behavior and prolonged survival, which increases the risk of developing multiple primary malignancies (MPM). Hormonal transformation of initially non-functioning pNETs is uncommon but may significantly worsen prognosis and complicate management. We present a complex case illustrating both phenomena.

Case Report: A 55-year-old woman was diagnosed in 2020 with an initially non-functioning, well-differentiated G2 pancreatic neuroendocrine tumor (Ki-67 index 5%) located in the body and tail of the pancreas, with liver and lymph node metastases. Her oncological history was notable for gastric MALT lymphoma treated surgically and with chemotherapy in 1995. First-line treatment with lanreotide achieved disease stabilization. Due to high somatostatin receptor expression demonstrated on ^68Ga-DOTA-TATE PET/CT, the patient underwent four cycles of ^177Lu-DOTATATE peptide receptor radionuclide therapy (PRRT), resulting in partial radiological remission and prolonged disease control.

During long-term follow-up, the patient developed three metachronous primary malignancies fulfilling criteria for MPM: basal cell carcinoma of the scalp (2022), left-sided ductal breast carcinoma treated with surgery and radiotherapy (2023), and HER2-positive right breast carcinoma requiring neoadjuvant chemotherapy and mastectomy (2024). Serial imaging revealed gradual progression of liver metastases beginning in 2023, while the primary pancreatic lesion remained relatively stable.

In 2025, the patient developed recurrent, clinically significant hypoglycemia requiring diazoxide therapy, nutritional support, and gastrostomy. Given the absence of hypoglycemia at initial diagnosis and the temporal association with metastatic progression, a possible hormonal transformation of the pNET toward insulin secretion was suspected, although definitive biochemical confirmation remains pending. The patient continues treatment with somatostatin analogues and everolimus under close endocrinological and oncological supervision.

Conclusions: This case highlights the complexity of managing advanced pNETs in long-term survivors, emphasizing the need for continuous reassessment of tumor biology. Clinicians should remain vigilant for late hormonal transformation and the occurrence of multiple primary malignancies. Multidisciplinary care integrating endocrinology, oncology, and nuclear medicine is essential for optimizing outcomes and ensuring patient safety.

EP964 - ECE_3035 - SMARCA4-Mutated Anaplastic Thyroid Carcinoma in a Young Adult: First Reported Case.

Joanna Januszkiewicz-Caulier[1,2], Michal Wagrodzki[3], Elwira Bakula-Zalewska[3] and Marek Dedecjus[1]

[1]Department of Endocrine Oncology and Nuclear Medicine, Department of Endocrine Oncology and Nuclear Medicine, Maria Skłodowska-Curie National Research Institute of Oncology, Warsaw, Poland (State Research Institute), Warszawa, Poland; [2]Departament of Oncological Endocrinology and Nuclear Medicin, Maria Skłodowska- Curie National Institute of Oncology, Warsaw, Poland; [3]Department of Pathomorphology, Maria Skłodowska-Curie National Research Institute of Oncology, Warsaw, Poland (State Research Institute), Warszawa, Poland

Background: Anaplastic thyroid carcinoma (ATC) is a rare and highly aggressive thyroid malignancy,affecting elderly patients. Although molecular profiling has become increasingly important in ATC, alterations of the SWI/SNF chromatin-remodelling complex, including SMARCA4 mutations, have not previously been reported in this tumour type.

Case Presentation: A 31-year-old male with no significant medical history presented with a rapidly enlarging neck mass, progressive dyspnoea and reduced exercise tolerance over approximately six weeks. Neck ultrasound revealed a large, heterogeneous, infiltrative tumour of the left thyroid lobe causing significant tracheal compression and associated cervical lymphadenopathy. Fine-needle aspiration biopsy showed malignant cells (Bethesda category VI) with suspicion of ATC; however, given the patient's young age, thyroid lymphoma was also considered. Core-needle biopsy with extensive immunohistochemical and molecular analyses excluded lymphoma, melanoma, sarcoma and NUT carcinoma, establishing the diagnosis of anaplastic thyroid carcinoma with a SMARCA4 mutation.

Staging computed tomography demonstrated stage IVB disease with extensive locoregional invasion and massive venous thrombosis extending from the right atrium to both internal jugular veins. The patient was not eligible for surgical or radiotherapeutic treatment. Therapeutic anticoagulation and systemic glucocorticoids resulted in transient clinical improvement. Rapid disease progression led to airway compromise requiring tracheal stenting, followed by initiation of palliative chemotherapy with carboplatin and paclitaxel.

Discussion: SMARCA4 alternations is a recognised drivers of several aggressive undifferentiated malignancies and is associated with rapid progression and poor prognosis. Its identification in ATC expands the molecular spectrum of this disease and may explain the unusually young age at presentation and aggressive clinical course.

Conclusions: To our knowledge, this is the first reported case of SMARCA4-mutated anaplastic thyroid carcinoma. The case highlights the importance of comprehensive molecular profiling in ATC, particularly in young patients or those with atypical clinical features, to improve diagnostic accuracy and inform future therapeutic strategies.

EP966 - ECE_3611 - Interplay between nutritional status and immunophenotype in patients with gastroenteropancreatic neuroendocrine tumors: results of a cross-sectional study

Alessia Filice, Franz Sesti, Tiziana Feola, Carla Pandozzi, Marianna Minnetti, Francesca Sciarra, Simona Puntil, Andrea Scala, Arianna Gagliardi, Alexandra Nistor, Ilaria Bonaventura, Dario De Alcubierre, Davide Masi, Mary Anna Venneri, Andrea Isidori, Lorenzo Donini and Elisa Giannetta

Department of Experimental Medicine, Sapienza University of Rome, Rome, Italy

Introduction: Nutritional status (body composition and functional status in particular) and immune profile are emerging determinants of prognosis and therapeutic response in oncology. However, the links between anthropometric and immune parameters in neuroendocrine neoplasms are still lacking.

Aim of the Study: To evaluate the relationship between body composition and immunophenotypic profile in patients with

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

gastro-entero-pancreatic neuroendocrine tumors (GEP-NETs), in order to identify potential prognostic or predictive markers.

Materials and Methods: A cross-sectional observational study was conducted, enrolling patients with histologically confirmed GEP-NETs. Body composition was estimated using bioelectrical impedance analysis (BIA). Muscle strength was evaluated by handgrip strength (HGS) and subsequently expressed as percentiles. Patients were stratified into two groups based on dominant-arm HGS: a "probable sarcopenic" group (HGS < 50th percentile) and a "non-sarcopenic" group (HGS ≥ 50th percentile). Peripheral blood mononuclear cell (PBMC) subpopulations were analyzed using flow cytometry.

Results: 22 patients (12 females, 10 males;mean age 62.3 ± 7.4 years) met the inclusion criteria (59.1% G1, 40.9% G2).Locally advanced or metastatic disease (stage III or IV) was present in 40.9% of patients. Based on HGS percentile cutoffs, 13 patients (59.1%) were classified as non-sarcopenic and 9 (40.9%) as probable sarcopenic. Significant correlations emerged between monocyte subsets, body composition and muscle strength: fat-free mass percentage (FFM%) correlated positively with non-classical monocytes ($P < .001$) and negatively with classical monocytes ($P = .008$), whereas fat mass percentage (FM%) showed opposite trends (respectively, $P < .001$ and $P = .008$). HGS displayed similar associations with monocyte subsets (respectively, $P = .037$ and $P = .028$). The probable-sarcopenic group also showed a higher proportion of classical monocyte compared to the non-sarcopenic group ($P = .011$). Among female patients, the proliferative index (Ki-67) correlated inversely with phase angle (PhA) ($P = .024$), which also emerged as independent predictor of Ki-67. Lower PhA values were found in women with lymph node and/or liver metastases compared with non-metastatic patients ($P = .039$). No significant associations were observed in the male group.

Conclusions: These findings suggest a potential interaction between nutritional status and immune profile in patients with neuroendocrine tumors, with possible prognostic and therapeutic implications. Larger studies are needed to confirm these observations, verifying the role that nutritional status can have as a consequence of neoplastic disease, as an etiopathogenetic component or as a prognostic factor in the evolution of the disease.

EP969 - ECE_3169 - Autoimmune endocrinopathies provide predictive efficacy and improved quality of life in cancer patients treated with immunotherapy—real world experience from Romania

Elena Lazar[1], Ioana Andreescu[2], Ioana Claudia Dan[2], Simona Coniac[3] and Corin Badiu[2,3]
[1]*Outpatients, Endocrinology, "A Trestioreanu" Institute of Oncology, Bucharest, Romania;* [2]*Research Department, Endocrinology IV, C.I. Parhon National Institute of Endocrinology, București, Romania;* [3]*Endocrinology, Endocrinology IV, "C Davila" University of Medicine and Pharmacy, Bucharest, Romania*

Background: High-quality real-world evidence (RWE) can provide reliable data upon the impact of immune check-point inhibitors (ICIs) in challenging cancer patients, usually underrepresented in randomized clinical trials (RCTs), but heavily treated in daily clinical practice. Frequently reported Endocrine-immune-related adverse events (E-irAEs) as thyroiditis or hypophysitis during ICIs treatment have been proposed as possible predictive biomarkers of response, meaning increased progression-free survival (PFS) and overall survival (OS).

Patients and Methods: This is a prospective analysis of 53 cancer patients, treated in a multidisciplinary and multi-institutional collaboration team approach, in Bucharest, Romania. The E-irAEs were evaluated using thyroid function and autoimmunity markers (TSH, fT4, ATPO) as well as adrenal reserve using short 250 ug iv Synacthene test. The quality of life (QoL) during ICIs was assessed using versions of EORTC QLQ-C30 questionnaires validated and translated into the Romanian language. Descriptive analysis was performed.

Results: A number of 33 thyroiditis were observed and treated by substitution treatment. Ten hypophysitis cases were treated by adrenal substitutive treatment using hydrocortisone 15-30 mg/day. Five patients developed both endocrine and non-E-irAEs. The QoL of cancer patients treated with ICIs and evaluated for E-irAEs in this prospective trial was significantly improved during the substitution hormonal therapy. We observed the trend toward earlier stages and more cancer sites treated with ICIs. We have noticed no Grade ≥3 E-irAEs.

Conclusions: RWE in national observational large cohort studies could bring more insightful information about clinical variables with impact on ICI's response in cancer patients. We highlight the emerging need of assessing the QoL of cancer patients experiencing E-irAEs, as they live longer with life-long hormonal treatment.

EP971 - ECE_1518 - Endogenous Cushing's syndrome of unusual etiology

Maria Jose Vallejo Herrera, Veronica Vallejo Herrera, Carmen Bautista Recio and Belen del Arco Romualdo
Hospital Regional de Málaga, Málaga, Spain

Cushing's syndrome is caused by hypercortisolism of endogenous origin (adrenal or pituitary origin), although it can also be exogenous, causing a metabolic syndrome associated with other typical features such as Cushingoid facies, hirsutism, and abdominal striae. Tumor hormone production by lung carcinoma or neuroendocrine tumors are rare causes of Cushing's syndrome, while Cushing's syndrome caused by a primary neuroendocrine renal tumor is extremely rare. We present an unusual case of this condition, the fundamental pillars of which are diagnosis with hormonal studies and imaging tests, and early control of hypercortisolism. Management of this condition by a multidisciplinary team can achieve a cure and a favorable long-term prognosis for these patients.

Cushing's syndrome (CS) is caused by an excess of corticosteroids or ectopic adrenocorticotropic hormone (ACTH). It can have

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

an exogenous origin (corticosteroid treatment) or an endogenous origin, most frequently a pituitary or adrenal origin, and rarely due to tumor production in neuroendocrine neoplasms, notably lung and gastrointestinal carcinoma. Cushing's syndrome associated with primary renal neuroendocrine neoplasia is exceptionally rare, as in the case presented here, with very few similar reports in the literature.

EP973 - ECE_3259 - Developing a standard dataset in the European Registries for Rare Endocrine and Bone Conditions (EuRREB): Multiple Endocrine Neoplasia type 1 (MEN1) module

Medard van den Broek[1], Mariya Cherenko[2], Natasha Appelman-Dijkstra[2], Francesca Giusti[3], Francesca Marini[3], Aurilia Cinzia[4], Maria Luisa Brandi[3], Petra Brügmann[4], Ludwig Schaaf[5], Frederic Castinetti[6], Faisal Ahmed[7], Alberto M. Pereira[8] and Gerlof D. Valk[1]
[1]University Medical Center Utrecht, Utrecht, The Netherlands; [2]Leids Universitair Medisch Centrum, Leiden, The Netherlands; [3]University of Florence, Firenze, Italy; [4]European MEN Alliance e.V., Wunstorf, Germany; [5]Klinikum Schwabing, Munich, Germany; [6]Aix-Marseille Université, Marseille, France; [7]University of Glasgow, Glasgow, Northern Ireland; [8]Amsterdam Umc, Amsterdam, The Netherlands

Background: Multiple Endocrine Neoplasia type 1 (MEN1) is a rare hereditary syndrome associated with significant morbidity and reduced life expectancy due to a high penetrance of several endocrine tumors and other related manifestations. International collaborations are essential for gaining deeper insights into this condition by generating robust high-quality clinical data and patient experiences through patient reported outcomes.

Purpose and Methods: The European Registries for Rare Endocrine and Bone Conditions (EuRREB) within the Core Registry platform allows to collect a set of core data elements and specific dataset within the condition specific modules (CSM) as well as patient reported outcome measures. Within the registry, the MEN1 module was created through the multistakeholder collaboration of clinicians, researchers and patient advocacy groups over the course of 2 years (with 10 experts from 4 different countries and 2 patient representatives). The purpose was to build a scalable framework to capture essential clinical information and patient-reported outcomes, with the capacity to support future observational studies, eventually leading to more knowledge about thepathophysiology, natural history and impact of MEN1 related manifestations.

Results: The initial dataset was launched December, 2023 with over 250 variables. Seven feedback sessions were conducted over the course of development of the module, based upon which the dataset was finalized with 118 unique variables, with the opportunity to collect repeated data to adequately capture the longitudinal follow-up of MEN1 patients.

As a result of the consensus, a beta version was launched in July 2025 and recently, the final version of the module was officially launched on **01-12-2025** to be available for all MEN1 patients, and clinicians within expertise centers throughout Europe.

Conclusions: This MEN1 module within EuRREB has the potential to serve as a multicenter international registry, providing an ideal foundation for advancing healthcare outcomes for this group of patients. All clinicians with experience in MEN1 are encouraged to take part in the module.

EP974 - ECE_3305 - Metastatic insulinoma with refratory hypoglycaemia: Challenges in clinical management

Ana Margarida Sobral[1], Alice Monsanto[1], Mariana Coelho[1], Adriana Duarte[1], Bárbara Jesus[1], Gustavo Rodrigues[1], Tânia Carvalho[1], Diogo Lameirão[2], Sofia Lopes[1], Ana Carreira[1], Mariana Lavrador[1], Inês Vieira[1], Joana Reis Guiomar[1], Diana Catarino[1], Daniela Guelho[1], Carolina Moreno[1], Joana Saraiva[1], Dírcea Rodrigues[1], Gracinda Costa[2] and Leonor Gomes[1]
[1]Coimbra, Portugal; [2]Serviço de Medicina Nuclear da Unidade Local de Saúde de Coimbra, Coimbra, Portugal

Introduction: Malignant insulinomas are uncommon pancreatic neuroendocrine tumors, characterized by locally advanced or metastatic disease. Clinically they present with severe hypoglycaemia. Their aggressive behaviour and limited response to conventional therapies, poses significant management challenges. We describe a case of unresectable metastatic insulinoma requiring a multimodal therapeutic approach.

Clinical Case: A 38-year-old man presented to the emergency department with recurrent episodes of altered consciousness associated with hypoglycaemia. Initial evaluation revealed symptomatic hypoglycaemia (plasma glucose 41 mg/dL) with biochemical evidence of endogenous hyperinsulinism (insulin 44.3 µIU/mL [1.9-23]; C-peptide 4.35 ng/mL [0.73-4.37]). His medical history was notable for well-controlled HIV infection. Iatrogenic causes for hypoglycaemia, adrenal insufficiency, and growth hormone deficiency were excluded. Family history was unremarkable.

Cross-sectional imaging identified multiple hepatic lesions, the largest measuring 61 mm, consistent with metastatic disease and a 34 × 19 mm pancreatic mass.

Histopathological analysis of a liver lesion confirmed metastatic grade 2 neuroendocrine tumor. Gallium-68 DOTANOC PET/CT demonstrated intense somatostatin receptor expression in the pancreatic lesion and corresponding hepatic and lymph node metastases. Genetic testing excluded MEN1 and MEN4 syndromes.

Medical therapy was initiated and progressively escalated, including high-dose diazoxide (up to 1,200 mg/day), dexamethasone (16 mg/day), short-acting octreotide and long acting pasireotide 40 mg afterwards. Despite this, hypoglycaemic episodes persisted, necessitating prolonged hospitalization with continuous high-volume intravenous 50% dextrose infusion and parenteral nutrition.

After presenting the case in multidisciplinary neuroendocrine tumor board, peptide receptor radionuclide therapy (PRRT) with lutetium-177 was planned, as surgical intervention was deemed infeasible.

The clinical course was complicated by opportunistic pneumonia and acute pulmonary oedema, attributed to immunosuppression

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

due to HIV infection, and high-dose diazoxide and glucocorticoid, resulting in admission to a level II care unit and delayed PRRT initiation.

Following clinical stabilization, the patient received the first cycle of Lu-177-DOTATATE on day 70 after admission. As glycaemic control progressively improved, concomitant medical therapy was gradually reduced, allowing hospital discharge on day 122 under monthly pasireotide 40 mg.

The patient subsequently completed three additional cycles of PRRT and remains under endocrinology follow-up, with sustained euglycaemia and biochemical remission. Follow-up Ga-68 DOTANOC PET/CT demonstrated a reduction in both size and radiotracer uptake of hepatic, nodal, and primary pancreatic lesions, suggestive of partial treatment response.

Conclusions: This case highlights the challenges of malignant insulinoma management and supports the role of PRRT as an effective option for controlling both tumor burden and refractory hypoglycaemia.

EP975 - ECE_3440 - Extremely aggressive course of an incidentally detected adrenocortical carcinoma despite complete surgical resection

Cristina Contreras Pascual[1] and Paloma Gonzalez Lazaro[2]
[1]Hospital Santa Bárbara, Soria, Spain; [2]Hospital General La Mancha Centro, Alcázar de San Juan, Spain

Adrenocortical carcinoma (ACC) is a rare and highly aggressive malignancy with poor prognosis, even after complete surgical resection. It presents a bimodal age distribution and may manifest through hormonal hypersecretion, mass-related symptoms, or as an incidental finding. Accurate diagnosis and prognostic stratification are essential for treatment planning, imaging, hormonal evaluation, and histopathological assessment. Although surgery is the most important treatment, recurrence and rapid progression are frequent. Mitotane is commonly used as adjuvant therapy, but its toxicity and uncertain impact on overall survival limit its applicability.

We report the case of a 66-year-old male with an incidentally discovered ACC, illustrating the limitations of current prognostic models. The patient had a history of smoking, alcohol consumption, hypertension, and genetically confirmed hypertrophic cardiomyopathy treated with an implantable cardioverter-defibrillator. An abdominal computed tomography (CT) was performed for mild alcohol-related pancreatitis, revealing a 14-cm right adrenal mass and contralateral adrenal hyperplasia.

Despite being clinically asymptomatic, hormonal evaluation demonstrated autonomous cortisol secretion (1-mg dexamethasone suppression test: cortisol 16.9 μg/dL) and androgen excess, with suppressed gonadotropins and elevated dehydroepiandrosterone sulfate (DHEA-S) levels (790 μg/dL). Staging with whole-body CT and bone scintigraphy showed no evidence of metastatic disease. The patient underwent right adrenalectomy two months after diagnosis.

Histopathological examination confirmed adrenocortical carcinoma with marked high-risk features, fulfilling six Weiss criteria: high nuclear grade (Fuhrman grade IV), mitotic rate >20/50 high-power fields, atypical mitoses, diffuse architecture >33%, extensive necrosis, and focal capsular invasion. The tumor measured 13 × 8 cm, weighed 1056 g, showed oncocytic areas, and had an extremely high Ki-67 proliferation index (75%). Surgical margins were negative (R0 resection), and pathological staging was pT3 (AJCC 8th edition), indicating highly aggressive tumor biology.

Despite complete resection, early postoperative progression was observed. One month after surgery, imaging revealed local recurrence and metastatic lymphadenopathy. Adjuvant mitotane was contraindicated due to comorbidities and toxicity risk. Chemotherapy with carboplatin and etoposide combined with radiotherapy was initiated, but the disease rapidly progressed with widespread metastases. The patient developed heart failure and ascites and subsequently died.

This case highlights the extreme aggressiveness ACC may exhibit despite early detection and optimal surgical management, emphasizing the urgent need for improved prognostic and molecular markers to better predict outcomes and guide individualized treatment strategies.

EP976 - ECE_2792 - Managing a case of carcinoid heart disease:The role of multidisciplinary team

Milena Yoveva[1,2,3], Gideon Mlawa[1], Aye Hline[1] and Furhana Hussein[1]
[1]Queen's Hospital, Romford, United Kingdom; [2]Acute Medicine, Barking, Havering and Redbridge University Hospitals NHS Trust, Romford, United Kingdom; [3]Acute Medicine, Barking, Havering And Redbridge University Hospitals Nhs Trust, Romford, United Kingdom

Introduction: Carcinoid Heart Disease (CHD) occurs in the majority of patients with Neuroendocrine Tumour (NET) and Carcinoid Syndrome (CS). The mechanism is poorly understood. It is thought that chronic exposure to high plasma serotonin levels from most commonly small intestinal NETs, causes fibrous changes of the endocardium. It predominantly affects the right side of the heart, in > 90% of cases, leading to tricuspid regurgitation in nearly all, and less commonly pulmonary regurgitation, tricuspid and pulmonary stenosis. Endocrinologists are often primarily responsible for these functioning NETs. Treatment strategies is delivered via an experienced NET MDT comprising medical oncologists, cardiologists, endocrinologists, surgeons, radiologists, gastroenterologists, histopatologists, nurse specialists.

Case: 73-year-old gentleman who was on 177 Lu-DOTATATE and Lanreotide for grade 2 metastatic neuroendocrine tumour, diagnosed 4 months earlier, was referred to a Cardiologist in April. He complained of leg swelling, tiredness, exhaustion, reduced appetite, nausea, weight loss of 2 stones in 6 months. Examination revealed regular pulse 92, blood pressure 110/70 in supine and 119/74 in standing, normal heart sounds, systolic murmur at left sternal edge, clear chest, moderate oedema to legs. ECG showed sinus rhythm, left axis, low voltage QRS. NT-proBNP was elevated at 865. Transthoracic echocardiogram revealed severely dilated RV with good longitudinal systolic function, paradoxical IV septal

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

motion, LV systolic function 50%, thickened tricuspid valve leaflets with restricted movement causing severe regurgitation, severely elevated pulmonary artery pressure, mild pulmonary stenosis, dilated IVC. He was admitted for management of heart failure, acute kidney injury on a background of chronic kidney disease, nutritional and psychological support. During his hospitalisation, he underwent further images as CXR, NM Lung perfusion, abdominal USS, TOE, CMR, HRCT thorax. He was reviewed by Oncology and Respiratory Team. He was discussed during Cardiac MDT and referred to a Cardiothoracic Surgeon and Pulmonary Hypertension Team. In June, he was admitted to a private hospital due to general decline and was treated in intensive care for a few days for encephalopathy. In July, he died peacefully in a Hospice.

Discussion and Conclusions: CHD is a major source of morbidity and mortality for CS patients. Measurement of 5-Hydroxyindoleacetic acid (5-HIAA), NT-proBNP and echocardiogram are useful in assessment of patients at risk from or with CHD. Management of heart failure, lowering 5-HIAA, and cardiac valve replacement in selected cases with expected survival > 12 months, arestrategies improving quality and length of life. Patient should be managed in CHD experienced centre.

EP977 - ECE_3223 - Adrenocortical Carcinoma in Li-Fraumeni Syndrome- current management in hereditary context

Ioana Claudia Dan[1], Andreea-Alexandra Grosu[1], Teodor Constantin[1], Maria Anghel[1], Viorica Nicuta[1] and Corin Badiu[1,2]

[1]Research Department, Endocrinology IV, C.I. Parhon National Institute of Endocrinology, București, Romania; [2]Endocrinology, Endocrinology IV, "C Davila" University of Medicine and Pharmacy, Bucharest, Romania

Introduction: Li-Fraumeni syndrome (LFS) is a rare hereditary cancer predisposition syndrome caused by pathogenic variants in the TP53 gene. It is characterised by a markedly increased lifetime risk of early-onset and multiple primary malignancies, most commonly adrenocortical carcinoma (ACC), breast cancer, central nervous system tumours, osteosarcomas, soft-tissue sarcomas, leukaemia and a broad spectrum of other solid tumours. The estimated lifetime cancer risk exceeds 90% in women and 70% in men.

Case Report: We present the case of a 30-year-old female with a history of hirsutism and basal hypercortisolism, but without other syndromic features at presentation. September 2024, hormonal evaluation revealed a disrupted cortisol circadian rhythm with incomplete suppression on dexamethasone suppression testing, while sex steroid and adrenal hormone profiles were otherwise unremarkable, with associated hypokalaemia. Computed tomography identified a well-defined left adrenal mass ($3.1 \times 5.0 \times 4.8$ cm) with heterogeneous unenhanced density (39-67 HU), raising suspicion for malignancy. The patient underwent left adrenalectomy in November 2024, during which a uterine leiomyoma was also excised.

Histopathological analysis confirmed high-grade conventional ACC (Weiss score 7, modified Weiss 5) with capsular and sinusoidal invasion, and negative surgical margins (R0). Immunohistochemistry demonstrated diffuse SF1 positivity, patchy synaptophysin and nuclear beta-catenin expression, a wild-type p53 pattern, and a Ki-67 index of 35-40%. Postoperative adrenal function was preserved. Adjuvant mitotane therapy was initiated but discontinued after less than five months due to gastrointestinal toxicity, without achieving therapeutic plasma levels; therapy-induced adrenal insufficiency necessitated glucocorticoid replacement therapy.

Given the patient's young age at ACC diagnosis and significant family history (father with prostate adenocarcinoma and thymoma at 51 years, paternal grandmother with breast cancer before 40 years), genetic testing was performed using whole exome sequencing (WES). This analysis identified a heterozygous pathogenic TP53 variant (NM_000546.6:c.800G>C;p.Arg267Pro;rs587780075), confirming LFS. Targeted testing revealed the same variant in the patient's father, asymptomatic sister, and niece (aged 4 years 11 months), who exhibited mildly elevated DHEA-S and tall stature, with normal imaging.

In May 2025, the proband underwent right mastectomy for ductal carcinoma in situ (pTis pN0, R0, ER/PR+), and prophylactic left mastectomy, which revealed focal atypical ductal hyperplasia and fibroadenomas.

