reflecting the conditions of the phase originating them. In the co-polymerization of acrylic acid and vinylpyrrolidone in a mixture of ethyl acetate and cyclohexane and using a stabilizer, the inter-phase transport of active chains is found to play a crucial role in determining the reaction rate, even though most of the polymer is produced in the continuous phase.

Ultrafast Relaxation Dynamics of Exciton in Poly-*p*-phenylenevinylene Oligomers

F. V. Moura, P. H. O. Neto, W. F. da Cunha, L. F. Roncaratti, R. Gargano and G. M. e Silva

University of Brasilia

fabiomoura@fis.unb.br

Introduction

Polymer-based solar cells have recently been widely studied as a potential low-cost replacement for the conventional ones. Besides, organic solar cells have others advantages like low toxicity, mechanical properties and ease of fabrication. Despite continued interest in electronic properties of these materials, an understanding of the basic processes remains elusive. Particularly, the phenomenological reasons for the ultrafast relaxation of excitons, recently observed in organic based compounds [1], are lacking. The time to geometrical relaxation on a exciton transition was estimated in 90 *fs* by means of a ultrafast pump-probe spectroscopy technique. However, the heterogeneous morphology of conjugated polymers thin films makes difficult to separate the effects of chain conformation and interchain contacts from the intrinsic electronic properties. In this sense we investigated the excitons generation in poly-*p*-phenylenevinylene (PPV) oligomers with a fully dynamics atomistic description.

Model and Methods

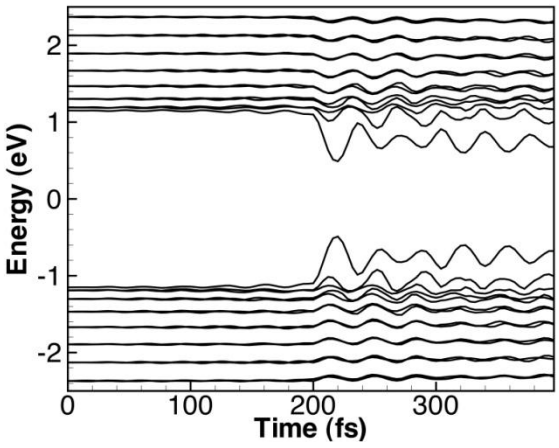
Using a modified version of the Hückel model Hamiltonian [2] to include temperature effects and photoexcitation process we studied the dynamic of both triplet and singlet excitons in a PPV sample. We take into account a nearest-neighbor hopping term in which the distance between carbons was considered. The temperature are incorporated on the method in a classical approach by means of a Langevin equation. The photoexcitation was simulated changing the molecular-orbital occupation number. In order to time evolute the system we applied the Ehrenfest molecular dynamic [3]. Introducing an expansion in terms of the eigenenergies and eigenstates of the electronic hamiltonian, we obtain the following time evolved wave function:

$$\psi_{k,s}(n,t_{j+1}) = \sum_l \left[\sum_m \phi^*_{l,s}(m,t_j)\psi_{k,s}(m,t_j)\right] \times exp\left(-i\frac{\varepsilon_l \Delta t}{\hbar}\right)\phi_{l,s}(n,t_j).$$

Results and Discussion

Our system is composed of a single chain of poly-*p*-phenylenevinylene, consisting of 8 monomers. We performed a photoexcitation at approximately 200 fs. As a result, a non-linear excitation was observed to take place by means of lattice distortion. Analyzing the collective behavior presented by the structure, the electronic state and its order parameter, we concluded that it has properties of a triplet polaron-exciton.

In the figure bellow, we present the time evolution of energy levels for the system. The energy levels shrinkage at approximately 220 *fs* represents the electron level promotion caused by an photon absorption.



After the excitation, starting at approximately 240 *fs*, it is clear the presence of the energy level behavior of a exciton, that remains a consistent throughout the simulation. It is important to note that the creation time of this structure is consistent with experimentally obtained time[1].

Conclusions

In this work, we investigated the relaxation mechanism of a photoexcitated carrier into both singlet and triplet polaron-exciton. The remarkable agreement of the exciton creation time with experimental evidences for PPV allows us to conclude that our model [3] is, in many aspects, a fundamental tool when it comes to the phenomenological understanding of the charge behavior in this important molecule.

Introduction. Organic coatings are effectively used for the protection of metals owing partly totheir capacity to act as a physical barrier between the metal surface and the corrosive environmentin which they perform their function [1,2]. Polyurethanesare very tough materials with high hardness and good chemical resistance.They can be tailor-made to gain properties which lead to versatile applications such ascoating systems for waterproofing and corrosion protection[3]. On the other hand, organic–inorganic hybrid coatingshas been received great attention due to its performance is much better than the single materials. In this way, this work is focused on the preparation and evaluation of ZrO_2-SiO_2 doped polyurethane films (2, 4, 6 and 8 wt-%) obtained on stainless steel 316L. The effect ofprocessing conditions was also analyzed including deposition time, different ZrO_2-SiO_2ratios and sintering treatments. In this paper, synthesis and characterization of ZrO_2-SiO_2 powders by sol-gel are reported.

Materials and Methods. Polyurethane (Desmodur E21®) provided by Bayer® (Mexico),N,N-dimethylformamide (DMF) as solvent, while ZrO_2-SiO_2nanoparticleswere prepared by sol-gel method (Figure 1) and zirconium n-propoxide (ZP;$Zr(OC_3H_7)_4$), acetylacetone (acac), tetraethoxysilane(TEOS), ammonium hydroxide (NH_4OH),ethyl alcohol (ethanol), deionized water and isopropyl alcohol(2-propanol) were utilized as starting materials. ZP (70 wt%in n-propanol solvent) solution was used withTEOS (>98%) and acac (99.5%) and isopropanol(99.7%)(solution 1). On the other hand, a second solution was prepared from TEOS diluted in ethanol and NH_4OH at vigorous stirring (solution 2); then, a solution 2 was added to the solution 1 and the resulting solution was stirred continuously for 15min., after that, deionized waterwas added and the obtainednanoparticles were subjected to heat treatment at 400, 600 and 800°C[7].The preparation of the PUR/ZrO_2-SiO_2 materials was as follows:the polymer solution at room temperature and a solution containing 10 mL of DMF and the designed amount of the ZrO_2-SiO_2 nanoparticles (2 wt%, 4 wt%, 6 wt% or 8 wt%) was added and stirred for 3 hours. The PUR/ZrO_2-SiO_2 films were obtained by casting the solution onto a glass plate and dried in a vacuum oven (10−2 Torr) for three days at 100°C.

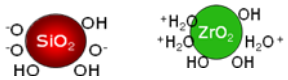

Figure 1. Sol-Gel Synthesis

Results and discussion. Different compositions of ZrO_2-SiO_2 nanoparticles were synthesized and heat treated (25:75, 50:50, 75:25wt%);representative XRD spectrafor 75:25 wt% composition are displayed in Figure 2. The oxide powders at 400 and 600°C areamorphous, while those at 800°C show the presence of tetragonal ZrO_2. Sol-gel-derived pure ZrO_2 preparedfrom a similar precursor system crystallizesat about 400°C, forming a metastable tetragonal phase. Then, the presence of SiO_2 could be inhibiting the tetragonal ZrO_2crystallization at low temperatures. On the other hand, 25:75 and 50:50 wt% compositions at the three different temperatures showed a similar behavior for 75:25 wt% composition at 400 and 600 °C.

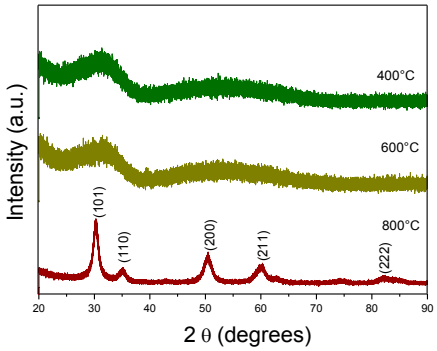

Figure 2. XRD of 75:25 wt% ZrO_2-SiO_2at 400,600,800°C

Conclusions. ZrO_2-SiO_2 powders by sol-gel were obtained. At low temperatures, an amorphous phase is observed and at higher temperature (800 °C), only tetragonal ZrO_2phase is detected. It is expected that these powders enhance the corrosion protection of polyurethane coatings.

Enhancement on Redox-Stability and Electrochromic Performance of Aromatic Polyamides Incorporating 3,6-Dimethoxycarbazolyl-substituted Triphenylamine Units

*Hui-Min Wang, Sheng-Huei Hsiao**

Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, Taipei, Taiwan

shhsiao@ntut.edu.tw

Abstract: New series aromatic polyamides (**8a-d**) with main-chain triphenylamine and pendent 3,6-dimethoxy-carbazol-9-yl units were synthesized from 4,4'-diamino-4''-(3,6-dimethoxycarbazol-9-yl)triphenylamine (**6**) and various aromatic dicarboxylic acids (**7a-d**) via the phosphorylation polyamidation technique. These polyamides were amorphous with good solubility in many organic solvents and could be solution-cast into flexible and strong films. They showed well-defined and reversible redox couples during oxidative scanning, with a strong color change from colorless neutral form to green and blue oxidized forms at applied potentials scanning from 0.0 to 1.3 V. They exhibited enhanced redox-stability and electrochromic performance as compared to the corresponding analogs without methoxy substituents on the active sites of the carbazole unit.

Synthesis and Properties of Novel Triptycene-Based Polyimides

*Hui-Min Wang, Sheng-Huei Hsiao**

Department of Chemical Engineering and Biotechnology, National Taipei University of Technology, Taipei, Taiwan

shhsiao@ntut.edu.tw

Abstract: Two new triptycene containing bis(ether amine)s, 1,4-bis(4-aminophenoxy)triptycene (**4**) and 1,4-bis(4-amino-2-trifluoromethylphenoxy)triptycene (**6**), were synthesized respectively from the nucleophilic chloro-displacement reactions of *p*-chloronitrobenzene and 2-chloro-5-nitrobenzotrifluoride with 1,4-dihydroxytriptycene in the presence of potassium carbonate, followed by palladium-catalyzed hydrazine reduction of the dinitro intermediates. The newly synthesized bis(ether amine)s were polymerized with six commercially available aromatic tetracarboxylic dianhydrides to obtain two series of novel triptycene-based polyimides **8a-f** and **9a-f** by using a conventional two-step synthetic method via thermal and chemical imidization. All the resulting polyimides exhibited high enough molecular weights to permit the casting of flexible and strong films with good mechanical properties. Incorporation of trifluoromethyl groups in the polyimide backbones improves their solubility without decreasing their physical properties. Most of the polyimides derived from the fluorinated monomer **6**, especially those prepared via the chemical imidization method, were soluble in aprotic polar solvents. In general, the trifluoromethyl-substituted **9** series polyimides showed a reduced color intensity, a slightly lowered glass-transition temperature (T_g), and comparable thermal stability as compared to the corresponding **8** series analogs. The fluorinated polyimides **9a-f** showed high T_g in the range of 272 – 335 °C and did not reveal significant decomposition before 500 °C in nitrogen or in air. The fluorinated polyimides **9d** and **9f** derived from diamine **6** with 4,4-oxydiphthalic anhydride (ODPA) and 4,4'-(hexafluoroisopropylidene)diphthalic anhydride (6FDA), respectively, could afford almost colorless thin films.

PREPARATION OF CONDUCTING POLYPYRROLE/POLYTETRAMETHYLENE ETHER (PTME) COMPOSITES

W. M. de Azevedo, J. Batista and Eduardo H. L. Falcão

Departamento de Química Fundamental, Universidade Federal de Pernambuco, Cidade Universitária, 50670-901, Recife,PE, Brazil

Abstract

In the last decade intensive enforce has been done towards the development of new solid state devices based on conducting polymers, such as solar cells, flexible electronics, electrochromic displays, modified electrodes, organic light emitting diodes, field effect transistors, memory devices, chemical, gas, bio sensors and radiation detectors. However, in order to be used as a suitable material for applications in a variety of technological fields one has to overcome certain limitations such as poor mechanical properties and processibility, instability in ambient conditions. Several approaches have been developed up to now to improve these properties, and one technique that stands out among them is the development of conducting composites.

In this work, the preparation of a polypyrrol/ **Poly(tetramethylene ether)** composite in high yield with good mechanical and electric properties is described. The method consists of one pot reaction where the pyrrol monomer and tetrahydrofuran are mixed in a beaker in the presence of strong acid. Soon after the acid is added to the solution the reaction starts, and after 24 hours the polymerization process is finished. The materials obtained can be thin of thicker film with soft or hard mechanical properties depending on the ratio of pyrrol/THF and the amount of acid used. The composition, morphology and electrical properties has been characterized by FTIR, SEM and conductivity measurements.

Synthesis of new membrane of fuel cells based on sulfonated block copolyimide

Maryam Oroujzadeh, Shahram Mehdipour-Ataei

Iran Polymer and Petrochemical Institute, P.O. Box 14965/115

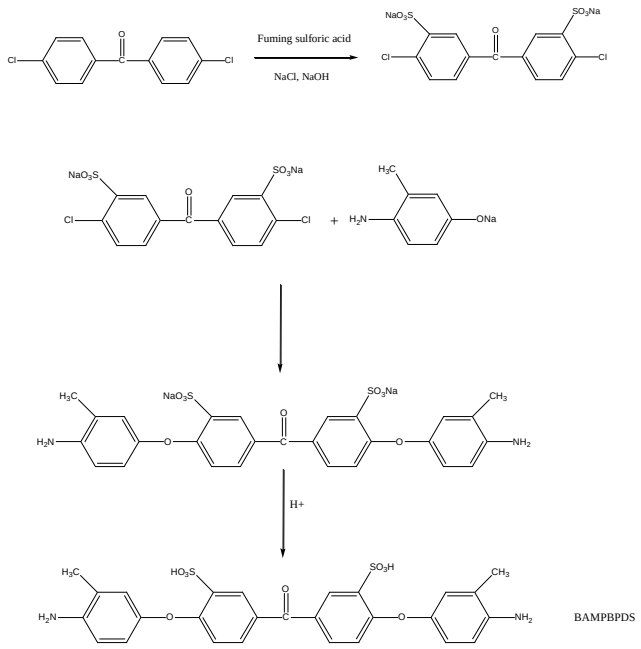
orujzadeh@yahoo.com

Nowadays, in modern world, energy consumption has become a necessity. At present, the major part of this energy, provide from combustion of fossil fuels and these resources has become an essential part of our modern life, but this consumption of fossil fuels has caused bad effects on the environment , so today there is an increasing interest on usage of alternative energy resources. Fuel cells are environmentally friendly devices for energy conversion and power generation. Proton exchange membrane fuel cells are one of the most promising classes of fuel cells and among these polymeric membranes aromatic polyimide is a suitable choice because of high decomposition temperature, high oxidative stability and good mechanical properties.

To produce a proton conductive and durable polymer electrolyte membrane for fuel cell applications, a series of sulfonated copolyimide containing flexible and aliphatic groups in the main chains were synthesized. Firstly, new sulfonated diamine 4,4'-bis(4-amino-3-methyl phenoxy)-benzhophenon-3,3'-disulfonic acid (BAMPBPDS) was synthesized by nucleophilic substitution reaction of 4-amino-3-methyl phenol with 4,4'-dichlorobenzhophenon-3,3'-disulfonicacid disodium salt (DCBPDS) in the presence of potassium carbonate and subsequent acidification with concentrated hydrochloric acid.(scheme 1) Then new sulfonated copolyimides with control degree of sulfonation were prepared via polycondensation reaction of sulfonated diamine BANBPDS in companion with two nonsulfonated diamines 4,4'-oxydianiline (ODA) and 1,8-diamino-3,6-dioxaoctane (DADO) and reaction with 1,4,5,8-naphtalene tetracarboxylic dianhydride (NTDA).