Conclusions: ACC may serve as an index tumour for diagnosing hereditary cancer syndromes. Early identification enables cascade genetic testing, facilitating detection and surveillance of at-risk relatives, and optimising clinical management for affected families

Abstract citation ID: lvag096.1259

EP978 - ECE_1428 - Simultaneous β-hCG and PTHrP secretion in a poorly differentiated high-grade urothelial carcinoma: A case report

Ismene Bilbao Garay[1,2], Clara Cerezo[1], Nerea Egaña Zunzunegui[1], Ane Amilibia Achucarro[1], Amaia Mendia[1], Nerea Diez[1], Sara Larrabeiti[1] and Cristina Garcia Delgado[1]

[1]Endocrinology Department, Hospital Universitario Donostia, San Sebastián, Spain; [2]Endocrinology, Hospital Universitario Donostia, San Sebastián, Spain

Introduction: Poorly differentiated high-grade urothelial carcinomas may be associated with a wide range of paraneoplastic syndromes due to aberrant expression of hormones, growth factors, cytokines, or their precursors. Tumours presenting with paraneoplastic manifestations usually display more aggressive biological behaviour and are associated with a worse prognosis. Simultaneous secretion of β-human chorionic gonadotropin (β-hCG) and parathyroid hormone-related peptide (PTHrP) in urothelial carcinoma is extremely rare.

Case Presentation: We report the case of a 51-year-old woman admitted to the Endocrinology Department for severe hypercalcaemia. Her medical history included excision of a benign gynaecological lesion several years earlier. One month before admission, she had undergone laparoscopic nephroureterectomy for a high-grade urothelial carcinoma, staged pT3N2.

Biochemical evaluation revealed suppressed parathyroid hormone (PTH) levels with markedly elevated PTHrP concentrations (7.7 pmol/L; reference range 0-1.5), consistent with humoral

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

hypercalcaemia of malignancy. Serum β-hCG levels were also significantly elevated (3,560 IU/L; reference range 0-5). Imaging studies identified multiple intraparenchymal nodules, and biopsy confirmed metastatic disease of urothelial origin.

An extended immunohistochemical study for gonadotropins was performed on several sections of the primary tumour, demonstrating positive β-hCG expression within the solid component showing sarcomatoid differentiation. This finding is uncommon and more typically described in urothelial carcinomas with trophoblastic differentiation, although it has also been reported in very poorly differentiated high-grade tumours.

Following the first cycle of chemotherapy, β-hCG levels decreased dramatically to 342 IU/L and became undetectable after the second cycle. This biochemical response was concordant with partial radiological remission.

Conclusions: Only a limited number of cases of urothelial carcinoma with simultaneous β-hCG and PTHrP secretion have been reported in the literature. Although exceedingly rare, this entity is associated with paraneoplastic syndromes, aggressive tumour behaviour, and the need for intensive multidisciplinary management. Elevated β-hCG levels in urothelial carcinoma may indicate a poorer prognosis and could represent a useful biomarker for monitoring treatment response.

EP1672 - ECE_3739 - Evolution of Tumor Grade and Intrapatient Heterogeneity in Neuroendocrine Tumors

Andreea Anne-Marie Brînzan[1,2], Iulia Florentina Burcea[1,2], Dobre Ramona[1,2] and Catalina Poiana[1,2]
[1]*"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania;* [2]*Pituitary and Neuroendocrinology Department, "C.I. Parhon" National Institute of Endocrinology, Bucharest, Romania*

Background: Neuroendocrine tumors (NETs) are increasingly recognized as dynamic neoplasms rather than biologically static entities. Accumulating evidence indicates that a subset of well-differentiated NETs undergoes biological progressive reprogramming over time, characterized by an increase in the Ki-67% proliferation index and grade evolution, while preserving neuroendocrine differentiation. This phenomenon reflects both temporal and spatial intrapatient heterogeneity, with clinically relevant discrepancies between primary tumors and metastatic lesions which may affect prognosis and therapeutic decision-making.

Materials and Methods: We conducted a retrospective observational study including NET patients managed at a tertiary referral center between January 2020 and January 2025. Among 143 screened patients, 17 fulfilled the inclusion criteria of having paired histological samples from both the primary and metastatic sites, allowing grade comparison. Tumors were classified according to World Health Organization (WHO) most recent criteria, with Ki-67% assessed in both samples. Patients were stratified into stable grade and grade progression groups (G1 to G2). Clinical characteristics, treatment strategies, response evaluation criteria in solid tumours (RECIST) and survival outcomes were analysed.

Results: Among 17 patients, grade discordance was observed in 6 cases (35%), all demonstrating a shift from G1 in the primary tumor to G2 in metastatic lesions, with a significant increase in Ki-67. This subset exhibited a longer mean disease duration compared to those with stable grading (8.3 vs 4.8 years), consistent with time-dependent biological progression. Tumor origin also differed between groups: pancreatic primaries comprised 50% of the progression cohort, whereas ileal tumors predominated among patients with stable grade (54.5%). Clinically, patients with grade progression experienced a higher burden of neuroendocrine symptoms, including increased incidence of carcinoid syndrome (66.7%) and carcinoid heart disease (66.7%). Importantly, this biological shift had direct therapeutic consequences, with patients in the progression group requiring systemic chemotherapy in 50% of cases, reflecting loss of disease control with standard therapies. Mortality was also higher in this group (50% vs 27.3%), and this pattern of evolution correlated with shorter overall survival, despite aggressive management.

Conclusions: Intrapatient heterogeneity and tumor grade evolution represent critical determinants of NET behaviour and prognosis, often leading to more aggressive disease over time. Our findings emphasize the importance of reevaluating tumor biology during disease evolution, rather than relying solely on the grade of the primary lesion; targeted reassessment of metastatic site, guided by clinical indicators and advanced functional imaging, is essential to ensure accurate characterization and optimal therapy selection.

EP983 - ECE_2480 - Outdoor Light at Night and the Progression of Cardiovascular-Kidney-Metabolic Syndrome

Shaoqing Wei[1,2], Fulin Wang[3,4], Wanzhou Wang[3,4], Chao Yang[1], Feifei Zhang[5] and Luxia Zhang[1,2,4]
[1]*Renal Division, Department of Medicine, Peking University First Hospital, Beijing, China;* [2]*Peking University, Beijing, China;* [3]*Peking University, National Institute of Health Data Science, Beijing, China;* [4]*Peking University Health Science Center, Institute of Medical Technology, Beijing, China;* [5]*Center for Digital Health and Artificial Intelligence, Peking University First Hospital, Beijing, China*

Introduction: Cardiovascular-kidney-metabolic (CKM) syndrome is a dynamic and progressive condition characterized by continuous transitions among metabolic dysregulation, chronic kidney disease, and cardiovascular dysfunction, and it imposes a substantial global disease burden. Outdoor light at night (LAN), an emerging environmental exposure, has been associated with circadian disruption and adverse cardiometabolic outcomes. However, evidence regarding the association between LAN exposure and longitudinal CKM progression across different stages remains limited. This study aimed to examine the association between LAN exposure and CKM progression.

Methods: Participants with Stage 1 CKM at baseline were included from the UK Biobank. LAN exposure was assessed using satellite-derived residential data and analyzed per interquartile range (IQR) increase. CKM stages including Stage 1, Stage 2,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Stage 4, and death were defined using biochemical measurements and International Classification of Diseases (ICD)-10 codes. A multi-state model was applied to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) for the association between LAN exposure and CKM progression across different transitions. Model 1 was adjusted for age and sex; Model 2 was further adjusted for smoking status, alcohol status, urbanicity, household income, and educational qualification.

Results: A total of 82,712 participants were included in the study. Higher LAN exposure was associated with increased risks of CKM progression across several key transitions. Higher LAN exposure per IQR increase was associated with an elevated risk of CKM progression from Stage 1 to Stage 2 (HR: 1.045, 95% CI 1.024-1.066) and from Stage 2 to Stage 4 (HR: 1.058, 95% CI 1.001-1.119), as well as a higher mortality risk among individuals with advanced CKM, particularly for the transition from Stage 4 to death (HR: 1.097, 95% CI 1.026-1.174]). Associations between LAN exposure and other transitions were not statistically significant.

Conclusions: Our findings indicate that higher LAN exposure is associated with the progression of CKM syndrome, particularly for transitions involving metabolic deterioration and late-stage mortality. These results highlight LAN as a potentially modifiable environmental risk factor in the CKM trajectory and underscore the importance of considering environmental factors when developing strategies for early risk stratification and prevention of CKM progression.

EP984 - ECE_3258 - Differential sensitivity of endocrine and non-endocrine tissues to cadmium-induced lipid peroxidation and the protective role of melatonin.

Aleksandra Gładysz[1], Jan Stępniak[1] and Małgorzata Karbownik-Lewińska[1,2]
[1]*Department of Endocrinology and Metabolic Diseases, Medical University of Lodz, Lodz, Poland;* [2]*Polish Moter's Memorial Hospital—Research Institute, Łódź, Poland*

Objectives: Exposure to a heavy metal, specifically cadmium (Cd), a recognized IARC carcinogen, poses a significant public health risk due to its ability to induce oxidative stress, inflammation, and endocrine disruption. This study investigated the protective potential of melatonin against Cd-induced oxidative damage to membrane lipids (lipid peroxidation, LPO) in porcine tissue homogenates. To evaluate tissue-specific susceptibility and antioxidant efficacy, the study compared two endocrine tissues (the thyroid and the ovary) with two non-endocrine tissues (the liver and the kidney).

Methods: Porcine tissue homogenates were incubated in the presence of tested Cd compound, ie cadmium chloride ($CdCl_2$, 2.5-1000 μM), with or without melatonin (0.1-5.0 μM). The malondialdehyde + 4-hydroxyalkenals (MDA + 4-HDA) level (LPO index) was measured spectrophotometrically.

Results: Cadmium treatment significantly increased LPO in the kidney (25-1000 μM) and in the liver (2.5-1000 μM), whereas no increase was observed in the thyroid and in the ovary. Melatonin exhibited tissue-specific protective effects, namely protection in the kidney was limited to higher melatonin concentrations (2.5-5.0 μM) against damage induced by 100-1000 μM Cd, while liver damage was mitigated by melatonin doses as low as 0.1 μM across the 250-1000 μM cadmium range. In the ovary, Cd (1000 μM) unexpectedly reduced basal LPO level, an effect further enhanced by 5.0 μM Mel.

Conclusions: This study demonstrates that cadmium-induced oxidative damage is highly tissue-specific, with the liver and the kidney exhibiting the highest sensitivity to lipid peroxidation. This vulnerability is likely due to specificity of these organs serving as the primary sites for cadmium accumulation and detoxifying properties of the liver and the kidney, such as for example the synthesis of metal-binding proteins like metallothionein. Melatonin serves as an effective antioxidant against cadmium toxicity, though its protective efficacy varies significantly across different organs. The liver exhibited the most consistent response to melatonin across a wide range of concentrations, potentially due to its high metabolic turnover and the hormone's synergy with hepatic antioxidant enzymes. In contrast, the kidney required significantly higher doses of melatonin to achieve protective effects. Interestingly, the thyroid's resistance to cadmium-induced LPO suggests that its high physiological oxidative activity (indispensable for hormone synthesis) paradoxically makes the organ less vulnerable to further pro-oxidative factors. Overall, these findings suggest that cadmium toxicity occurs via, among others, a mechanism of lipid peroxidation. Additionally, they support the potential of melatonin as a preventive agent against heavy metal-induced oxidative stress, particularly in non-endocrine organs.

EP985 - ECE_2290 - Investigation of the effects of sweeteners on AVP and OT secretion

Krisztian Sepp[1], Anna Laszlo[2], Marianna Radács[3], Peter Kiss[3], Márta Gálfi[3] and Zsolt Molnár[3]
[1]*Metabolic and Endocrine Center, Department of Internal Medicine, University of Szeged, Szeged, Hungary;* [2]*Department of Applied Statistics, Hungarian University of Agriculture and Life Sciences, Institute of Mathematics and Natural Sciences, Gödöllő, Hungary;* [3]*Institute of Applied Health Sciences and Environmental Education, Department of Environmental Biology and Education, Juhász Gyula Faculty of Education, University of Szeged, Szeged, Hungary*

The material and energy processes of homeostasis are determined, among other things, by glucose metabolism in vertebrates. The neuroendocrine system plays a dominant role in this cascade processes that maintain sugar metabolism. However, the use of sweeteners modifies the synthesis results of the mechanism networks mentioned above, which can even generate endocrine disrupting (ED) effects. The aim of our work is to study the effects of sugar substitute compounds on hormone release in the presence of arginine vasopressin (AVP) and oxytocin (OT) bases and histamine (HIS).

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

In vivo experiments were conducted on Wistar rats (♂; bw: 80-100 g) with sweeteners [aspartame (40.0 mg/kg bw), saccharin (0.2 mg/kg bw), xylitol (40.0 mg/kg bw), stevia (40.0 mg/kg bw), glucose (40.0 mg/kg bw), K-acesulfame (40.0 mg/kg bw), and erythritol (0.05 g/500 cm^3)] via a gastric tube for 16 weeks. The untreated group served as the control. After exposure, the neurohypophyses of the rats were dissociated enzymatically (trypsin [0.2 mg/ml], DNAase I and II [10 µg/ml], Dispase [1 mg/ml]), and mechanical (Nylon-Blutex 80 µm = Ø] dissociation, monolayer primary cell cultures (NH) were prepared (n = 3 in each series of experiments) in 24-well Costar culture dishes (with 3 technical replicates). The AVP and OT hormone secretion functions of confluent NH cultures were checked as an *in vitro* model with non-specific (+30 mM [K^+]) and specific (+10^{-6} M [5-HT]) activation. Baseline and then HIS-receptor-activated AVP and OT release were followed in the presence of 10^{-6} M HIS *in vitro* over 120 min. Secreted AVP was determined by RIA, and OT was determined using ELISA, which was expressed relative to the protein content of NH cultures detected using the modified Lowry method. The results were analysed using a two-way ANOVA test. The results showed that *in vivo* sugar substitute treatments modified the basal AVP and OT secretion. Furthermore, they also altered the AVP and OT release functions measurable in the presence of HIS in the sugar substitute compounds. Based on our results, we can attribute a possible ED effect to the sweeteners studied.

EP986 - ECE_2656 - Beyond the tumour: endocrine toxicities of hormonal and targeted anti-cancer therapies

David Lopez-Lazaro, Muhammad Sohail Akhtar, Shebina Liz Mathews and Cornelius Fernandez James
Diabetes & Endocrine, Pilgrim Hospital Boston (United Lincolnshire Hospitals NHS Trust), Boston, United Kingdom

Introduction: Endocrinopathies are common with immune checkpoint inhibitors but relatively rare with other systemic anti-cancer treatments. Here, we will discuss a few endocrinopathies.

Case Presentation: A 64-year-old gentleman with metastatic prostate cancer presented with headaches, dizziness and hypotension. He had been on Abiraterone with prednisolone for 4 years, the latter inadvertently discontinued. Labs showed euvolemic hyponatremia. Morning cortisol 87. Post synacthen cortisol 296. He was managed as adrenal crisis and stabilised.

A 83-year-old gentleman with post-thyroidectomy hypothyroidism, receiving LHRH analogues and Apalutamide for metastatic hormone-sensitive prostate cancer, presented with worsening hypothyroidism, requiring doubling of Levothyroxine dose. Upon discontinuation of Apalutamide due to newly developed lung cancer, he developed symptomatic iatrogenic hyperthyroidism, requiring a decrease in Levothyroxine dose to baseline.

A 73-year-old woman with a background of recurrent metastatic breast cancer on Alpelisib presented with recurrent vomiting. Bloods showed pH 7.28, Ketones 4.5 and glucose of 18.8-DKA secondary to Alpelisib. She was discharged and started on a BD Insulin regimen.

Discussion: Case 1: Abiraterone selectively inhibits CYP17A1, leading to suppression of androgen and cortisol. It is used in castration-resistant metastatic prostate cancer, always with prednisolone to suppress ACTH and mineralocorticoid excess. Abiraterone could cause secondary adrenal insufficiency when prednisolone is inadequate or interrupted. Recognition and glucocorticoid replacement, often at stress doses, are essential to prevent deterioration.

Case 2: Apalutamide and Enzalutamide, selective androgen receptor blockers used in prostate cancer, are known to cause hypothyroidism. Mechanisms include enhanced biliary excretion (increased hepatic UDP-glucuronosyl-transferase) and decreased gastrointestinal absorption (unknown mechanism) of levothyroxine. Apalutamide discontinuation can result in hyperthyroidism, unless levothyroxine doses are promptly adjusted

Awareness of this reversible drug effect is essential to ensure timely dose modification

Case 3: Alpelisib and capivasertib inhibit the PI3K/AKT pathway, disrupt insulin signalling, and reduce GLUT4-mediated glucose uptake, causing hyperglycemia and DKA. When these agents are discontinued, insulin sensitivity improves, lowering glucose levels, requiring prompt insulin dose reduction.

Conclusions: An increased awareness of anti-cancer agent associated endocrinopathies will empower endocrinologists to manage these conditions. Key learning points: Abiraterone, used in castration resistant prostate cancer should always be prescribed with prednisolone to prevent secondary adrenal insufficiency and mineralocorticoid excess. Apalutamide can cause reversible hypothyroidism, especially in those with pre-existing hypothyroidism, and TFT monitoring is vital. Alpelisib causes insulin resistance, therefore regular glucose monitoring must be performed to titrate insulin, especially in pre-existing diabetes.

EP987 - ECE_1253 - Risk factors and reversibility of endocrine complications in children and adolescents with chronic iron deficiency anemia

Fawziya Alyafei, Ashraf Soliman, Nada Alaaraj, Noora Alhemaidi, Noor Hamed, Shayma Ahmed and Ahmed Elawwa
Hamad Medical Center, Pediatric Endocrinology, Doha, Qatar

Background: Iron deficiency anemia (IDA) remains the most prevalent micronutrient deficiency worldwide, particularly affecting children and adolescents in low- and middle-income settings. While the hematological manifestations of IDA are well recognized, emerging evidence highlights its broader impact on endocrine development, including growth retardation, pubertal delay, and neuroendocrine dysfunction. The pathogenesis of these endocrine sequelae involves impaired cellular oxygenation, mitochondrial dysfunction, and hormonal axis disruption. Understanding the reversibility of these effects following iron repletion and identifying modulating factors such as nutrition, pubertal stage, environment, and genetics is essential for effective prevention and intervention.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Objective: To review the literature from the past 25 years evaluating the endocrine consequences of chronic iron deficiency anemia in children and adolescents, quantify the impact of key risk factors, and examine the reversibility of endocrine dysfunction following treatment.

Methods: A systematic review of studies from 1999 to 2024 was performed using PubMed, Scopus, and relevant pediatric and endocrine databases. Inclusion criteria were studies assessing endocrine outcomes (eg, growth, puberty, thyroid, adrenal, GH-IGF axis) in patients aged 0-18 years with diagnosed IDA. Extracted data included sample size, age, iron status, endocrine abnormalities, treatment modalities, and recovery patterns. Real-world impact estimates were synthesized based on prevalence and odds ratios.

Results: Six principal risk factors were identified as major contributors to endocrine complications in pediatric IDA, with the following estimated impact based on pooled evidence:

- **Chronic iron deficiency (50%)**: associated with growth retardation, short stature, and pubertal delay.
- **Delayed treatment initiation (40%)**: linked to irreversible neurodevelopmental deficits and suboptimal catch-up growth.
- **Nutritional deficiencies (35%)**: particularly vitamin D and zinc deficiency, exacerbating skeletal and hormonal issues.
- **Delayed puberty (30%)**: both a consequence and a compounding factor of IDA-related endocrine disruption.
- **Environmental stressors (25%)**: such as food insecurity and high-altitude living, which increase metabolic strain.
- **Genetic susceptibility (20%)**: Polymorphisms in iron metabolism or hormone regulation genes may predispose individuals to endocrine vulnerability.

The reversibility of endocrine dysfunction was variable. While growth velocity often improved with iron repletion, pubertal normalization and cognitive gains were less consistent, especially in cases with prolonged deficiency. Early diagnosis and comprehensive nutritional and hormonal monitoring were key to better outcomes.

Conclusions: Endocrine complications in pediatric IDA are multifactorial and partially reversible. Prompt intervention, nutritional support, and individualized care plans considering pubertal status, environmental context, and genetic background are critical to mitigate long-term endocrine sequelae.

EP1674 - ECE_1157 - Metabolic effects of sucralose below the acceptable daily intake: pooled evidence from 14 randomised trials

Leen Zayer[1], Zarish Hussain[1], Sharon Shiju[1], Bindhu Nair[1], Naji Alamuddin[1], Christopher Corpe[2] and Nitya Kumar[1]
[1]*Muharraq, Bahrain;* [2]*Kings College London, London, United Kingdom*

Background: The non-nutritive sweetener, Sucralose, is widely used in sugar-reduction strategies but may not be metabolically inert.

Objective: To assess the association of sucralose with insulin resistance (HOMA-IR), insulin sensitivity (Matsuda index), and OGTT-stimulated insulin response (tAUC120), and to examine dose and exposure duration effects.

Data Sources: Embase, Cochrane, and Scopus (final update March 14, 2025), plus trial registries and reference lists.

Study Selection: Randomized human trials reporting pre/post data for ≥1 prespecified metabolic outcome with sucralose exposure.

Data Extraction, Synthesis and Appraisal: Dual independent extraction; random-effects meta-analysis with Hartung-Knapp adjustments; meta-regression for association with dose and duration; RoB2, funnel plots and Egger tests for bias assessment; GRADE assessment for certainty of evidence.

Results: Fourteen trials ($n = 754$) were included ($n = 383$ for insulin response; $n = 300$ for HOMA-IR; $n = 215$ for Matsuda). Sucralose was associated with reduced insulin sensitivity (Matsuda pooled mean difference = 0.52, 95% CI 0.08 to 0.95; $I^2 = 0\%$) and increased insulin resistance (HOMA-IR mean difference = -0.42, CI −0.70 to −0.14; $I^2 = 78.5\%$). Overall effects on insulin $tAUC_{120}$ were imprecise, but longer exposure (≥30 days) was significantly associated with higher OGTT insulin response ($tAUC_{120}$ MD = −1632; 95% CI −2807 to −458; $I^2 = 0\%$); meta-regression supported a duration–effect relationship. No dose–response gradient was detected; small-study and sensitivity analyses did not materially change conclusions

Conclusions and Implications: In non-diabetic adults, sucralose exposure increases fasting insulin resistance, reduces insulin sensitivity, and—after ≥30 days—raises OGTT insulin response. Effects occurred at typical-use, sub-ADI exposures, indicating metabolic activity below toxicology-based thresholds. Clinical counselling and clearer labelling (mg per serving/container) may be warranted; diabetes-specific, ≥12-week RCTs with weight-normalised dosing are needed

Abstract citation ID: lvag096.1267

EP989 - ECE_3962 - Slipped capital femoral epiphysis following growth hormone replacement in a child with Panhypopituitarism secondary to Craniopharyngioma: A Case Report

Francisca Leitão H.[1], Beatriz Tavares Da Silva[2], Alice Monsanto[3], Leandro Kasuki[4], Elisa Lamback[4], Christhiane Fialho[4], Luiz Eduardo Wildemberg[4] and Mônica Gadelha[4]
[1]*Unidade Local de Saúde de Almada-Seixal, Almada, Portugal;* [2]*Centro Hospitalar Universitário Santo António, Porto, Portugal;* [3]*Unidade Local de Saúde de Coimbra, Coimbra, Portugal;* [4]*Neuroendocrinology, Instituto Estadual do Cérebro Paulo Niemeyer, Rio de Janeiro, Brazil*

Introduction: Recombinant human growth hormone (GH) is widely prescribed in children and adolescents with GH deficiency or short stature secondary to chronic medical conditions. Although GH therapy is generally considered safe, several

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

uncommon adverse effects have been reported, including increased intracranial pressure, glucose metabolism alterations, hypothyroidism, and musculoskeletal complications. Among these, slipped capital femoral epiphysis (SCFE) is a rare but potentially severe condition, typically occurring within the first months of treatment, particularly during periods of accelerated linear growth. Patients with underlying endocrine disorders and obesity appear to be at increased risk.

Case Report: We report the case of a 13-year-old boy with panhypopituitarism secondary to an adamantinomatous craniopharyngioma. The patient initially presented with progressive visual impairment, headaches, marked short stature, delayed puberty, and obesity. He underwent subtotal surgical resection of the tumor followed by adjuvant fractionated radiotherapy, with persistent gonadotropic, thyrotropic, and somatotropic deficiencies.

At 14 years and 7 months of age, recombinant human GH therapy was initiated after confirmation of GH deficiency. At treatment onset, the patient had a height below the 3rd percentile, delayed bone age, and obesity. Two months after GH initiation, during a period of rapid linear growth, he developed progressive right hip pain radiating to the thigh and knee, accompanied by gait disturbance. Symptoms later became bilateral and persistent.

Given the temporal association with GH therapy and the emergence of musculoskeletal symptoms, SCFE was suspected, and GH treatment was immediately discontinued. Imaging studies, including computed tomography and magnetic resonance imaging, demonstrated bilateral physeal widening and early posterior epiphyseal displacement, consistent with bilateral SCFE. The patient subsequently underwent bilateral *in-situ* percutaneous screw fixation with satisfactory stabilization.

Conclusions: This case illustrates SCFE as a rare but clinically significant complication of GH therapy, particularly in patients with multiple predisposing factors such as panhypopituitarism, obesity, delayed puberty, and rapid growth velocity. Early clinical manifestations may be subtle and nonspecific, leading to delayed diagnosis and increased risk of long-term complications. Clinicians should maintain a high index of suspicion for SCFE in children receiving GH therapy who present with hip, thigh, or knee pain, especially during the early phases of treatment. Prompt imaging evaluation, orthopedic referral, and temporary suspension of GH therapy are essential to prevent irreversible morbidity. This case underscores the importance of close multidisciplinary monitoring in pediatric patients undergoing GH replacement therapy.

Abstract citation ID: lvag096.1268

EP990 - ECE_1126 - Severe hyponatreamia revealing suspected autoimmune polyglandular syndrome type 2 in a patient labelled as panhypopituitarism: A diagnostic challenge

Paolo Augusto Romero Merino[1], Raysha Shirley Silva Jordan[2] and Luz Marina Medina Puma[3]
[1]*Hospital Clinico Universitario of Valladolid, Valladolid, Spain;*
[2]*Universidad Nacional de San Antonio Abad del Cusco, Cusco, Peru;*
[3]*Hospital Nacional Sergio E.Bernales, Lima, Peru*

Background: Hyponatraemia is a common but potentially life-threatening presentation of adrenal insufficiency. In patients previously diagnosed with panhypopituitarism, adrenal crisis is often attributed to secondary adrenal insufficiency. However, discordant biochemical findings should prompt reassessment of the underlying endocrine diagnosis and consideration of autoimmune polyglandular syndromes.

Case Presentation: A 63-year-old woman with a long-standing diagnosis of panhypopituitarism (reported as probable Sheehan syndrome) on chronic levothyroxine and glucocorticoid replacement (with documented treatment interruption) and a previous diagnosis of type 2 diabetes mellitus was admitted with a progressive 1-2-month history of anorexia, functional decline, intermittent confusion, and hypoxaemia in the context of community-acquired pneumonia. Past history included an ischaemic stroke with left hemiparesis and severe frailty with immobility-related complications. Initial evaluation showed hypoxaemia (SpO_2 88% on room air), acute kidney injury on chronic kidney disease, malnutrition, and pressure ulcers.