Scheme 1. Preparation of BAMPBPDS

IR-spectrum and H-NMR were used to confirm the structure of copolymers and the thermal properties of copolymers were investigated with TGA and DSC. Membranes were prepared by solution casting method. The physical properties such as ionic exchange capacity (IEC), water uptake and proton conductivity were investigated. These polymers showed promising properties for application as a proton exchange membrane for fuel cells.



Scheme 1. Preparation of BAMPBPDS

Functional PolyHIPE Materials for Metal Adsorption

E. Hilal Mert[1], Mehmet Arif Kaya[2], Hüseyin Yıldırım[1,2]

[1]Yalova University, Faculty of Engineering, Polymer Engineering Department, 77100 Yalova, Turkey
[2]Yildiz Technical University, Department of Chemistry, 34220 Istanbul, Turkey

hmert@yalova.edu.tr, husyil@yildiz.edu. tr

High internal phase emulsion (HIPE) is a water-in-oil (w/o) emulsion, consisting of at least 74% of disperse phase of the total emulsion volume and the ratio of the disperse phase can reach up to 99%. Continuous phase of a HIPE contains monomers, a cross-linker, and a surfactant whereas aqueous phase usually contains an electrolyte[1]. Cross-linking of a HIPE results in the formation of highly porous, low-density material named poly(high internal phase emulsion) (polyHIPE).

Surface properties of polyHIPE monoliths can be varied according to their chemical composition and preparation conditions. Generally, surface area of polyHIPE materials obtained this way is around 5 $m^2 g^{-1}$ and their pore size is between 5 – 100 µm. However, their surface area could be increased by using a porogen or increasing the ratio of cross-linking[2].

The simplicity of the preparation of polyHIPE polymers and their structural properties enables them to use in many different areas. For instance polyHIPE materials can be used in industrial applications such as filtration technology and ion exchange systems. They can be used as scavengers in batch and flow-through processes and for removal of metals from contaminated water sources. However, synthesize of functional polyHIPE polymers are limited; because of the polar character of monomers that are suitable for modification.

In this study, a new synthetic approach to prepare functional polyester based polyHIPE materials by using a commercial unsaturated polyester resin was described. The originality of this research is based on the cross-linking of the HIPEs. Our study involves commercial unsaturated polyester resin curing process in HIPEs. Cross-linking was achieved through the double bonds of polyester by using monomer mixtures; consequently, polyester remained as the main chain in the polymer matrix.

HIPEs that contain 85% of water as internal phase were prepared by using unsaturated polyester, glycidylmethacrylate (GMA), divinylbenzene (DVB) and triethanolamine (TEA) as emulsion stabiliser. Macroporous low-density polyester based polyHIPE monoliths were obtained by removal of internal phase after the cross-linking of HIPEs with GMA-DVB mixtures via thermal initiation. Macroporous polyHIPE beads were prepared via suspension polymerization of the pre-obtained HIPEs. In such studies hydroxyl ethyl cellulose was used to stabilize dispersed droplets of HIPEs in the suspension medium.

The morphological structures of the polyHIPE materials were investigated by scanning electron microscopy (SEM) and Brauner-Emmet-Teller (BET) molecular adsorption method was used to determine the specific surface areas and average pore sizes.

Modification of the polyHIPE monoliths and microbeads was carried out with chelating ligands such as ethylenediamine (EDA), hexamethylenediamine (HMDA) and 4-aminosalysilic acid (ASA). Elemental analysis was used to confirm the modification of polyHIPE materials. The adsorption capacities of the modified polyHIPE materials for Ag(I), Cu(II) and Cr(III) were determined under non-competitive conditions at pH 3 at room temperature. The adsorption capacities of the modified materials were determined by atomic absorption spectroscopy (AAS).

Development Of Gel-like Dispersions For Bio-lubricant Applications Using Castor Oil and Different Cellulose Pulp Samples

N. Núñez, J.E. Martín-Alfonso, J.M. Franco, C. Valencia, M.J. Díaz, C. Gallegos

Departamento de Ingeniería Química. Universidad de Huelva, Facultad de Ciencias Experimentales. Campus de "El Carmen", 21071, Huelva (Spain).

barragan@uhu.es

Introduction

Lubricating greases basically consist of a thickening agent, generally metal soaps or urea derivatives, dispersed in lubricating liquid, mineral or synthetic oil, forming a colloidal suspension (Sacchettini et al., 1985; NLGI, 1994). The performance of lubricating greases depends on the nature of its components and the microstructure achieved during processing (Delgado et al., 2005). The inclusion of polymers in grease formulations has been a common practice for many years. Polymers have played a significant role as additives in greases for modification of some performance characteristic such as dropping point, appearance, structure, tackiness, water resistance, and bleed. The rheological modification induced by polymeric additives affects the viscoelasticity of lubricating greases, which is important for preventing loss of lubricant or reinforcing sealing properties, but also the flow properties under working conditions (Martín-Alfonso et al., 2009). As the main components of lubricating greases are considered non-biodegradable materials, there is a general tendency to promote the replacement of these by renewable resources, increasing the use of eco-friendly consumer products.

Taking in account these considerations, in this work, the possibility of using different cellulosic polymers as bio-thickener agents to formulate gel-like dispersions in castor oil, potentially applicable as biodegradable lubricating greases, is explored. Cellulosic polymers from different raw materials and submitted to different pulping process and/or several acidic treatments were characterized and used to prepare these formulations.

Materials

Castor oil (211 cSt at 40ºC, Guinama, Spain) was selected as biodegradable lubricating oil. Ethyl cellulose (M_n 66000 g/mol; 49 % ethoxy content) from Sigma-Aldrich was used as gelling agent to modify the castor oil rheological properties, as previously described (Sánchez et al., 2010). Different industrial cellulosic pulps were used to prepare gel-like dispersions in the castor oil medium. Commercial grade Kraft cellulose pulp from *Eucalyptus globulus* was kindly supplied by ENCE, S.A. (Huelva factory, Spain) together with other two cellulose pulp samples obtained at different pulping process stages of the factory i.e. outflow of digesters and first process stage of bleaching (DPo), respectively.

Apart from the industrial pulps supplied by ENCE, other pulps produced in the laboratory such as Kraft and mechanical pulps from *Pinus radiata*; mechanical and semi-mechanical pulps from *Eucaliptus globulus* and a recycled pulp sample, were also used in this work.

Solvents and other chemicals employed were of reagent grade and used as received from Sigma-Aldrich.

Results, discussions and conclusions

The influence that cellulosic pulp characteristics and composition exert on the rheological properties and mechanical stability of the resulting gel-like dispersions was evaluated. From the experimental results obtained, it can be deduced that the rheological response of cellulosic polymer-based gel-like dispersions is mainly a consequence of the balance between the cellulose polymerization degree and lignin and α-cellulose contents. However, cellulosic pulp-based dispersions studied generally present poor mechanical stability or low consistency indexes, as well as higher leakage tendencies, at high temperatures, than that expected for lubricating greases.

Modification of High Ortho Novolac: A Novel Si/Acrylate Modified Resin and Its Surface Coating Properties

S. Emik, T.B. İyim, S. Özgümüş*

Istanbul University, Engineering Faculty, Chemical Engineering Department 34320 Avcilar, Istanbul / TURKEY

s.emik@istanbul.edu.tr

Introduction

Phenolic resins comprise a large family of oligomers and polymers, which are various products of phenols, reacted with formaldehyde. They are versatile synthetic materials with a large range of commercial applications such as thermal insulation materials, molding powders, laminating resins, adhesives, binders, surface coatings, impregnates, and composite material, because of their excellent ablative properties, structural integrities, thermal stability and solvent resistances [1-3]. On the other hand, in general, phenolic resins are inherently brittle due to their high cross-link density, and consequently, their application, especially in resin industry, has significantly been limited by inherent brittlenesss [4]. Long since, toughening and improving the thermal and mechanical properties of phenolic resins have been important and much attended research area. The main aim of this work is to improve the thermal resistance and brittleness of high ortho novolac resin (N), which is reactive than other novolac resins. For this purpose, firstly high ortho novolac resin was prepared according to the known procedure [5-7] and then modified in two stages. The first stage was the modification of N with a silicone containing vinyl monomer, trimethoxyvinylsilane. In the second stage, the silicone and vinyl modified novolac, (VSMN), was reacted with an acrylic monomer, methylmetacrylate. The modification reactions yield a novel resin, (VSMN-A), which should be easily used as a surface coating material; has higher thermal resistance, flexibility and better film properties than those of pure novolac resin.

Materials and Methods

Phenol (P), formaldehyde (FA) (37% aqueous solution stabilized with 10% methanol), trimethoxyvinylsilane (TMVS), methylmethacrylate (MMA), and the rest of materials that used in reactions were all purchased from Merck AG, and in analytical or synthesis grade. High ortho novolac resin was prepared according to a known procedure [5-7]. The first modification stage of N was performed by the reaction of TMVS and N in the presence of p-toluene sulfonic acid as catalyst, which yields a silicone and vinyl groups incorporated N resin, VSMN. In the second modification stage, to obtain an acrylic modified resin (VSMN-A), VSMN was reacted with MMA in the presence of benzoil peroxide as initiator.

The investigation of the surface coating properties of resins were performed according to related DIN or ASTM standards and thermal properties were investigated by TGA and DSC analysis. The thermal gravimetric analysis were carried out by Shimadzu TGA 50A instrument with a heating rate 10oC/sec, under air, and in DSC analysis Seteram DSC 131 instrument was used. FT-IR spectra of the all resins were recorded by Digilab Excalibur FTS 3000 MX instrument in the range of 400–4000 cm-1

Results and Discussion

The TGA results of the resins were given in Figure 1. As it seen from figure, after the modification reactions the modified resin VSMN-A exhibit higher thermal resistance than pure N.

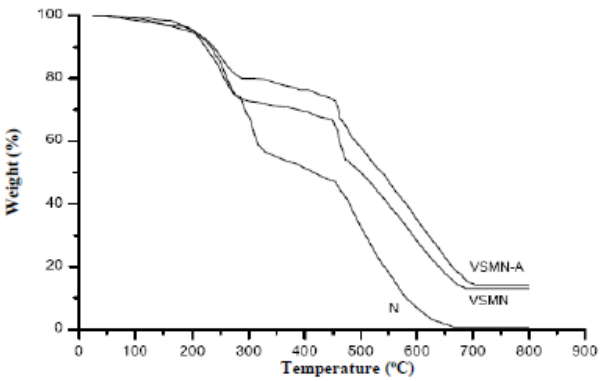

Figure1. The TGA curves of the resins.

Table 1 summarizes some surface coating properties of the resins, as it clearly seen that, by the modification reactions more flexible, and gloss resins were obtained.

Table 1. Surface coating properties of the resins.

Resin	Hardness (König s)	Adhesion (%)	Drying Degree	Gloss (at 45°)	Impact Res. (%)
N	230	<35	7	75	10
VSMN	220	85	7	80	20
VSMN-A	185	100	7	85	>60

Conclusions

In this work high ortho novolac resin was successfully modified with Si and acrylic moieties to obtain more thermal resistance and better surface coating properties than those of pure novolac.

a Department of Chemistry, University of Wrocław, 14 F. Joliot-Curie, 50-383Wrocław, Poland; b Wrocław Research Center EIT+ Ltd., 147/149 Stabłowicka, 54-066 Wrocław, Poland.

e-mail: szaf@wchuwr.pl

Introduction. Compounds with unsaturated elemental carbon chains constitute the most fundamental class of carbon-based molecular wires. Such one-dimensional assemblies are attracting a great deal of attention from the standpoints of fundamental, physical, and chemical properties and are potentially useful in the development of nano-scale electronic devices. These rod-like structures are also interesting for polymer science due to their ability to undergo topochemical 1,n-polymerization.1

On the other hand the benzoxazines are already known as valuable synthons in interesting group of commercially used polymers. Contribution will present synthesis and characterization of benzoxazine end-capped di and tetraynes. Initial tests on polymerization of these compounds will also be shown.

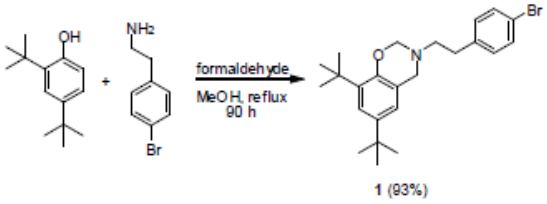
Materials and Methods. Solvents were treated by standard methods. Substrates were purchased from Aldrich and used as received. 1H and 13C NMR spectra were detected using Bruker ESP 300E or 500 MHz spectrometer.

Differential scanning calorimetry was conducted using a Perkin-Elmer DSC-7. Thermogravimetric analyses were determined with a SETARAM Setsys TG-DTA 16. IR analysis were recorded with a Bruker IFS 66/S. Mass spectrometric measurements were performed using a Bruker micrOTOF-Q electrospray mass spectrometer.

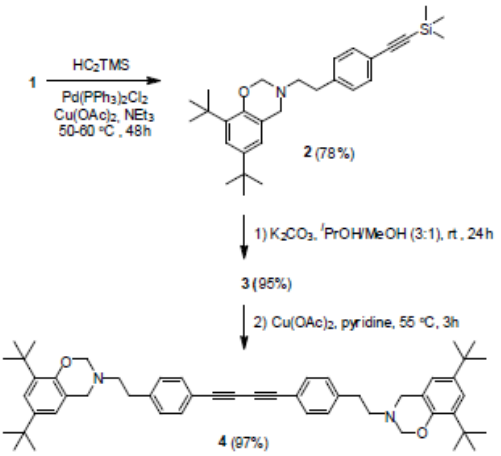
Preparation of initial 6,8-di-*tert*-butyl-3-(4-bromophenethyl)- 3,4-dihydro-*2H*-benz[1,3]oxazine. To a solution of 2,4-di-*tert*-butylphenol (2.77 g, 13.3 mmol) in 100 mL of MeOH *p*-bromophenethylamine (2.10 mL, 13.3 mmol) and formaldehyde (2.10 mL, 26.6 mmol) were added. Mixture was refluxed for 90 h. The solvent was evaporated and the oily residue was dissolved in 10 mL of MeOH and placed in a freezer (-30 °C). After 2 days white solid precipitated. It was filtered off and washed with a small amount of ice-cold MeOH. Yield 3.68 g (64%). mp 117 °C; NMR (500 MHz, CDCl3); 1H: δ = 7.39 (d, J = 8.4 Hz , 2H), 7.15 (d, J = 2.5 Hz, 1H), 7.09 (d, J = 8.4 Hz, 2H), 6.79 (d, J = 2.5 Hz, 1H), 4.86 (s, 2H), 4.02 (s, 2H), 2.99 (t, J = 7.7 Hz, 2H), 2.84 (t, J = 7.7 Hz, 2H), 1.37 (s, 9H), 1.28 (s, 9H). 13C: δ = 150.8, 142.3, 139.2, 136.8, 131.6, 130.7, 122.1, 122.0, 120.1, 119.1, 81.7, 53.1, 51.4, 35.0, 34.5, 34.4, 35.0, 34.5, 34.4, 31.7, 29.8. HRMS(ESI): calcd for C24H33BrNO 430.1740 [M + H]+; found 430.1702. EA: calcd for C24H32BrNO: C 66.97, H 7.49, N 3.25; found: C 67.03, H 7.73, N 3.17.

Results and Discussion. 2,4-Di-*tert*-butylphenol and *p*-bromophenethylamine were combined in MeOH under typical Mannich conditions to give benzoxazine **1** in 93% yield (Scheme 1). This has been modified *via* Sonogashira coupling into trimethylsilyl-substituted derivative **2** (78%), which after deprotection (**3**, 95%) and oxidative coupling gave diyne **4** in 97% yield as shown in Scheme 2.

Compounds **1-4** were characterized by spectroscopic methods and gave correct elemental analysis.

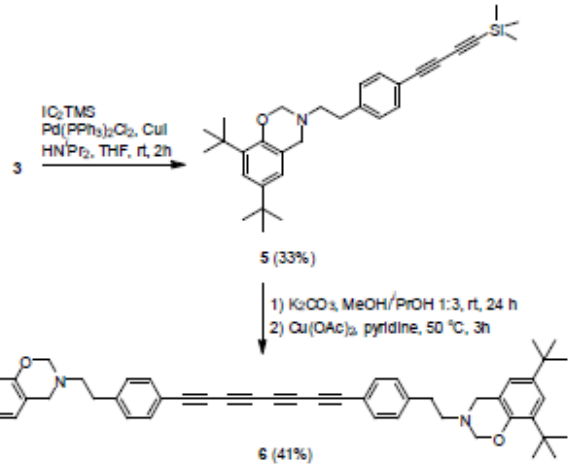


Scheme 1



Scheme 2

Deprotected **3** could easily be transformed into diyne **5** (33%) which after *in situ* deprotection and dimerization gave octatetrayne **6** in 41% yield as shown in Scheme 3.



Scheme 3

Compounds 4 and 6 were polymerized under standard conditions using PCl5 as an initiator.

Abstract Body: long chain crosslinkers, polyethylene glycol diacrylate 400 (PEGDA) and polyethylene glycol dimethacrylate330 (PEGDMA), and short chain crosslinker, *N*,*N*′-Methylenebisacrylamide (MBA), were utilized to prepare crosslinked poly(acrylic acid) microgels via precipitation polymerization. To investigation effect of crossslinkers chain length on properties and structure of polymer, FTIR spectra were used for elucidating the structure of samples (Fig. 1) and apparent viscosity was used to determine optimum crosslinker concentration (Fig. 2), also. Indeed, these microgels follow by closely packed hard sphere model and power low behavior too. The alcohol absorbency, gel content and T_g were improved by utilizing PEGDA as the crosslinker. Rheological measurements of the water-swollen gels showed superior storage modulus with the long chain crosslinker (Fig. 3). $\overline{M}_c$ was calculated by the Flory-Rehner equation [2] and rubber elasticity theory. In addition viscosity coefficient *(m)* and flow behavior index *(n)* of Ostwald equation were investigated as well.

Polymeric hybrid material and their specific functionalization, have attached great interest, due their chemical, thermal and mechanical properties performance, relative to their equivalent non hybrids. The organic and inorganic parts are combined by interactions such as hydrogen bonds and chemical covalent bonds. In this kind of system, the inorganic fraction acts as a reinforcing agent to improve hardness, strength and thermal stability of the organic polymeric fraction.[1, 2,3,4]

Siloxane based materials concentrate great interest because of their excellent chemical, physical and electric properties, but there the low interactions between molecules do not leave those materials to form fibers and films. In order to overcome this fact, the primary structure of the siloxane could be modified by side chain funcionalization or by changing the main chain, forming hybrid materials.[3]

Hybrid materials are used in several and diverse areas, such as medical products, fabrication of electronic devices, dielectric materials, protective and high performance coatings.

The enhancement of the hybrid material properties can be achieved by incorporating a variety of materials such as carbon nanotubes, layered silicates and polyhedral oligomeric silsesquioxanes (POSS) into common polymers.

In this work we would like to present two new hybrid polymers, the poly(methylmethacrylate – co - isobutyl acrylate – co - glycidyl methcrylate – co - vinyltriethoxysilane) and Poly(methylmethacrylate – co - isobutyl acrylate – co - glycidyl methcrylate – co – vinyltriethoxysilane – co – (isobuthyl) propylmethacrylate (POSS). These copolymers were prepared by a solution polymerization..[5]

The chemical structure of the hybrid co-polymers prepared was confirmed by Fourier transformed Infrared spectroscopy (FTIR) and proton nuclear magnetic resonance (^{1}H-NMR). These copolymers were used to prepare transparent films. Their surface morphology was evaluated by optical microscope analysis (OM). The hybrid co-polymer films free surface energy was determined using static contact angle determinations (CA). The dispersive and polar energy components for the free surface energy (SE) were also determined. The thermal stability of the hybrid materials prepared was also evaluated by termogravimetrical analysis (TGA).

From these results, it was possible to verify that we could prepare the proposed copolymers, using a solution polymerization methodology. It was possible to incorporate the POSS derivative monomer in the polymer structure. The synthesis and isolation methodology does not affect the functional groups integrity presented in the polymeric structure, as has been verified by the FTIR and ^{1}H-NMR analysis. The copolymers films prepared are transparent and presents a regular surface morphology (OM analysis). The incorporation of the POSS part increases the thermal resistance (verified by TGA analysis) of the final material and the hydrophobic character of the copolymer film surface (CA and SE analysis).

Introduction: Hydrogels are three-dimensional cross-linked polymeric structures which are able to swell in aqueous environments [1]. The hydrophilicity of these materials is due to the presence of water compatible groups such as -OH, -COOH, -$CONH_2$, and -SO_3H [2] and the ability to swelling with water depends firstly on the type of polymers and on the degree of crosslinking [3]. Hydrogels are becoming increasingly important because of their potential applications in industry. They are used for preparation of membranes in water purification and separation, catheters, contact lenses, agriculture, food industry, medicine, and biotechnology [4-5]. Heavy metal ions contamination causes a serious environmental problem because of their increased discharge, toxic nature [6]. Today, high levels of heavy metals in water resources have been caused several acute and chronic illnesses in humans [7]. Therefore, there is a need to develop technologies that can remove excessive heavy metal ions found in water [8]. The conventional methods for the removal of heavy metals from wastewater include coagulation and flocculation, oxidation or ozonation, membrane separation, and adsorption [9]. Among all the treatments proposed, adsorption is one of the more popular methods for the removal of pollutants [10].

The aim of this work was to synthesis, characterization and applications of N-vinyl pyrrolidone (NVP) and itaconic acid (IA) based hydrogels. For this purpose, poly(N-vinyl pyrrolidone-itaconic acid) copolymeric hydrogels [poly(NVP-co-IA)] were obtained by free radical polymerization in aqueous media.

Materials and Methods: Hydrogel synthesis experiments carried out as follows: Monomer (IA) was dissolved in dissolved in deionized water in glass tubes. Then NVP, and crosslinking agent (N,N methylene bisacrylamide (NMBA)) was added to this tube. The required amounts of ammonium persulfate (APS) as initiator and tetramethylethylenediamine (TEMED) as accelerator were added. The solution was purged with nitrogen gas for 10 min. to eliminate dissolved oxygen in the system. The polymerization reactions were carried out for 20°C at 72 h. At the end of the polymerization reactions, the hydrogels were washed fresh water to remove any unreacted monomers and initiators. The hydrogel were dried under vacuum at 50°C during 24 h for using swelling and heavy metal adsorption experiments.

Water absorption (swelling) capacities of hydrogels were determined by tea bag method. To apply this method, a tea bag that was made of 250-mesh nylon screen, contains a known amount of dried hydrogel sample was immersed entirely in water and kept there to attain swelling equilibrium for a certain time (Q_t), then hung up for 1 min. to drain the excess solution, and weighed. The water uptake was calculated to the following equation.

$$Q_t = (W_{wet} - W_{dry})/W_{dry}$$

where Q_t is the swelling ratio for a given time, W_{wet} and W_{dry} are the weights of the swollen gel and the dry sample, respectively. In case of equilibrium swelling ratio, the Q_t symbol is given as Q_e.

Heavy metal adsorption experiments were carried out at ambient temperature. Stock solution containing Cu^{2+} and Pb^{2+} ions were prepared by dissolving metal acetate salts in distilled water and by using diluted HNO_3 pH of stock solution was adjusted to 4. A fixed amount of hydrogel (0.75 g) were immersed in 50 mL of stock solution (8 mmol metal ion/L), and the mixture was stirred with a magnetic stirrer. The amount of residual metal ions in the aliquots of withdrawn solution was followed by atomic absorption spectrometer (AAS) (Varian SpectrAA FS-220) up to 72 h. Metal ion removal capacities of the copolymers (mmol/$g_{copolymer}$) were calculated as follows:

$$(C_i - C_t) \times V / M_{copolymer}$$

where C_i, initial concentration of metal ions in the solution (mmol/L); C_t, the concentrations of metal ions in the solution after metal ion removal (mmol/L); V, volume of the solution (L); and $M_{copolymer}$, the weight of hydrogel (g).

The mechanical properties of hydrogels were also determined with Zwick/Roell universal tensile testing instrument. Stress-strain measurements were performed on poly(NVP-co-IA) hydrogel with differing crosslinker concentrations.

Results and Discussion: As expected, increasing the percentage of crosslinking agent content in feed composition from 0.5 to 4 decreases the equilibrium swelling ratios (Qe) from about 550 to 35 mg H_2O/g hydrogel, respectively. The adsorption capacities of poly(NVP-co-IA) hydrogels for Cu^{2+} and Pb^{2+} were increased with the increase of the adsorption time. In addition, increasing the percentage of crosslinking agent content in feed composition from 1 to 4, increases the values of elastic modulus for poly(NVP-co-IA) hydrogels from about 171 to 1831 kPa, respectively.

Conclusions: According to the results, the poly(NVP-co-IA) copolymeric hydrogels have better mechanical properties than NVP and IA homopolymers. And we can say that, poly(NVP-co-IA) hydrogels can be used as an adsorbents for removal of Cu^{2+} and Pb^{2+} ions from wastewater.

Introduction: Hydrogels are three dimensionally cross-linked polymer network structures composed of hydrophilic homo- or hetero- copolymers, which are able to swell in aqueous environments [1]. The hydrophilicity of these materials is due to the presence of water compatible groups such as -OH, -COOH, etc. [2] and the ability to swelling with water depends firstly on the type of polymers and on the degree of crosslinking [3]. Today, hydrogels are used for preparation of membranes in water purification and separation, catheters, contact lenses, agriculture, food industry, medicine, and biotechnology [4-5].

Residual synthetic dyes are the major contributors to color in wastewaters generated from textile and dye manufacturing industries [6]. High levels of residual dyes in wastewaters have been caused several problems. Colored water is not only esthetically undesirable but also blocks sunlight which is essential for many chemical reactions which are necessary for aquatic life [7]. Therefore, there is a need to develop technologies that can remove excessive synthetic dyes found in an industrial effluent [8]. The conventional methods for the removal of dyes from wastewater include coagulation and flocculation, oxidation or ozonation, membrane separation, and adsorption [9]. Among all the treatments proposed, adsorption is one of the more popular methods for the removal of dyes [10].

The aim of this work was to synthesis, characterization and applications of N-vinyl pyrrolidone (NVP) and crotonic acid (CA) based hydrogels. In this case, firstly, poly(N-vinyl pyrrolidone-crotonic acid) copolymeric hydrogels [poly(NVP-co-CA)] were obtained by free radical polymerization in aqueous media. Then, swelling behaviours, adsorption properties and mechanical strengths of hydrogels were investigated.

Materials and Methods: Hydrogel synthesis experiments carried out as follows: Monomer (CA) was dissolved in dissolved in deionized water in glass tubes. Then NVP, and crosslinking agent (N,N methylene bisacrylamide (NMBA)) was added to this tube. The required amounts of ammonium persulfate (APS) as initiator and tetramethylethylenediamine (TEMED) as accelerator were added. The solution was purged with nitrogen gas for 10 min. to eliminate dissolved oxygen in the system. The polymerization reactions were carried out for 20°C at 24 h. At the end of the polymerization reactions, the hydrogels were washed fresh water to remove any unreacted monomers and initiators. The hydrogel were dried under vacuum at 50°C during 24 h for using swelling and cationic dye such as Safranine T (ST), Brilliant Green (BG) and Brilliant Cresyl Blue (BCB) adsorption experiments.

Water absorption (swelling) capacities of hydrogels were determined by tea bag method. To apply this method, a tea bag that was made of 250-mesh nylon screen, contains a known amount of dried hydrogel sample was immersed entirely in water and kept there to attain swelling equilibrium for a certain time (Q_t), then hung up for 1 min. to drain the excess solution, and weighed. The water uptake was calculated to the following equation.

$$Q_t = (W_{wet} - W_{dry})/W_{dry}$$

where Q_t is the swelling ratio for a given time, W_{wet} and W_{dry} are the weights of the swollen gel and the dry sample, respectively. In case of equilibrium swelling ratio, the Q_t symbol is given as Q_e.

Dye adsorption experiments were carried out in beaker flasks containing 50 mL of synthetic dye solution at room temperature. Hydrogel (0.05 g) was added to the cationic dye solution (500 mg/L) for the determination of adsorption capacity. After desire treatment period (1., 3., 5., 7., 24., 48. and 96. hours) the residual dye concentration in the solution was determined colorimetrically with a spectrometer by the measurement of absorbance at the maximum absorption wavelength, that is, 530, 618 and 622 nm for ST, BG, and BCB, respectively. All of the experiments were done at their natural pH value of dye solutions and were carried out in triplicate. The adsorption capacities (mg dye/g hydrogel) of hydrogels were calculated using the following equation:

$$q_e = (C_o - C_e)V/m$$

where q_e (mg/g) is the adsorbed amount of dye per gram hydrogel, C_o and C_e are the initial solution concentration (mg/L) and equilibrium concentration (mg/L), respectively; V is the volume of the solution; and m is the amount of the hydrogel used (g).

The mechanical properties of hydrogels were also determined with Zwick/Roell universal tensile testing instrument. Stress-strain measurements were performed on poly(NVP-co-CA) hydrogel with differing crosslinker concentrations.

Results and Discussion: As expected that increasing the percentage of crosslinking agent content in feed composition, decreases the Q_e values. The adsorption capacities of hydrogels for ST, BG, and BCB were increased with the increase of the adsorption time. In addition, increasing the percentage of crosslinking agent content in feed composition, increases the mechanical strength of poly(NVP-co-CA) hydrogels.

Conclusions: The results showed that, the poly(NVP-co-CA) copolymeric hydrogels have different mechanical strength due to percentage of crosslinking agent content in feed composition. In addition, synthesized poly(NVP-co-CA) hydrogels can be used as an adsorbents for removal of cationic dyes such as ST, BG, and BCB from wastewater.

Biodegradable Thermo-Sensitive Polyurethane-Based Foams for Tissue Engineering

J. Girones[a], *J.A. Mendez*[b], *J. San Roman*[a]

a) Instituto de Ciencia y Tecnologia de Polimeros, (CSIC), Biomateriales, C/Juan de la Cierva, 3, 28006 Madrid. b) Grup LEPAMAP, Universitat de Girona, Campus Montilivi, 17071 Girona

jgirones@ictp.csic.es

Introduction

Due to their availability in a wide range of physical properties and their excellent tissue compatibility, polyurethanes have found several biomedical applications, as implantable devices or as supporting material. Polyurethanes have been extensively studied as biodegradable and/or injectable porous scaffolds for tissue repair.[1] On the other side, since the mid-1990's lineal poloxamers, have been the subject of many studies and some have been approved by the FDA and the EPA for its use in controlled drug release and tissue engineering. Nevertheless, in spite of their large clinical potential, their poor mechanical properties, high permeability and limited stability rendered these biomaterials inappropriate for most biomedical applications.[2, 3]

In this work, we present novel thermosensitive biodegradable polyurethane scaffolds based on a star-shaped poloxamer. The hydrophylicity of the PUR, as well as it biodegradation kinetics, could be controlled by selecting the appropriate biodegradable polyester used as chain extender. In addition, the potential application of this material in tissue engineering was analyzed.

Materials & Methods

The star-shaped PEO-PPO-PEO copolymer, with a commercial code Bayfit 10WF15® was supplied by Bayer in purified form. PPO:PEO ratio was determined as 5:1 (PEO 12-13%wt) whilst the proportion primary: secondary hydroxyl groups was found to be 70:30 (NMR). Described as first electrostatic interactions, cloud point was 14ºC (Nano-DSC from 1% aqueous solutions). As chain extenders, homo- and copolymers of D,L-lactide (La) and ε-caprolactone (Cl) with Mw ranging from 500 to 4000Da were synthesized by ring-opening polymerization.