Results: Arterial blood gas revealed severe hyponatraemia (Na^+ 115.9 mmol/L) with alkalemia (pH 7.537) and hypocapnia (pCO_2 25.3 mmHg). Morning serum cortisol was profoundly low (0.05 µg/dL; reference 6.2-19.4) with markedly elevated ACTH (663 pg/mL; reference 7.2-63.3), confirming adrenal crisis and suggesting a primary component of adrenal failure despite the previous label of panhypopituitarism. Thyroid function tests showed free T4 1.00 ng/dL (reference 0.72-1.56), free T3 2.45 pg/mL (reference 2.42-3.98), and elevated TSH 10.7 µIU/mL (reference 0.27-4.2), which was inconsistent with isolated central hypothyroidism. Vitamin D insufficiency (25-hydroxyvitamin D 19.5 ng/mL) and hypocalcaemia (total calcium 7.83 mg/dL) were also documented. The patient was treated with intravenous hydrocortisone, supportive care, antibiotics, and correction of electrolyte abnormalities, with subsequent improvement in serum sodium and clinical status.

Conclusions: This case highlights that, even in patients labelled as panhypopituitarism, adrenal crisis may present with biochemical patterns inconsistent with secondary adrenal insufficiency. Markedly elevated ACTH with very low cortisol should prompt reassessment of adrenal axis aetiology and avoid diagnostic anchoring. The combination of primary adrenal insufficiency, hypothyroidism and diabetes raised suspicion of autoimmune polyglandular syndrome type 2. Although the patient carried a previous diagnosis of type 2 diabetes mellitus, latent autoimmune diabetes in adults (LADA) could not be excluded in the absence of pancreatic autoantibody testing. Autoimmune screening (21-hydroxylase antibodies, thyroid antibodies and diabetes-related antibodies) should be considered when APS-2 is suspected.

Keywords adrenal crisis, hyponatraemia, autoimmune polyglandular syndrome, APS-2, Addison's disease, hypothyroidism, LADA

EP991 - ECE_1551 - Reduced empathy and impaired emotion recognition in patients with arginine vasopressin deficiency

Liv-Helen Lang, Sara-Jessica Camerin, Michelle Müller, Andi Nikaj, Matthias Liechti, Cihan Atila and Mirjam Christ-Crain
University Hospital Basel, Basel, Switzerland

Introduction: Patients with arginine vasopressin (AVP) deficiency (formerly central diabetes insipidus) often report social and emotional deficits and heightened anxiety. Growing evidence suggests that these symptoms may, at least partly, reflect concomitant OXT deficiency. OXT plays a key role in increasing empathy and improving emotion recognition. This analysis aimed to examine empathy and emotion recognition in patients with AVP deficiency compared to controls, and to assess the effects of MDMA (3,4-methylenedioxymethamphetamine), a pharmacological stimulus of OXT, on these measures.

Methods: Analysis of a double-blind, placebo-controlled, crossover study including patients with AVP deficiency and healthy controls matched according to age, sex, BMI, and menopause/hormonal contraceptives. Participants received a single oral dose of MDMA (100mg) and placebo in random order, with a wash-out period of two weeks. A computer-based *Facial Emotion Recognition Task* and a *Multifaceted Empathy Test* were conducted 150 min after drug intake. The statistical analyses were performed using linear mixed-effects models.

Results: Fifteen patients and 15 controls were included (median age 34 [IQR, 25-46] vs 35 [26-48] years; 53% female). Under placebo, OXT levels were comparable between patients and controls (62 pg/mL [55-70] vs 66 pg/mL [56-74]). Following MDMA, OXT increased approximately fivefold in controls but remained unchanged in patients (92 pg/mL [79-110] vs 540 pg/mL [273-844]). Under placebo, direct empathy was lower in patients than controls (median 5.28 vs 5.62), driven by reduced empathy for positive emotions (4.50 vs 5.25). Under MDMA, direct empathy remained lower in patients (4.53 vs 5.58), with MDMA decreasing empathy for positive emotions in patients (3.55) but increasing it in controls (5.85). Linear mixed-effects modeling demonstrated significant effects mainly on the empathy dimension ($P < .001$) and emotional valence ($P = .006$), as well as a significant group × emotional valence interaction ($P < .001$). In emotion recognition, patients showed overall reduced accuracy compared with controls across both placebo and MDMA ($P = .012$), most pronounced for sadness and fear. Mixed-effects analysis confirmed significant effects of facial emotion ($P < .001$) without a significant group × emotion interaction, indicating a global reduction in facial emotion recognition accuracy in patients.

Conclusions: Patients with AVP deficiency exhibit reduced empathy and impaired emotion recognition compared to controls. MDMA amplified these deficits, suggesting an altered response likely linked to OXT deficiency.

EP992 - ECE_2106 - Metastatic diffuse large B-cell lymphoma mimicking pituitary apoplexy

Margarida Gonçalves[1], Jorge Henrique Carmona Alexandrino[1], Ana Margarida Sousa[1], Nuno Jesus[1], Luís Gadelho[1], Leopoldina Pereira[2], Rute Caçola[3] and Gustavo Rocha[1]
[1]*Endocrinology, Unidade Local de Saúde de Vila Nova de Gaia/Espinho, Vila Nova de Gaia, Portugal;* [2]*Neurosurgery, Unidade Local de Saúde de Vila Nova de Gaia/Espinho, Vila Nova de Gaia, Portugal;* [3]*Internal Medicine, Unidade Local de Saúde de Vila Nova de Gaia/Espinho, Vila Nova de Gaia, Portugal*

Introduction: Pituitary metastases are rare and involvement by hematologic malignancies is particularly uncommon, with systemic lymphoma being the most frequently reported cause. While lymphoma typically presents with constitutional symptoms, pituitary involvement may lead to atypical endocrine and neurological manifestations, occasionally mimicking acute pituitary disorders.

Case Report: A 59-year-old male with past history of metabolic surgery one year earlier, treated with proton-pump inhibitor and a multivitamin, presented to the emergency room complaining of acute headache, visual deficit and palpebral ptosis. During the preceding week he reported progressive asthenia and had sought emergency care for abdominal pain. Cranial MRI demonstrated an infiltrative lesion involving the anterior floor of the third ventricle, hypothalamic region, pituitary stalk, and posterior pituitary, with extension into the suprasellar cistern, causing anterior displacement and compression of the optic chiasm and molding of the optic tracts. An associated osteolytic lesion was also identified. Further workup revealed: cortisol 1.9 µg/dL (6.2-19.4); TSH 1.04 mIU/L (0.35-4.94); free T4 0.42 ng/dL (0.70-1.48); prolactin 43.0 ng/mL (4.0-15.2). These findings were consistent with adrenal insufficiency and secondary hypothyroidism, raising suspicion for pituitary apoplexy. Corticosteroid replacement was initiated, followed by levothyroxine, with clinical improvement. The patient subsequently developed arginine vasopressin deficiency, treated with desmopressin. As pituitary apoplexy was not confirmed and there was no indication for emergent neurosurgical intervention, he was discharged.

The day after discharge, the patient suffered a cardiopulmonary arrest with successful resuscitation and subsequently developed recurrent sustained ventricular tachycardia. An electrophysiological study identified right bundle branch reentry ventricular tachycardia, which was successfully ablated. Due to recorrent abdominal pain, a thoracoabdominal-pelvic CT scan revealed multiple lesions of probable neoplastic origin, including a left adrenal mass, a lesion in the right renal sinus, multiple abdominopelvic tumor implants and adenopathies, probable pulmonary metastases, intracardiac filling defects and a secondary lytic lesion in the left iliac bone. Cervical lymph node biopsy established the diagnosis of diffuse large B-cell lymphoma. The patient's clinical condition rapidly deteriorated and he died shortly thereafter without receiving lymphoma-directed therapy.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Discussion: This case highlights the diagnostic challenge of infiltrative sellar–suprasellar lesions, which have a broad differential diagnosis. Although the acute presentation initially suggested pituitary apoplexy, radiological features and subsequent clinical evolution were inconsistent with this diagnosis. Pituitary involvement by systemic lymphoma, though rare, should be considered in rapidly progressive cases with atypical imaging findings and carries a high mortality risk.

EP993 - ECE_2869 - Evolving Hyponatraemia in Post-Vaccination Inflammatory Demyelinating Neuropathy: From Early ADH Dysregulation to Persistent SIADH

Muhammad Ali and Adhithya Sankar
Department of Endocrinology and Diabetes, Salford Royal NHS Foundation Trust, Manchester, United Kingdom

Background: Hyponatraemia is a recognised complication of Guillain–Barré spectrum (GBS) inflammatory neuropathies and is frequently labelled as SIADH. The mechanism may be time-dependent, and early diagnostic anchoring can misdirect management.

Case: A 79-year-old man developed distal paraesthesiae and progressive ascending weakness with autonomic features (urinary retention and constipation) shortly after COVID-19 and influenza vaccinations. CSF analysis demonstrated albuminocytologic dissociation, supporting an immune-mediated inflammatory demyelinating polyradiculoneuropathy. He developed prolonged hypotonic hyponatraemia with wide fluctuations (serum sodium 115-136 mmol/L; serum osmolality 246-263 mOsm/kg). Early urine indices were discordant, with persistently concentrated urine (urine osmolality 428-638 mOsm/kg) but highly variable urine sodium (<10-118 mmol/L), failing to consistently meet SIADH criteria and suggesting evolving non-osmotic ADH dysregulation related to acute neuroinflammation and autonomic dysfunction. He later deteriorated with symptomatic severe hyponatraemia (nadir 115 mmol/L) with features consistent with established SIADH (hypotonic serum osmolality 246-250 mOsm/kg with inappropriately concentrated urine osmolality 428-638 mOsm/kg and inappropriate natriuresis, urine sodium up to 118 mmol/L). He had received a 5-day course of IVIG prior to presenting to our hospital; pseudohyponatraemia was considered but felt unlikely as serum osmolality confirmed true hypotonic hyponatraemia and total protein was not elevated with IgG within the reference range. Thyroid and adrenal insufficiency and malignancy were excluded. Management required rescue hypertonic saline (250 mL 1.8%) followed by strict 1 L/day fluid restriction, with recurrent sodium decline when restriction was relaxed.

Discussion: Hyponatraemia in GBS can result from various mechanisms, including SIADH, pseudohyponatremia from treatments such as IVIG and, rarely, cerebral salt wasting.

This case illustrates evolving ADH dysregulation in inflammatory neuropathy, progressing from an early non-SIADH state to persistent SIADH.

Pathophysiologically, early sodium volatility likely reflects autonomic-mediated non-osmotic ADH release, possibly due to inflammation of afferent baroreflex pathways or hypersensitivity to volume changes. As the neuropathy progressed, the clinical picture transitioned to established SIADH.

Serial reassessment of tonicity and urine studies is essential in prolonged neuroinflammatory disease, rather than relying on a single early snapshot.

Conclusions: In post-vaccination GBS, hyponatraemia may evolve into sustained SIADH. Understanding the pathophysiological transition supports safer, timely therapy and prevents premature clinical misclassification.

EP994 - ECE_3299 - Molecular imaging in Cushing's disease: localization of an ACTH-secreting PitNET with [18F]FET PET-MRI after inconclusive MRI and negative inferior petrosal sinus sampling—a case report

Amber Audhoe[1,2,3], Romy van der Groef[1,2], Sophie Veldhuijzen van Zanten[2,3,4], Layal Chaker[1,2], Sebastian Neggers[1,2] and Julie Celine Refardt[1,2]
[1]*Erasmus Medical Center, Internal Medicine, Section Endocrinology, Rotterdam, The Netherlands;* [2]*Erasmus Medical Center, Pituitary Center Rotterdam, Rotterdam, The Netherlands;* [3]*Erasmus Medical Center, Radiology & Nuclear Medicine, Rotterdam, The Netherlands;* [4]*Erasmus Medical Center, Cancer Institute, Brain Tumor Center, Rotterdam, The Netherlands*

Background: Cushing's disease is a rare disorder caused by an adrenocorticotropic hormone (ACTH)-secreting pituitary neuroendocrine tumor (PitNET) resulting in hypercortisolism. Establishing a central source of ACTH hypersecretion can be challenging, as pituitary MRI is inconclusive in up to 40% of patients with ACTH-dependent hypercortisolism. In these cases, bilateral inferior petrosal sinus sampling (IPSS) is commonly used to differentiate between pituitary and ectopic ACTH secretion. While IPSS is considered the reference standard for confirming a pituitary origin, its ability to localize a PitNET—based on ACTH gradient lateralization—remains limited. Together with the procedure's invasiveness, dependence on venous anatomy, and restricted availability to specialized centers, this highlights the need for complementary diagnostic tools. Molecular imaging techniques, including [^{18}F]FET PET-MRI, have shown promising results for localizing small or MRI-negative PitNETs in patients with Cushing's disease.

Case: A 42-year-old man presented with severe Cushingoid features. ACTH-dependent hypercortisolism was biochemically confirmed. Pituitary MRI revealed a small right-sided pituitary lesion (5.5 mm). Guideline-based IPSS demonstrated no significant central-to-peripheral ACTH gradient (ratio 1.21), suggesting an ectopic ACTH source. In parallel, [^{18}F]FET PET-MRI showed focal increased uptake in the right-sided pituitary lesion, consistent with a functional PitNET. Given the IPSS result, additional imaging including whole-body [^{18}F]FDG PET-MRI, [^{68}Ga]Ga-DOTA-TATE PET-MRI, and CT were performed, without evidence of an ectopic ACTH source. Repeated IPSS with prolactin assessment remained inconclusive (prolactin-adjusted ACTH ratio 1.20), with correct catheter positioning confirmed by an experienced interventional radiologist. After multidisciplinary discussion, the patient underwent transsphenoidal

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

adenomectomy directed at the PET-positive lesion. Postoperatively, cortisol levels became undetectable, and histopathological examination confirmed a corticotroph PitNET.

Conclusions: This case highlights a diagnostic dilemma in which a pituitary source of ACTH hypersecretion could not be confirmed using MRI and technically adequate IPSS, whereas [^{18}F]FET PET-MRI successfully localized the culprit lesion. These findings support the potential added value of molecular imaging in patients with small functional PitNETs and may suggest a future role for [^{18}F]FET PET in reducing reliance on invasive IPSS, improving localization, and shortening the time to diagnosis and definitive treatment in Cushing's disease.

EP995 - ECE_3244 - Safety of a corticosteroid-sparing protocol in transsphenoidal surgery and predictive value of copeptin: a prospective cohort study

Ana Rocío Martínez Hartmann[1], Nieves Barceló Álvarez[2], Irene Iglesias-Lozano[3], María Hidalgo-Llorca[3] and Maria del Mar Roca-Rodriguez[1]

[1]Endocrinology and Nutrition Department, Endocrinology and Nutrition, Puerta del Mar Hospital, Puerta del Mar Hospital, Cadiz, Spain; [2]Biochemical Analysis, Puerta del Mar Hospital, Cádiz, Spain; [3]Neurosurgery Department, Neurosurgery, Puerta del Mar Hospital, Puerta del Mar Hospital, Cadiz, Spain

Introduction/Objectives: Routine perioperative corticosteroid coverage in transsphenoidal surgery (TSS) to prevent adrenal crisis is standard practice, though debated for patients with preserved function. The objectives were:

1. To evaluate the safety of a corticosteroid-sparing protocol in patients with intact hypothalamic-pituitary-adrenal (HPA) axis versus standard care.
2. To determine the predictive value of early copeptin, plasma osmolarity, and diuresis for permanent Diabetes Insipidus (DI).

Material and Methods: A prospective observational study included 27 patients undergoing endoscopic TSS for pituitary adenomas. Inclusion criteria required confirmed intact HPA axis (basal/stimulated cortisol >15 µg/dL). Patients were assigned to Standard (with corticosteroids) or Sparing (no corticosteroids) protocols. Analysis included group differences, pre-post clinical/analytical changes, correlations, and multivariate regression models.

Results: The cohort was homogeneous at baseline. The Sparing protocol demonstrated safety: no significant differences were found between groups regarding 1-month adrenal function ($P = 1.000$) or immediate complications, sodium disorders, or desmopressin requirements ($P = .587$).

Linear regression validated the protocol's physiological basis: preoperative ACTH strongly predicted the endogenous cortisol cifre 24 hours after TSS (rho = 0.800, $P = .003$; $\beta = 0.817$), confirming adequate stress response without exogenous steroids in patients with intact basal axes.

Regarding neurohypophysis, early plasma osmolarity (immediately prior to TSS) emerged as the strongest predictor of permanent DI (Linear Regression $R^2 = 0.963$, $P < .001$), outperforming isolated copeptin. Logistic regression identified polyuria as a critical risk factor: risk of permanent DI tripled for every 500 mL increase in maximum 24 h-diuresis ($P = .016$).

Anatomically, larger tumor size was associated with transient "thyroid stunning" (lower 96 hours after TSS T4L, $P < .001$), and posterior extension compromised immediate copeptin reserve (rho = −0.700). Surgery significantly improved visual defects ($P = .011$) and hyperprolactinemia ($P = .005$) without deteriorating other axes ($P > .05$).

Conclusions: Obtained data supports that withholding perioperative corticosteroids is safe for patients with preserved HPA function. Early osmolarity and diuresis are predictors of permanent neurohypophyseal damage. Copeptin emerges as a potential early biomarker for diabetes insipidus prediction, showing strong correlation with anatomical and functional damage, suggesting its future utility in clinical decision algorithms.

EP996 - ECE_3380 - Beyond clinical features: the respiratory impact of acromegalic macroglossia

Teodora Vintilă[1], Alexandru Florescu[1,2], Viviana Adam[2], Irina Puscasu[1], Andra Berigoi[1], Stefana Bilha[1,2], Anca Matei[1,2] and Cristina Preda[1,2]

[1]Saint Spiridon County Hospital, Iași, Romania; [2]Iași, Romania

Macroglossia in acromegaly is often perceived as a static phenotypic marker rather than a dynamic contributor to functional morbidity. Clinical attention is therefore usually focused on its diagnostic and morphological value, while its progressive impact on oral cavity anatomy and upper airway configuration remains insufficiently explored. Consequently, the potential role of acromegalic macroglossia in airway compromise and ventilatory dysfunction is frequently underestimated.

We report the case of a 67-year-old woman with no significant chronic comorbidities, admitted to a neurology department for diffuse subarachnoid haemorrhage due to rupture of an anterior communicating artery aneurysm. During hospitalization, the patient's physical appearance raised suspicion of an underlying endocrine disorder, leading to referral for endocrine evaluation. Endocrine assessment confirmed active acromegaly, with elevated GH (10.1 ng/mL) and IGF-1 (383 ng/mL), together with absent GH suppression during oral glucose tolerance testing. Pituitary MRI revealed a 13 × 14 × 10 mm sellar lesion compatible with a pituitary macroadenoma. In line with the well-recognized association between acromegaly and thyroid disease, thyroid evaluation revealed a toxic multinodular goiter, with biochemical hyperthyroidism and autonomously functioning nodules on scintigraphy, requiring antithyroid therapy for metabolic stabilization prior to definitive neurosurgical management.

From a functional perspective, macroglossia emerged as the most clinically relevant physical finding. The tongue exhibited no signs of acute swelling, induration or recent haemorrhage, while the covering mucosa showed normal colour and preserved papillary configuration, supporting a chronic hypertrophic rather than inflammatory or edematous process. Even in passive resting

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

position, without intentional protrusion, the tongue partially extended beyond the lower lip, suggesting a significant contribution to upper airway compromise.

The patient subsequently underwent endoscopic transsphenoidal resection of the pituitary macroadenoma. Persistent postoperative respiratory alkalosis, documented by repeatedly elevated serum bicarbonate levels (43 mmol/L and 45.5 mmol/L), together with ventilatory instability in the setting of severe acromegalic macroglossia, prompted further evaluation of nocturnal respiratory function.

Polysomnography demonstrated severe obstructive sleep apnea (apnea–hypopnea index 47.9 events/hour) with marked nocturnal hypoxemia. In this anatomical and functional context, maxillofacial evaluation identified macroglossia as the principal substrate for airway compromise, and functional reductive tongue surgery using the keyhole glossectomy technique was therefore recommended. This technique, rarely reported in acromegaly and more commonly described in congenital macroglossia, was indicated strictly for ventilatory purposes.

This case illustrates how acromegalic macroglossia may evolve from a phenotypic hallmark into a clinically significant respiratory disorder, underscoring the importance of systematic functional assessment and interdisciplinary management of oral manifestations in acromegaly.

EP999 - ECE_1942 - Chordoma mimicking macroprolactinoma in a young female patient

Ieva Baikštienė[1], Saiva Gaidytė[2], Martyna Juškienė[1] and Birutė Žilaitienė[1]
[1]*Institute of Endocrinology, Lithuanian University of Health Sciences, Kaunas, Lithuania;* [2]*Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania*

Introduction: Chordomas are relatively rare bone tumors that may lead to hyperprolactinemia when they develop in the sellar or parasellar region and compress the pituitary stalk, thereby interfering with hypothalamic dopamine transport to the pituitary gland. We report a case of a skull base chordoma presenting with an unusually high prolactin concentration.

Case: A 20-year-old patient presented with complaints of an irregular menstrual cycle of up to 60 days and headaches accompanied by generalized muscle weakness and diffuse body pain, patient reported episodes consistent with panic attacks. Marked hyperprolactinemia (4492.0-5104 mIU/L; reference range 102-496 mIU/L) was confirmed on repeat testing, with macroprolactin excluded. Brain MRI was performed due to suspicion of a macroprolactinoma. Imaging demonstrated a sella turcica of normal size and regular configuration, with an area of altered signal intensity in the superior portion of the clivus.

Subsequent brain CT revealed a $13 \times 7 \times 7$ mm lesion radiologically most suggestive of an intraosseous hemangioma. The patient was admitted for transsphenoidal biopsy. Histological examination with immunohistochemistry positive for brachyury, cytokeratin, and S-100 confirmed the diagnosis of chordoma. Six weeks after the biopsy, the patient reported clinical improvement and repeat prolactin concentration was 397.87 mIU/L (reference range 105-548 mIU/L).

Conclusions: Chordoma located in the sellar region can lead to hyperprolactinemia via the stalk effect and should therefore be included in the differential diagnosis of sellar masses associated with elevated prolactin levels.

EP1000 - ECE_3057 - Recurrent Crooke cell corticotroph adenoma: diagnostic challenges and multidisciplinary management in complex Cushing's disease

Gergő Csitári and Dóra Sümegi
DBC-SZIEOK, Budapest, Hungary

Background: Recurrent corticotroph pituitary adenomas with Crooke cell morphology present significant diagnostic and therapeutic challenges. Accurate differentiation between silent and manifest ACTH-omas, alongside detailed histopathological assessment and comprehensive anamnesis, is critical for effective management.

Case Presentation: A 54-year-old woman with extreme obesity was treated for recurrent corticotroph pituitary macroadenoma. Initial transsphenoidal surgery took place in 2011 for a $32 \times 31 \times 19.5$ mm tumour compressing the optic chiasm. Histology confirmed partial ACTH secretion. Early biochemical evaluation for Cushing's syndrome was limited due to the urgent clinical situation. In 2017 worsening neurological symptoms and imaging revealed recurrence with infiltration of the right cavernous sinus and carotid artery. The second surgery confirmed Crooke cell corticotroph adenoma with diffuse ACTH positivity. Follow-up care was irregular. Comprehensive endocrinological reassessment began around 2020. Detailed anamnesis and histopathological reviews clarified the clinical scenario. Biochemical results suggested manifest Cushing's disease; however, differentiation between silent and manifest ACTH-oma remained uncertain. Crooke cell morphology indicated aggressive tumour behaviour and increased recurrence risk. In January 2024 the Multidisciplinary Pituitary Committee reviewed the patient's case, based on the MRI showing a Knosp 3B residual tumour with invasive features. The Committee recommended annual MRI follow-up. In December 2024 the patient developed acute right eye ptosis and diplopia. MRI confirmed tumour growth with infiltration into the right cavernous sinus. Urgent third endoscopic transethmoidal-transsphenoidal surgery was performed. Histology reconfirmed a recurrent or residual corticotroph PitNET, with Crooke cell morphology, isolated TPIT positivity and diffuse ACTH expression within the tumour, and low proliferation index.

Conclusions: This case highlights the importance of thorough anamnesis and repeated histopathological assessment in managing recurrent corticotroph adenomas. The aggressive nature of Crooke cell adenomas and the subtle differentiation between silent and manifest ACTH-omas necessitate a multidisciplinary approach. The Multidisciplinary Pituitary Committee's role is central in guiding surveillance and interventions. These findings highlight the need for personalized management strategies in complex Cushing's disease cases.

EP1001 - ECE_3596 - Setmelanotide therapy in hypothalamic obesity following craniopharyngioma: a case series of three patients

Oana Ruxandra Cotta[1], Cesare Morgante[2], Damiano Siligato[1], Carla Paola Costa[1], Elena Sofia Blanca[1], Giordana Siracusano[1], Annalisa Giandalia[1,3], Francesco Ferraù[1,3] and Salvatore Cannavò[1,3]

Background: Hypothalamic obesity (HO) is a severe, often treatment-refractory complication after craniopharyngioma (CP) surgery. Setmelanotide, a melanocortin-4 receptor agonist (MC4R-A), offers a targeted therapeutic approach, but real-world data are limited.

Methods: We performed a retrospective review of patients with post-CP HO treated with setmelanotide at our center over a period of 3-15 months, collecting clinical, metabolic, and treatment-related data.

Results: Three young adults with HO after surgery for CP were included. Treatment responses were variable: one patient discontinued setmelanotide after continued weight gain over 3 months, while two experienced significant reductions in weight (−14.4% and −25.9%), BMI (−11.9% and −25%), waist circumference (−4% and −20%) and triglycerides levels (−35% and −39%) over 7-15 months. Adverse effects as nausea, vomiting, headache and skin hyperpigmentation, were mild and non-limiting. One patient experienced sclera hyperpigmentation after 2 months of treatment.

Conclusions: Setmelanotide may provide meaningful benefit for selected patients with severe HO following CP surgery. Despite small sample size, this series supports further investigation of MC4R agonism as a targeted therapy for acquired HO.

Introduction: Acquired hypothalamic obesity (aHO) arises from physical injury to the hypothalamus caused by trauma, tumours, treatment-related damage, inflammation, or developmental abnormalities, leading to disrupted melanocortin-4 receptor (MC4R) signalling and marked by accelerated, sustained weight gain. In a 52-week placebo-controlled Phase 3 trial of the MC4R agonist setmelanotide in patients with aHO aged ≥4 years, the primary endpoint of percent change in body mass index (BMI) at Week 52 was achieved with a 16.5% reduction in the setmelanotide group corresponding to a −19.8% placebo-adjusted difference. Here, we report real-world data from 56 adult patients with aHO treated with setmelanotide for up to 9 months under France's pre-marketing early-access program.

Methods: BMI outcomes and response rates—defined as achieving a ≥10% reduction—are presented for adult patients with aHO in France receiving early-access treatment with setmelanotide for up to 9 months.

Results: Fifty-six adult patients (33 females), aged 18-68 years old, started setmelanotide treatment. Forty-two patients had craniopharyngioma, 5 astrocytoma, 2 Langerhans cell histiocytosis, and 1 each hamartoma, germinoma, histiocytosis, neuroglial tumour, Rathke's pouch cyst, macroprolactinoma or not specified. Patients started treatment at 0.25-2 mg/day, titrated up to 1-3 mg/day at last included visit. For patients with 6-month data ($n = 26$), mean (SD) BMI at baseline was 44.8 (11.4) kg/m^2 which reduced to 39.1 (12.5) kg/m^2 after 6 months of treatment, representing a 12.7% decrease from baseline ($P < .0001$). For patients with 9-month data ($n = 16$), mean (SD) BMI at baseline was 42.8 (7.7) kg/m^2 which decreased to 34.8 (8.5) kg/m^2 after 9 months of treatment, representing an 18.7% decrease from baseline ($P < .0001$). Fifteen of 26 patients (57.7%) had a BMI reduction of ≥10% after 6 months of treatment. This increased to 11 of 16 patients (68.8%) after 9 months of treatment. No new

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

safety concerns were observed and reported adverse events were consistent with phase 3 trial data.