PUR scaffolds were prepared by the salt leaching method following the pre-polymer technique.[4] In short, the poloxamer was used as polyol and reacted with 1,6-hexamethyldiisocianate (HMDI). The resultant isocyanate-terminated prepolymer was mixed with the porogen and the chain extender and put into 8mm in diameter by 12mm thick Teflon molds to render the scaffolds. An NCO:OH ratio of 1.15 was targeted.

Results

Effect of porosity and porogen crystal size

The salt (sodium chloride) particles used as porogen were milled and sieved into fractions: 0-150, 150-200, 200-250, 250-400 and >400μm. Scaffolds with porosity between 80 and 95% were prepared. Leaching was verified by mass loss, thermogravimetric analysis and SEM. Polyurethane scaffolds prepared with porogen content below 80% wt did not loss all the salt, evidencing non-fully interconnected pore network. In absence of organic solvents, scaffolds with porosity above 90% were not possible to obtain since disintegrated during leaching.

Mechanical – Thermal properties

Scaffolds withstood the action of stress load and underwent an elastic recovery without detectable hysteresis. The PUR foams showed no appreciable thermal degradation untill 300ºC. After leaching, scaffolds preserved the original dimensions when placed in aqueous solutions at 20-40ºC. However, when cooled below the poloxamer cloud point, scaffolds swelled and absorbed water.

The amount and nature of the polyester chain extender had a big influence on the thermal swelling of the scaffolds. The swelling capacity of the scaffold diminished progressively with porosity and was directly related with poloxamer content. PEG chain extenders presented the higher swelling (over 10 fold). Nevertheless, scaffolds extended with PCL or P(CL-co-LA) copolymers presented increments above 300%.

Incubation in SBF

In order to study their biodegradation and to grow apatite, the polyurethane scaffolds were immersed in 1.5SBF (changed twice a week) at 37ºC. By changing the nature of the chain extender (composition, conformation, molecular weight…) we were able to obtain scaffolds that withstood structural integrity shape for less than a day or over 6 months.

Even after 60 days scaffolds no sign of apatite precipitation could be detected by SEM. In order to increase the bioactivity of the polyurethane-based scaffolds, these were dip-coated with Bioglass 45S5, rinsed and were immersed in 1.5SBF. PCL-extended scaffolds observed by SEM after 60 days showed the presence of large number of hydroxyl apatite microparticles (EDX) at the surface of the pore walls, suggesting the preservation of some osteoconductive character commonly assigned to PCL.

Development of green coatings made from biopolymers for environmental friendly packaging

Rullier, B. Bonino, J-P., Menu, M-J., Gressier, M., Ansart, F.

CIRIMAT, Université Paul Sabatier, 118 Route de Narbonne, 31062 TOULOUSE Cedex 9 - FRANCE

rullier@chimie.ups-tlse.fr

The preservation of our environment goes through the replacement of toxic and dangerous substances by new green environmental-friendly products and the improvement of products biodegradability. This context has as an immediate consequence the development of renewable resources. Especially, thanks to their biodegradable properties, biopolymers can constitute an answer to environmental issues. The food industry is one of the main users of plastics through the food packaging. The first role of a packaging is to protect its content. The preservation of food products required specific packaging with very efficient barrier properties towards especially oxygen and/or water. Our work aims at developing new coatings made from biopolymers such as proteins, polysaccharides or fatty acids. These coatings have been processed on a biodegradable plasticized-starch substrate. In order to study barrier properties to the oxygen and the water, oxygen permeability and contact angle measurements have been carried out. Our results show that the coatings made from fatty acids have a wettability lower than the one obtained directly for the substrate without coating, indicating a better barrier property to water, probably due to the hydrophobic feature of fatty acid. We observed also that contact angle measurements are not directly correlated to oxygen permeability but provide complementary information. Coatings can have equivalent oxygen permeability values, but different wettabilities.

Post-Curing of Photo-Polymeric Dental Composites - Effects on Mechanical and Dielectrical Performance

Johannes Steinhaus[1,2], *Bernhard Moeginger*[1], *Daniel Lyssek*[1], *Berenika Hausnerova*[2]

[1] Bonn-Rhein-Sieg University of Applied Science, Department of Natural Sciences, D-53359 Rheinbach, Germany

e-mail: Johannes.Steinhaus@h-brs.de

Introduction: Photo-curing dental filling materials are highly filled acrylic resins having a paste-like consistency. Immediately after light-curing for 40 to 60s the flexural modulus of such composites is in the order of 7 to 8 GPa. During the first days after curing their flexural modulus is increased up to 10-15 GPa due to the post-curing processes [1, 2]. Precise measurements of the evolution of the mechanical properties require elaborate methods, e.g. **D**ynamic **M**echanical **A**nalysis, **T**hermo-**M**echanical **A**nalysis, time dependent hardness testing, etc., and a thorough sample preparation [3]. For deeper insights into both the curing process and the long-term application properties of dental composites a real-time investigation during the first days after photo-curing is essential [4]. The aim of these investigations is to find a quantitative correlation of the changes of the ion viscosity measured by a dielectric analyzer (DEA) and the mechanical properties during the post-cure. Therefore, simultaneous DEA and DMA measurements were performed in the DMA oven using a single cantilever device. At the fixed end of the sample holder the DEA sensor was placed affirming both measurements at a single sample. Then the mechanical and dielectric properties were compared in a time range of some days. As the post-cure is driven by unreacted monomers the remaining increase of the crosslink density is determined by the shift of the glass transition temperatures after a heating run up to 200°C.

Materials: A nano-hybrid photo-curing dental filling composite consisting of acrylic resins (~11%), micro- and nano-scale glass particles (~ 88%), and additives (initiator, accelerator, stabiliser, colour, etc. (~1%).

Equipment and Methods:

DMA device: Netzsch DMA 242C, single cantilever bending mode at a frequency of 1Hz in the oven

DEA device: Netzsch DEA 230/1 and interdigitated Mini-IDEX sensors (sensor surface: 5x7mm², electrode distance: 100µm) at a frequency of 10Hz.

Sample: rectangular beam (1x5x34mm³), light-cured according to DIN ISO 2000

The sample was slightly pressed to 1mm thickness on the DEA-Sensor, light cured for 60s. The measurements started 5 minutes later.

All measurements were performed in 2 steps. In a first step the post-curing was monitored for 12, 24, 36, 48 or 72h at 36°C. In the second step the test chamber was heated with 5 K/min from 36°C to 200°C twice, in order to determine the glass transition temperatures of the post-cured and the annealed state.

Results and discussion: During the isothermal post-cure the DEA and DMA curves show the same time dependency which can be described in a zero order approach as logarithmic on time (Fig. 1). The DMA measurement shows a 30 to 40% increase of the flexural modulus during the first 24h of post-curing. The DEA curve shows the same time dependency although the ion viscosity is increased by approximately 70%.

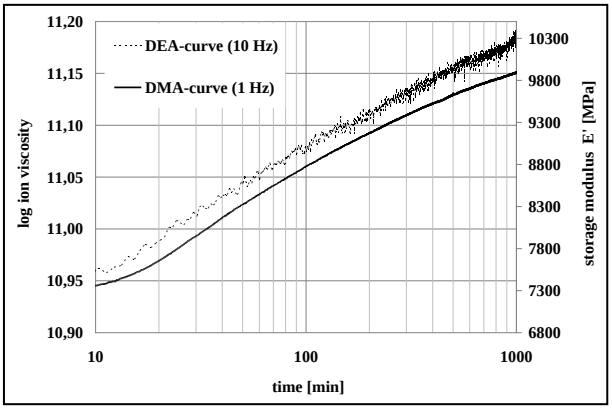

Fig. 1: DEA and DMA curves during isothermal post-curing at 36°C.

Between the 1st and 2nd heating run of the post-cured sample a shift of T_g to higher temperatures is observed due to curing processes taking place if the matrix mobility is significantly exceeded above T_g (Fig. 2). Evaluation of the inflexion points of the 1st and 2nd DMA curve shifts the T_g from 75 to 125°C. The DEA curves also show inflexion points at 73°C in the 1st heating run and at about 140°C in the 2nd heating run. It is found that the DEA indicates a slightly larger T_g-shift. This may be attributed to the fact that ions and dipoles are affected in a different way by the glass transition process.

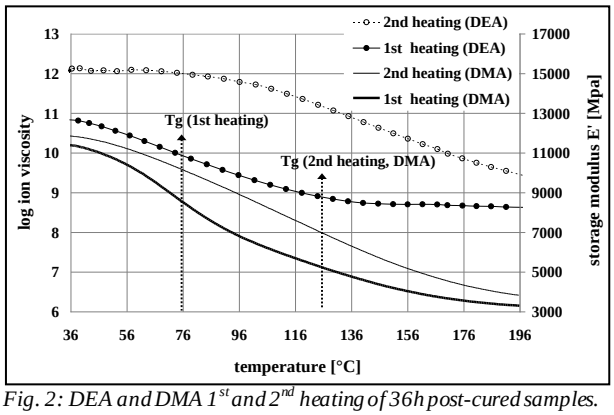

Fig. 2: DEA and DMA 1st and 2nd heating of 36h post-cured samples.

Conclusions: Simultaneous DEA and DMA measurements yield the same time dependency. This leads to the assumption that the mechanical properties of such composites may be determined using ion viscosity data and a calibration curve. Furthermore, it is shown that light curing at body temperature does leave unreacted molecules in the composites which lead to thermally stimulated post-curing processes if the temperature is raised above the actual T_g.

Introduction

Skin is the biggest organ in the body representing by 15% of its weight and with an equivalent surface of 1.7 m^2 in an adult individual. This organ is responsible of the body isolation, stimuli perception and thermal protection.

Due to this external location of this organ, skin is always in contact with the extracorporeal environment, which can be extremely aggressive against him. One of the most incident aggressions against skin is that related with burn injuries, producing necrotic phenomena depending on the deep affectation. This effect is resulting from the thermophilic, hydrophilic and high thermal conductivity character of skin.

Current treatment of burn skin is based on rehydratation of the burnt area with antibiotic supply.

In this work the incorporation of hydrolised collagen has been studied as cell proliferation promoter [1] after disease, expecting a material capable to offer a palliative help in the treatment of such kind of patients.

Materials and methods

Hydrolised chitosan powder obtained from bovine muscular tissue has been kindly supplied by Proteïn, S.A. (Celrà, Spain) and was used without any prior purification. Chitosan, kindly provided by ICTP, CSIC (Madrid, Spain) was used as polymeric support of collagen. Chitosan was previously purified by solubilisation at low pH (acetic acid 1% w/v) and reprecipitation with a solution of NaOH (9 % w/v) until neutral pH. Moreover, partial deacetylation was carried out under alkali conditions. A solution of glutaraldehyde (40% w/v) (Aldrich) has been used as crosslinking agent for chitosan.

Hybrid chitosan-hydrolised collagen films (HCHCF) were prepared by casting. Chitosan, hydrolised collagen and glutaraldehyde were dissolved in a buffer solution (acetic acid/acetate 0.25 M). The solution was placed on Petri dishes and water was evaporated at room temperature for 72 h. Figure 1a shows HCHCF films after casting. Better formulations were chosen for making dressings using medical gauze as support.

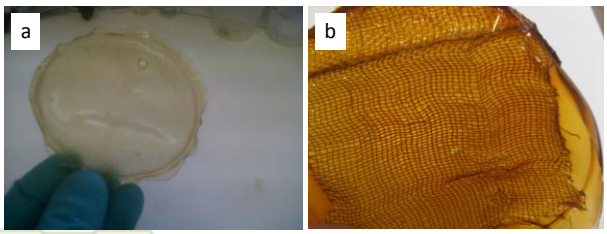

Figure 1. a) Hybrid chitosan-hydrolised collagen film obtained by casting. Chitosan-hydrolised collagen dressing oftained from formulation Col50-L

The films were characterized as follows: water absorption capacity, delivery of collagen, polymer-polymer interactions (FT-IR), thermal properties (DSC, TGA) and microscopic characterization.

Results and discussion

In terms of collagen composition, two different formulations were prepared: loaded with 30 and 50 wt% regarding chitosan content. Talking about glutaraldehyde (crosslinker) three compositions were formulated: 0.75, 2.0 and 5.0 wt% regarding chitosan content. The formulations prepared in this work are summarized in table 1.

Formulation	Collagen (wt%)*	Glutaraldeyde (wt%)*
Col30	30	0
Col30-L	30	0.75
Col30-M	30	2.0
Col30-H	30	5.0
Col50	50	0
Col50-L	50	0.75
Col50-M	50	2.0
Col50-H	50	5.0

Table 1. Compositions of hybrid chitosan-collagen films.

Plain chitosan has the capacity to absorb water until 76% (pH 7.4, T^a: 37ºC). Collagen induces an increase of water uptake until values close to 180% in just 15 min, attributed to its high hydrophilicity. Collagen is released in a very short time because it is not attached neither physically nor chemically to chitosan, confirmed by FT-IR.

The addition of glutaraldehyde induces chitosan crosslinking and an increase in T_g of chitosan. In order to have higher flexibility of the film lower values of glutaraldehyde (L) addition must be used to build the dressing. Figure 1b shows the dressing made with the formulation Col50-L. The dressing shows high flexibility, high water absorption capacity and total release of collagen in a short period of time.

Conclusion

Chitosan is a good support as collagen carrier to release it in a very short period of time to induce faster growing of cells in burn treatments.

peter.krajnc@uni-mb.si; slugovc@tugraz.at

Polymerisation of norbornene or mixtures of norbornene and dicyclopentadiene in the continuous phase of a high internal phase emulsion via ring opening metathesis (ROMP) was performed. The 2nd generation UMICORE initiator **(M2)** was used to start ROMP under high internal phase emulsion (HIPE) conditions1. Different norbornen base formulations (e.g. 20 mol% and 80 mol% dicyclopentadiene, or a 1:1 mixture) were investigated. Highly porous (up to 80%) open cellular monolithic materials with pores approximately 5 µm in diameter and with interconnecting pores approximately 2 µm in diameter were obtained (Figure 1, 2). Morphology of the resulting poly(norbornene) and poly(DCPD-conorbornene) polyHIPEs have been studied with Scanning Electron Microscopy analysis. The mechanical properties of copolymers were studied by tensile strength test. High E-modules of about 80 MPa characterized this novel class of polyHIPE materials.

The lately in literature described use of two-photon based photo-processes for producing optical applications arises the need of development and investigation of suitable functional optical materials, especially for advanced applications in the field of optoelectronics and microelectronics such as optical waveguides on printed circuit boards (PCBs). In such materials the optical as well as the mechanical and thermal properties are very important, because functionality, stability and processability of the material depend strongly on these properties. Modification of the material usually influences more than one property and can change the processability of the material. In polymers, for example, the material properties are influenced by modification of the crosslinking reaction.

In this work the influence on the material properties of two newly developed optical silicone-based materials using a different cross-linking mechanism is described. The materials are photoreactive and three-dimensional waveguides can be inscribed by two-photon laser patterning (TPA). The crosslinking in the material occurs in one case through the vinyl terminated diphenylsiloxane-dimethylsiloxane copolymer and a hydride (Si-H) component, and in the other case through an epoxy terminated diphenylsiloxane-dimethylsiloxane copolymer and an amine component. For the TPA functionality different types of acrylate and methacrylate monomers were introduced in both materials and photo-polymerized by femto-second laser excitation using a selected photoinitiator.

Both materials were characterised by Fourier transform infrared spectroscopy (FTIR) and thermal gravimetric analysis (TGA). The optical waveguides were characterised by phase contrast microscopy. Optical transparency, thermal stability and processability as well as the quality of produced waveguides are compared.