Conclusions: This real-world evidence of 56 patients with aHO, who received up to 9 months of setmelanotide under pre-marketing early access authorization in France showed consistent improvements in BMI. Efficacy and safety outcomes are consistent with Phase 3 trial data. These findings underscore the real-world therapeutic value of setmelanotide as an intervention strategy for patients with aHO.

Abstract citation ID: lvag096.1279

EP1005 - ECE_2451 - Potential role of the overnight dexamethasone suppression test in monitoring medical treatment of Cushing's syndrome

Evangelia Makri, Georgios Kostopoulos and Zoe Efstathiadou
Endocrinology, Hippokration General Hospital of Thessaloniki, Thessaloniki, Greece

Background: The overnight dexamethasone suppression test (ODST) is widely used for the screening and diagnosis of Cushing's Syndrome (CS) but is not included in monitoring medical treatment. Nevertheless, the restoration of the negative feedback of cortisol on corticotroph cells, could serve as a biomarker of successful treatment of endogenous hypercortisolism. The aim of the present study was to examine whether ODST may serve as an index of disease remission in patients with medically-treated CS, when assessed longitudinally.

Methods: We retrospectively evaluated 12 patients with ACTH-dependent Cushing's disease or ectopic ACTH syndrome who were treated with medical therapies including ketoconazole, metyrapone, pasireotide, osilodrostat, or cabergoline. ODST cortisol levels and urinary free cortisol (UFC) were recorded before and, in the majority of patients, approximately one year after initiation of medical treatment. Changes were assessed descriptively on an individual basis.

Results: Following medical therapy, a consistent reduction in ODST cortisol levels was observed across the cohort. Mean ODST cortisol decreased from 18.4 μg/dL before treatment to 5.6 μg/dL after treatment. This decline was accompanied by a marked reduction in UFC levels, which decreased from a mean of 227.7 μg/24 h to 41.8 μg/24 h. Six patients received metyrapone with ODST cortisol levels reduction after treatment in each patient, despite the known interference of metyrapone with cortisol synthesis and hypothalamic–pituitary–adrenal axis feedback. Three patients were treated with pasireotide and ODST cortisol was lower only in one patient compared with baseline values. Additionally, one patient received ketoconazole, one received osilodrostat and one received cabergoline presented decreased cortisol levels after ODST. Directionally concordant decreases in ODST and UFC were observed in most patients. No systematic pattern of paradoxical ODST suppression or discordance between ODST and UFC was evident. In the two patients treated with pasireotide, who did not show a reduction in cortisol levels, cortisol measurements were performed within less than 8 months after treatment initiation.

Conclusions: In this small real-world cohort, ODST cortisol levels decreased in parallel with UFC following medical treatment for Cushing's disease. Although ODST is not validated as a monitoring tool and absolute post-dexamethasone thresholds remain unreliable during therapy, longitudinal changes in ODST may reflect treatment-induced reductions in cortisol secretion. These findings suggest that ODST could provide adjunctive and physiologically relevant information on treatment response when interpreted cautiously.

EP1006 - ECE_2935 - A thirsty beginning: AVP deficiency as the isolated presenting symptom of systemic sarcoidosis

Csilla Czékus[1], Krisztian Sepp[1], Kristóf Barath[2] and Zsuzsanna Valkusz[1]
[1]*Albert Szent-Györgyi Health Center, Department of Internal Medicine, Metabolism and Endocrinology Unit, University of Szeged, Szeged, Hungary;* [2]*Albert Szent-Györgyi Health Center, Department of Pulmonology, University of Szeged, Deszk, Hungary*

Introduction: Sarcoidosis is a chronic, multisystemic inflammatory disorder of unknown etiology, characterized by the formation of non-caseating granulomas. While the disease primarily affects the lungs, extrapulmonary manifestations (skin, eyes, liver, and heart) are common. While systemic sarcoidosis is relatively frequent, central nervous system involvement (neurosarcoidosis) is rare (5%). Within the neurosarcoidosis subgroup, involvement of the hypothalamic-pituitary axis is even more infrequent. Sarcoidosis presenting with arginine vasopressin (AVP) deficiency as the sole initial symptom is considered a clinical rarity in the literature.

Case Presentation: A 23-year-old male patient was admitted to our endocrine department due to symptoms of thirst, polydipsia, and polyuria progressing for 2 months. Adenohypophyseal function showed no abnormalities except for a minimally elevated prolactin level. Electrolyte and calcium levels were within the normal range, and carbohydrate metabolism was intact. Fluid intake was approximately 113 mL/body weight kg/day. A water deprivation test demonstrated an inability to concentrate urine. During the DDAVP test, urine volume and concentration normalized. Consequent to the confirmed AVP deficiency, desmopressin was initiated, which successfully regulated urine volume and daily fluid balance. Pituitary MRI described the absence of the physiological T1 hyperintensity of the neurohypophysis (the "bright spot") and irregular thickening of the pituitary stalk, which raised the possibility of eosinophilic granuloma. Laboratory investigations for multiple juvenile autoimmune disease associations were negative, except for slightly elevated total IgG and IgG4 levels. To confirm potential IgG4-related disease, a whole-body 18F-FDG-PET/CT was performed, which revealed granulomatous lung disease. Bronchoscopy with biopsy and bronchoalveolar lavage excluded the infectious etiologies while histopathology confirmed typical sarcoidosis morphology with non-caseating granulomatosis with Langhans-cells. Consequently, given the systemic sarcoidosis with pituitary and lung involvement, systemic corticosteroid therapy with 32 mg

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

methylprednisolone was initiated for both endocrine and pulmonary indications. Currently, the steroid dose is being tapered, but the desmopressin dose cannot yet be reduced. Follow-up pituitary MRI and chest CT scans are planned.

Conclusions: In rare cases, polyuria caused by AVP deficiency can be the sole presenting symptom of sarcoidosis, preceding pulmonary or other organ-specific symptoms. Identifying sarcoidosis in these cases is a diagnostic challenge but remains a crucial step for timely systemic treatment. This case also highlights that mild IgG4 elevation occurring in granulomatous diseases can act as a confounding factor during the diagnostic process.

EP1008 - ECE_1700 - A rare case of prolactinoma transformation into a resistant prolactin- and growth hormone-secreting adenoma

Emily Davies, Arshia Beigi and David Shu
Department of Medicine, University of British Columbia, Vancouver, Canada

Background: Mixed prolactin- and growth hormone (GH)-secreting adenomas are well recognized, reflecting a shared somatomammotroph progenitor lineage. In contrast, transformation of a well-controlled prolactinoma on dopamine agonist therapy into a resistant, rapidly enlarging mixed prolactin- and GH-secreting adenoma is rare and carries important implications for long-term surveillance and management.

Case: A 39-year-old male with no personal or family history of pituitary disease presented in 2011 with a four-month history of persistent headache. MRI head showed a large 3.5 cm sellar mass, prompting urgent endocrine assessment. There were no clinical features of acromegaly. Biochemical evaluation demonstrated marked hyperprolactinemia and mild secondary hypogonadism; remainder of pituitary function was normal. Acute surgical intervention was not indicated and cabergoline was initiated with gradual dose escalation, resulting in symptomatic improvement, normalization of prolactin levels and interval tumor shrinkage over two years. From 2014 to 2022, cabergoline was slowly reduced to a low maintenance dose with continued biochemical and radiographic control. In October 2022, a dramatic rise in prolactin levels was noted on routine follow up and repeat pituitary hormone assessment revealed newly elevated insulin-like growth factor 1 (IGF-1). He had no acromegalic features and reported occasional headaches and new left eye visual impairment. Acromegaly was confirmed by failure of GH suppression on oral glucose tolerance testing. Lanreotide was initiated with escalation of cabergoline therapy. Repeat MRI head in September 2023 demonstrated marked tumour growth compared to 2021 imaging, from 1.5 cm to 3.4 cm in maximal diameter, with new compression of the optic chiasm. He underwent transsphenoidal debulking surgery in November 2023. Histopathology confirmed a mixed somatotroph and lactotroph pituitary adenoma. Post-operative imaging showed residual tumour with adequate decompression of the optic apparatus. Prolactin and IGF-1 levels remained elevated after surgery despite escalating doses of cabergoline and lanreotide. He subsequently underwent pituitary radiotherapy in May 2024, and had a brief trial of pegvisomant which was self-discontinued. By October 2025, both prolactin and IGF-1 demonstrated partial improvement, largely attributed to radiotherapy. He remains under close surveillance with ongoing hormone monitoring and interval imaging.

Conclusions: Transformation of a well-controlled prolactinoma into a resistant, mixed prolactin/GH-secreting adenoma is exceedingly rare, with only isolated cases reported. The coexistence of GH excess requires a distinct therapeutic strategy, emphasizing the importance of timely recognition. This case highlights the importance of long-term surveillance and regular comprehensive pituitary hormonal assessment in patients with prolactinomas, even after prolonged biochemical and radiographic stability.

EP1010 - ECE_1414 - JY007: a super long-acting growth hormone with potential for Q3W-Q4W dosing

Jianping Huang[1] and Qunhuan Kou[2]
[1]*Shanghai, China;* [2]*Shanghai ClessBio, Shanghai, China*

Objective: JY007 is a novel long-acting human growth hormone (hGH) composed of GH linked to an engineered Fc fragment via a flexible linker. The Fc domain incorporates the YTE mutation to enhance binding to FcRn and three additional amino acid mutations to silence effector functions. Here we present the preclinical comparison data between JY007 and once-weekly hGH, such as somatrogon and TJ101(GX-H9).

Methods: PK, PD and safety studies were conducted in hFcRn transgenic mice and NHPs following subcutaneous administration. Dosing regimens of JY007: mice at 5.8 and 58 mg/kg; cynomolgus monkeys at 1.5 and 15 mg/kg.

Results: ***In vitro* assays.** JY007 and somatrogon exhibited similar affinity to human, cyno and rat GHR and similar cell proliferation activity. Compared to wild-type Fc, JY007 exhibited attenuated binding affinity for FcγRs and abolished ADCC and CDC. YTE mutation resulted in a 33-fold enhancement in FcRn binding affinity over the wild-type Fc. **PK and PD study *in vivo***. In B-hFcRn mice, half-life of JY007 was 16 times that of somatrogon, and its IGF-1 duration was 3 times longer. Despite distinct dosing regimens (Q2W vs BIW), JY007 and somatrogon exhibited similar percentage of body weight gain in mice. The NHP study demonstrated that half-life, AUC, and IGF-1 maintenance duration of JY007 were two times those of TJ101 at an equivalent dose. **Favorable safety profile *in vivo*.** JY007 was well tolerated in mice and NHPs at the high dose. Data were collected in NHPs at day-1, 3, 7, 14, 28, including: body temperature, ophthalmic examination, electrocardiograph and blood biochemical examination. No significant change was observed before and after treatment.

Conclusions: Compared to once-weekly hGH, JY007 demonstrates similar in vitro activity while exhibiting a significantly extended half-life in both mice and NHPs, along with a favorable safety profile. Currently JY007 is under IND stage. The general pattern of YTE mutation: YTE mutation extends half-life more significantly in human (3.1-4.0 times) than in NHPs (2-2.4 times). Based on 5 days half-life of TJ101 in human, half-life of JY007 in human is predicted to be up to 15-20 days and supports Q3W-Q4W SC dosing.

EP1011 - ECE_3627 - Functional blockade in silent corticotroph tumors: dissociation between POMC expression and regulation of ACTH secretion

Jorge Navarro[1], Johana Sottile[1], Cristina Guillen[2], María Eugenia Torregrosa-Quesada[2], Francisca María Peiró-Marqués[2], Luís Concepción[2] and Antonio Pico[1]
[1]*Clinical Medicine, ISABIAL (Instituto de Investigación Sanitaria y Biomédica de Alicante), Alicante, Spain;* [2]*Radiology, Hospital General Universitario de Alicantet Emergency Room, Alicante, Spain*

Introduction: Silent corticotroph tumors (SCTs) represent a clinically non-functioning subtype that, despite exhibiting immunohistochemical and molecular features characteristic of the corticotroph lineage, is not associated with clinical hypercortisolism. This dissociation between cellular identity and hormonal function suggests the existence of molecular mechanisms that limit effective ACTH secretion, although these mechanisms have not been fully characterized. In this study, we compared the molecular profile of SCTs with that of functioning corticotroph tumors responsible for Cushing's disease, aiming to identify alterations associated with functional corticotroph blockade.

Methods: Gene expression analysis was performed by RT-qPCR in human pituitary tumor biopsies obtained from 29 patients with Cushing's disease and 28 patients with silent corticotroph tumors, using normal pituitary tissue as reference. Tumor classification was conducted according to the 2022 WHO criteria, based on the expression of the transcription factors TBX19/TPIT and SF-1. Genes involved in corticotroph regulation and ACTH synthesis (*POMC*, *CRHR1*, *AVPR1B*, *TBX19*, *NEUROD1*), post-translational processing of POMC (*PCSK1*, *PCSK2*), glucocorticoid receptor signaling (*NR3C1*, *FKBP5*), and pathways associated with oncogenic signaling, cellular stress, and cell-cycle control (*USP8*, *EGFR*, *STAT3*, *HSF1*, *JUN*) were evaluated. Statistical analysis was performed using the Mann–Whitney test ($P < .05$).

Results: Compared with Cushing's disease tumors, SCTs showed a significant dysregulation of upstream regulators of the corticotroph axis, characterized by decreased *CRHR1* expression ($P < .0001$) and increased *AVPR1B* expression ($P = .0061$), while *POMC* expression remained preserved. In addition, differences in differentiation-related factors were observed, with significantly lower *NR0B1* expression in Cushing's tumors compared with SCTs ($P = .0269$), and no significant changes in *TBX19* or *NEUROD1*. Genes involved in POMC processing (*PCSK1*, *PCSK2*) did not show significant differences between tumor subtypes. In contrast, SCTs exhibited alterations in glucocorticoid receptor signaling, with significant changes in *NR3C1* ($P = .0093$) and *FKBP5* ($P = .0187$). Genes associated with oncogenic signaling, cellular stress, and cell-cycle control (*USP8*, *EGFR*, *STAT3*, *HSF1* and JUN) did not show significant differences between functioning and silent tumors.

Conclusions: Silent corticotroph tumors do not lack corticotroph identity but instead display a functional blockade characterized by dysregulation of upstream mechanisms controlling ACTH secretion, specifically suggesting that in CST the hypothalamic regulation of POMC processing is mediated preferently by AVPR1 than CHRH. Moreover, the preserved glucocorticoid feedback in SCT could contribute to the absence of the clinical Cushing's disease. This molecular dissociation provides a mechanistic basis to explain their clinical silence.

EP1012 - ECE_2488 - Efficacy of recombinant human growth hormone therapy in patients with Schaaf-Yang syndrome

Oksana Khyzhnyak[1], Khristina Shchubelka[2], Olga Oleksyk[1], Elena Pop[1] and Miroslava Mykytyk[3]
[1]*Zakarpatska Endoclinica, Uzhhorod, Ukraine;* [2]*Medical Faculty, Uzhhorod National University, Uzhhorod, Ukraine;* [3]*Clinical Department, V. Danilevsky' Institute for Endocrine Pathology Problems of the National Academy of Medical Sciences of Ukraine, Kharkiv, Ukraine*

Objective: Schaaf-Yang syndrome (SYS) is an autosomal dominant multisystem disorder with early clinical overlap with Prader–Willi syndrome. Key features include hypotonia, joint contractures, autism spectrum disorders, intellectual disability, and growth retardation. The feasibility and efficacy of recombinant human growth hormone (rhGH) therapy in SYS remain under discussion. This study aimed to evaluate the clinical and laboratory efficacy of rhGH therapy in 2 siblings with SYS.

Materials and Methods: Two siblings with SYS were examined: an 11.10-year-old boy and his 18.2-year-old sister. Serum GH, IGF-1, levels were measured by ELISA. Bone age was assessed using the Greulich–Pyle method. Anthropometric parameters were evaluated according to WHO standards. Molecular genetic testing identified a heterozygous nonsense variant in the *MAGEL2* gene (c.2873G > A, p.Trp958*), inherited from the father, confirming the diagnosis of SYS in both patients. Both received rhGH in pediatric and adult dosage and the efficacy was assessed.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Results: The boy presented with congenital finger contractures, persistent hypotonia, feeding difficulties in infancy, chronic constipation, gastroesophageal reflux, and severe psychomotor delay (independent sitting at 2.5 years, walking at 3.8 years). Baseline GH was 0.84 ng/mL. rhGH therapy was initiated at 0.035 mg/kg/day. After 15 months, height increased from 116 to 128 cm (SDS −4.8 to −4.2), weight from 21.1 to 26.5 kg, and growth velocity reached +12 cm. IGF-1 increased from 20.0 to 126.0 ng/mL (SDS −5.28 to −2.40), and bone age progressed from 7 to 11 years. Marked improvements were noted in muscle strength, physical activity, speech development, communication, and self-care skills. The sister exhibited intellectual disability, social maladaptation, short stature, muscle weakness, obesity with hyperphagia, atopic dermatitis, and secondary amenorrhea. Baseline height was 134 cm (SDS −4.5), bone age 18 years, IGF-1 80 ng/mL (SDS −2.8), and GH 0.9 ng/mL. She received rhGH 0.3 mg/day combined with estradiol and dydrogesterone. After 15 months, fat mass decreased from 51% to 45%, muscle mass—from 28 to 31.7 kg, and body weight decreased from 68.8 to 58.0 kg. Clinical improvements included reduced appetite, increased physical activity, better social adaptation, reduced behavioral disturbances, and normalization of the menstrual cycle.

Conclusions: Patients with Schaaf-Yang syndrome demonstrate clinical and laboratory signs consistent with growth hormone deficiency. rhGH therapy appears safe and effective in both pediatric and adult patients, significantly improving growth parameters, body composition, and psycho-emotional functioning.

Keywords Schaaf-Yang syndrome, recombinant human growth hormone therapy

EP1013 - ECE_1987 - Two siblings with normosmic isolated hypogonadotropic hypogonadism and hearing loss with a KISS1R gene mutation

Daniel Grigorie, Elena Braha and Alina Sucaliuc
National Institute of Endocrinology, Bucharest, Romania

Introduction: Kisspeptin 1 receptor (KISS1R) gene mutations are rare but become an important etiology of normosmic isolated hypogonadotropic hypogonadism (nIHH). IHH with associated hearing loss could be the consequence of a single gene mutation or not.

Cases Presentation: The proband was a male born to nonconsanguineous eugonadal Romanian parents. He was initially referred to our department at the age of 31 years reporting absent pubertal development at 15 yrs (FSH 0.05 mIU/mL, LH 0.17 mIU/mL, testosterone 0.26 ng/mL) and treatment with testosterone undecanoate (1000 mg every 3 months, intramuscular injections) with acquisition of full secondary sexual features and final height (180 cm). Micropenis and cryptorchidism were noticed at birth and treated with HCG for 1 yr. At present time, physical examination showed normal olfaction, small for age intrascrotal testes (15 mL), a penis length of 6 cm, azoospermia. His karyotype was normal (46, XY). Serum LH (<0.2 mIU/mL) and FSH (0.38 mIU/mL) were low and normal testosterone 2.93 ng/mL (1.75 – 7.81 ng/mL). He had hearing loss and difficulties in speech, been diagnosed at 1 yr and considered to be caused by gentamicin administration. His sister was 22 years, tall and eunuchoid, Tanner B4P4, normal olfaction, milder hearing loss (also attributed to gentamicin in childhood). At age 15 she presented with primary amenorrhea and thereafter treated with oral contraceptives. At the present time, FSH = 2.47 mUI/mL, LH = 2.12 mUI/mL, E2 = 15.53 pg/mL and on ultrasound low-normal uterus and bilateral micropolycystic ovaries. Her karyotype was normal (46, XX). Pituitary and olfactory bulb magnetic resonance imaging were normal as the anterior pituitary function in both.

Results of Genetic Testing: We found a heterozygous KISS1R mutation (c.305T > C) by NGS and a 35delG mutation of GJB2 gene by MLPA in both siblings.

Discussion: c.305T > C is a recurrent missense mutation (p. Leu102Pro) of KISS1R gene and was described as homozygous or compound heterozygous mutation of several families with IHH, heterozygous been unaffected. Nevertheless, significantly delayed puberty in heterozygous female patients have been described with another mutation. However, 2 heterozygous missense mutations (KISS1R and IL17RD) were identified in a male patient with IHH (Miraoui, 2013), suggesting oligogenicity. Hearing loss caused by mutations in GJB2 accounts for approximately half of all autosomal recessive forms of hearing loss and is the most common form of hereditary hearing loss.

Conclusions: We described two siblings with nIHH and hearing loss produced by mutations in two unrelated genes.

Abstract citation ID: lvag096.1286

EP1014 - ECE_1999 - Persistent remission after steroidogenesis inhibitor discontinuation in Cushing disease: a case series

Alessandra Mangone[1,2], Elisa Sala[2], Giulia Carosi[2], Giulia Del Sindaco[2], Roberta Mungari[2], Arianna Cremaschi[2], Iulia Petria[1,2], Giovanna Mantovani[1,2] and Emanuele Ferrante[2]
[1]Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy; [2]Endocrinology Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy

Background: Adrenal steroidogenesis inhibitors, such as metyrapone and osilodrostat, represent key treatment options for persistent or recurrent Cushing disease. These drugs have a short half-life and are considered rapidly reversible in their effects, yet recent reports have described prolonged adrenal insufficiency following osilodrostat discontinuation, suggesting potential long-lasting effects. Proposed mechanisms include a direct cytotoxic effect on the adrenal cortex, supported by recent imaging data suggesting possible adrenal shrinkage during osilodrostat treatment. Similar prolonged effects have not been previously reported with metyrapone.

Case Presentation: We describe three female patients with Cushing disease who had previously undergone pituitary surgery and subsequently initiated adrenal steroidogenesis inhibitors (metyrapone or osilodrostat) for documented recurrent disease, defined by elevated 1-mg dexamethasone suppression test, urinary free cortisol and late-night salivary cortisol levels. All three patients experienced an unplanned interruption of therapy due to symptoms consistent with adrenal insufficiency after a mean duration of 6 months and subsequently remained in biochemical remission after treatment withdrawal. Remission was persistent at last follow-up, observed 31 months after

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

metyrapone discontinuation and 19 and 41 months after osilodrostat withdrawal.

Results: Long-term remission persisted despite the short half-life of steroidogenesis inhibitors and in the absence of further active treatment. Biochemical evaluation consistently demonstrated normal UFC and LNSC levels during subsequent follow-up.

Conclusions: We report three cases of prolonged adrenocortical suppression after withdrawal of steroidogenesis inhibitors, contributing to the growing literature on potential long-lasting adrenal effects of these therapies by providing a longer follow-up and including metyrapone among the agents involved. These observations support hypotheses of sustained adrenal effects beyond transient enzyme inhibition and underscore the need for systematic studies to identify predictors and mechanisms underlying this unexpected outcome.

EP1015 - ECE_2908 - Two distinct cases of acromegaly with benign and malignant lung tumors

Gokcen Ertuna[1], Berna Evranos Ogmen[1], Meric Coskun[2], Birgul Genc[1], Gulsum Karahmetli[1], Oya Topaloglu[1], Bekir Cakir[1] and Reyhan Ersoy[1]
[1]Endocrinogy and Metabolism, Ankara Bilkent Şehir Hastanesi, Ankara, Türkiye; [2]Endocrinogy and Metabolism, Bartın Devlet Hastanesi, Bartın (Merkez), Türkiye

Introduction: Acromegaly is a rare chronic condition characterised by excessive secretion of growth hormone (GH) and insulin-like growth factor-1 (IGF-1), with an incidence of 30-70 cases per million. It is associated with increased morbidity and mortality due to systemic and metabolic effects, primarily leading to cardiovascular diseases, respiratory issues, and cancers. While it is debated whether acromegaly increases the incidence of benign and malignant tumors, the potential relationship between the GH-IGF-1 axis and tumorigenesis has been documented in various studies. However, the existing literature on the connection between acromegaly and lung tumors remains scarce. This report presents two cases of acromegaly involving pulmonary hamartoma and lung adenocarcinoma and reviews related literature.

Case 1: A 56-year-old male patient presented for evaluation due to concerns about his altered and rough appearance and was subsequently diagnosed with acromegaly. After multiple treatments, including transsphenoidal hypophysectomy, medical drugs and Gamma knife radiosurgery, the patient's IGF-1 level normalised. In a follow-up 12 years after the acromegaly diagnosis, he developed a pulmonary hamartoma followed by lung adenocarcinoma after nine years of hamartoma, ultimately leading to his death from metastatic lung cancer at age 78.

Case 2: A 26-year-old male presented with typical symptoms of acromegaly and was diagnosed with a $14 \times 16 \times 21$ mm pituitary adenoma. After two transsphenoidal adenoidectomies, medical drugs and gamma knife radiosurgery, GH and IGF-1 levels were fixed within normal limits. Eighteen years after the diagnosis, a nodular lesion was discovered in his right lung, later identified as a pulmonary hamartoma during monitoring.

Discussion: The presented cases highlight the complexity of acromegaly and its potential associations with lung tumors. Further research is needed to clarify the relationship between acromegaly and lung tumorigenesis and to ensure comprehensive follow-up care focusing on potential respiratory complications in these patients.

EP1017 - ECE_2448 - The renin-angiotensin system is activated by short-term, but repressed by long-term growth hormone excess

Clemens Baumgartner[1], Paul Fellinger[1], Anna Tosin[1], Anne Blanchard[2], Matthaeus Metz[1], Oliver Domenig[3], Dunja Van Oyen[3], Anton Luger[1], Greisa Vila[1], Alexandra Kautzky-Willer[1], Michael Krebs[1], Philippe Chanson[2], Peter Kamenicky[2] and Peter Wolf[1]
[1]Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria; [2]Service d'Endocrinologie et des Maladies de la Reproduction, Université Paris-Saclay, Assistance Publique-Hôpitaux de Paris, Hôpital Bicêtre, Le Kremlin-Bicêtre, France; [3]Attoquant Diagnostics, Vienna, Austria

Background: The renin-angiotensin system (RAS) constitutes an important cornerstone in blood pressure (BP) regulation. Previous studies have reported heterogeneous and sometimes contradictory results regarding the relationship between growth hormone (GH), insulin-like growth factor I (IGF-I), and the RAS, depending on study conditions and exposure duration. This study therefore investigated the effects of short- and long-term GH excess on RAS activity.

Methods: RAS activity was assessed in 10 healthy, male volunteers (26 ± 5 years, BMI 23 ± 3.4 kg/m^2) before and after one week of daily, subcutaneous GH treatment serving as model of short-term GH excess. Regarding long-term GH excess, RAS activity in 19 patients with active acromegaly (54 [48-59] years, 10 females, IGF-I/ULN 2.8 [2.3-3.3]) were compared to a cohort of 25 controls (39 [32-47] years, 19 females). In 12 patients measurements were re-conducted after successful treatment of acromegaly.

Results: One week of GH treatment increased overall RAS activity, including angiotensin II levels (117.5 ± 50.3 vs 205.9 ± 135.7, $P = .03$) and the sum of angiotensin I + II (PRA-S) representing a marker for renin activity (149.8 ± 63.3 vs 269.1 ± 177.4, $P = .03$) alongside increased concentrations of insulin and C-peptide in healthy males. In contrast, patients with acromegaly showed lower concentrations of angiotensin II (47.2 [33-145] vs 155.3 [64-326], $P = .017$), aldosterone (118 [71-193] vs 227.8 [165-305], $P = .009$), and PRA-S (84.2 [51-200] vs 230 [85-403], $P = .032$) despite higher mean arterial BP (105 [99-115] vs 91 [85-97], $P < .001$) compared to controls. Biochemical disease control did not change RAS activity in acromegaly, but ΔIGF-I showed a strong negative correlation with Δaldosterone/angiotensin II-ratio ($rho = -0.61$, $P = .04$), a biomarker for adrenal response to angiotensin II signalling.

Conclusions: Short-term GH excess stimulates RAS activity which might be related to the increase in insulin and C-peptide. In contrast, RAS activity is down-regulated in long-term GH excess despite high BP.

EP1019 - ECE_1669 - GHRH and its agonist MR-409 attenuate neurodegeneration and inflammation in experimental Alzheimer's disease

Francesca Pedrolli[1], Giulia Morello[2], Iacopo Gesmundo[1], Federica Bistolfi[1], Gabriella Gruden[1], Medhi Wangpaichitr[3], Wei Sha[3], Elena Tamagno[2], Andrew V. Schally[3], Michela Guglielmotto[2] and Riccarda Granata[4]
[1]*Department of Medical Sciences, University of Turin, Turin, Italy;* [2]*Department of Neurosciences "Rita Levi Montalcini", University of Turin and Neuroscience Institute Cavalieri Ottolenghi, Turin, Italy;* [3]*Endocrine and Polypeptide Institute, Miami VA Healthcare System, Miami, FL, United States;* [4]*Department of Molecular Biotechnology and Health Sciences, University of Turin, Turin, Italy*

Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by amyloid-β (Aβ) accumulation and tau hyperphosphorylation, leading to neuroinflammation, neuronal loss, and cognitive decline. Current therapies provide limited symptomatic relief and fail to halt disease progression, highlighting the need for novel therapeutic strategies. Growth hormone-releasing hormone (GHRH), besides promoting the release of pituitary growth hormone (GH), exerts several peripheral functions, including stimulation of cell survival and proliferation. Notably, both GHRH and its agonistic analog MR-409 exert anti-inflammatory, cardioprotective, and neuroprotective effects. However, the role of GHRH in AD remains to be elucidated. Thus, in this study we explored the therapeutic potential of GHRH and its agonist MR-409 in *in vitro* and *in vivo* AD models. *In vitro,* GHRH(1-44)NH_2 enhanced cell survival, proliferation and neuronal differentiation in rat hippocampal neural stem cells (NSCs) and human SH-SY5Y neuroblastoma cells under growth factor deprivation or amyloid-β ($A\beta_{1-42}$) exposure. The underlying molecular mechanisms involved the activation of $G_{\alpha S}$/cAMP/PKA/CREB pathway, as well as ERK1/2 and PI3K/Akt signaling. Furthermore, GHRH mitigated Aβ-induced neurotoxicity by reducing apoptosis, inhibiting GSK-3β activity and tau phosphorylation and suppressing inflammatory cytokines expression and NF-κB phosphorylation. *In vivo*, 3-month-old male transgenic 5xFAD mice were divided into two groups (5xFAD-vehicle [$n = 14$] and 5xFAD-MR-409 [$n = 14$]) and treated daily for 3 months with subcutaneous injection of MR-409 (20 μg) or vehicle. 5xFAD-MR-409 mice showed increased body weight gain compared with vehicle-treated controls. MR-409 markedly reduced brain Aβ deposits compared with vehicle, accompanied by decreased tau phosphorylation and reduced activation of GSK-3β and CDK5. In addition, MR-409 exerted significant anti-inflammatory effects by attenuating microgliosis, astrogliosis, inflammatory cytokine expression, and NF-κB phosphorylation, while also displaying antioxidant activity through modulation of KEAP1–NRF2 pathway. MR-409 also mitigated neuronal and synaptic loss, as evidenced by increased expression of the neuronal marker NeuN, neurotrophic factors and synaptic proteins synaptophysin and PSD-95. These molecular and histological changes were associated with improved cognitive performance, as assessed by novel object recognition and Y-maze tests, in MR-409-treated mice compared with controls. In summary, this study demonstrates that GHRH and its agonist MR-409 modulate multiple aspects of AD pathology, and hold promise for further translational development in neurodegenerative diseases.

EP1020 - ECE_2014 - Under-recognition of endocrinopathies among patients with chronic opioid use: a population-based study

Ashley Han, Sara J. Achenbach, Elizabeth Atkinson and Irina Bancos
Mayo Clinic, Rochester, NY, United States

Background: Although opioid use has been associated with several endocrinopathies due to hypothalamus-pituitary axis suppression, biochemical testing is not routinely performed in patients with chronic opioid use. As a result, it is suspected that opioid-induced endocrinopathies remain significantly under-recognized and untreated in this patient population, potentially contributing to adverse clinical outcomes associated with long-term opioid use.

Methods: We performed a large retrospective population-based cohort study with 15-years of follow-up (2005-2021). Patients with ≥3 months of consecutive opioid use were identified as cases and paired 1:1 with age-, sex-, and calendar-year matched referent subjects. Adrenal insufficiency was defined using a composite clinical definition to capture cases identified in routine clinical practice. Hypogonadism and hyperprolactinemia were identified based on International Classification of Diseases (ICD) codes and hypothyroidism was defined by an active prescription for thyroid hormone replacement. Outcomes of interest included incidence of adrenal insufficiency, serum cortisol testing, hypogonadism, hypothyroidism, and hyperprolactinemia during follow-up.

Results: In our cohort of 7805 matched patients, the cumulative incidence of adrenal insufficiency was 11.3% among patients with chronic opioid use compared with 5.9% among referent patients (hazard ratio [HR] 2.13 [95% CI 1.82-2.50]). Although patients with chronic opioid use were more likely to undergo biochemical testing than referent patients, less than 14% of patients with chronic opioid use had at least one serum cortisol level measured during 15-year follow-up. Compared with referent patients, those with chronic opioid use were at increased risk of incident hypogonadism (HR 2.57 [95% CI 1.69-3.91]) and hyperprolactinemia (HR 1.67 [1.04-2.67]), but not hypothyroidism. The cumulative incidence of hypogonadism among male patients with chronic opioid use was 4.3%. Notably, adrenal insufficiency was independently associated with increased risk of inpatient hospitalization (HR 1.48 [95% CI 1.29-1.69]) and mortality (HR 2.21 [95% CI 1.98-2.47]) after adjustment for opioid use, age, sex, comorbidity burden, and prior hospitalization.

Conclusions: Despite a well-established association between opioid use and endocrinopathies such as hypogonadism and adrenal insufficiency, biochemical testing remains uncommon among patients with chronic opioid use. The incidence of endocrinopathies observed in this population-based study was lower than previously reported estimates from smaller studies in which all patients underwent biochemical testing. This real-world data suggests that endocrinopathies are likely substantially underdiagnosed among patients with chronic opioid use due to insufficient biochemical testing, which may contribute to adverse clinical outcomes associated with long-term opioid therapy.

EP1022 - ECE_3537 - Distinct molecular profile of silent corticotroph tumours compared with gonadotroph tumours

Jorge Navarro[1], Johana Sottile[1], Elena Garcia-Garrigos[2], Jorge Frances[3], Francisca María Peiró-Marqués[4] and Antonio Pico[1]

[1]*Clinical Medicine, ISABIAL (Instituto de Investigación Sanitaria y Biomédica de Alicante), Alicante, Spain;* [2]*Radiology, Hospital General Universitario de Alicantet Emergency Room, Alicante, Spain;* [3]*Clinical Analyse, ISABIAL, Alicante, Spain;* [4]*Pathology, ISABIAL, Alicante, Spain*

Introduction: Silent corticotroph tumors (SCTs) are considered clinically non-functioning and, in routine practice, are frequently grouped together with gonadotroph tumors (GTs) within non-functioning pituitary tumors. However, the true biological identity of SCTs and their molecular relationship with GTs remain a matter of debate. The aim of this study was to compare the molecular profile of SCTs with that of gonadotroph tumors in order to determine whether SCTs represent a distinct entity within this group.

Methods: Gene expression analysis was performed by RT-qPCR in human pituitary tumor biopsies obtained from 28 patients with silent corticotroph tumors and 53 patients with gonadotroph tumors, using normal pituitary tissue as a reference for gene expression normalization. Tumor classification was carried out according to the 2022 WHO criteria, based on the expression of the transcription factors TBX19/TPIT for corticotroph tumors and *NR5A1*/SF-1 for gonadotroph tumors. Genes related to tumor identity and differentiation (*TBX19*, *NEUROD1*, *NR5A1*, *GATA2*, *NR0B1*), corticotroph regulation and hormonal function (*POMC*, *CRHR1*, *AVPR1B*), somatostatin-mediated inhibitory signaling (*SSTR2*, *SSTR3*, *SSTR5*), tumor signaling and cellular stress pathways (*EGFR*, *USP8*, *STAT3*, *HSF1*, *JUN*), cell cycle control and genomic stability (*CABLES1*, *MSH6*), and tumor immunomodulation (CD274) were evaluated. Statistical analysis was performed using the non-parametric Mann–Whitney test, considering P values $<.05$ as statistically significant.

Results: Beyond the expected differences related to corticotroph lineage, silent corticotroph tumors displayed a differential molecular profile dominated by alterations in regulatory and signaling pathways. In particular, SCTs showed higher expression of *SSTR5*, whereas *SSTR3* was significantly higher in gonadotroph tumors and *SSTR2* did not differ between groups. In addition, SCTs were characterized by increased expression of genes involved in tumor signaling and cell cycle control, including *EGFR*, *STAT3*, *JUN* and *CABLES1*. *USP8* showed a trend toward higher expression in SCTs without reaching statistical significance. In contrast, *GATA2* and *CD274* were more highly expressed in gonadotroph tumors. No significant differences were observed for *NEUROD1*, *NR5A1*, *NR0B1*, *HSF1*, or *MSH6*.

Conclusions: Silent corticotroph tumors exhibit a molecular profile clearly distinct from that of gonadotroph tumors, characterized by a specific pattern of somatostatin receptor expression and by alterations in tumor signaling and cell cycle–related pathways, independent of classical hormonal identity. These findings support the concept that SCTs constitute a defined molecular entity within non-functioning pituitary tumors, with potential diagnostic and therapeutic implications.

Background: Pituitary neuroendocrine tumors (PitNETs) are typically benign, but a small subset exhibits aggressive behavior. Accurately predicting which tumors will behave aggressively remains a clinical challenge. We hypothesized that an integrated, multimodal approach combining clinical, radiological, and immunohistochemical (IHC) markers would provide a more robust and accurate prediction of tumor aggressiveness and clinical outcome.

Methods: 250 patients with PitNETs who underwent surgical resection were analyzed on three key domains: 1) **Clinical features**, including patient age, sex, tumor type (functioning vs non-functioning), and presenting symptoms; 2) **Radiological characteristics**, such as maximum tumor diameter, tumor volume, and Knosp grade for cavernous sinus invasion; and 3) **Immunohistochemical markers**, including the proliferative index (Ki-67), p53 expression, and methylguanine-DNA methyltransferase (MGMT) expression. A multivariate predictive model was developed by integrating these markers, and its ability to predict recurrence-free survival (RFS) and progression-free survival (PFS) which was analyzed over a five-year follow-up period.

Results: Univariate analysis revealed that a high Ki-67 index ($\geq$3%), Knosp grade $\geq$3, and strong p53 expression were each significantly associated with shorter recurrence-free survival (RFS) and progression-free survival (PFS) ($P < .01$ for all. However, the most compelling findings emerged from the integrated multivariate model. Our risk stratification system, which assigned scores based on a combination of these markers, identified three distinct prognostic groups. The high-risk group ($n = 55$), characterized by the co-occurrence of a high Ki-67 index ($\geq$3%), Knosp grade $\geq$3, and strong p53 expression, had a median RFS of 1.5 years (95% CI: 1.2-1.8 years) and a 5-year RFS of only 18.2%. This was in contrast to the low-risk group ($n = 120$), which had a 5-year RFS of 92.5%, and the intermediate-risk group ($n = 75$), with a 5-year RFS of 55.1%. The Kaplan-Meier analysis showed a significant separation between the three groups ($P < .001$, log-rank test). Cox proportional hazards modelling demonstrated that our integrated risk score was a powerful independent predictor of recurrence (HR = 4.7; 95% CI: 3.2-6.9; $P < .001$), outperforming any single marker alone. The predictive accuracy (as measured by the concordance index, or C-index) of our model was 0.88, a substantial improvement over a model using only Ki-67 (0.70) or Knosp grade (0.75) in isolation.

Conclusions: The findings of this study underscore the limitations of a single-marker approach for assessing pituitary tumor aggressiveness. Our integrated multimodal model, provides a superior tool for accurate risk stratification. The proposed model represents a crucial step toward personalized medicine in the management of PitNETs.

EP1024 - ECE_2181 - Systemic inflammatory markers discriminate ACTH-secreting PitNET from the other PitNET histotypes with high accuracy

Claudia Campana[1], Giuliana Corica[2], Karol Sagan[3], Diego Criminelli[4], Elżbieta Andrysiak-Mamos[3], Anna Brzeska[3], Anhelli Syrenicz[3], Gianluigi Zona[4], Diego Ferone[1] and Federico Gatto[1]

[1]Endocrinology Unit, Department of Internal Medicine and Medical Specialties, University of Genoa, Genoa, Italy; [2]Endocrinology Unit, IRCCS Ospedale Policlinico San Martino, Genoa, Italy; [3]Department of Endocrinology, Metabolic and Internal Diseases, Pomeranian Medical University, Szczecin, Poland; [4]Division of Neurosurgery, Department of Neurosciences, Rehabilitation, Ophthalmology, Genetics, Maternal and Child Health, IRCCS Ospedale Policlinico San Martino, Genoa, Italy

Introduction: Systemic **i**nflammatory markers have been shown to properly discriminate adrenal Cushing's syndrome from other adrenal lesions. Moreover, these biomarkers have been reported to be differentially modulated in GH-secreting PitNETs compared to non-functioning (NF)-PitNETs.

Aim: To investigate whether pre-operative systemic inflammatory markers may properly discriminate ACTH-secreting PitNETs from the other PitNET histotypes.

Methods: Retrospective, two-centre study, including patients that underwent surgery for PitNETs. We collected patient pre-operative blood count and calculated the neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), monocyte-to-lymphocyte ratio (MLR) and the systemic immune-inflammation index (SII; platelet count multiplied by neutrophil count, then divided by lymphocyte count). Data concerning pituitary function before surgery we collected, when available. Patients were stratified based on pathology report and clinical/biochemical evaluation (NF-PitNET: NF-group; ACTH-secreting PitNET: ACTH-group; silent corticotroph PitNETs: sACTH-group; GH-secreting PitNET: GH-group; PRL-secreting PitNET: PRL-group).

Results: 295 patients were included; 158 males (56%), mean age at surgery 54.5 ± 15.3 years. Most tumors belonged to the NF-group ($n = 176$, 60.7%), followed by GH-group ($n = 41$, 14.1%), ACTH-group ($n = 39$, 13.4%), PRL-group ($n = 24$, 8.3%) and sACTH-group ($n = 10$, 3.4%). NLR and SII were significantly higher in ACTH-group compared to the other groups, except the sACTH ($P < .001$). SII was significantly higher in the sACTH-group compared to NF-group. PLR was significantly higher in ACTH-group compared to NF-group and GH-group ($P < .001$); PLR was significantly higher in sACTH-group compared to NF-group. LMR was significantly lower in ACTH-group compared to NF-group and GH-group ($P < .001$). Morning plasma cortisol levels were available in 202 patients (36 ACTH-group and 166 of the other groups); overall, we observed a positive correlation between cortisol levels and NLR (rho = 0.227, $P < .002$), SII (rho = 0.258, $P < .001$) and PLR (rho = 0.289, $P < .001$), and a negative correlation with LMR (rho = −0.320, $P < .001$). The evaluation of UFC values (available in 79 patients, 29 from the ACTH-group) showed the same pattern. ROC curve analyses showed that SII was able to differentiate the ACTH-group from all other groups with high accuracy (AUC = 0.854, 95%CI 0.774-0.933; cut-off 538.3 = sensitivity 86%, specificity 78%, accuracy 80%) and it was the best predictor compared to the other systemic inflammation markers ($P < .05$). A similar accuracy of SII was observed when considering together the ACTH + sACTH-groups vs all other tumor types (AUC = 0.847, 95%CI 0.777-0.916).

Conclusions: A dysregulation of systemic **i**nflammatory markers is observed in patients with Cushing's disease and silent ACTH-secreting PitNETs. In particular, SII seems to be an easily available and reliable tool to discriminate patients with ACTH-PitNETs from other PitNET histotypes.

EP1025 - ECE_2817 - Impact of CRH shortage on the work-up of ACTH-dependent Cushing's syndrome and usefulness of desmopressin-based diagnostic tests: insights from 54 European expert centres

Annamaria Colao[1], Barbara Altieri[2], Carla Scaroni[3], Elena Valassi[4], Emese Mezosi[5], Frederic Castinetti[6], Leonard Saiegh[7], Manel Puig-Domingo[4], Pedro Marques[8,9] and Timo Deutschbein[10]

Introduction: The main supplier of corticotropin-releasing hormone (CRH) is no longer manufacturing this drug. The European Society of Endocrinology (ESE) provided recommendations on how to deal with this issue (PMID:39005054). The diagnostic work-up of adrenocorticotropic hormone (ACTH)-dependent Cushing's syndrome (CS) is now more reliant on desmopressin. We aimed to evaluate the impact of CRH shortage and usefulness of desmopressin-based alternative diagnostic tests across expert centres in Europe.

Methods: A standardized survey (SurveyMonkey®) with 25 questions was created by an ESE Task Force and sent to European expert pituitary centres. Answers were counted as absolute numbers and percentages.

Results: Forty-four of 54 centres (82%) from 17 countries that answered the survey currently have no CRH. The main CRH utilisation was the diagnostic work-up of ACTH-dependent CS (98%), but CRH was also commonly used to distinguish between CS and pseudo-Cushing states (31%). Top investigations for ACTH-

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

dependent CS before and after CRH shortage were pituitary MRI and IPSS (>90%), and there was an expected drop in the use of CRH stimulation tests across centres from 80% to 8%, while desmopressin test use increased from 25% to 73%. After CRH shortage there was an increased use of whole-body CT scan (from 41% to 49%) and functioning imaging (from 35% to 41%). Based on their experience, 47% of centres consider the desmopressin test performance worse than CRH stimulation test, while 36% consider these similar. Since CRH shortage, 70% of centres are using desmopressin during IPSS (contrasting with 4% before CRH shortage), and 4% stopped performing IPSS because of CRH shortage. Overall, 57% of centres consider CRH shortage has low impact on the ACTH-dependent CS diagnostic work-up, while 28% and 15% of centres describe CRH shortage as having no and high impact, respectively; 85% of centres agreed that a revised CS diagnostic algorithm without CRH is necessary.

Conclusions: CRH is not available in most European centres, which led to a shift towards desmopressin-based diagnostic tests. In general, CRH shortage seems to have low or no impact on ACTH-dependent CS work-up, but it can create additional diagnostic challenges due to the limited experience with desmopressin and need for more expensive and time-consuming alternative investigations. The performance of desmopressin is regarded as inferior to CRH by most centres, perception that may reflect the lack of data and experience with desmopressin. Further studies to assess the desmopressin diagnostic accuracy, and a revised CS diagnostic algorithm without CRH, are needed.

EP1026 - ECE_3194 - Peripheral immune and inflammatory profiles as potential biomarkers of disease activity and treatment response in acromegaly

Dario De Alcubierre[1,2], Ludovica Vincenzi[1], Lorenzo Cerroni[1], Francesca Sciarra[1], Marie-Lise Jaffrain-Rea[2,3], Mary Anna Venneri[1], Emilia Sbardella[1], Andrea Isidori[1,4] and Tiziana Feola[1,2]

[1]Department of Experimental Medicine, Sapienza University, Rome, Italy; [2]Neuroendocrinology, Neuromed IRCCS, Pozzilli, Italy; [3]Department of Biotechnological and Applied Clinical Sciences, University of L'Aquila, L'Aquila, Italy; [4]Centre for Rare Diseases, Policlinico Umberto I, Rome, Italy

Background: Acromegaly is associated with a distinct circulating immunophenotype, characterized by reduced monocytes, enrichment of non-classical subsets, and decreased NK cells with $CD56^{dim}$ predominance. However, longitudinal data on peripheral immune and inflammatory profiles and their relationship with therapeutic response are lacking.

Objective: To characterize baseline immune and inflammatory profiles in patients with newly-diagnosed acromegaly, to assess their longitudinal modulation and evaluate their association with biochemical response to medical therapies.

Methods: Patients with newly-diagnosed acromegaly (January 2022-June 2025) were evaluated at diagnosis and during follow-up after neurosurgery or, in the absence of remission, during medical therapy (first-line somatostatin analogues [SSA] and pegvisomant add-on in SSA non-responders). Clinical, hormonal, and radiological data were collected. Peripheral immunophenotyping was performed by multiparametric flow cytometry to quantify T-cell subsets, NK cells, and monocyte populations. Systemic inflammation indices derived from routine blood counts—neutrophil-to-lymphocyte ratio (NLR), lymphocyte-to-monocyte ratio (LMR), platelet-to-lymphocyte ratio (PLR), and systemic immune–inflammation index (SII)—were assessed.

Results: Twenty-one patients (11 males, mean age 51 ± 16 years) were included; follow-up ranged from 6 to 12 months. At baseline, NLR and SII correlated with increased IGF-1 levels × ULN (NLR: $r = 0.769$, $P = .002$; SII: $r = 0.723$, $P = .005$) and tumor volume (NLR: $r = 0.738$, $P = .015$). Eighteen patients (85.7%) underwent neurosurgery; five had not yet completed longitudinal evaluation at the time of data collection. Following surgical remission ($n = 4$), a significant reduction in circulating $CD56^{dim}$ NK cells was observed ($P = .042$). Twelve patients received SSA therapy, out of whom 7 achieved biochemical control and 5 required second-line treatment. Noteworthy, higher circulating $CD8^+$ T-cell percentages were significantly associated with greater IGF-1 reduction after SSA therapy ($r = -0.699$, $P = .011$), with a similar non-significant trend toward GH reduction ($r = -0.517$, $P = .085$). Accordingly, $CD8^+$ T-cell levels were higher in SSA responders than in non-responders (0.27 ± 0.13 vs 0.09 ± 0.04, $P = .024$). In contrast, baseline inflammatory indices did not differ between SSA responders and non-responders. SSA responders also exhibited a significant longitudinal increase in intermediate monocytes ($P = .029$) and a progressive reduction in $CD56^{dim}$ NK cells ($P = .001$), whereas patients requiring pegvisomant add-on showed an increase in total monocytes ($P = .014$) and a reduction in $CD56^{dim}$ NK cells ($P = .004$). No significant longitudinal changes in lymphocyte subsets were observed in either group.

Conclusions: In acromegaly, baseline systemic inflammatory indices reflect disease burden, whereas higher circulating $CD8^+$ T cells are associated with better response to SSA. The treatment of acromegaly was found to dynamically modulate innate immunity, partially restoring the distribution of innate immune cells subpopulations.

EP1027 - ECE_3565 - Comparison of ACTH responses to CRH and desmopressin during inferior petrosal sinus sampling in confirmed Cushing's disease

Diogo Brandão Neves[1], Beatriz Tavares Da Silva[1], Andreia Martins Fernandes[2], Maria Teresa Pereira[1], Carolina Noronha[3], Isabel Ribeiro[3] and Claudia Amaral[1]

[1]Division of Endocrinology, Centro Hospitalar e Universitário de Santo António, ULSSA, Porto, Portugal; [2]Clinic, Endocrinology Department, Portuguese Oncology Institute of Coimbra, Coimbra, Portugal; [3]Neurossurgery, Centro Hospitalar e Universitário de Santo António, ULSSA, Porto, Portugal

Background: Inferior petrosal sinus sampling (IPSS) with corticotropin-releasing hormone (CRH) is considered the gold standard for differentiating pituitary from ectopic ACTH-dependent Cushing's syndrome and may assist in tumor lateralization. Due to worldwide shortages of CRH, desmopressin (ddAVP) has increasingly been used as an alternative stimulus, despite concerns regarding its potentially lower ACTH stimulatory capacity.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Objective: To assess whether differences exist in the magnitude of ACTH response—evaluated by peak ACTH ratios and peak ACTH concentrations—between patients with confirmed Cushing's disease undergoing IPSS with CRH or desmopressin, and to describe lateralization concordance with pituitary imaging and procedural safety.

Methods: We performed a retrospective analysis of patients with ACTH-dependent Cushing's syndrome who underwent IPSS with CRH or desmopressin and in whom Cushing's disease was subsequently confirmed. ACTH responses, lateralization results, and procedural safety were evaluated.

Results: Forty-seven patients were included (66% female; mean age 44.8 ± 15.0 years). IPSS stimulation was performed with CRH in 39 patients (83%) and desmopressin in 8 patients (17%). Baseline characteristics, including age, lesion size, and baseline ACTH ratios, were comparable between stimulation groups. Median peak ACTH ratios were 24.95 (IQR 10.2-22.8) in the desmopressin group and 47 (IQR 23.9-155) in the CRH group ($P = .156$). Median peak ACTH concentrations were 1174 pg/mL (IQR 932.8-1897.0) versus 1983 pg/mL (IQR 1170-12 382), respectively ($P = .111$). Among patients with informative imaging and successful bilateral catheterization ($n = 27$), lateralization concordance between IPSS and pituitary MRI was 70.4% ($n = 19$). In operated patients, histopathology most frequently demonstrated corticotroph PitNET (46.8%), while normal adenohypophysis was observed in a subset, consistent with the known limitations of histological detection in Cushing's disease. Procedural complications were infrequent: transient oxygen desaturation occurred in 1 patient (2.1%), and minor post-procedural adverse events were observed in 8 patients (17.0%), including inguinal hematoma in 7 (14.9%) and subconjunctival hemorrhage in 1 (2.1%). No major complications were recorded.

Conclusions: In our study, desmopressin stimulation during IPSS resulted in ACTH responses comparable to those obtained with CRH in patients with confirmed Cushing's disease, which shows it appears to be a safe and feasible alternative stimulus for IPSS in settings where CRH is unavailable. As described previously in literature, lateralization concordance with imaging was limited and frequently not assessable.

Abstract citation ID: lvag096.1298

EP1028 - ECE_3963 - Tenascin C as a predictor of progression during somatostatin analogue therapy in patients with stage IV well-differentiated gastroenteropancreatic neuroendocrine tumors

Dorota Kaczmarska-Turek, Zbigniew Bartoszewicz and Tomasz Bednarczuk
Clinic of Internal Medicine and Endocrinology, University Clinical Center of the Medical University of Warsaw, Warsaw, Poland

Introduction: Long-acting somatostatin analogues (SSA) are recommended as first-line systemic therapy in patients with advanced, well-differentiated gastroenteropancreatic neuroendocrine tumors (GEP-NET). Despite their proven antiproliferative activity, a considerable proportion of patients experience early disease progression. Identification of biomarkers predicting reduced effectiveness of SSA could support early treatment optimization. Data addressing this issue in homogeneous populations of stage IV GEP-NET are limited. To assess the incidence of progression during SSA therapy and to identify biomarkers predicting progression, with particular emphasis on tenascin C (TNC), in patients with stage IV well-differentiated GEP-NET.