Supramolecular Block Copolymers: Synthesis and Investigation of the Crystallization Behavior.

The crystallization in block copolymers under homogeneous- and heterogeneous nucleation is currently well understood revealing the strong influence of crystallisation in competition to micropahse separation[1]. We present synthetic strategy and investigations on crystallization processes in weakly interacting supramolecular pseudo-block-copolymers composed of poly(ε-caprolactone)-b-poly(isobutylene) (PCL-b-PIB) blocks, connected via specifically interacting hydrogen-bonds of thymine/2,6-diaminotriazine. Due to the presence of hydrogen bonds, acting as a partially reversible attractive force between polymer blocks, the presented systems should display a dynamic character during crystallisation. In order to obtain PCL modified with supramolecular receptors, acetylene telechelic PCL was synthesized in the first step, proceeding via ring opening polymerization using 5-hexyn-1-ol as the initiator. In the next step acetylene functionalized PCL was connected with an azide functionalized thymine using a copper (I) mediated 1,3-dipolar cycloaddition ("click" reaction[2]). In order to obtain PIB modified with supramolecular receptors, the azide functionalized PIB
was prepared and modified with 2,6-diaminotriazine via the "click"- reaction[3]. Covalent mixing of thymine functionalised PCL with the 2,6-diaminotriazine-substituted PIB generated the supramolecular pseudo-block copolymers. Investigations of the crystallisation behaviour via non isothermal DSC measurements revealed a strong decrease in the crystallisation temperature of the block copolymers in comparison to the homopolymers. The Avrami analysis of the block copolymers (via isothermal DSC measurements) showed Avrami-exponents close to 3, indicative of a confluence of the growing crystals during the crystallization process. SAXS-measurements revealed a strong Leibler-peak which is retained in the melt state is probably originating from the microphase separation of PCL and PIB blocks.
The presented pseudo-block copolymers represent the first of their kind, demonstrating the strong energy of crystallization in comparison to microphase separation.

Introduction

Epoxy resins are among the most widely used materials in the coating of electronic devices. This is because they present good properties in terms of electrical insulation, adhesion to various components and thermal stability.

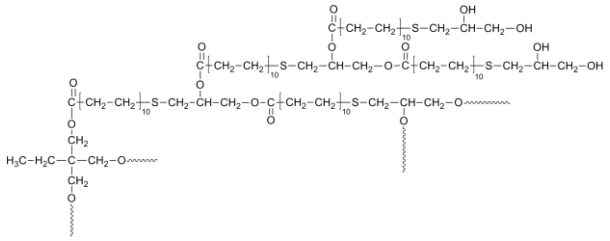
Hyperbranched polymers (HBPs) have been added to epoxy resins in order to improve some of their properties such as processability, reworkability or toughness.

In our case, we have synthesized a hyperbranched polymer with terminal hydroxyl groups to be able to link the HBP to the structure and long aliphatic chains that have proved to yield phase separation in similar systems.[1] In addition, the presence of sulfur in the structure of the polymer can lead to the formation of a macroinitiator by means of UV irradiation that can be further cured by thermal treatment.

Materials and Methods

Triethylamine, 1,1,1-tris(hydroxymethyl) propane (TMP), 10-undecenoil chloride, 1-thioglycerol and 2,2-dimethoxy-2-phenylacetophenone (DMPA) from Aldrich was used as received. THF was dried before using.

The cycloaliphatic resin 3,4 - epoxycyclohexyl- methyl-3',4'- epoxycyclohexyl carboxylate (CE) from Huntsman was used. Triphenylsulfonium hexafluoro- antimonate (PI, $Ph_3S^+SbF_6^-$, Aldrich) was added as an actual content of 4 phr with respect to the epoxy content. HBP, whose schematic structure is shown in **Scheme 1**, was added in a range between 5 and 15 phr.



Scheme 1. Chemical structure of the HBP.

The HBP was synthesized as described by C. J. Hawker et al.[2] for a similar structure, which in their case was a dendrimer. TMP was first esterified with undecenoyl chloride by a classical methodology. The salts formed were removed by filtration and the product extracted with HCl and water. Then it was dissolved in the minimal amount of THF and 1-thioglycerol and DMPA (0.4%mol) were added. The mixture was irradiated for 2 hours with 365 nm UV light at room temperature. The product was precipitated in diethyl ether. These two steps were repeated twice until a 3rd generation HBP was obtained. The chemical structure was confirmed by ^1H and ^{13}C-NMR and the molecular weight and polydispersity were determined by GPC.

Results and Discussion

The synthesized HBP was blended with the epoxy resin (CE) and we studied its curing. We first irradiated the sample at room temperature with UV light in the presence of photoinitiator to generate the thermal initiator, because tioethers are converted into sulfonium salts.[3] It is worthy to point out that some UV curing of the epoxide also takes place. We were able to quantify this amount by means of photo-DSC experiments. As the amount of HBP was increased the percentage of epoxides reacted was reduced. Three hours of thermal postcuring at 150ºC was required to teach full cure.

In order to confirm if the OH groups of the polymer were chemically incorporated to the network we determined the gel percentage of the cured materials. In all cases this was quantitative. Hydroxyl groups can be incorporated in epoxy networks by the AM mechanism that takes place in cationic systems.

Dynamomechanical analysis (DMTA) was performed to the cured samples and in all cases high values for the maximum of tan δ were obtained but the highest one was for the sample containing 5 phr of HBP.

Thermogravimetric analysis was also carried out in the thermosets with no significant differences between samples.

Conclusions

A new hyperbranched polymer was synthesized by means of successive esterification with undecenoyl chloride and thiol-ene UV-assisted click reaction.

The obtained HBP was successfully copolymerized with CE in a dual process (UV plus thermal treatment).

We can assume that the HBP becomes incorporated to the network as the gel content was quantitative for all the samples.

The Tgs of all thermosets obtained are high (above 200ºC) and the thermal stability is not influenced by the amount of HBP.

Synthesis of new methacrylates bearing phosphonic acid groups for an application in dental materials

Catel, Y.; Fischer, U.; Moszner, N.

Ivoclar Vivadent AG, Research and Development, Bendererstrs 2, FL 9494 Schaan, Liechtenstein

Yohann.Catel@ivoclarvivadent.com

Introduction

Acidic monomers are of particular interest in the field of dental materials. They could either be phosphates, carboxylic or phosphonic acids. As key component in self-etching adhesives, they are able to etch enamel and dentin surfaces, promote the infiltration of the adhesive into the demineralised surfaces and mediate the formation of a bond to a composite.[1] It has also been demonstrated that some acidic monomers are able to chemically adhere to the dental tissues (hydroxyapatite).[2] These interactions may enhance sealing for the prevention of nano-leakage and thus extend bonding longevity. [2a]

Dental composites are made of an organic matrix (dimethacrylates, photoinitiator, additives) and inorganic fillers.[3] These materials do not provide an efficient bond to the tooth tissue. To overcome this drawback, it has been suggested that the incorporation of acidic monomers to the organic matrix may result in an adhesion of the composite to the tooth.[4]

To improve the efficiency of commonly used dental materials, the synthesis of new acidic monomers is highly desired. It has been demonstrated that phosphonic acids are good candidates for chemical adhesion.[2b,5] Hence, we focused on the preparation of various monomers (aliphatic, aromatic, fluorinated, etc.) bearing phosphonic acid groups. Both monomethacrylates and crosslinking monomers were selected. In this work, we described the synthesis and the applications of the new monomers **1-7** (Figure 1).

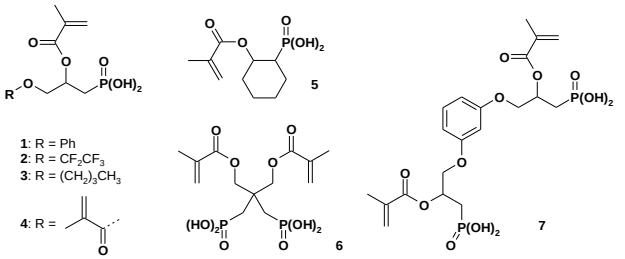

Figure 1: Structure of monomers 1-7

Results and discussion

Monomers **1-3**, **5** and **7** were easily prepared in 3 steps with good to moderate yields. The first step involved the preparation of hydroxyphosphonates by the opening of an epoxide ring with triethylphosphite in the presence of zinc chloride. The resulting hydroxyphosphonates were acylated by reaction with methacrylic anhydride, in the presence of triethylamine and a catalytic amount of 4-dimethylaminopyridine. The silylation of phosphonates with bromotrimethylsilane, followed by a methanolysis, provided the desired acidic monomers. Monomer **4** was synthesized in 5 steps, from glycidol, in a 38% global yield. First, the hydroxyl group of glycidol was protected using 3,4-dihydro-2H-pyran with a catalytic amount of pyridinium p-toluenesulfonate (PPTS). The resulting epoxide was then opened with triethylphosphite in the presence of zinc chloride. The deprotection of the tetrahydropyran group (THP) easily provided the corresponding diol. An acylation, followed by the mild deprotection of the phosphonate group, provided the monomer **4**. As for the crosslinking monomer **6**, it was synthesized in 5 steps from 2,2-bis(bromomethyl)-1,3-propanediol in a 27% global yield. The diol was first protected with 2,2-dimethoxypropane using a catalytic amount of PPTS. Then, the resulting acetal was subjected to a Michaelis-Becker reaction to provide the corresponding diphosphonate. In the third step, the diol was deprotected using Amberlyst H-15 in methanol. After an acylation and a deprotection of the phosphonate groups, monomer **6** was obtained.

In order to evaluate their acidity, each monomer was dissolved in a EtOH:water (1:1) solution (20 %wt) and the pH values were measured. The values were all bellow 1.5, showing the great ability of these monomers to etch the dental tissues. Furthermore, the ability of these phosphonic acids to demineralize HAP was investigated via a ^{13}C NMR spectroscopic study.

The reactivitiy of the synthesized monomers in photopolymerization was also studied. Thus, each monomer was copolymerized with N,N'-diethyl-1,3-bis(acrylamido)-propan (DEBAAP) (acidic monomer:DEBAAP = 1:9) and the rate of polymerization was investigated by photo-DSC.

In order to evaluate the adhesive properties of methacrylates **1-7**, new dental adhesive were formulated. Most of these adhesives showed high bond strength values and confirmed a strong bond between a restorative composite and dentin.

Conclusion

The new acidic monomers **1-7** were efficiently synthesized in 3 to 5 steps. It has been demonstrated that they are able to demineralize the dental tissues. Their reactivity in photopolymerization as well as their adhesive properties were also investigated. These new methacrylates are good candidates for applications in dental formulations.

cgonzalen@uc.cl

INTRODUCTION

Conjugated polymers.[1] composed of repeated small aryl ring molecules such as benzene, thiophene or others, are of broad interest due to their optical, electronic and magnetic properties.[2] These characteristics have been utilized in different devices such as: organic electronic and optoelectronic, including light emitting diodes (LED), field-effect transistors (FET) and photovoltaic cells.[3] For many of these applications the control of the band gap is essential, thus small values and broad absorption bands can be designed to facilitate the efficiency of photon harvesting. Electronic properties promote charge separation and transport.[4]

EXPERIMENTAL PART

The preparation of dicarboxylic acid monomer (3) was realized by two away from 2,5-dibromothiophene (Fig. 1). A Vilsmeier adduct prepared with tosyl chloride, pyridine and DMF was employed in the polycondensation between the new monomer and five different silicon-containing diphenols.

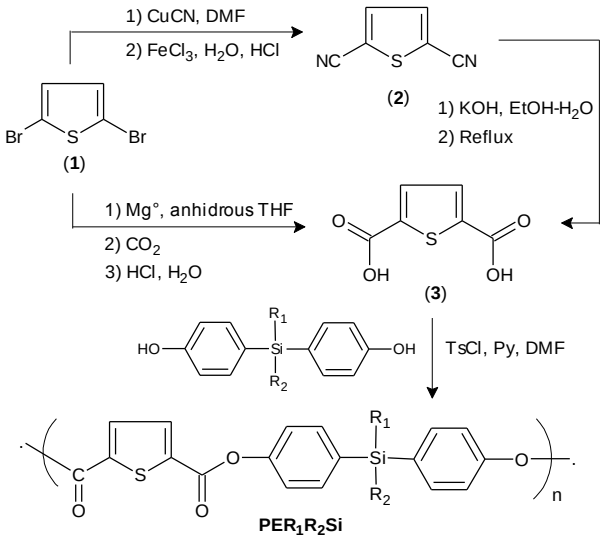

Fig. 1. Preparation of PER_1R_2Si.

RESULTS

Poly(ester)s by direct polycondensation of thiophene 2,5-dicarboxylic acid (**3**) and five different diphenols (**4a-e**), were synthesized using tosyl chloride/pyridine/dimethylformamide system as a condensing agent. The resulting polymers were obtained in good yields and were characterized by FT-IR, NMR (^1H, ^{13}C, ^{135}dept and ^{29}Si). These polymers were completely soluble in aprotic solvent, such as DMF, DMSO and NMP. The range of effective mass of the polymers is $1x10^5$ - $2x10^5$ m/z, which was determined by electrospray ionization mass spectrometry (ESI-MS). The factor of asymmetry and steric hindrance prevents a dense packing of the polymeric chains, showing a decrease in the glass transition temperature from -78 to -51 °C and loss of thermal stability (141-171 °C). Optical band gap of the polymers were 4.54 to 4.48 eV, related with an insulator behavior. The molecular arrangement was investigated with X-ray diffraction. All samples exhibited a degree of ordering, which was associated with two monoclinic lattices. Additionally, the electrical properties were studied by the two-point method with contacts on top of the films (Fig. 2). The samples were previously polarized in an external electric field, showing a better alignment of the dipoles in the direction of the field, resulting in an increase of conductance.

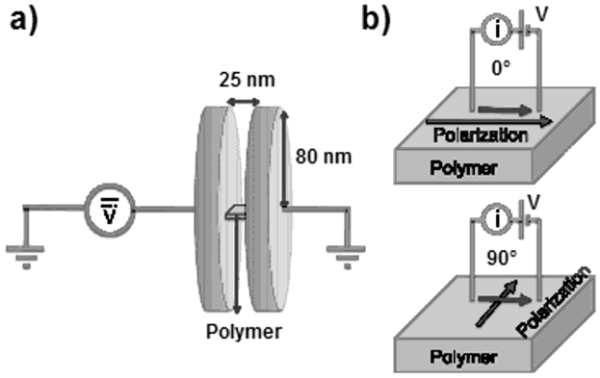

Fig. 2. (a) Experimental set up to polarize the polymers (voltage 2-16 V). (b) Once the polymer was polarized, the two-point method was used to measure the current parallel (0°) and perpendicular (90°) to the polarization.

INTRODUCTION

Poly(amide-imides)s have been widely used like opto-electronic materials, adhesives, composite materials, fiber and film material.[1] Additionally, it have been developed as alternative materials offering a compromise between excellent thermal stability, good solubility in highly polar solvents, low Tg and easier processability with respect to poly(imide)s.