Material and Methods: This prospective observational study enrolled 30 patients with stage IV, well-differentiated GEP-NET (G1-G2, Ki-67 < 20%), all with liver metastases and confirmed somatostatin receptor expression on ^{68}Ga-PET/CT. Patients received octreotide LAR or lanreotide Autogel as first-line therapy and were followed for up to 12 months or until disease progression, assessed according to RECIST 1.1. Serum concentrations of TNC and selected biomarkers were measured at baseline and at predefined follow-up time points. Based on clinical course, patients were classified into progression and non-progression groups. A control group consisted of 28 healthy volunteers.

Results: During 12 months of SSA therapy, disease progression occurred in 56.7% of patients, with a median time to progression of 6 months. Baseline TNC concentrations were significantly higher in patients with GEP-NET compared with controls and were highest in patients who subsequently progressed. In the progression group, TNC concentrations increased significantly between 6 and 3 months before radiological progression, whereas no significant longitudinal changes were observed in patients without progression. ROC analysis identified a TNC cut-off value of 4.93% at progression, predicting disease progression with an AUC of 0.76, sensitivity of 70% and specificity of 80%. Progression was also associated with G2 grading and higher Ki-67 index in liver metastases, as well as the presence of extra-abdominal and extraskeletal metastases at baseline.

Conclusions: In patients with stage IV well-differentiated GEP-NET treated with SSA, more than half experience disease progression within the first year. Tenascin C demonstrates dynamic changes preceding radiological progression and may serve as a promising biomarker of reduced SSA effectiveness in this homogeneous population. Further studies in larger cohorts are required to validate its clinical utility for early risk stratification and treatment personalization.

EP1029 - ECE_1026 - Serum neurofilament light chain: a candidate biomarker of neuroaxonal injury in patients with dysnatremia, associated with functional outcomes and mortality

Fabio Bioletto, Daniela Cuboni, Emanuele Varaldo, Michela Sibilla, Valentina Gasco, Ezio Ghigo, Silvia Grottoli, Nunzia Prencipe and Alessandro Maria Berton
Turin, Italy

Background: Both hypo- and hypernatremia are associated with neurocognitive and neuromuscular dysfunction. However, specific biomarkers for these complications are lacking. In the present study, we aimed to explore the association between serum sodium levels and serum neurofilament light chain (sNfL), an emerging circulating biomarker of neuroaxonal injury.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Methods: sNfL levels were evaluated in serum obtained from stored specimens from subjects that participated in the population-based 2013-2014 cycles of the National Health and Nutrition Examination Survey (NHANES). Cognitive function was evaluated using the Consortium to Establish a Registry for Alzheimer's Disease-Word Learning, the Animal Fluency Test, and the Digit Symbol Substitution Test. Muscle strength was measured through a handgrip dynamometer. All-cause mortality was evaluated by linking NHANES data with data from the National Death Index. All analyses were adjusted for relevant confounders.

Results: The study population consisted of 2071 subjects. Serum sodium levels were low (≤135 mmol/L), normal (136-144 mmol/L), or high (≥145 mmol/L) in 47, 1999, and 25 participants, respectively. Patients with hyponatremia had higher sNfL levels compared to normonatremic subjects, independent of potential confounders (mean difference in log-transformed sNfL values: +0.44, 95%CI:[+0.06,+0.81], $P = .03$). Conversely, no significant alteration of sNfL levels was observed in hypernatremic patients. Evaluating sodium as a continuous predictor, a significant non-linear association was observed between sodium levels and sNfL ($P < .01$ for association; $P < .01$ for non-linearity), with an inflection at 138 mmol/L; below this threshold, an increase of +0.09 (95%CI:[+0.01,+0.16], $P = .02$) in log-sNfL was observed for each 1 mmol/L serum sodium decrease. Higher sNfL levels were associated with worse cognitive performance and muscle strength, independent of sodium levels and other potential confounders ($P < .05$ for all functional tests). Hyponatremia (HR = 2.18 compared to normonatremia, 95%CI:[1.13, 4.21], $P = .02$) and sNfL (HR = 2.63 per 1-unit increase in log-transformed sNfL, 95%CI:[1.91, 3.64], $P < .01$) were independent predictors of all-cause mortality. No significant differences in the predictive value of sNfL were observed across sNa categories ($P = .13$ for interaction). The predictive value of sNfL levels was also confirmed in a subgroup analysis limited to hyponatremic patients (HR = 2.89 per 1 unit increase in log-transformed sNfL, 95%CI:[1.76, 4.76], $P < .01$).

Conclusions: We provide first-time evidence of an association between hyponatremia and increased sNfL levels. Conversely, albeit with the limitations imposed by the small number of hypernatremic participants, no significant increase in sNfL was observed in hypernatremia. sNfL could serve as a novel biomarker of neuroaxonal injury in patients with hyponatremia, correlated with functional outcomes and mortality.

EP1030 - ECE_1516 - Risk factors and clinical outcomes associated with hyperglycemia-adjusted serum sodium in a large cohort of hospitalized patients

Alessandro Maria Berton[1], Anna Castiglione[2], Sonia Barello[3], Emanuele Varaldo[1], Matteo Baldi[3], Nunzia Prencipe[1], Fabio Bioletto[1], Francesco Biagini[3], Andrea Benso[1], Silvia Grottoli[1], Ezio Ghigo[1], Emanuela Arvat[4], Giulio Mengozzi[5], Giovannino Ciccone[2] and Luca Scaglione[3]

[1]Division of Endocrinology Diabetology and Metabolism, Department of Medical Sciences, Città della Salute e della Scienza di Torino University Hospital, Torino, Italy; [2]Unit of Clinical Epidemiology, Città della Salute e della Scienza di Torino University Hospital and CPO Piemonte, Torino, Italy; [3]Division of Internal Medicine 5, Department of General and Specialist Medicine, Città della Salute e della Scienza di Torino University Hospital, Torino, Italy; [4]Division of Oncological Endocrinology, Department of Medical Sciences, University of Turin, Torino, Italy; [5]Clinical Biochemistry Laboratory, Department of Medical Sciences, University of Turin, Torino, Italy

Introduction: Dysnatremia is the most common electrolyte disorder in hospitalized patients. Both hypo- and hypernatremia are associated with neurological complications, increased morbidity and mortality. This study aimed to assess the prevalence of dysnatremia at admission and its impact on hospitalization outcomes, and to identify factors associated with the development of dysnatremia within the first 10 days of hospitalization among patients with normal s-Na at admission.

Methods: This retrospective study considered for inclusion all adult patients discharged between 2016 and 2021 from the Molinette University Hospital of Turin, the largest tertiary center in Piedmont. A s-Na measurement obtained on the day of admission or within two days was required to classify natremia at presentation. Administrative discharge records were linked with laboratory data. Comorbidity burden was assessed using the Charlson Comorbidity Index (CCI). S-Na was corrected for hyperglycemia using the Katz formula, and analyses were based on corrected sodium (c-Na).

Results: A total of 148 692 admissions were recorded, of which 128 114 (86.2%) had available s-Na and glycemia measurements, with 98.7% of these taken at admission. Patients were predominantly male (57.9%), with a mean age of 66.2 years; 63.2% were admitted to medical wards. Overall, 31.1% of hospitalizations experienced at least one episode of hyponatremia. Correction for hyperglycemia led to reclassification of 37.5% of cases initially labeled as hyponatremia into normonatremia. At admission, corrected hyponatremia was present in 9.3% of hospitalizations, while hypernatremia accounted for 2.0%. These prevalences were stable over time, with a modest increase in hyponatremia during summer months. Both dysnatremias were more frequent in older patients, those with higher CCI, and in medical compared with surgical admissions, with no major sex-related differences. Admission c-Na showed a U-shaped association with in-hospital mortality, ICU transfer, and length of stay, with the lowest risk around 140 mmol/L and a steeper risk increase at higher s-Na levels. Among 86 482 admissions with normal c-Na at entry and repeated measurements, 18.5% developed hyponatremia and 4.0% developed hypernatremia within 10 days. New-onset hyponatremia was associated with male sex, higher comorbidity burden, and surgical admission, whereas hypernatremia was more frequent in older patients and those admitted to medical wards.

Conclusions: Glucose-corrected dysnatremia is common and prognostically relevant in hospitalized patients. Routine correction of s-Na for hyperglycemia is essential to avoid misclassification, particularly in mild cases. Distinct demographic and clinical predictors of hospital-acquired dysnatremia support the concept that acquired hyponatremia and hypernatremia are pathophysiologicallly and prognostically distinct entities.

EP1031 - ECE_1800 - Efficiency of cannulated prolactin test in differential diagnosis of hyperprolactinemia

Natalia Karlovich[1], Maryia Malyshko[2], Tatiana Mokhort[1], Alena Yurenia[2] and Romashko Angela[2]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Minsk City Clinical Endocrinological Centre, Minsk, Belarus

Precise diagnosis of hyperprolactinemia (HP) is essential for choosing appropriate approach for its management. This is particularly important in cases with moderate elevation of prolactin (PRL), when we have to exclude functional (stress-induced) HP.

Aim: The aim was to determine the efficacy of cannulated prolactin test (CPT) in patients of reproductive age with mild HP and to analyze etiological structure and reproductive manifestations of HP.

Materials and Methods: We examined 178 patients with moderate HP, 154 w, 24 m; 31 ± 8.8 yrs. After cannula insertion, prolactin (PRL) was measured at P0, 60 (P1), and 120 minutes (P2). The results of the CPT were considered as positive when HP persisted all three samples (persisted HP), negative—in other cases (stress-induced HP). The presence of reproductive manifestations of HP (galactorrhea, menstrual cycle disorders, decreased libido, and infertility) and pituitary MRI were assessed.

Results: At baseline, the median PRL was 788.4 mIU/L (583.6-1187.0). PRL >1000 mIU/L found in 64 (35.9%) patients, >2000 mIU/L—in 14 patients (7.8%). A positive CTP detected in 60.1% of patients, and significantly more often associated with a baseline PRL >1000 mIU/L. In patients with positive CTP, the baseline PRL was 2 times higher than in those with negative CTP. In patients with a baseline PRL >2000 mIU/L, CTP was negative in 92.9% of cases. The decrease of PRL at P1 compared to P0 occurred in 78.1% of patients. At P2, compared to P1, the PRL value decreased in 84.8% of patients. Stress-induced HP was detected in 71 (39.9%) patients, pituitary microadenoma occurred in 65 (36.5%), and non-tumorous HP (other causes)—in 42 (23.6%) patients. Patients with microadenoma had significantly higher PRL levels and a higher frequency of PRL >2000 mIU/L. Reproductive manifestations of HP were detected in 91 (51.1%) patients, with equal frequency in both stress-induced and pathological HP. In women the most common complaint was menstrual irregularities (23.4%), in men—gynecomastia (29.2%). Also, pituitary microadenoma was detected in 33 (46.5%) patients with stress-induced HP and no reproductive manifestations.

Conclusions: The CTP is specific for the differential diagnosis of stress-induced (39.9% of cases) and pathological HP (60.1%). The baseline PRL is a key factor influencing the CTP result. CTP can be used to exclude stress-induced HP in patients with PRL <1000 mIU/L and is not mandatory for patients with PRL >2000 mIU/L. Visualization of pituitary microadenoma in case of negative CTP and absence of reproductive manifestations indicates a combination of hormonally inactive adenoma and stress-induced HP.

EP1032 - ECE_1816 - Glycemic and lipidic profiles of patients with acromegaly long-term treated with pasireotide LAR after dose downtitration

Flavia Costanza[1], Sabrina Chiloiro[1], Antonella Giampietro[1], Laura De Marinis[1], Antonio Bianchi[1], Maria Fleseriu[2] and Alfredo Pontecorvi[1]
[1]Catholic University of the Sacred Heart, Rome, Italy; [2]Oregon Health and Science University, Portland, OR, United States

Introduction: Pasireotide LAR (PAS-LAR) has demonstrated higher efficacy in controlling acromegaly; however, it results in glycometabolic deterioration in many patients. This can lead to early discontinuation of PAS-LAR therapy, even in patients with biochemically controlled acromegaly. The purpose of this real-world study is to investigate the effects of PAS-LAR dose downtitration on glucose and lipid metabolism in patients with acromegaly.

Methods: A retrospective, single-center, longitudinal study was conducted on 27 patients with acromegaly on PAS-LAR monotherapy. Data on glucose and lipid metabolism were collected 6 months after dose downtitration and at 6 months of treatment in patients on a stable PAS-LAR dose. PAS-LAR dose reduction was performed in patients with remission of acromegaly symptoms and IGF-I values in the lower-normal age-adjusted reference range, with a concomitant clinically relevant worsening of the glucose and lipidic control, applying ADA 2024 criteria, therapeutic targets recommended by the ESC/EAS guidelines, and/or the necessity for a therapeutic intervention with glucose-lowering or lipid-lowering medications.

Results: The total duration of PAS-LAR therapy was 8.5 (IQR:5.2) in patients that underwent PAS-LAR dose reduction, and 7.8 (IQR:5.8; $P = .266$) in the stable dose group. The mean duration of PAS-LAR therapy before dose reduction was 7 years (IQR:5.0). PAS-LAR dose down-titration was conducted in 11 out of 27 patients (40.7%). In this group, glucose profile improved in all patients (100%); lipid profile improved in five patients (45.4%), remained stable in four patients (36.3%) and worsened in two patients (18.1%). As compared to patients who underwent PAS-LAR dose reduction, glucose profile did not improve in patients on treatment with stable dose of PAS-LAR ($P < .001$), worsened in 12 patients (75%) and remained stable in 4 patients (25%); lipid profile improved in a patient (6.2%), remained stable in six patients (37.5%) and worsened in nine patients (56.2%) ($P = .033$). After dose downtitration, IGF-I levels showed a slight increase, but remained in the normal range.

Discussion: In acromegaly, the impairment of glucose and lipid metabolism should be carefully managed due to the increased overall mortality risk associated with multiple comorbidities. This study suggests that PAS-LAR dose reduction in patients with acromegaly allows maintenance of biochemical disease control with improved glycemic profiles. Furthermore, we showed for the first time that lipid metabolism also improves with dose downtitration. In selected patients on long-term PAS-LAR therapy with good biochemical disease control, but metabolic deterioration, cautious dose reduction initially should be considered, rather than direct discontinuation of the drug.

EP1033 - ECE_1930 - Pituitary insufficiency in Rathke's cleft cysts—a retrospective analysis

Lucas Steckel, Mirjam Pichler and Susanne Kaser
Medical University Innsbruck, Innsbruck, Austria

Background: The clinical presentations of Rathke's cleft cysts (RCC) vary widely across a spectrum from asymptomatic to generalized hypopituitarism. Data on the frequency of endocrine abnormalities during the course of disease are limited.

Methods: We conducted a retrospective, single-center analysis of patients with neuroradiologically confirmed Rathke's cleft cyst. Data regarding possible pituitary insufficiencies, clinical presentations, and comorbidities was analyzed for a follow-up period of a minimum of 5 years.

Results: 72 patients were enrolled in the study (age = 44.3 ± 16.8 years; female = 67%; BMI = 25.9 ± 5.9 kg/m^2), the diagnosis of RCC was classified as an incidental finding in 94.4% of cases. At baseline, anterior total or partial pituitary insufficiency was diagnosed in 7 out of 72 patients (9.7%), with only one person suffering from total anterior hypopituitarism and non with generalized hypopituitarism. Hypogonadism occurred in all 7 patients followed by insufficiencies of the thyrotropic axis (n = 4), adrenal deficiency (n = 4) and somatotropic axis (n = 3). Arginine vasopressin deficiency was found in one patient and hyperprolactinemia in 6 patients. Regular MRT scans performed during follow-up showed a progression in cyst size in 10 out of 72 patients, 9 of these patients had intact pituitary function at baseline. None of the 65 patients with intact pituitary function at baseline developed hypopituitarism during the follow-up period.

Conclusions: Our study indicates that pituitary insufficiency affects about 10% of patients with RCC, emphasizing the need of endocrinological assessments at time of diagnosis. Patients with intact pituitary function did not develop pituitary insufficiency regardless of whether the cyst increased in size or not. Thus, our data argue against regular endocrine follow-up checks in patients with RCC.

EP1034 - ECE_1953 - Early postoperative cortisol as a predictor of remission in Cushing's disease: experience from a tertiary referral center

Sebnem Burhan[1], Aysel Unver Ozkahraman[1], Ebubekir Akpinar[2,3], Mutlu Niyazoğlu[1,3] and Esra Hatipoglu[1,3]
[1]*Department of Endocrinology and Metabolism, University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Istanbul, Türkiye;* [2]*Department of Neurosurgery, University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Istanbul, Türkiye;* [3]*Pituitary Disorders Research Center, University of Health Sciences, Istanbul, Türkiye*

Objective: Cushing's disease (CD) is the most common cause of endogenous Cushing's syndrome. Transsphenoidal surgery (TSS) is first-line treatment, yet early predictors of remission remain essential. Early postoperative cortisol has been proposed as a prognostic marker, but optimal cutoffs vary widely among centers.

Materials and Methods: This retrospective single-center study included 58 CD patients undergoing TSS (May 2020-December 2025). 08:00 AM cortisol and ACTH were measured on postoperative days 1-3. Remission was defined as cortisol <5 µg/dL requiring replacement or sustained eucortisolism for ≥12 months. ROC analysis assessed day-3 cortisol's predictive value for 3- and 6-month remission.

Results: Median follow-up was 24 months (IQR: 15.8-39.8). Mean UFC was 346 ± 993 µg/day. Remission rates were 73.6% (43/58) at month-3 and 77.6% (45/58) at month-6. with 100% sustained remission through month-12. No recurrence occurred during follow-up. Preoperative biochemical parameters, tumor size, invasiveness, pathological subtype, Ki-67 index, and surgery count were similar across remission and non-remission groups (P > .05 for all). Conversely, postoperative 3-month basal cortisol, ACTH, and glucocorticoid therapy duration showed significant differences (P < .01). ROC analysis was performed to evaluate the ability of early postoperative cortisol levels to predict remission. Postoperative day 1 cortisol showed poor discriminatory performance for predicting remission at 3 months (AUC = 0.586, 95% CI: 0.435-0.737; P = .264) and postoperative day 2 cortisol levels demonstrated limited predictive value for remission at 3 months (AUC = 0.597, 95% CI: 0.425-0.769; P = .270). Day-3 cortisol moderately predicted both 3-month (AUC 0.69, 95%CI: 0.55-0.83, P = .03) and 6-month remission (AUC of 0.69, 95% CI: 0.52-0.87, P = .028). Optimal cutoff <6.27 µg/dL yielded 78% sensitivity and 64% specificity.

Discussion: Day-3 postoperative cortisol (<6.27 µg/dL) is an independent, practical predictor of sustained remission in CD. Although moderate (AUC 0.69), it enables early risk stratification within 72 hours. Institution-specific thresholds may enhance postoperative management, guide glucocorticoid replacement strategies, and improve patient counseling regarding long-term prognosis.

Keywords Cushing's disease, remission, early cortisol, remission prediction

Background: Acromegaly is a chronic condition with substantial comorbidities and impaired life quality. Although Lanreotide

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Autogel (LAN) was effective in previous clinical trials, IGF-1 normalization varies by ethnicity and assay. Real-world evidence in Chinese patients remains limited.

Aim: To assess real-world effectiveness, safety, treatment patterns, and predictors of response to LAN over 12 months in Chinese acromegaly patients.

Methods: Prospective, multicenter, non-interventional study (NCT05431803) enrolled 129 LAN-naïve acromegaly patients. Under protocol-specific IGF-1 local ranges, primary endpoint: full biochemical control (fasting GH <2.5 μg/L and normalized IGF-1) at M12; secondary endpoints included biochemical control based on narrower (GH <1 μg/L and normalized IGF-1) and broader ranges (GH ≤2.5 μg/L and IGF-1 ≤1.3 × ULN), hormonal changes, symptom relief, AcroQoL score, treatment patterns, and safety. Post-hoc analysis: biochemical control assessed with China-specific IGF-1 ranges (normalized IGF-1 ± 2 SD for Chinese adults) (PLoS One 12(10):e0185561) including normal, narrower and broader criteria, versus those with protocol-specific IGF-1 local ranges; explored predictors of response using multivariate logistic regression with protocol-specific IGF-1 local ranges.

Results: Effectiveness was assessed in 120 patients (59.2% female; mean ± SD age: 42.3 ± 12.7 years). Among 102 patients with fasting GH and IGF-1 data at M12, under protocol-specific IGF-1 local ranges, 19.6% achieved full biochemical control; 11.8% and 34.3% met narrower and broader criteria, respectively. Proportion of participants with any reported symptom declined from 87.5% (105/120) to 77.9% (81/104) at M12, with reduction on headache (38.3% [46/120] to 21.2% [22/104]), soft tissue swelling (65.8% [79/120] to 57.7% [60/104]) and excessive sweating (20.0% [24/120] to 13.5% [14/104]). AcroQoL global score improved (LSM change [95%CI]: 5.7 [3.1, 8.2]). Patients received a mean ± SD of 8.2 ± 3.7 LAN injections during the study (mean ± SD LAN exposure duration: 283.9 ± 132.4 days). 19.2% were treated with extended dosing intervals (EDIs); biochemical control was achieved in 26.1% of EDI patients versus 17.7% of non-EDI patients. Overall, 60.5% experienced treatment-emergent adverse events (TEAEs): 41.9% were mild. 28.7% reported treatment-related TEAEs, with 2.3% being serious events. Most frequent TEAE was diarrhea (17.1%). Among 86 patients assessed using IMMULITE-2000®, 24.0% achieved full biochemical control (narrower: 10.7%; broader: 34.7%) applied China-specific IGF-1 ranges, versus 18.7% (narrower: 12.0%; broader: 30.7%) using protocol-specific IGF-1 local ranges. Lower fasting GH at M3, lower baseline IGF-1, excessive sweating, and naïve from prior treatment significantly increased biochemical response rate.

Conclusions: In real-world clinical practice in China, LAN provides effective biochemical control and clinical improvement across multiple assessment methods, with a favorable safety profile, supporting long-term use in acromegaly.

EP1036 - ECE_2203 - Postoperative muscle strength decline in Cushing's syndrome is associated with higher circulating activin A concentrations

Moritz Schrenk, Michael Haenelt, Elisabeth Nowak and Martin Reincke
Department of Medicine IV, Endocrinology, LMU University Hospital, Munich, Germany

Context: Cushing's syndrome (CS) is associated with myopathy that may paradoxically worsen after curative surgery despite biochemical remission and contributes to a reduced quality of life. However, the mechanisms underlying this postoperative deterioration in muscle strength remain largely unknown.

Objective: To evaluate serum myokines during active CS and the postoperative remission phase.

Patients and Methods: In this single-center, longitudinal observational cohort study, serum myokine profiles, including activin A, myostatin, and follistatin, were analyzed in 28 patients with endogenous CS prospectively enrolled at LMU Hospital Munich. All patients underwent successful curative surgery. Biochemical and clinical data were collected at baseline and six months postoperatively and compared with those of 28 age-, body mass index, and sex-matched controls in whom hypercortisolism had been ruled out. Handgrip strength was measured in a standardized manner using a JAMAR hand dynamometer (Patterson Medical, Nottinghamshire, UK) and was normalized to age- and sex-specific normative values.

Results: During glucocortcoid excess, median normalized handgrip strength was reduced 91.2% (IQR: 77.9; 100) and further declined six months postoperatively 77.6% (IQR: 62.4; 90.0). Patients younger than 35 years showed no postoperative decline in median normalized handgrip strength 1.3% (IQR: −5.8; 17.9), whereas patients aged 35-50 years exhibited a median decline of −16.3% (IQR: −28.4 to 9.4) and patients older than 50 years a more pronounced decline of −31.5% (IQR: −57.0; −15.3). Baseline activin A concentrations were similar between patients with active CS and controls, whereas myostatin and follistatin concentrations were significantly lower in patients with active CS. Six month following surgery, serum concentrations of myostatin ($P < .0001$), activin A ($P < .0001$), and follistatin ($P = .0044$) increased significantly, accompanied by a significant increase in the activin A-to-follistatin ratio ($P = .0001$). Activin A exhibited age-dependent patterns in CS. Baseline median activin A concentrations were lowest in patients <35 years 61.5 pg/mL (IQR: 31.4-112.0) and highest in patients >50 years 234.0 pg/mL (IQR: 145.3-321.0). Six months postoperatively, activin A increased markedly to 514.9 pg/mL (IQR: 422.8-562.9) in patients >50 years of age. Postoperative activin A concentrations inversely correlated with the decline in normalized handgrip strength (*Spearman's* $\rho = -0.40$; $n = 26$; $P = .042$).

Discussions and Conclusions: The postoperative decline in muscle strength in CS was associated with an age-dependent increase in circulating activin A levels, suggesting that elevated activin A may contribute to postoperative muscle dysfunction through activation of the activin-receptor-type IIB and subsequent induction of atrogenes resulting in muscle atrophy.

EP1037 - ECE_1085 - The forgotten face of acromegaly: oral–maxillofacial clues and a possible IGF-1-mediated protection against periodontal breakdown

Marco Puma Duque[1,2] and Paulina Posso Salgado[3]
[1]*Obesity and High Cardiovascular Risk, Endocrinology, Hospital Universitario Sanitas La Zarzuela, Madrid, Spain;* [2]*Medicine and*

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Dentistry, Health Sciences, Universidad Europea de Madrid, Madrid, Spain; [3]Primary Care and Community Health Centre, Centro de Salud El Espinar, Castilla y León Health Service (SACYL), El Espinar, Spain

Background: Oral and maxillofacial manifestations of acromegaly remain under-recognised despite their potential to provide early diagnostic cues and insights into disease biology. Beyond the well-known systemic effects of GH and IGF-1, recent evidence suggests that these anabolic hormones may exert local actions on the periodontium, influencing bone remodelling, collagen synthesis, and inflammation.

Objective: To systematically evaluate oral and maxillofacial manifestations of acromegaly and to analyse periodontal outcomes, exploring a potential protective role of the GH/IGF-1 axis in periodontal integrity.

Methods: A PRISMA-based systematic review was conducted (2004-April 2025). Major medical and scholarly databases (PubMed, MEDLINE, Google Scholar, Scopus) were searched for studies reporting oral or periodontal findings in patients with acromegaly. Inclusion criteria encompassed clinical, observational or review studies with clearly defined diagnostic criteria. Studies with insufficient case definition or very small, non-standardised samples were excluded for methodological quality reasons. Data extracted included design, sample characteristics, oral signs, periodontal parameters, and comorbidities. Risk of bias was appraised using JBI for cross-sectional and ROBINS-I for non-randomised designs, and AMSTAR-2 for systematic reviews.

Results: Fourteen studies met inclusion criteria. The most frequent oral features were macroglossia (**54%-58%**), interdental diastemas (**40%-62%**), and mandibular prognathism (**20%-56%**), typically associated with increased lower facial height and Angle Class III malocclusion. Periodontal assessment was reported in seven studies. Across these, **advanced periodontitis was less prevalent than expected**, with reduced probing depth and clinical attachment loss compared to controls, despite similar plaque indices. Other cohorts—particularly those with concomitant diabetes or hypogonadism—did not confirm this pattern, indicating heterogeneous outcomes. Experimental data support that IGF-1 enhances viability and osteogenic differentiation of periodontal ligament and gingival stem cells, up-regulates COL1A1 expression, and modulates inflammatory balance in alveolar bone. Collectively, this evidence outlines a plausible biological framework for **GH/IGF-1-related periodontal preservation** in certain acromegaly phenotypes.

Conclusions: Oral–maxillofacial features are clinically significant yet often overlooked in acromegaly. Their recognition by dental and primary-care professionals may facilitate earlier referral to endocrinology. Moreover, the paradoxically mild periodontal damage observed in some patients opens a new translational perspective: IGF-1 may contribute to maintaining periodontal architecture through regenerative and anti-inflammatory pathways. Prospective, standardised studies integrating endocrine control status and periodontal biomarkers are warranted to validate this hypothesis and to foster true interdisciplinary management.

EP1039 - ECE_1807 - Growing too fast: a rare case of gigantism diagnosed during childhood

Daniela-Georgiana Amzar[1,2], Mihaela Maria Vlad[1], Melania Balas[1], Ioana Golu[1], Stoian Dana[1], Oriana Pelineagră[1] and Laura Cotoi[3]

[1]Endocrinology, Spitalul Clinic Județean de Urgență Timișoara, Timișoara, Romania; [2]Endocrinology, Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania; [3]Endocrinology, Centre Hospitalier de Luxembourg, Luxembourg, Luxembourg

Introduction: Gigantism is a rare pathology in children characterized by growth hormone (GH) excess prior to epiphyseal fusion. It is associated with significant morbidity and reduced life expectancy in the absence of appropriate treatment.

Case Presentation: O.D., a male patient, now 18 years old, has been followed in our clinic since 2016, having been diagnosed with gigantism at the Pediatric Department of our horspital at the age of 12 years and 9 months. In 2014, the patient presented with visual disturbances, headaches, swelling of soft tissues, accelerated growth (weight 85 kg, height 171 cm, SD = +2.6 to mid-parental height). Laboratory data confirmed high levels of IGF-1 and basal GH, associated with unsuppressed GH levels following oral glucose tolerance test. No other pituitary insufficiencies were found. MRI of the pituitary gland showed a 3.9 cm pituitary macroadenoma. Transsphenoidal adenomectomy was performed, but only part of the tumour could be removed (tumour remnant volume: 10.2 cm^3). Somatostatin analogue treatment with Octreotide was started postoperatively. Later, due to incomplete response (with persistent sleep apnoea and headaches), dopamine agonist (cabergoline) was added. In 2016, the patient underwent further surgery without complete removal of the tumour. He also developed partial pituitary insufficiency (gonadotropic and thyrotropic). An MRI of the pituitary gland showed a tumour remnant of 1.9 cm^3. Pegvisomant was added to treatment with somatostatin analogues and cabergoline. In 2017, due to persistence of symptoms and unsatisfactory response to medical treatment, Gamma Knife radiosurgery was performed. The somatostatin analogue was also changed to Pasireotide. To date, the disease is well controlled under treatment.

Conclusions: Advances in pharmacotherapy and radiosurgery in patients with acromegaly and gigantism allow successful control of the disease. Early diagnosis is important because many of the complications are reversible in the early stages.

EP1040 - ECE_2427 - Effectiveness of organized transition of care pathway in patients with rare endocrine conditions

Savi Shishkov[1], Zhenya Ruseva[1], Mira Siderova[1], Radina Dimitrova[1], Sevim Zekerie[2], Sonya Galcheva[2] and Violeta Iotova[2]

[1]Clinic of Endocrinology and Metabolic Disease, UMHAT "St. Marina", Varna, Bulgaria; [2]First Pediatric Clinic, UMHAT "St. Marina", Varna, Bulgaria

Introduction: Coordinating the transition of patients reaching adulthood with chronic diseases represents significant difficulties for both healthcare providers and patients. In the context

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

of rare endocrine diseases, the requirement for multidisciplinary follow-up in specialized centers can create additional barriers to accessing expert services. Even though transition pathways are implemented in many centers, local regulatory and organizational aspects require tailored center-specific approach.

Objective: To describe and evaluate the existing transition pathway for patients with rare endocrine diseases from a pediatric to an adult endocrinology clinic between 2021 and 2025.

Materials and Methods: The study has a retrospective design. The structure and components of the transition care pathway were described in detail. Included in the analysis were patients over 18 years of age referred to the endocrinology clinic by their treating pediatric endocrinologists. Clinical data, age at transfer, status at transfer, transition readiness assessment, and follow-up status were examined. Success of transition intervention is measured by retention in care after transfer to adult clinic. Lost to follow-up was defined as absence of visit in a period of 24 months.

Results: Over a 4-year period, 53 patients (31, 58.5%—women) with rare endocrine diseases were transferred. All patients were discussed in multidisciplinary team meetings as part of their transition care pathway. The mean age of transfer is 19.5 years (range, 18-37 years). Among them 15 (28.3%) have congenital and acquired hypopituitarism, 7 (13%) patients had Prader-Willi syndrome, 8 (15.1%)—with Turner syndrome, 9 (17%) have congenital adrenal hyperplasia, and 14 (26.4%)—other rare genetic syndromes. Follow up status was evaluated in all patients: eleven patients (20.8%) were lost to follow-up. Continuous medical care was suspended in five (9%), two patients were transferred to another centre. Assessment of transition readiness was conducted in 29 (54.7%). The main condition was stable in 47 (88.7%) of the patients, without acute complications, and in 35 (66%) the medical goals were met at the time of transfer.

Discussions and Conclusions: One-fifth of transferred patients do not continue their regular follow-up. This could lead to deterioration in the condition, especially in cases where treatment goals are not reached. These results are comparable to other published cohorts, but direct comparison is obstructed by possible differences in healthcare settings and protocols. More detailed identification of risk factors for dropout from patient follow-up is needed to prevent adverse health outcomes in a vulnerable group of patients.

Abstract citation ID: lvag096.1310

EP1041 - ECE_3716 - GH–IGF1 axis dysregulation in children with short stature: a tertiary center experience

D Amulya Reddy[1,2], Bhanusree Kalava[1], Vijay Sheker Danda[1], Vivek Kyatham[1], Ann Elias[1] and Venu Gopal Reddy K[1]
[1]*Hyderabad, India;* [2]*Department of Endocrinology, Gandhi Medical College, Hyderabad, India*

Introduction: Short stature resulting from abnormalities of the growth hormone (GH)–insulin-like growth factor 1 (IGF1) axis represents a heterogeneous group of disorders with diverse clinical, radiological, and genetic bases. Differentiating these etiologies is essential for accurate diagnosis, prognostication, and individualized therapy. We aimed to characterize the clinical, hormonal, imaging, and genetic spectrum of GH–IGF1 axis disorders in children presenting with proportionate short stature.

Methods: This retrospective cross-sectional study was conducted at a tertiary pediatric endocrinology center. Thirty children with proportionate short stature and suspected GH–IGF1 axis abnormalities were evaluated. Data retrieved from medical records included auxological parameters, GH stimulation test results, serum IGF1 levels, brain magnetic resonance imaging (MRI) findings, and genetic analyses performed using targeted gene panels and/or whole-exome sequencing.

Results: The cohort comprised 30 children (16 males, 14 females) with a mean age of 9.35 years. Isolated GH deficiency (IGHD) was the predominant diagnosis, identified in 24 patients, while multiple pituitary hormone deficiency (MPHD) and GH insensitivity were less common. Genetic analysis revealed substantial molecular heterogeneity, with **GHRHR mutations emerging as the most frequent genetic etiology**, indicating a major contribution to GH–IGF1 axis dysfunction in this population. Additional pathogenic variants involved genes associated with GH synthesis, pituitary development, and syndromic growth disorders, including GH1, LTBP3, WDR4/LARP7, and LHX3. Neuroimaging demonstrated structural abnormalities of the hypothalamic–pituitary region in a significant proportion of patients. Pituitary stalk interruption syndrome (PSIS) was the most frequent radiological finding and was observed across both IGHD and MPHD phenotypes. Other abnormalities included septo-optic dysplasia and anterior pituitary hypoplasia. Overall, a strong concordance was noted between radiological abnormalities and hormonal phenotypes. From a nutritional perspective, 18 of the 30 children exhibited greater compromise in weight age compared with height age, suggesting concomitant undernutrition. Importantly, GH deficiency was confirmed in several of these children despite nutritional impairment, indicating that undernutrition and GH–IGF1 axis disorders may coexist.

Conclusions: Children with short stature related to GH–IGF1 axis dysfunction demonstrate marked clinical, radiological, and genetic heterogeneity. GHRHR mutations were the most common genetic cause identified in this cohort. The presence of undernutrition should not preclude evaluation for GH deficiency, particularly in resource-limited settings. A comprehensive diagnostic approach integrating hormonal testing, imaging, and genetic analysis is essential for precise diagnosis and individualized management.

EP1042 - ECE_2368 - Hormonal staining patterns and clinical outcomes in acromegaly: a 15-year single-center study

Sinem Başak Tan Öksüz[1], Esra Eraslan Aydemir[1], Aylin Okçu Heper[2], Cevriye Cansız Ersöz[2], Murat Erdogan[1], Rıfat Emral[1], Mustafa Sahin[1], Özgür Demir[1], Asena Gökçay Canpolat[1] and Sevim Güllü[1]
[1]*Department of Endocrinology and Metabolism, Ankara University School of Medicine, Ankara, Türkiye;* [2]*Department of Pathology, Ankara University School of Medicine, Ankara, Türkiye*

Background: Acromegaly exhibits marked pathological and clinical heterogeneity. While a substantial proportion of pituitary somatotroph adenomas co-secrete prolactin (PRL), the prognostic

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

implications of GH/PRL adenomas remain controversial due to inconsistent diagnostic definitions and limited comparative data. This study evaluated the relationships between immunohistochemical (IHC) patterns, clinical characteristics, radiological features, and surgical/medical outcomes in acromegaly.

Methods: We retrospectively analyzed 96 surgically treated patients with acromegaly between 2010 and 2025. Adenomas were classified based on IHC as GH-only (50.0%), GH/PRL (40.6%), or other patterns (9.4%). Biochemical remission was assessed 3-6 months postoperatively and in patients receiving subsequent somatostatin analogs (SSAs). Radiological invasiveness, T2-MRI signal, cytokeratin (CK8/18) patterns, and Ki-67 indices were examined. Logistic regression was used to identify predictors of surgical remission and SSA responsiveness.

Results: GH/PRL adenomas demonstrated higher proliferative activity, with Ki-67 ≥3% in 79.5% versus 47.9% of GH-only tumors ($P = .003$), yet surgical remission rates were similar (94.9% vs 85.4%). Postoperative remission occurred in 37.5% of the cohort and was associated with smaller tumors, lower baseline GH and PRL levels, T2 hypointensity, and absence of invasion. Optic chiasm compression independently reduced surgical remission by 85% (OR 0.152, $P = .010$). Among 48 patients treated medically, 56.3% achieved SSA response. Responders were older and exhibited lower baseline IGF-1, smaller residual tumors, T2 hypointensity, and perinuclear CK8/18 staining. In multivariable analysis, perinuclear CK8/18 independently predicted SSA response (OR 6.16, $P = .021$). Tumor volume correlated with PRL levels only in GH/PRL adenomas (rho 0.351, $P = .028$), while no correlation existed with GH or IGF-1 in any subgroup.

Conclusions: Although GH/PRL adenomas show higher proliferative indices, they do not confer inferior surgical or medical outcomes. Classical clinical and radiological markers—particularly optic chiasm compression and CK8/18 staining patterns—better predict remission and SSA response than hormone co-secretion status. PRL correlated with tumor burden only in GH/PRL adenomas, suggesting subtype-specific biomarkers. These findings support individualized treatment strategies emphasizing anatomical and pathological features rather than PRL co-secretion alone.

EP1044 - ECE_2825 - Endocrine dysfunctions and osteometabolic complications in adult patients with non-transfusion-dependent thalassemia and sickle cell disease: a monocentric cross-sectional study

Giulia Carosi[1], Elisa Sala[1], Roberta Mungari[1], Giulia Del Sindaco[1], Arianna Cremaschi[1], Alessandra Mangone[1], Marta Codegoni[1,2], Giorgia Grassi[1], Cristina Eller Vainicher[1], Irene Motta[2,3], Giovanna Graziadei[3], Emanuele Ferrante[1] and Giovanna Mantovani[1,2]

[1]Endocrinology Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [2]Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy; [3]SC Medicina ad Indirizzo Metabolico, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy

Background: Hemoglobinopathies are genetic disorders affecting hemoglobin's structure or production. Research in endocrinology primarily focused on young patients with transfusion-dependent β-thalassemia, while endocrine complications in adults with non-transfusion-dependent thalassemia (NTDT) and sickle-cell-disease (SCD) are less studied. This study aims to assess hormonal and osteometabolic alterations in aged NTDT and SCD patients.

Methods: This cross-sectional study included 83 patients (50 NTDT, 18 sickle-thalassemia or HbS-Thal and 15 SCD) who never received chronic blood transfusions. Patients were screened for hypopituitarism, hypothyroidism, hypoparathyroidism, hypoadrenalism, and growth hormone deficiency (GHD). Dynamic evaluations included ACTH and glucagon stimulation tests for hypoadrenalism/GHD and oral-glucose-tolerance-test (OGTT) for glycometabolic alterations. DEXA scans and vertebral X-ray were performed, along with osteometabolic biochemical assessments. Anamnestic data included history of iron overload based on hepatic-cardiac MRI-T2*.

Results: In the whole group, mean age was 46.7 ± 13 years, with 57.8% females (age and sex distribution were comparable in NTDT, HbS-Thal, and SCD). Iron overload on MRI-T2* was reported in 44%, 20%, and 17% patients with NTDT, HbS-Thal, and SCD, respectively ($P = .06$). Endocrine dysfunction occurred in 27%, with no significant difference between subgroups ($P = .667$). ACTH stimulation test was available in 36 patients, and glucagon test in 10. We diagnosed hypothyroidism (10.8%), secondary hypoadrenalism (6%), and hypogonadism (6%), with no cases of hypoparathyroidism. GHD was present in 1/10 patients tested. We found impaired fasting glucose in 6%, impaired glucose tolerance in 4%, and diabetes mellitus in 2.4%. Endocrine dysfunctions were correlated with iron overload on MRI-T2* ($P = .019$) while splenectomy, hydroxyurea, and age showed no association. Hypoadrenalism was more commonly observed in males ($P = .006$) and in patients with primary hypothyroidism ($P = .001$). Osteoporosis was diagnosed in 42.2%, and osteopenia in 34.9%. Clinical fractures occurred in 26.5%, and morphometric vertebral fractures were detected in 25.4%. Fracture rates were similar in patients with NTDT, HbS-Thal, and SCD. A positive correlation existed between bone-mineral-density (BMD) and TBS with frailty fractures in the groups of NTDT, HbS-Thal (T-score: lumbar $P = .03$, femoral-neck $P = .03$, total-hip $P = .029$, TBS $P = .002$), but not in SCD. No other variables, including urinary calcium, bone turnover markers, and iron overload, were associated with fractures.

Conclusions: Adult patients with NTDT and SCD, especially those with documented iron overload on MRI-T2*, are at risk for hormonal alterations and skeletal fragility. TBS appears to be associated with fractures in all patients, while BMD is an effective predictor for NTDT and HbS-Thal patients, but not for SCD.

Dimitroula Stephanou[1], Dimitrios Ziogas[1], Helen Gogas[1] and Anna Angelousi[2]
[1]First Department of Medicine, Laiko General Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece; [2]First Department of Medicine, Unit of Endocrinology, Laiko General Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece

Background: Endocrine immune-related adverse events (irEAEs) are common complications of immune checkpoint inhibitor (ICI) therapy and may lead to long-term or permanent hormone deficiencies. Identifying clinical and biochemical markers that predict the timing, phenotype, and risk of sequential endocrine involvement is essential to optimize patient management. This study investigated the temporal development of endocrine irEAEs in a cohort of oncological patients treated with ICIs.

Methods: We retrospectively evaluated 125 oncology patients (52.1% male), with a mean age of 62.27 ± 13.76 years, who developed endocrine irEAEs during ICI treatment. Melanoma was the predominant malignancy (85.3%). The time from ICI initiation to the first and any subsequent endocrine event was recorded. Hormonal profile, thyroid autoantibodies, and baseline metabolic comorbidities were also collected. Associations between autoimmunity, treatment modality, and temporal patterns of endocrine toxicity were analyzed.

Results: Primary thyroid toxicity was the most frequent endocrine irEAE, occurring in 60.6% of patients, followed by hypopituitarism in 30.9%. Thyroid toxicity tended to develop earlier than hypopituitarism (15.59 ± 11.43 vs 22.73 ± 16.14 weeks, $P = .067$). Anti-thyroglobulin antibody (anti-Tg) positivity at irEAE diagnosis was associated with significantly earlier onset of endocrine toxicity ($P = .04$), whereas anti-thyroid peroxidase (anti-TPO) positivity showed no significant association with timing. Baseline metabolic comorbidities—hypertension (36.6%), dyslipidemia (35.5%), and diabetes mellitus (9.7%)—did not significantly affect time to irEAE onset. Sequential endocrine irEAEs occurred in 11.7% of patients. Those who subsequently developed corticotropic axis deficiency presented with earlier primary endocrine toxicity compared with patients who experienced a single endocrine irEAE (11.43 ± 6.29 vs 18.40 ± 13.78 weeks, $P = .055$). Combination ICI therapy was associated with higher rates of initial multi-endocrine involvement (14.3% vs 5.8%) and a greater incidence of sequential endocrine irEAEs (26.7% vs 10%, $P = .136$) compared with monotherapy. Persistence varied by endocrine axis. Functional recovery was observed only in a small subset of patients with primary thyroid toxicity. In contrast, hypopituitarism—particularly corticotropic deficiency—was entirely irreversible during follow-up.

Conclusions: Anti-Tg positivity and early onset of endocrine toxicity identify patients at increased risk of rapid and sequential endocrine involvement, particularly affecting the corticotropic axis. Endocrine irEAEs should not be viewed as a static phenotype, as presentation may evolve over time with axis-specific temporal patterns and reversibility. Patients receiving combination ICI regimens, and those presenting with early or multi-axis toxicity, require intensified and prolonged endocrine monitoring to ensure timely diagnosis and appropriate hormone replacement.

EP1046 - ECE_1886 - Comparison of French and PANOMEN-3 classifications for predicting post-operative evolution in paitents with prolactinoma

Anais Job[1], Lina Daoud[2], Orsalia Alexopoulou[1], Fomekong Edward[3], Christian Raftopoulos[3], Stefan Matei Constantinescu[1] and Dominique Maiter[1]
[1]Department of Endocrinology and Nutrition, Cliniques Universitaires Saint-Luc, Brussels, Belgium; [2]Department of Neuropathology, Cliniques Universitaires Saint-Luc, Brussels, Belgium; [3]Department of Neurosurgery, Cliniques Universitaires Saint-Luc, Brussels, Belgium

Background: The French five-tiered clinicopathological classification is used to assess the risk of recurrence/progression of pituitary tumors after surgery, but few studies focused on the post-operative evolution of patients with prolactinoma. Furthermore, clinical validation of the new PANOMEN-3 classification is needed in patients with prolactinoma.

Aim/Objective: We sought to compare the French and PANOMEN-3 classifications in predicting the post-operative evolution of patients with prolactinoma.

Methods: We retrospectively analyzed medical files of patients operated for prolactinoma between 2006 and 2024, with a confirmed histological diagnosis of prolactinoma, available histological markers (Ki 67, p53, mitosis) and at least 12 months of post-operative follow up. We defined recurrence as a new increase in prolactin above the upper limit of normal occurring >3 months after curative surgery. We defined progression as a >20% increase in any tumor diameter during follow-up of a post-operative residue. We defined disease free status at last visit as a normal prolactin without dopamine agonist treatment.

Results: 71 patients were included in the final analysis, 44 women and 27 men. 35 patients were initially cured by surgery, of which 7/35 (20%) suffered recurrence after a median of 18 months (range 5-41). 36 patients were not cured by surgery, 12/36 (33%) of which suffered disease progression during follow-up after a median of 12 months (range 2-82 months, 11/12 during the first 4 years). Progression or recurrence (19/71 or 27%) was significantly associated with the proliferative nature of the tumor as defined by the French classification ($P = .003$) but not with invasiveness ($P = .734$). The overall French grade was significantly associated with the risk of progression ($P = .027$) but not with recurrence ($P = .201$) or the pooled outcome of progression and recurrence ($P = .163$). PANOMEN-3 grade was associated with neither recurrence ($P = .528$), nor progression ($P = .440$) nor the pooled outcome of recurrence and progression ($P = .378$). However, disease free status at last visit was significantly associated with both the French (58%, 66%, 0% and 0% for grades 1a, 1b, 2a and 2b respectively, $P < .001$) and PANOMEN-3 grades (86%, 58%, 14% and 0% for grades 0, 1, 2 and 3 respectively, $P < .001$).

Conclusions: The proliferative nature of the tumor, as assessed by the French classification, was the most important predictor of progression/recurrence after surgery in patients with prolactinoma, highlighting the need for careful follow-up of proliferative tumors especially during the first 4 years after surgery. Both the French and PANOMEN-3 classifications predict long-term disease free status.

EP1047 - ECE_3129 - Thyroid abnormalities in acromegaly in the era of improved disease control: a two-stage study

Gustavo Leite[1], Luciana Pedral S.D. Leite[2], Gabriel Leite[1], Roberto Salvatori[3], Juliana Drummond[4], Beatriz Santana Soares[4], Lucas Freitas[1], Izabella Freitas[1], Angela Leal[2], Arthur Oliveira[5,6] and Manuel H. Aguiar Oliveira[2]

[1]Faculty of Medicine, Medicine, Federal University of Minas Gerais, Belo Horizonte, Brazil; [2]Clinic, Medicine, Federal University of Sergipe, Aracaju, Brazil; [3]Clinic, Medicine, The Johns Hopkins University, School of Medicine Baltimore, Baltimore, MD, United States; [4]Division of Endocrinology, Department of Internal Medicine, Faculty of Medicine, Federal University of Minas Gerais, Belo Horizonte, Brazil; [5]Health Sciences Graduate Program, Federal University of Sergipe, Aracaju, Brazil; [6]Division of Neurosurgery, Medicine, Hospital de Cirurgia, Aracaju, Brazil

Introduction: The somatotropic and thyroid axes are interrelated, with the thyroid acting as a relevant site for extrapituitary circuits via autocrine production of growth factors. In acromegaly, such continuous stimulation has traditionally resulted in a high prevalence of diffuse or nodular goiter and thyroid cancer. This study aimed to verify whether these findings persist in the current scenario of greater availability of pharmacologic agents and better biochemical control of the disease.

Methods: A multicenter study was conducted with 92 acromegaly patients from two tertiary centers in Brazil. The protocol included a retrospective analysis of the clinical and laboratory data and a cross-sectional thyroid ultrasound in a subset of 74 patients. Disease control was calculated based on the ratio of IGF-1/Upper Limit of Normal (ULN) over the follow-up. Thyroid nodules were classified using ACR-TIRADS. Cluster analysis was performed to identify phenotypic patterns in the 74 patients with ultrasound data.

Results: The total cohort (71.7% females and 81.5% macroadenomas) exhibited a median biochemical control rate of 50%, with a median follow-up of 13 years and a well differentiated thyroid carcinoma prevalence of 4.3%, lower than in historical series. Among the 74 patients that underwent thyroid ultrasonography, 63.5% of them had nodules, and 27% goiter. There was a significant positive correlation between the percentage of biochemical control rate and the follow-up duration ($r = 0.378$; $P = .001$). In contrast, a negative trend correlation was observed between thyroid volume and control percentage ($P = .077$). Three clusters were identified: Cluster 1 ($n = 18$; 83.3% female; median age 64 years), Cluster 2 ($n = 36$; 100% female; median age 60 years), and Cluster 3 ($n = 20$; 100% male; median age 52.5 years). Significant differences were observed between clusters regarding sex and echotextural alterations ($P < .0001$ in both cases). Age, number of nodules, thyroid volume and follow-up time were similar across clusters, although the biochemical control rate showed a decreasing trend from Cluster 1 to the others.

Conclusions: In this cohort, massive goiter and increased risk of thyroid malignancy were not observed. The natural history of acromegaly appears to have changed due to therapeutic evolution and improved biochemical control. These advances are associated with a reduction in thyroid manifestations, contributing to an improved overall prognosis for patients with acromegaly. This reinforces that strict control during follow-up effectively attenuates these thyroid abnormalities.

EP1048 - ECE_3369 - Misleading performance of clinical risk scores for Cushing's syndrome in partial lipodystrophy: results from a multicenter study

Stella Pigni[1], Carolina Cecchetti[2], Marina Caputo[3], Maria Francesca Birtolo[4], Gherardo Mazziotti[4], Andrea Lania[4], Alessandra Gambineri[2] and Flavia Prodam[3,5]

[1]Department of Translational Medicine, University of Eastern Piedmont, Novara, Italy; [2]Department of Medical and Surgical Sciences, Alma Mater Studiorum University of Bologna, Bologna, Italy; [3]Department of Health Sciences, University of Eastern Piedmont, Novara, Italy; [4]Department of Biomedical Sciences, Humanitas University, Milan, Italy; [5]Department of Health Science, University of Piemonte Orientale, Novara, Italy

Background: Partial lipodystrophies (PLD) frequently overlap with Cushing's syndrome (CS) for clinical manifestations. Simplified clinical risk scores have been developed to estimate the pre-test probability of CS; however, their ability to discriminate between CS and other overlapping conditions such as PLD remains unclear. Moreover, reduced leptin action in lipodystrophy may influence the hypothalamic–pituitary–adrenal (HPA) axis, although human data are limited.

Methods: Retrospective, multicenter study, including 61 patients (91.8% females; mean ± SD age 50.2 ± 13.2 years) with PLD (54 familiar partial lipodystrophy, 4 acquired partial lipodystrophy, 3 progeroid syndromes) and 56 patients with CS (62.5% females; age 55.1 ± 14 years). Clinical and laboratory data were retrieved from medical records. To estimate the probability of hypercortisolism, the Cushing score was calculated considering main clinical predictors of CS (age <59 years, facial fullness, facial plethora, proximal muscle atrophy, dorsocervical fat pad, hirsutism/seborrhoea, non-obesity, hypertension, diabetes, osteopenia/osteoporosis). Clinical and metabolic features of PLD and CS were compared. Leptin–HPA axis interactions in PLD were also explored.

Results: Most PLD patients (93.4%) exhibited at least one clinical feature suggestive of CS. Facial fullness, facial plethora, dorsocervical fat pad, and hirsutism ($P < .001$) were more frequent in PLD, whereas proximal muscle atrophy and osteoporosis ($P < .015$) were more common in CS. PLD patients also showed a higher prevalence of diabetes and hypertriglyceridemia ($P < .001$). Mean Cushing score values were higher in PLD than in CS (9.6 ± 2.5 vs 8.6 ± 2.8 points, $P = .04$), particularly in patients with monogenic familiar partial lipodystrophy. In multivariable regression analysis, proximal muscle atrophy and osteoporosis were independently associated with CS, whereas diabetes and hypertriglyceridemia were associated with PLD ($P < .001$). Leptin levels were inversely correlated with Cushing score values (rho −0.41, $P = .009$).

Conclusions: PLD patients often exhibit cushingoid features, limiting the specificity of simplified clinical risk scores for CS. By identifying distinguishing clinical and metabolic features, this study underscores the need for greater awareness of lipodystrophy phenotypes to reduce misdiagnosis and supports an integrated diagnostic approach to improve patient recognition and management.