EXPERIMENTAL PART

Diphenylsilarylen and L-aminoacid-containing chiral dicarboxylic acid were prepared from *o*-bromoxylene (Fig. 1). These monomers were employed in a direct polycondensation with (4-aminophenyl)diphenylsilane using triphenylphosphite (TPP)/pyridine, $CaCl_2$ and NMP as condensating system.[2]

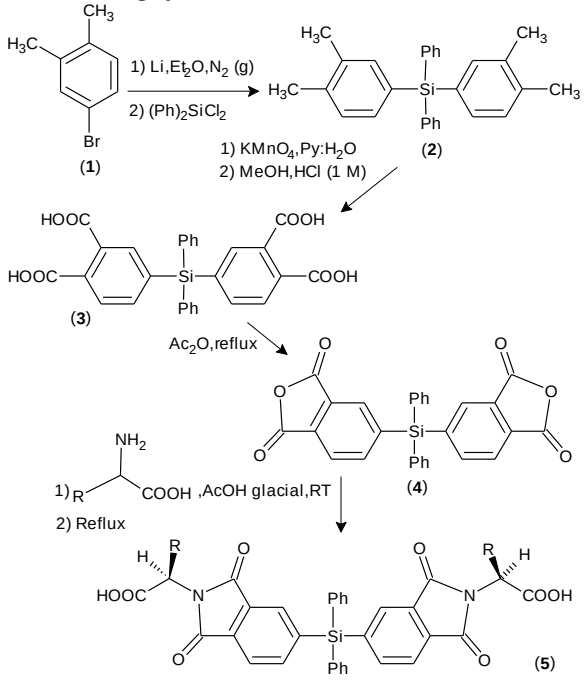

Fig. 1. Synthesis of chiral dicarboxylic acids. R= -CH_3, $(CH_3)_2CHCH_2$-, $(CH_3)_2CH$- and $PhCH_2$-.

RESULTS

Optically active poly(amide-imides)s were synthesized by direct polycondensation between an aromatic diamine and a dicarboxylic acid containing both the diphenylsilylene unit. Polymers were obtained in good yields and showed a high solubility in common aprotic polar solvent. The precursors were characterized by elemental analysis (EA), FT-IR and NMR spectroscopy (^1H, ^{13}C and ^{29}Si). Additionally, the main vibrations of the functional group (C=O, C=C or N-H) in the polymers with respect to the temperature, were characterized by Raman spectroscopy (Fig. 2).

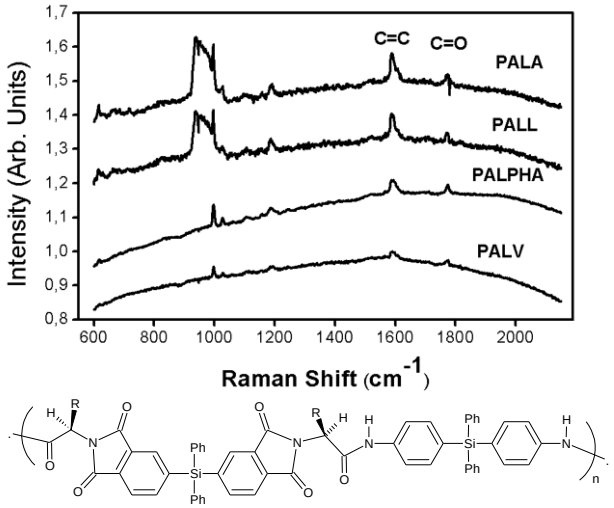

Fig. 2. Raman spectra at room temperature. R: PALA= -CH_3, PALL= $(CH_3)_2CHCH_2$-, PALV= $(CH_3)_2CH$- and PALPHA= $PhCH_2$-.

The glass transition temperature (T_g) was determined by studying the Raman peaks behavior and corroborated by DSC (Fig. 2). Thermal stability was studied by TGA. The molecular weight of the compounds was obtained by MALDI-TOF mass spectrometry and their optical properties were analyzed by UV/Vis diode array. On the other hand, the electronic properties of the polymers as well as the delocalization of charge carriers within of the structure have been analyzed by conductance-voltage curves showing that these materials are excellent candidates for integrated opto-electronic applications.

INTRODUCTION

Poly(amides) and poly(imides) are high-performance polymers with thermal and mechanical properties, which made them useful for advanced technologies.[1] One of the main problems of this kind of polymers is the low solubility, which affects their processability. It is known in this sense that the polymer solubility is related to the presence of flexible and polar units, the meta-oriented aromatic rings and also the presence of several functional groups in the polymeric chain.[2-4] In this sense, it is possible to obtain soluble polymers with lower Tg values but maintaining the thermal stability. On the other hand, the presence of silylaromatic units in the polymeric chain, also can increase the solubility due to the ionic character of the C-Si bond.[5] In this work we described the synthesis, characterization and thermal properties of poly(imide-diamides) derived from diacids that contain both groups: imide and amide, which were synthesized from tetrachloro or tetrabromo phthalic anhydride and aminoacids as flexible units. These diacids were polymerized with an aromatic diamine containing the Si atom in the structure

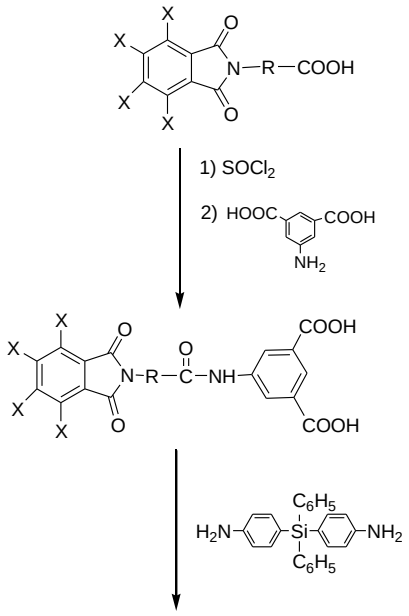
EXPERIMENTAL PART

The chlorinated or brominated 2-phthalimidyl-R-acids were obtained from tetrachloro or tetrabromo phthalic anhydride and the following aminoacids: glycine, L-alanine, L-phenylalanine, L-valine, L-leucine, L-isoleucine and p-aminobenzoic. These chlorinated or brominated acids reacted with thionyl chloride and then with 5-amino-isophthalic acid in order to obtain the monomeric diacids.[6] The diamine bis(4-aminophenyl)diphenylsilane was obtained according to a described procedure.[7]

Poly(imide-diamides) were obtained from the diacids and the diamine with triphenyl phosphite, pyridine and $CaCl_2$ in N-methyl-2-pyrrolidone. The mixture was stirred a 120 ºC and precipited in methanol. Polymers were filtered, washed, dried until constant weight and characterized.

RESULTS

Poly(imide-diamides) were obtained according to the scheme showed in the figure.



Poly(imide-diamide)

X: Cl, Br.

Where R: CH_2 (Cl-PIDA-I, Br-PIDA-I); $CH(CH_3)$ (Cl-PIDA-II, Br- PIDA-II); $CH(CH_2\text{-}C_6H_5)$ (Cl-PIDA-III, Br-PIDA-III); $CH\text{-}CH(CH_3)_2$ (Cl-PIDA-IV, Br- PIDA-IV); $CH\text{-}[CH_2\text{-}CH(CH_3)_2]$ (Cl-PIDA-V, Br-PIDA-V); $CH(CH\text{-}CH_3)\text{-}CH_2CH_3$ (Cl-PIDA-VI, Br-PIDA-VI); $p\text{-}C_6H_4$ (Cl-PIDA-VII, Br-PIDA-VII)

Poly(imide-diamides) were characterized by IR, ^{1}H, ^{13}C and ^{29}Si NMR, and the results were in agreement with the proposed structures. The η_{inh} values were obtained in order to estimate the molecular weights of the polymers. The thermal properties, glass transition temperature Tg, and the thermal decomposition temperatures TDT, were measured and the values related to the polymeric structures and the nature of the halogen atoms in the imide group.

The use of nanotechnology to improve the pharmacokinetics of drugs presents the challenge of the inclusion of hydrophilic low molecular-weight species (HLMWS) in nanoparticulate systems. Chemical modifications achieved to bind these molecules to nanoparticles affect significantly the structure activity relationships of the drugs.[1] In order to include non-modified HLMWS in nanoparticles, strong chemical interactions with the nanoparticle matrix are needed, such as Van der Waals forces, hydrogen bonds, hydrophobic forces, and aromatic-aromatic interactions.

Water-soluble polymers may be constituents of these nanoparticulate matrices. HLMWS containing aromatic charged groups may present strong interactions with polymers bearing aromatic groups in their structure. As an example, molecules such as methelyne blue, rhodhamine 6G, triphenyltetrazolium chloride, or chlorpheniramine maleate undergoe strong interactions with poly(sodium 4-styrenesulfonate) (PSS).[2]

Cytidine (CTDN) is a nucleoside chosen as model drug of Nucleoside / Nucleotide Reverse Transcriptase Inhibitors, used in antiviral treatment. CTDN presents aromatic character and high solubility. Is a molecule sensitive to environmental pH. The UV-Vis spectra of CTND (Figure 1) show a change on the local maximum by increasing the pH, and have an isosbestic point at 265 nm. PSS has the capacity of move to lower energy the isosbestic point and increase the pKa of CTDN. In consequence, PSS promote the formation of protonated CTDN[3]. Other polyanions such as poly(sodium vinyl sulfonate) (PVS), poly(styrene-alt-maleic acid) (P(S-alt-MA)), and poly(acrilyc acid) (PAA), only produce a discreet change on the pKa and did not affect the isosbestic point. Diafiltration experiments showed a higher ability of PSS to bind CTDN, and a high sensitivity to the addition of NaCl was found. H^1-RMN spectroscopy showed that PSS produces an upfield shift of CTDN aromatic signals, as a signal of the existence of aromatic-aromatic interactions between both species. This behavior is not observed in the presence of NaCl.

Nanoparticles were made by ionic complexation at pH 4 between the different anionic polymers and chitosan, a cationic polymer. The effect of varying molar ratios of charges (n+/n-) and total amount of charge in solution (n+ + n-) was evaluated. Nanoparticles with PSS, P(S-alt-MA) and PVS were prepared. The total amount of charge varied between 1 and 6 mM. It was found that the optimal conditions were 4 mM of total charges and n+/n- between 0.3 and 2.2 (Figure 2). However, n+/n- 1.5 was chosen since CTDN bound to the polyanions is expected to be located at the inner core of the nanoparticle. The nanoparticles were loaded with CTDN and the load efficiency analyzed by HPLC.

Dendrimers are highly branched and have well-defined architectures with a number of special chemical and physical properties [1, 2]. Their highly branched and uniform structures can be used in the field of coatings industry, chemical sensors and drug delivery systems [3].

Recently, the use of PPI dendrimers as co-initiators in photoinitiated radical polymerization, has been tested [4]. The photopolymerization was carried out with UV radiation employing benzophenone and thioxanthone as sensitizers. The investigation of the structure of the resulting polymers suggested the presence of stretched polymer chains around the dendrimer. In another study, macrophotoinitiators were prepared using DAB dendrimers and thioxanthone as sensitizer in the UV system[5]. These initiators were found suitable for use in aqueous systems. The use of dendrimers as co-initiators seems to be promising and it was therefore of interest to investigate the extension of their use to the visible zone of the spectrum. Additionally Poly(propylene imine) dendrimers were recently used as the hydrogen donor for type II photoinitiation of methylmethacrylate monomer in free radical polymerization [6].

There are two types of photoinitiators in free radical polymerization: an alpha type scission initiator (type I) and a hydrogen abstraction type photoinitiator (type II). Because the initiation is based on a bimolecular reaction, type II photoinitiators are generally slower than type I photoinitiators, which are based on a unimolecular formation of radicals. Benzophenone (BP) is a well known type II photoinitiator (PI) for the radiation curing of coatings printing inks, etc. After triplet state excitation, benzophenone is able to abstract hydrogen from ether, amine, alcohol or thiol functional co-initiators. Thus, reactive centers can be generated on
co-initiator molecules to initiate free radical polymerization

As a macrophotoinitiators, up to third generation of dendrimer was synthesized[7]. Initial core of all dendrimers was based on poly(propylene oxite) amine (Jeffamine®). At the second stage, previously synthesized 2-acryloyl thioxanthone was coupled to amine terminated dendrimers. All the reactions were performed by using microwave irradiation technique. The photophysical and photochemical properties of these photoinitiators were studied. Later absorption characteristics of Jeff-(3)-Thioxanthone (J-(3)-TX), Jeff-(6)-Thioxanthone (J-(6)-TX) and Jeff-(12)-Thioxanthone (J-(12)-TX) were determined in different solvents. The fluorescence emission spectra of Jeff-(3,6,12)-TX were also ivestigated by exciting at λ_{exc} = 395 nm.

In conclusion, BP/Me- β-CD water soluble photoinitiator was readily prepared in a conventional complexation procedure, and fully characterized by ^{1}H-NMR, UV and FT-IR. Laser flash photolysis and phosphorescence studies show that BP/Me-β-CD complex is similar to the parent benzophenone compound after the complexation reaction. However, these inclusion complexes could initiate polymerization of acrylamide in aqueous media.

Introduction. The availability of new crystalline polyolefins by control of catalyst "chain-walking" offers the opportunity to study crystalline properties of new polymer structures similar to the most common polyolefin commodities. Living polymerization of 1-butene with an α-diimine Ni(II) catalyst generates new crystalline polybutenes with unique chain microstructures.[1] A normal (1,2) insertion followed by a subsequent chain-walking to the fourth carbon results in a (4,2) addition. Conversely, a regio (2,1) inversion followed by chain-walking produces (4,1) linkages leading to a sequence of four consecutive methylenes in the backbone chain. In addition, when high selectivity for (4,2)-enchainment is exhibited a (4,2)-enchained poly(1-butene) is obtained. This polybutene is isostructural with poly(*trans*-2-butene). In this work we study crystalline properties of the novel polybutenes with a similar content of (4,2) and (4,1) additions and different content of stereo defects.

Materials and Methods. The molecular characteristics of the two polybutene samples studied are as follows. From ^{13}C NMR, (4,2) additions (~96 mol%), stereo errors (9 or 16 mol%); (4,1) additions (~ 4 mol%), and zero (1,2) additions in both samples. The combined (4,2) and stereo defects are 12, (4,2PB12) and 21 mol% (4,2PB21) for the most and the least crystalline samples studied. From GPC, Mw = 54,000 Dalton, Mw/Mn = 1.5.

The melting peaks, T_m, heat of fusion, ΔH, and overall crystallization kinetics were followed by DSC (Perkin Elmer DSC7). Wide and small angle x-ray diffractograms (SAXS, WAXD) were obtained at ambient temperature on samples that were previously isothermally crystallized either in the DSC or in thermostated baths. The degree of crystallinity derived by WAXD, X_c, was determined from the x-ray powder diffraction profiles of samples isothermally crystallized at different temperatures, T_c. The WAXS pattern of molten 4,2PB was used as amorphous halo. Crystal and interlamellar thicknesses were obtained from SAXS profiles via one-dimensional correlation function analysis. Spherulitic morphology and linear growth rates were analyzed by polarized optical microscopy and a Linkam hot stage, and lamellar morphology by AFM in non-contact AC mode. The densities were measured at room temperature in a water/isopropanol density gradient column calibrated with standards glass floats.

Results and Discussion. *Crystalline Structure*. In spite of a relatively low tacticity (mm <0.8), and a significant content of (4,1) defects, WAXD patterns exhibit two relatively sharp crystallographic reflections at 2θ = 16.9 and 19.7 degrees, consistent with high order chain-packing symmetry. Unlike *i*PP and poly(1-butene) that display polymorphism with increasing stereo defects or increasing crystallization temperature, the crystallographic phase of 4,2PB is maintained with increasing T_c or defects. The WAXD-derived degree of crystallinity (X_c) is low (<30 %) in 4,2PB21, and exhibits a modest 37 to 52 % increase in a large T_c range in the sample with 12 mol% defects.

Under isothermal crystallization, 4,2PB12 develops relatively thick lamellar crystallites (~ 95 Å thick by AFM) that aggregate in highly ordered spherulites. This feature and the relatively high crystallinity content for a copolymer with a high content of structural defects suggests co-crystallization of the stereo defects, similarly to the inclusion of stereo defects in *i*PP crystallites. With increasing chain defects the structural irregularities break down the spherulitic and lamellar habits.

Thermodynamic Parameters. Degrees of crystallinity of isothermally crystallized specimens were combined with density measurements, heat of fusion, and lamellar thicknesses to estimate the densities of the crystalline and amorphous phases, ρ_c = 0.9494 g/cm^3 and ρ_a = 0.8698 g/cm^3, respectively, and the heat of fusion per mole of crystalline unit (ΔH° = 132.6 J/g). Accounting for a re-structuring of crystallites during melting, the crystallites thicknesses and melting temperatures were analyzed with the simplified Gibbs-Thompson equation to extract values of the equilibrium melting temperature and the basal surface free energy of the crystallites. The value of $T_m°$ = 135 ± 4°C. The defects reduce the $T_m°$ value of 4,2PB in reference to expectations for the defect free chain and values. At a 12 mol% defect level, the $T_m°$ is similar to the value for form I of *i*poly(1- butene), and significantly lower than for *i*PP and *s*PP. However, the heat of fusion per mole of crystalline units (8670 J/mol) is similar to the values of *i*PP and *s*PP in spite of a larger repeat unit. From the Gibbs-Thompson relation, the interfacial free energy is σ_e = 77 erg/cm^2. This value is supported by a basically identical σ_e value obtained from an analysis of lamellar growth rates according to secondary nucleation theory. The σ_e value of 4,2PB is similar to values obtained for polyethylene and *i*PP homopolymers (~ 70 erg/cm^2), and lower than for *i*PP copolymers with about the same content of defects. This feature suggests a relatively flexible conformation that favours chain folding in the novel poly(butenes).

Conclusion. The thermodynamic and structural properties of 4,2PB synthesized with a α-diimine Ni(II) catalyst have been analyzed. Stereo and (4,1) regio are defects that hinder the crystallization, as given by the decreasing rates, decreased levels of crystallinity and lowered melting temperatures with increasing defect content.

e-mail: ysgal@kiu.ac.kr

Introduction

Substituted polyacetylenes are highly desirable due to their greater oxidative stability compared with the polyacetylene itself. And also, the attachment of pendant groups can also add to the functional properties of the material.[1,2]

The conjugated polyelectrolytes such as poly(propiolic salt)s, triethylammonium salt of poly(6-bromo-1-hexyne), poly(dipropargylammonium salt)s, and poly(ethynylpyridine) were reported.[1] We have also reported the preparation of various ionic conjugated polymers having different functionalities.[1,2] Due to their extensive conjugation and ionic nature, these ionic polyacetylenes have potentials as materials for mixed ionic and electronic conductivity, energy storage devices such as batteries, permselective membrane, and light-emitting devices.[1]

Here, in a series of synthesis of conjugated polymers, we report the synthesis of a self-dopable ionic conjugated polyacetylene via the activated polymerization of 2- and 3-ethynylpyridines by the ring cleavage of designed cyclic compounds.

Experimental

2 and 3-Ethynylpyridines (Aldrich Chemicals.,) were used as receivesd. An ionic conjugated polymews were synthesized by the activated polymerization of 2 or 3-ethynylpyridines by using such ring-openable compounds as propiolactone, 1,3-propanesultone, 1,4-butanesultone, etc. As the polymerization reaction proceeded, the color of reaction mixture was changed from the light brown of the initial mixture into dark red solution. And the viscosity of reaction solution was also increased. After the polymerization time, the resulting polymer solution diluted with additional DMF was precipitated into an excess amount of ethyl ether, followed by filtration. The collected powder was dried under vacuum overnight at 40 ^{o}C for 24 h.

Results and Discussion

Ionic self-dopable conjugated polyacetylenes were easily prepared by the activated polymerization of 2- and 3-ethynylpyridine with the ring-cleavage reaction of designed cyclic compounds without any additional initiator or catalyst. As the reaction proceeded, the color of reaction mixture was changed from the light brown of the initial mixture into dark red solution. And the viscosity of reaction solution was also increased. This polymerization proceeded well in relatively mild reaction condition to give high yields of polymer.

The molecular structures of the resulting ionic polyacetylenes were characterized by such instrumental methods as infrared, NMR, and UV-visible spectroscopies. FT-IR spectra of 2-ethynylpyridine, cyclic compound, and resulting ionic polyacetylene were measured and compared. FT-IR spectrum of an ionic polyacetylene did not show the acetylenic C≡C bond stretching (2110 cm^{-1}) and acetylenic ≡C-H bond stretching (3293 cm^{-1}) frequencies of 2-ethynylpyridine. Instead, the C=C stretching frequency peak of conjugated polymer backbone around 1575-1670 cm^{-1} became relatively more intense than those of the C=C and C=N stretching frequencies of 2-ethynylpyridine. The electro-optical and electrochemical properties of ionic polyacetylenes were studied by using UV-visible and photoluminescence (PL) spectroscopies and cyclic voltammograms (CV). The absorption spectra of polymers exhibits characteristic absorption peak at visible region, which is due to the $\pi \rightarrow \pi^*$ interband transition of conjugated polymers. The photoluminescence spectrum of an ionic conjugated polymer with N-propylsulfonate functional group showed that the photoluminescence maximum peak is located at 552 nm corresponding to the photon energy of 2.25 eV. The cyclovoltammograms of polymer exhibited the irreversible electrochemical behaviors between the oxidation and reduction peaks. The oxidation current density of polymer versus the scan rates is approximately linear relationship in the range of 30 – 120 mV/sec. It was found that the the kinetics of the redox process of polymer is almost controlled by the reactant diffusion process from the oxidation current density of polymer versus the scan rates.

Conclusions

We synthesized various ionic conjugated polyacetylenes by simple activated polymerization of ethynylpyridine without any additional catalyst or initiator. These self-dopable polyacetylenes may be used as material candidates for chemical sensors, OLEDs, solar cells, etc.

Porous polymer surfaces with superhydrophobic/superhydrophilic micropatterns: towards genome-on-a-chip cell microarrays

*Florian L. Geyer[1,2], Urban Liebel[1], Erica Ueda[1], Pavel A. Levkin[1,2]**

Living cells are extremely complex biological systems and a variety of cell assays have been developed to study these systems *in vitro*. In the last few years, cell microarrays have emerged as a promising technique that enables cell assays in a highly parallel and miniaturized manner.[1-3] However, due to cross-contamination and cell migration problems, the density of most current cell microarrays is still limited.

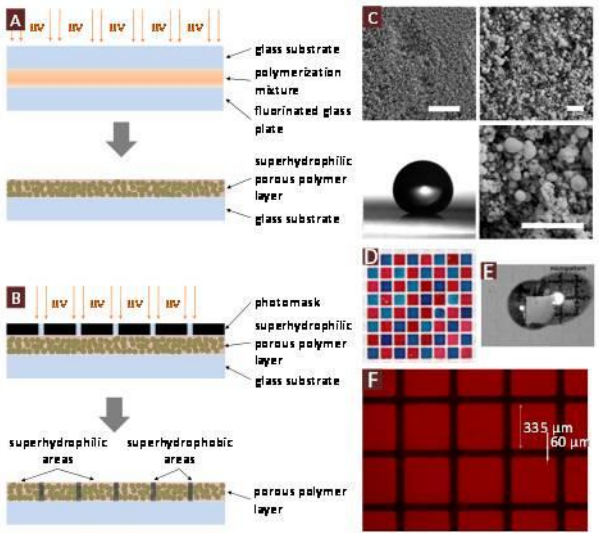

Figure 1. (A) Scheme of the preparation of a superhydrophilic porous polymer film on a glass substrate by UV-initiated free-radical polymerization. (B) Fabrication of the superhydrophobic grid-like pattern on the superhydrophilic surface by UV-initiated photografting. (C) Water droplet on the superhydrophobic polymer; SEM images of the same polymer. Scale bars: top left - 10 µm, top right and bottom - 1 µm. (D) The array with microspots filled with alternating water solutions of red and blue dyes. (E) A water droplet on a single superhydrophilic microspot. (F) Fluorescent microscope image showing the array with spots filled with Rhodamine 6G.

We discovered a way to overcome these problems using a porous superhydrophilic polymer, poly(2-hydroxyethyl methacrylate-*co*-ethylene dimethacrylate), coated onto a substrate and patterned with superhydrophobic barriers[4,5] using photografting - a surface modification technique. Cell experiments carried out with several commonly used cell lines confirmed preferential adhesion and proliferation of cells on the superhydrophilic spots and virtually no cell growth on the superhydrophobic barriers. In addition, the narrow superhydrophobic gaps between the spots proved to be highly efficient barriers against cell migration. Because of the extreme difference in wettability between the superhydrophilic and superhydrophobic areas, this method allows us: (1) to significantly reduce the distance between the microspots and (2) to achieve precise control over the size and (3) geometry of the microspots. Moreover, the transparency of the porous polymer inside the hydrophilic spots allows for microscopic investigation to be carried out. This allows us to increase the amount of spots on one 11 x 7 cm² area (standard microtiter plate size) to about 50000 square spots large enough to accommodate at least 100 cells to deliver statistically valid read-out data. Spotting solutions are adsorbed in the porous structure of the spots, while the superhydrophobic pattern prevents spreading to adjacent spots, thus also eliminating the serious problem of cross-contamination.

We envision that this technology based on a porous polymer coating will enable fabrication of "genome-on-a-chip" cell microarrays and will transform genome-wide cell screening experiments into a significantly more affordable and convenient biological tool.

Introduction:

Over the last years, the conducting polymers found a new interest from both academic and industrial points of view due to their interesting properties and possible applications, in the conversion of solar energy into electrical and/or chemical forms. In order to diminish the dependence of the fossil fuels and in this way the greenhouse gases, the solar power is considered as eco-friendly energy, an attractive alternative due its large abundance and consistency [1,2].
For this purpose, the use of polymer semiconductors as photoactive electrodes and photovoltaic devices attracts much attention of a large scientific community [3]. Such materials are not only able to function in a similar way to inorganic semiconductors but have additional advantages including environmental friendliness, low cost, light weight, easy fabrication, and potentially manufacturable as large-area coatings. They have been considered as promising materials for organic light conversion devices, in particular, for solar cells and photodetectors.

Our aim in this contribution was focused on a study of photoctalytic process in order to product the hydrogen using polymer semiconductor materials such as doped polyaniline (emeraldine salt).

2. Experimental

The powder was cold pressed into pellets under 1 kbar. In order to minimize the contact resistance, silver paint was deposited on the back pellet by spot welding a copper wire. The pellets were mounted in Teflon holders to give a projected surface area of 1.32 cm^2.
PEC measurements were done in NaOH (1 M) electrolyte under potentiostatic conditions using a three electrode cell with a large Pt counter electrode and a saturated calomel reference electrode (SCE). The electrode potential was monitored by a computer controlled potentiostat (Voltalab PGZ 301, Radiometer).
The electrode was illuminated through a flat optical window by a 200 W tungsten lamp.
Prior each run, A nitrogen stream was passed over the solution to remove dissolved oxygen, the purging rate was maintained constant at 10 mL mL^{-1} during 35 min.
50 mg of powder (PANI) was suspended by magnetic stirring in a double walled Pyrex reactor in 250 mL of aqueous Na_2SO_3 (0.1 M) solution.
The light source was an assembly of three tungsten lamps which are predominantly in the 400-900 nm (max. 650 nm), disposed around the reactor.

Hydrogen in the outgoing gas was identified by gas chromatography. The amount was collected volumetrically with a water manometer in an inverted burette via water displacement. Blank runs were carried out and no hydrogen was evolved in the dark.
The experiments were repeated three times with very reproducible results

Results and discussion:

The photoelectrochemical properties of polyaniline (emeraldine-salt) (PANI) doped was investigated by the photocurrent technique and capacitance measurements in various electrolytes. The volume evolved of H_2 as showed in Figure 1 reveals the applicability of this material for the photocatalytic conversion. The photocatalytic properties have been evaluated for the first time according to the H_2 evolution under visible light.

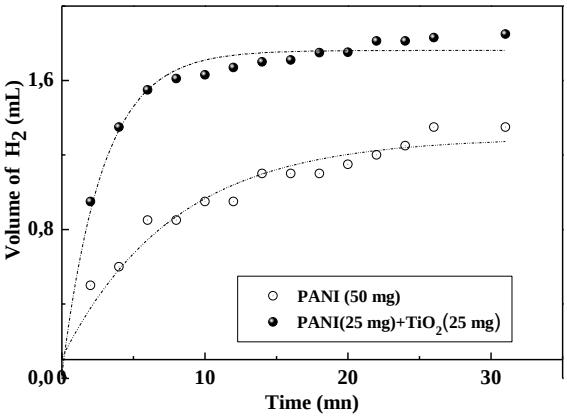

Figure 1: Volume evolved H_2 versus irradiation time on Na_2SO_4 solution (0,1 M)

Therefore, favorable valence band position for water reduction makes the PANI as an ideal photocathode. Our results indicate that the doped PANI is able to generate incident photon to chemical chemical efficiency of 4% under an intensity of 20 mW cm^{-2}.

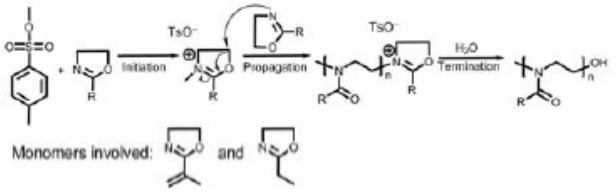
Introduction

Hydrogels or aquagels are solid, three-dimensional networks consisting of hydrophilic polymer chains that can be obtained from chemical or physical cross-linking processes. They are water-swellable, but not soluble. Due to their high water content, hydrogels are often highly biocompatible with minimal absorption of proteins. Hence, aquagels possess a wide range of potential applications, especially in the fields of tissue engineering and drug delivery,[1] which are closely related to the chemical structure of their components and the networks' morphologies.[2]

Given the FDA approval for poly(2-ethyl-2-oxazoline) and poly(2-phenyl-2-oxazoline), it is surprising that the group of poly(2-oxazoline)s has been scarcely considered for hydrogel formation so far (21 CFR 175.105).

Materials and Methods

Poly(2-oxazoline)s can be synthesized by living cationic ring-opening polymerization. Different functionalities are achieved through consumption of monomers with various side-chains. Moreover, the living nature enables a target-oriented synthesis of tailor-made block copolymers (Scheme 1).[3]



Scheme 1: Ring-opening polymerization of poly(2-oxazoline)s.

Results and Discussion

Microwave-assisted heating has enabled to shorten the reaction times of the polymerization of 2-oxazolines significantly by factors up to 400, while the living character of the polymerization is maintained (Figure 1).[4;5]

Under microwave irradiation, several hydrogels were synthesized to create sub-libraries of this novel material class (Figure 2). During the polymerization of poly(2-isopropenyl-2-oxazoline), cross-linking occurs, the mechanism of which was investigated thoroughly.

In this poster presentation, the mechanism of hydrogel formation and material characterizations of the synthesized hydrogels, in particular the correlation hydrogel composition - swelling degrees in different solvents will be shown.

Figure 1: Biotage Initiator 8.

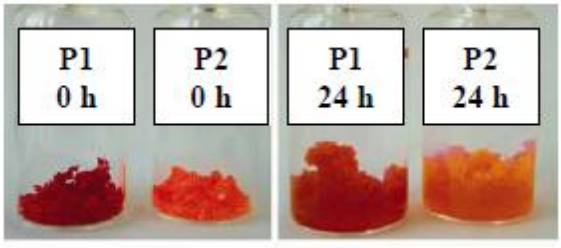


Figure 2: Poly(2-isopropenyl-2-oxazoline) (**P1**) and poly(2-ethyl-2-oxazoline)-co-poly(2-isopropenyl-2-oxazoline) (**P2**) with trapped Eosin Y in dry (left) and in swollen state (right; in water).

Conclusion

Poly(2-isopropenyl-2-oxazoline)- based hydrogels can easily be synthesized by microwave-assisted polymerization protocols. Swelling degrees can be tailor-fabricated by the copolymer composition.

Ionic liquids (ILs) have received a great deal of attention in recent years and a diverse array of these materials has been synthesised. Much of the interest has been due to their unique solvent properties and low volatility that have been put to use in a wide range of synthetic applications in so-called "green chemistry". Attention has been mainly directed towards modifying ILs to manipulate solvent and electrochemical properties. ILs have excellent thermal stability, low volatility, they can also have wide electrochemical potential windows and in some cases they offer unique solubility properties.

The synthesis of a serie of imidazolium-based ILs (1-*n*-alkyl-3-methylimidazolium, where *n* = 4, 6-8, 12) was performed and their physicochemical properties were investigated. The water vapour sorption behaviour of ILs was examined. Equilibrium moisture content was determined as a function of the relative humidity at 25 °C by means of microgravimetric technique. The influence of the chemical structure, including the type of anion and length of the alkyl chain, on the water vapour sorption has been studied. The experimental results indicate the sorption capacity increase with the decrease of the alkyl chain length.

The synthesized ILs were immobilised in porous polymer membranes in order to study the potential of using supported ionic liquid membranes for gas and liquids separation. Different aspects were investigated, such as the evaluation of the membrane stability and the influence of the IL chemical structure on the permeability and gas selectivity.

Thermophysical, electrical and mechanical properties of ethylene-vinylacetate copolymer (EVA) filled with wollastonite fibers coated by silver

Igor.Krupa@savba.sk

Common industrial polymers, in general, are materials with very low value of thermal and electrical conductivity. However, many industrial applications including circuit boards, heat exchangers, electronics protection, etc require an improvement the thermal conductivity of plastics. Similarly, plastics with improved electrical conductivity are used as heating elements, temperaturedependent resistors and sensors, self-limiting electrical heaters and switching devices, antistatic materials for electromagnetic interference shielding of electronic devices.

Metal-coated inorganic fibers are often as a substitute for metals in electrically and thermally conductive composites. The advantages are the easiness of metallization of convenient substrates, high conductivity, low density and lower prices when compared to metals. Among the most frequently metalized substrates are glass fibers, carbon fibers and mica.

Here we will present a preparation of composites filled with new type of conductive fibers based on silver coated wollastonite. SEM micrograph of silver coated wollastonite fibers is shown in Figure 1.

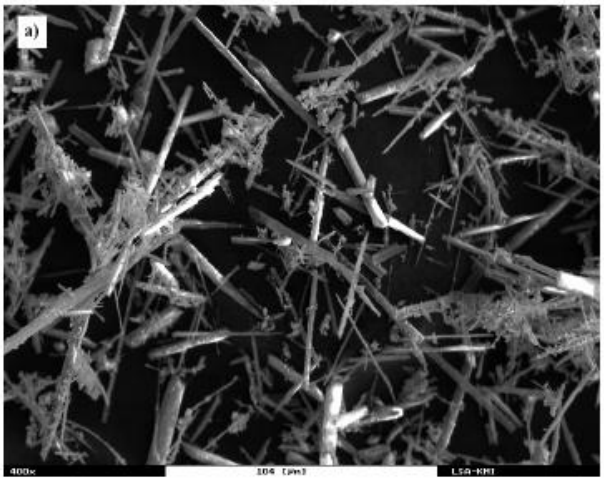

Fig.1 SEM micrograph of coated wollastonite.

The fibers were used for the preparation of elastic, highly electrically and thermally conductive polymeric composites based on ethylene-vinylacetate copolymer. It was shown that silver coated fibers significantly improved both the thermal and electrical conductivity of composites despite the low silver volume content. The electrical percolation threshold was found about 8 vol.% and the highly electrical conductivity value (1.8×105 S.m-1) is reached for 29 vol.% of filler fraction.

The experimental results were discussed and compared to various theoretical models.

Introduction

Traditional solid-phase extraction (SPE) sorbents are silica-based, however polymeric sorbents are becoming increasingly popular due to their enhanced stability and sorption properties. In addition, recent advances in polymerisation techniques, which have allowed the facile synthesis of appropriately sized particles, and the ease with which polymer sorbents can be functionalised, make polymers ideal for use as SPE sorbents.[1] The retention properties of such materials can be enhanced further by carrying out Davankov-type hypercrosslinking reactions to yield sorbents with high specific surface areas.[2]

This work combines the concepts of polymeric sorbents, hypercrosslinking and functionalisation chemistry to produce novel polymeric materials tailored for use in ion-exchange SPE.

Materials and Methods

Swellable, micrometer-sized polymer particles were synthesised using precipitation polymerisation[3], with ultra-high specific surface areas being introduced subsequently into the particles through Davankov-type hypercrosslinking reactions.[4] Pendent ion-exchange groups were installed into the polymers with ease, either by the use of functional monomers or through post-polymerisation chemical modification reactions (Figure 1).

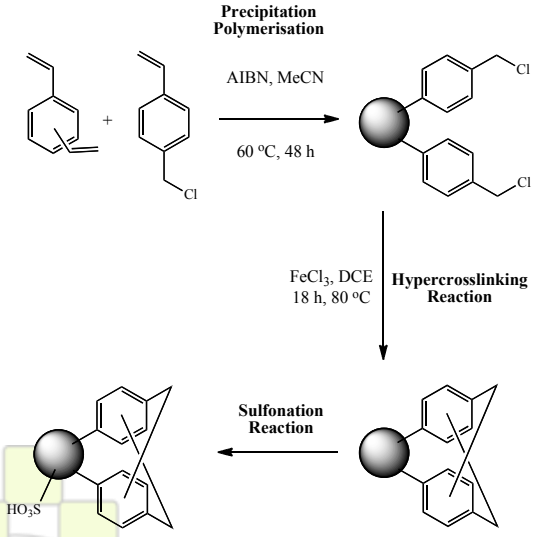

Figure 1 – Synthesis of ultra-high specific surface area strong cation-exchange sorbent.

Results and Discussion

Strong and weak anion- and cation-exchange sorbents, with specific surface areas in excess of 1,000 m^2/g, were all synthesised using this generic synthetic methodology. An example of the synthesis of a strong cation-exchange sorbent is presented in Figure 1.

The polymers were then exploited as sorbents in ion-exchange SPE. For example, the impressive performance of the strong cation-exchange (SCX) materials were demonstrated in the SPE of basic pharmaceuticals from environmental water samples. The novel sorbents were benchmarked against commercially available sorbents, and were found to compare favourably.

Conclusions

Ultra-high specific surface area polymer microspheres with ion-exchange functionality were prepared and successfully applied as sorbents in ion-exchange SPE.

Introduction

Polyvinylpyrrolidone (PVP), a well known biocompatible polymer, is a water-soluble amphiphilic nontoxic polymer commonly used in a wide range of applications in the pharmaceutical and nutritional area, cosmetics, personal hygiene, paintings, etc.

However, PVP lacks reactive groups, which limits the possibility of adding new functions to the polymer in order to modify its physical and chemical properties. Our group has recently developed a strategy that allows preparing vinylpyrrolidone (VP) functionalized with sulphonic groups [1]. VP containing carboxylate groups was prepared based on the method described by Bencini et al. [2]. These two monomers were copolymerized with VP in order to obtain functionalized PVP by a bottom-up approximation.

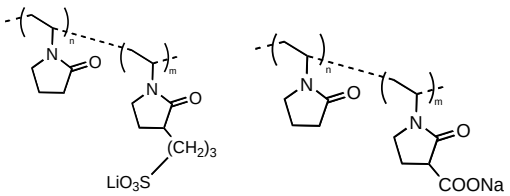

Fig1: Structure of the polymers.

Copolymer, telomers and hydrogels were prepared using these new compounds. The aim of the present work was to study their biocompatibility in order to check them for potential applications as biomaterials.

Materials and Methods

The copolymers were synthesized by free radical polymerization in water with AIBN as initiator. The molar amount of modified VP was ranging from 0 to 100%. Nitrogen was flushed through the polymerizing solution for 30 min. The polymers were purified by dialysis using membranes with pore-size of Mw cut-off 3500.

The telomers were synthesized by free radical polymerization in water with AIBN as initiator and isopropylmercaptan as transfer agent. The molar amount of modified VP was 5 and 10%. Nitrogen was flushed through the polymerizing solution for 30 min. The polymers were purified by dialysis using membranes with a pore-size of Mw cut-off 800.

The hydrogels were prepared by photopolymerization with Ciba-Geigy Irgacure 369 as initiator using the novel crosslinker shown in figure 2. Different hydrogels were obtained by changing the molar amount of modified VP and crosslinker.

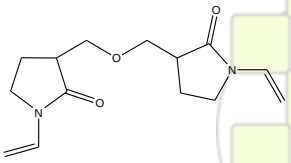

Fig 2: Structure of the new Crosslinker.

The biocompatibility was tested in vitro in fibroblasts 3T3 letting the cells grow for 24 hours and then adding the water soluble polymers and incubated them for another 24 hours. The results were analyzed by using the Alamarblue assay, based on the reduction of the reactive once it gets into the living cells, and the Picogreen assay based on the amount of remaining DNA after a few cycles of freezing and thawing of the cells.

Results and Discussion

Copolymers with Mn between 2.3-10x10^4 KDa, telomers with Mn between 8-1.5x10^3 KDa (calibration of SEC was carried out with PEG standars in water) and hydrogels with 1 and 10 molar % of crosslinker were obtained. The chemical structures were confirmed by conventional techniques such as ^{1}H-NMR and FTIR. All the copolymers and telomers show high level of biocompatibility in the range of concentration indicated in figure 3 for both assays and the difference between control and highest concentrations are not significantly different.

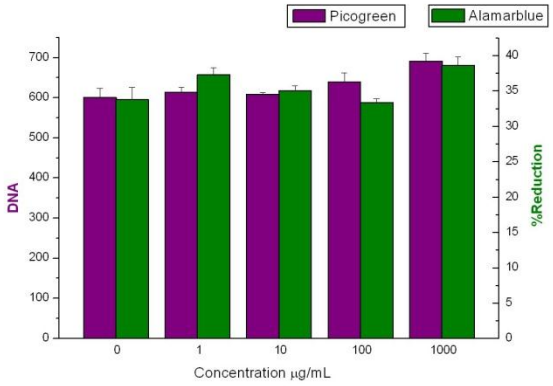

Fig 3: Alamarblue and Picogreen results of one copolymer.

The hydrogels also show no cell adhesion due to the hydrophilicity of the chemical structure.

Conclusions

The new copolymers, telomers and hydrogels were as biocompatible as PVP. The new functionalities of the PVP bases polymers can furthermore be safely used in biological environment.

Addition of Polymer to Viscoelastic Solutions of Living Micellar Chains

Pletneva V.A., Molchanov V.S., Philippova O.E.

Physics Department of Moscow State University

molchan@polly.phys.msu.ru

Introduction. Due to hydrophobic aggregation surfactant molecules are able to form enormously long wormlike micelles (also known as living chains) in water medium in the presence of salt. These surfactants are widely used to tune viscoelastic properties of solutions. It was demonstrated that in some cases the addition of polymer chains can increase significantly the viscoelasticity of the surfactant solution. The hydrophilic polymer having hydrophobic side groups can interact with wormlike micelles forming a common network in the system. The present paper is focused on the study of the influence of polymer structure and its concentration on the rheological properties of surfactant/polymer solutions.

Materials. Potassium oleate was used as the surfactant and hydrophobically modified polyacrylamide (HM PAAm) was used as the polymer. Living chains of the surfactant were obtained by adding salt (potassium chloride) screening repulsion on the surface of the micelles.

Method. Viscoelastic properties of the solutions were examined by means of Haake rheometer RS 150.

Results and Discussion.

It was shown that the addition of HM PAAm leads to the increase of the viscosity, the elastic modulus and the frequency range of elastic response of the system (G'>G''). To study the effect of molecular weight of polymer on the rheological properties of surfactant/polymer system we used two polymer samples of the same composition with the following molecular weights: $0.14 \cdot 10^6$ g/mol (short polymer) and $1.17 \cdot 10^6$ g/mol (long polymer). First, the effect of the addition of small amount (0.2 wt.%) of polymer was studied. This concentration is close to the overlap concentration of polymer chains C* estimated for the long polymer. At the same time, it is well below the C* for the short polymer. So, at this concentration the polymer chains interact only with micelles. As it could be expected the viscosity of surfactant/polymer solution with long polymer is higher than that for the system with short polymer. This result can be explained as follows. On the one hand, the long polymer links more micelles, on the other hand, it has a longer relaxation time. This explanation is confirmed by the increase of the elastic modulus (indicating to higher number of entanglements) and the increase of the frequency range of elastic response.

Next we studied surfactant/polymer system at higher concentration of polymer (1.2 wt.%), which is close to C* concentration of short polymer. At these conditions the effect of molecular weight of polymer on the rheological properties becomes more pronounced. This may be explained by the fact that at this concentration the chains of long polymer entangle with each other, which increases the total number of entanglements in the system. Thus, it was shown that the rheological properties of the surfactant/polymer solution depend essentially on the molecular weight of polymer.

At the next stage of the research the influence of the content of hydrophobic groups of the polymer on the rheological properties of the surfactant/polymer solution was examined. For this purpose two polymer samples with different number of hydrophobic groups 0.5 mol.% and 1.0 mol.% were used, other characteristics of the polymers being identical. The concentration of polymer was chosen close to C* value: 0.3 wt.%. It was shown that with increasing content of hydrophobic groups in the polymer the viscosity increases by one order of magnitude, the elastic modulus increases by a factor of 5 and the range of elastic response becomes much larger. All these effects may be explained by the formation of additional crosslinks due to penetration of larger number of hydrophobic groups in the micelles. Thus, it was proved that the number of hydrophobic groups directly controls viscoelastic properties of surfactant/polymer solutions.

Hereafter, the effect of polymer concentration was studied while surfactant content was fixed. The polymer concentration varied from 0.1 wt.% (below C*) to 1.5 wt.% (above C*). Above overlap concentration side groups of polymer chains can form hydrophobic domains. It was observed that the viscosity and the elasticity increase significantly with increasing concentration of polymer.

Conclusions. Thus, it can be concluded, that the addition of HM polymer into wormlike micelles solution can significantly change viscoelasticity, the effect being depending on the structure and the content of the polymer.

e-mail: d.solovieva@mail.ru

Introduction:
Design of the polymer materials for advanced application is an actual problem of the polymer and physical chemistry, modern technology and chemical engineering. One of the ways of its decision is the copolymerization of various vinyl monomers and obtaining the materials with desirable properties [1, 2].

Materials and Methods:
Copolymerization of N-vinylpyrrolidone (VP) with maleic anhydride (MA) and methylmethacrylate (MMA) in bulk in the presence of benzoil peroxide (Fig.1, curves 1, 3, 4, 6-8) and in its absence (Fig.1, curves 3, 5, 9) was performed. The copolymer conversion was studied by ^{1}H NMR (Fig.1, curves 1, 3, 4) spectroscopy (DMSO d_6, TMS, 400 MHz), dilatometry (Fig.1, curves 2, 5, 6, 9) gravimetry (Fig.1, curves 7, 8) methods.

Results and Discussions:
Monomer interaction with each other and with benzoil peroxide was shown by UV-spectroscopy, ^{1}H- and ^{13}C-NMR methods. The structures of molecular complexes were calculated. Dilatometry curves (Fig.1) of the copolymerization procedure show the acceleration effect which is connected with participation of all monomers (especially N-vinylpyrrolidone) in the process. There are some formation of cooligomers in addition to copolymers were found. The numerous effects were found by gravimetry and the analysis of solutions after deposit allocation after clearing of the basic product [1,2]. According to a monomer expenditure through the set time intervals the reaction rates of the formation of copolymers and cooligomers were defined. The model of copolymerization, the description of the general rate of process and structure of copolymers was proposed.

Table 1. Parameters of copolymerization based on vinylpyrrolidone (VP), maleic anhydride (MA), methylmethacrylate (MMA).