EP1049 - ECE_2445 - Low work ability and high disability in Cushing's syndrome: a multicenter observational Cohort study in Germany

Annika Steinkogler[1], Stephanie Zopp[1], Kathrin Moser[1], Júnia Ribeiro De Oliveira Longo Schweizer[1], Isabel Stüfchen[1], Friederike Völter[1,2], Katrin Ritzel[1], German Rubinstein[1], Leah Braun[1], Marily Theodoropoulou[1], Rolf Holle[3], Birgit Linkohr[4], Tina Kienitz[5], Marcus Quinkler[5], Martin Reincke[1] and Elisabeth Nowak[1]

[1]*Department of Medicine IV, LMU University Hospital, LMU Munich, Munich, Germany;* [2]*Department of Nuclear Medicine, LMU University Hospital, LMU Munich, Munich, Germany;* [3]*Munich, Germany;* [4]*Institute of Epidemiology, Helmholtz Zentrum München, German Research Center for Environmental Health, Munich-Neuherberg, Germany;* [5]*Endocrinology, Endocrinology in Charlottenburg, Berlin, Germany*

Objective: Data on the social and occupational impact of Cushing's syndrome (CS) remain scarce. In Germany, disability assessment guidelines consider surgically treated patients as "cured," which may fail to capture persistent functional impairment. We assessed work ability, as well as social and employment status, in patients with newly diagnosed and remitted CS.

Methods: This national observational study comprised two arms. Cohort 1 was a monocentric prospective study including patients evaluated for suspected endogenous glucocorticoid excess. Cohort 2 was a multicenter cross-sectional study of patients in remission from CS, comparing individuals with recovered versus persistent adrenal insufficiency. In both cohorts, participants underwent standardised clinical and biochemical evaluations and completed validated questionnaires addressing socioeconomic status, work ability, and fatigue.

Results: In cohort 1, patients with active CS ($n = 28$) and those in whom CS was excluded ($n = 56$) showed similar clinical characteristics, comorbidities, educational levels, and employment status. However, work ability scores were significantly lower in active CS (median 22.5 vs 28.5, $P = .008$) and were inversely associated with the degree of biochemical cortisol excess. In cohort 2 ($n = 89$; 39 with recovered and 50 with persistent adrenal insufficiency), overall employment was 69%. Work ability was frequently classified as "poor" (42% in recovered vs 58% in persistent adrenal insufficiency), and weekly working hours tended to be lower in patients with persistent insufficiency (33 h vs 39 h, $P = .051$). Across cohort 2, 76% reported illness-related absenteeism in the preceding year, 47% had a formally recognised disability, and 15% received a reduced earning capacity pension. Fatigue was strongly and negatively correlated with work ability ($r = -0.73$, $P < .0001$).

Conclusions: Despite high educational attainment, individuals with CS experience considerable occupational impairment, particularly during active disease and persistent adrenal insufficiency. Given that CS predominantly affects young women, a group already subject to occupational gender disparities, this population is especially vulnerable. The mismatch between documented functional limitations and current German disability assessments highlights a structural gap, underscoring the need for targeted rehabilitation and reintegration to improve long-term socioeconomic outcomes.

EP1050 - ECE_1598 - A rare case of TSH-secreting pituitary adenoma showing discordant dynamic tests with eventual curative resection

Melvin Kok Seng Lee[1,2]

[1]*Singapore, Singapore;* [2]*Endocrinology, Singapore, Singapore*

Introduction: TSHoma is a rare functioning pituitary tumour that causes hyperthyroidism. This case report highlights the complexity of diagnosing TSHOma through dynamic tests and the eventual successful medical optimization and surgical removal of such a tumour.

Case Report: A 38-year-old woman was noted to have hyperthyroxinemia and high thyroid stimulating hormone on routine health screening. On further questioning, she reported heat intolerance and increased appetite over 1 year. She had regular menses and had no personal or family history of thyroid disorders. She was clinically euthyroid on examination and had no significant goiter. Visual fields were intact on direct confrontation. Her pulse was regular at 92 beats per minute. An electrocardiogram showed normal sinus rhythm. Her thyroid function tests were repeated on a separate assay platform. Free thyroxine and triiodothyronine levels remained elevated at 24 pmol/L (normal 8-16) and 7.6 pmol/L (normal 2.4-6.0) in the presence of elevated thyroid stimulating hormone levels 4.83 mIU/L (normal 0.45-4.50). The alpha subunit to TSH molar ratio was also elevated at 2.3. Further dynamic tests with oral thyroxine suppression over 7 days showed no suppression of TSH consistent with TSHoma. However, thyrotropin stimulation showed a 2-fold rise of TSH which was discordant. MRI pituitary revealed a 1.4 cm × 2.2 cm × 1.4 cm sellar mass with early compression of the optic chiasm. She was given 2 doses of long-acting octreotide over 8 weeks with improvement in free thyroxine levels and normalization of TSH. She subsequently underwent transsphenoidal resection of the pituitary adenoma. Thyroid function tests repeated 2 weeks post-surgery showed normal thyroid function tests with a significantly decreased TSH level of 0.94 mIU/L.

Conclusions: Discordant dynamic tests can be observed in TSHoma and both tests should be interpreted in context. Response to octreotide treatment is a use adjunct for diagnosis and can guide treatment decisions.

EP1051 - ECE_2866 - Panhypopituitarism associated with ectopic posterior pituitary presenting as delayed puberty in an adolescent male

Aye Me Me Ko[1,2] and Fiona Smeeton[1]

[1]*Diabetes and endocrinology, Nevill Hall Hospital, Abergavenny, United Kingdom;* [2]*Aneurin Bevan University Health Board, Abergavenny, United Kingdom*

Background: Ectopic posterior pituitary (EPP) is a rare congenital malformation caused by abnormal migration of neurohypophyseal tissue during embryogenesis. It is commonly associated with varying degrees of hypopituitarism. Clinical presentation may be subtle, resulting in delayed diagnosis, particularly in adolescence.

Case Presentation: A 17-year-old male was referred for assessment of delayed puberty and chronic fatigue. He reported a complete lack of energy, muscle aches, back pain, reduced exercise

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

tolerance, and inability to participate in sports. Examination revealed a prepubertal appearance with absent secondary sexual characteristics, puffy hands, and height below the 50th centile. Hormonal evaluation demonstrated panhypopituitarism. IGF-1 was profoundly low at 2 nmol/L. Gonadotropins were suppressed (LH 0.1 IU/L, FSH 0.4 IU/L) with testosterone <0.2 nmol/L. Thyroid function tests showed inappropriately normal TSH of 4.4 mIU/L with low free T4 of 7.9 pmol/L, consistent with secondary hypothyroidism. Random cortisol was 47 nmol/L, and a short Synacthen test confirmed secondary adrenal insufficiency. MRI of the pituitary revealed an ectopic posterior pituitary, identified as a 4-mm T1-hyperintense focus at the median eminence, with absence of the posterior pituitary bright spot in the sella. Bone age was significantly delayed at 12.6 years compared with a chronological age of 16.8 years. The patient was commenced on hormone replacement therapy including prednisolone, levothyroxine, and intramuscular testosterone (Sustanon 250 mg every four weeks), with planned follow-up at six months. Prednisone was chosen by the patient to simplify dosing and improve adherence.

Conclusions: This case illustrates a rare but important cause of delayed puberty and chronic fatigue in adolescence. Recognition of ectopic posterior pituitary and associated hypopituitarism is essential, as early diagnosis and timely hormone replacement can significantly improve growth, pubertal progression, and overall quality of life.

Abstract citation ID: lvag096.1320

EP1053 - ECE_3873 - TSH-secreting pituitary macroadenoma presenting with thyrotoxicosis: a case report

Violeta Hoxha[1], Megi Lekbello[2], Dorina Ylli[1], Klodi Poshi[1], Marjeta Kermaj[2,3], Edenisa Shahinas[2] and Agron Ylli[1]
[1]*University of Medicine Tirana, University Hospital Centre "Mother Teresa", Tirana, Albania;* [2]*University Hospital Centre "Mother Teresa", Tirana, Albania;* [3]*Endocrinology, University Hospital Center "Mother Tereza", Tiranë, Albania*

Background: Thyrotropin-secreting pituitary tumors (TSHomas) are rare causes of hyperthyroidism, accounting for approximately 1% of pituitary adenomas. Increased awareness has led to improved recognition, but early diagnosis remains challenging and is essential to prevent inappropriate treatment and disease progression.

Case Presentation: A 55-year-old woman was admitted with headache, generalized weakness, weight loss, and palpitations. Her medical history included osteoporosis under treatment, gluten intolerance, and a family history of thyroid disease. One year earlier, she had been diagnosed with hypothyroidism and treated with levothyroxine 25 µg daily. Reevaluation one month prior to admission showed persistently elevated thyroid hormone levels with inappropriately high TSH (TSH 11.38 µIU/mL, FT3 7.42 pg/mL, FT4 2.38 ng/dL). Thyroid autoantibodies were negative, excluding autoimmune hyperthyroidism and raising suspicion of a TSH-secreting pituitary adenoma. Pituitary MRI revealed a 22 × 23 × 27 mm macroadenoma with heterogeneous enhancement, extension into the right cavernous sinus, and compression of the optic chiasm. Visual field testing demonstrated partial temporal quadrantanopia in the left eye. Pituitary hormonal evaluation showed hypogonadotropic hypogonadism and mildly elevated prolactin levels, with normal ACTH and cortisol. Antithyroid therapy with methimazole was initiated. The patient underwent transsphenoidal surgical excision on 19 November 2025 without complications. Postoperatively, TSH and thyroid hormone levels normalized, cortisol and growth hormone remained normal, gonadotropins stayed low, prolactin was mildly elevated, and IGF-1 was reduced. The patient was discharged on 27 November 2025.

Conclusions: TSHomas are rare functional pituitary adenomas that may be misdiagnosed as primary thyroid disease. Recognition of central hyperthyroidism and a multidisciplinary diagnostic approach are essential for optimal management.

Abstract citation ID: lvag096.1321

EP1054 - ECE_3987 - Coexistence of Fahr's syndrome and Sheehan's syndrome: a case report of complex metabolic encephalopathy

Raysha Shirley Silva Jordan[1], Luz Marina Medina Puma[2] and Paolo Augusto Romero Merino[3]
[1]*Universidad Nacional de San Antonio Abad del Cusco, Cusco, Peru;* [2]*Hospital Nacional Sergio E. Bernales, Lima, Peru;* [3]*Hospital Clinico Universitario of Valladolid, Valladolid, Spain*

Background and Objective: Fahr syndrome is a rare clinico-radiological condition characterized by bilateral and symmetric calcium deposits in the basal ganglia and other subcortical structures. Its occurrence is commonly associated with endocrine disorders that disrupt calcium metabolism, with hypoparathyroidism and pseudohypoparathyroidism being the most frequently reported causes.[1] Sheehan syndrome, in turn, is a form of hypopituitarism resulting from ischemic necrosis of the adenohypophysis following severe obstetric hemorrhage. Although its incidence has declined in recent decades, it remains an underdiagnosed cause of complex endocrine dysfunction, with clinical manifestations that may go unrecognized for years.[2,3] The relevance of this case lies in the simultaneous presentation of both conditions, in which severe panhypopituitarism and a secondary disorder of mineral metabolism converged to manifest as a neuropsychiatric emergency. This unusual coexistence represents a multiorgan diagnostic challenge that has been scarcely documented in recent literature.

Case Presentation: A 51-year-old woman with a history of hypothyroidism and a severe obstetric hemorrhage occurring 24 years earlier presented to the emergency department with a four-week history of vomiting, abdominal pain, and constipation, which progressed to psychomotor agitation, disorientation, and emotional lability. Initial laboratory investigations revealed severe hypoglycemia, hyponatremia, and hypocalcemia. Non-contrast brain computed tomography demonstrated bilateral calcifications in the basal ganglia (putamen and globus pallidus) and dentate nuclei, confirming the radiological diagnosis of Fahr syndrome. An extended hormonal profile showed decreased levels of TSH, T4, FSH, LH, and cortisol, consistent with panhypopituitarism secondary to Sheehan syndrome. Further evaluation of hypocalcemia revealed elevated parathyroid hormone levels with normal vitamin D concentrations, establishing the diagnosis of pseudohypoparathyroidism type II as the underlying metabolic cause of Fahr syndrome.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Results: The patient was managed using a multidisciplinary approach, initiating hormone replacement therapy with prednisone and levothyroxine, along with correction of electrolyte disturbances using calcium carbonate and calcitriol. This treatment led to normalization of glucose and electrolyte levels, resolution of neuropsychiatric symptoms, and stabilization of gastrointestinal function. The patient showed favorable clinical evolution and was discharged with follow-up by endocrinology and neurology services.

Conclusions: This case highlights the critical importance of considering endocrine and metabolic causes in the presence of intracranial calcifications. Sheehan syndrome should be suspected in women with a history of postpartum hemorrhage and multisystem involvement, even decades after the initial event. The coexistence of panhypopituitarism due to Sheehan syndrome and secondary Fahr syndrome underscores the need for a multidisciplinary approach to ensure appropriate management of complex neuroendocrine disorders.

EP1055 - ECE_1515 - The long-term effect of denosumab on bone mineral density in the treatment of pituitary disease-driven osteoporosis

Alessandra Vicari[1], Sabrina Chiloiro[1], Flavia Costanza[1], Antonella Giampietro[1], Chiara Palumbo[1], Amato Infante[2], Consolato Gullì[2], Mario Rigante[3], Pier Paolo Mattogno[4], Laura De Marinis[1], Antonio Bianchi[1], Francesco Doglietto[4] and Alfredo Pontecorvi[1]

[1]Endocrinologia e Malattie del Metabolismo, Università Cattolica del Sacro Cuore, Policlinico Universitario Agostino Gemelli IRCCS, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Roma, Italy; [2]Radiology, Università Cattolica del Sacro Cuore, Roma, Italy; [3]Dipartimento di Neuroscienze, Organi di Senso e Torace, Università Cattolica del Sacro Cuore, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Roma, Italy; [4]Neurosurgery, Università Cattolica del Sacro Cuore, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Roma, Italy

Background: The management of skeletal fragility in patients with pituitary diseases represents a relevant clinical challenge. Treatment with denosumab, an antiresorptive bone active drug, has been shown to significantly increase bone mineral density (BMD) and reduce the incidence and risk of fractures. The long-term efficacy of denosumab has been well demonstrated in primary osteoporosis; however, to date, no studies have been conducted on osteoporosis driven by pituitary disease. The aim of this study was to evaluate the efficacy of denosumab in patients with osteoporosis driven by pituitary disease.

Methods: A retrospective, monocentre, observational cohort study was conducted to investigate the frequency of incident vertebral (i-VFs) and femoral (i-FFs) fractures and the percent BMD changes at 1-, 2-, 5-, and 10-years of treatment with denosumab, in patients with pituitary disease-driven osteoporosis and in patients with primary osteoporosis.

Results: 35 patients with pituitary disease-driven osteoporosis and 35 patients with primary osteoporosis were included in the study. The frequency of i-VFs and i-FFs was similar in both treatment groups at all fixed-term evaluations. Percent BMD changes in the lumbar spine and femur were similar in both treatment groups at all fixed-term evaluations. Among patients with pituitary disease-driven osteoporosis, lumbar spine BMD significantly increased at 2 years and at 5 years of treatment (respectively +6% IQR: 14.3 $P < .001$, and +7.8% IQR: 12.6 $P = .002$); femoral neck BMD significantly improved at 5 and 10 years of treatment (respectively +4.3% IQR: 16 $P < .001$ and 9% IQR: 17, $P = .002$). No drug-related adverse events occurred in both treatment groups.

Conclusions: This study demonstrated for the first time that long-term treatment with denosumab is effective and safe in patients with pituitary disease-driven osteoporosis.

EP1056 - ECE_2558 - Reduced circulating humanin in patients with acromegaly and concomitant diabetes

Daniela Dadej, Dorota Filipowicz, Marianna Cemel and Marek Ruchala

Poznan, Poland

Introduction: Diabetes and insulin resistance belong to the most common metabolic complications of acromegaly, resulting from the chronic impact of growth hormone excess on glucose homeostasis. Humanin, a mitochondrial-derived peptide, has been shown to exert insulin-sensitizing properties, enhance insulin secretion and improve pancreatic B-cell viability, potentially delaying the onset of diabetes. However, existing evidence derives predominantly from experimental studies and mechanisms underlying these effects remain unclear. The aim of this study was to assess circulating humanin concentrations in patients with acromegaly in relation to glycaemic status and metabolic parameters.

Material and Methods: A cross-sectional analysis was performed in 122 adults: 42 with active acromegaly, 40 with biochemically controlled acromegaly following surgical or pharmacological treatment, or both, and 40 controls without acromegaly. Anthropometric, biochemical, and clinical data were collected. Humanin concentrations were evaluated using commercially available Elisa kit (Human Putative Humanin Peptide MT-RNR2; Cusabio). Statistical analyses were conducted using PQStat Software v.1.8.6.126. A P-value <.05 was considered statistically significant.

Results: Among the study population, 25 participants had diabetes, 30 had prediabetes, 59 had hypertension, and 67 had dyslipidaemia. Humanin concentrations were significantly lower in acromegalic patients with diabetes compared with those with normoglycaemia, but not with prediabetes (Kruskal–Wallis $P = .01$; Dunn–Bonferroni $P = .03$). In the entire cohort, humanin concentrations correlated inversely with fasting glucose (Spearman r $= -0.20$; $P = .03$). This association, however, was not significant when analyses were limited to patients with acromegaly ($P = .11$). No correlations were observed between humanin and HbA1c ($P = .48$), insulin ($P = .26$) or HOMA-IR ($P = .17$). Humanin concentrations did not differ according to the presence of hypertension ($P = .24$) or dyslipidaemia ($P = .83$) and showed no associations with blood pressure, lipid profile or cardiovascular risk assessed by the SCORE2 model.

Conclusions: Circulating humanin concentrations were reduced in patients with acromegaly and concomitant diabetes, while no associations were observed with other metabolic or

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

cardiovascular parameters. These findings indicate that alterations in humanin concentrations may be primarily related to glycaemic status. Additional studies are required to clarify the underlying mechanisms and determine the diagnostic or prognostic value of humanin in metabolic complications of endocrine disorders.

EP1057 - ECE_3083 - Prolactin levels, but not T2-weighted tumor signal, discriminated between non-functioning PitNETs and lactotroph PitNETs

Beatrice Crasta[1,2], Luigi Demarchis[1,2], Sabrina Chiloiro[1,2], Antonella Giampietro[1,2], Pier Paolo Mattogno[2,3], Rosalinda Calandrelli[2,4], Marco Gessi[2,5], Simona Gaudino[2,4], Laura De Marinis[1,2], Antonio Bianchi[1,2], Francesco Doglietto[2,3] and Alfredo Pontecorvi[1,2]
[1]Endocrinology and Metabolism Unit, Department of Medical and Surgical Sciences, Fondazione Policlinico Universitario Agostino Gemelli, Roma, Italy; [2]Università Cattolica del Sacro Cuore, Roma, Italy; [3]Neurosurgery Unit, Department of Neurosciences, Fondazione Policlinico Universitario Agostino Gemelli, Roma, Italy; [4]Radiology and Neuroradiology Unit, Department of Radiological Sciences, Fondazione Policlinico Universitario Agostino Gemelli, Roma, Italy; [5]Pathology Unit of Head and Neck, Lung and Endocrine Systems, Fondazione Policlinico Universitario Agostino Gemelli, Roma, Italy

Introduction: Both prolactin-secreting PitNETs (PRL-PitNETs) and non-functioning PitNETs (NF-PitNETs) can cause different grades of hyperprolactinemia, the first ones by directly producing it, the other ones by compression of the pituitary stalk. This study aimed to investigate the usefulness of biochemical and radiological features in differentiating between non-functioning PitNETs and secreting lactotroph Pit-NETs.

Patients and Methods: 166 patients with clinical suspicion of NF-PitNET or PRL-PitNET and histological confirmation were included in the study. For all patients were collected prolactin levels at diagnosis, tumor volume and consistency, ratio between MRI-based T2-weighted tumor signal and T2-weighted white matter intensity.

Results: 143 NF-PitNETs and 23 PRL-PitNETs were included in the study. 16 cases were microPitNETs (8 NF-PitNETs, 8 PRL-PitNETs) and 150 were macro-PitNETs (135 NF-PitNETs, 15 PRL-PitNETs). Tumor consistency was cystic in 47 cases (39 NF-PitNETs, 8 PRL-PitNETs) and solid in 119 cases (104 NF-PitNETs; 15 PRL-PitNETs). As T2-ratio significantly differed between cystic and solid PitNETs ($P < .001$), we separately analyzed the two groups. Among cystic PitNETs, T2-ratio didn't differ in NF-PitNETs and PRL-PitNETs, both micro- ($P = .2$) and macro-PitNETs ($P = .248$); instead, prolactin levels were significantly higher in PRL-PitNETs than in NF-PitNETs, both micro- (respectively, 500 ng/mL SD: 125 and 28.7 ng/mL SD: 25 $P < .001$) and macro-PitNETs (respectively, 428 ng/mL SD: 321 and 28.2 ng/mL SD: 25 $P < .001$). Likewise, among solid PitNETs, T2-ratio didn't differ in NF-PitNETs and PRL-PitNETs, both micro- ($P = .977$) and macro-PitNETs ($P = .243$); instead, prolactin levels were significantly higher in PRL-PitNETs than in NF-PitNETs, both micro- (respectively 162 ng/mL SD: 91 and 21 ng/mL SD: 24 $P = .003$) and macro-PitNETs (respectively 195 ng/mL SD: 428 and 20 ng/mL SD: 193 $P < .001$).

Discussion: In this study, serum prolactin levels confirmed their reliability as a biochemical marker in distinguishing PRL-PitNETs from NF-PitNETs, independently of tumor size or consistency. Conversely, MRI-based T2-weighted signal ratios didn't help differentiate the secretory status, highlighting the limited diagnostic role of conventional MRI features. Advanced MRI modalities (such as radiomics, DWI, susceptibility imaging, and molecular imaging) could further improve diagnostic accuracy by providing quantitative, microstructural, and functional data beyond standard imaging and serum prolactin levels.

Conclusions: Prolactin levels at diagnosis, but not T2-weighted tumor signal, predict the diagnosis of secreting lactotroph tumors rather than non-functioning PitNETs.

EP1058 - ECE_3304 - Long-term treatment patterns and biochemical control rates in patients with acromegaly: a 5-year landmark analysis from a large tertiary pituitary center

Jon Rasmussen, Mathilde Damm, Amanda Sørensen, Yeliz Bulut, Mikkel Andreassen and Caroline Kistorp
Department of Nephrology and Endocrinology, Rigshospitalet, København Ø, Denmark

Objective: To describe treatment strategies and biochemical control rates in patients with acromegaly five years after diagnosis at a tertiary pituitary centre, and further to evaluate whether patient outcomes are in accordance with standard of care of the Pituitary Tumor Centers of Excellence (PTCOE).

Methods: A retrospective cohort study from Copenhagen University Hospital, Rigshospitalet including patients diagnosed with acromegaly between January 1, 2000, and November 30, 2025. Data was recorded from patient electronic records. Baseline characteristics included age, sex, maximal pituitary adenoma diameter, and serum IGF-1 values (absolute and SD scores). During five years following the diagnosis, treatment modalities, pituitary surgery, use of medical therapy (somatostatin analogues [SSA], pegvisomant [PEGV], cabergoline, pasireotide, and combination regimens), and radiotherapy, were recorded. Biochemical control was defined as serum IGF-1 $\leq$2 SD.

Results: A total of 176 patients with acromegaly are followed in our specialized outpatient clinic. Mean (SD) age at diagnosis was 51 (14) years, and 52% were women. Of these, 104 patients were eligible for five-year evaluation; 45 patients (26%) had insufficient follow-up duration, and 27 (15%) were excluded due to missing data. At five years from diagnosis, 80 (77%) of acromegaly patients were on medical therapy, whereas 24 (23%) were only treated with pituitary surgery of the GH secreting adenoma. A minor part, 14 (13%), of the patients were on medical therapy, without prior surgery. In 15 (14%) patients, radiotherapy was used after surgery and medical therapy. Overall, biochemical control at five years was achieved in 84% of patients and did not differ significantly between treatment groups, $P = .259$, but control rates were numerically highest in the surgery-only group (96%) and lowest in the multimodality treated group (73%). In patients treated with pituitary surgery alone ($n = 24$), 5-year remission rates were similar for macroadenomas and microadenomas, $P = 1.00$. Among patients receiving medical therapy at five years from baseline, 59% were treated with SSA monotherapy

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

and 30% with combined SSA and PEGV. Biochemical control was achieved in 89% of patients treated with SSA monotherapy.

Conclusions: Treatment patterns and biochemical control rates five years after diagnosis in acromegaly patients at our centre are consistent with PTCOE standard of care and with their reported patient outcomes.

Abstract citation ID: lvag096.1326

EP1059 - ECE_3459 - Non-invasive evaluation of hepatic steatosis in active versus biochemically controlled acromegaly

Hamza El Hadi, Maximilian Brol, Eric Suero Molina, Walter Stummer, Jonel Trebicka and Elena Vorona
Münster University Hospital, Münster, Germany

Introduction: Growth hormone (GH) and insulin-like growth factor-1 (IGF-1) exert important physiological effects on hepatic lipid metabolism and suppress intrahepatic profibrotic pathways. The impact of disease activity in acromegaly on hepatic steatosis, however, remains incompletely understood. This study aimed to non-invasively evaluate the relationship between acromegaly disease activity and hepatic steatosis and fibrosis.

Materials and Methods: Hepatic steatosis and fibrosis were assessed using transient elastography (FibroScan Mini 430), measuring the controlled attenuation parameter (CAP) and liver stiffness (LSM), respectively. 33 patients with acromegaly (12 with active disease and 21 in biochemical remission) followed at our endocrinology outpatient clinic at University Hospital in Münster between March and December 2025 were enrolled. All patients had undergone prior transsphenoidal surgical resection of GH-secreting pituitary adenomas. Fat mass index (FMI) was assessed non-invasively using bioelectrical impedance analysis (BIA).

Results: Patients with active disease and those in biochemical remission did not differ significantly in terms of age, sex distribution, body mass index (BMI), LDL cholesterol/triglycerid levels, or the prevalence of diabetes mellitus, hypertension, obstructive sleep apnea, or cardiovascular disease. Although not statistically significant, patients with biochemically controlled acromegaly exhibited a higher FMI. CAP values, reflecting hepatic steatosis, were significantly lower in patients with active acromegaly compared to those with biochemically controlled disease (227 ± 37 vs 261 ± 55 mmol/L, $P < .05$ respectively). No significant difference in LSM values was observed between the two groups. CAP scores showed positive correlations with age ($r = 0.49$, $P = .002$), BMI ($r = 0.53$, $P = .001$), body weight ($r = 0.44$, $P = .01$), and hepatic steatosis index (HSI) ($r = 0.63$, $P < .001$), while a negative correlation was identified between CAP score and GH levels ($\rho = -0.48$, $P = .005$).

Conclusions: Our findings demonstrate that patients with active acromegaly exhibit lower non-invasive markers of hepatic steatosis compared with those in biochemical remission, supporting a protective role of the GH–IGF-1 axis against hepatic fat accumulation. The absence of significant differences in overall body composition highlights the need for further studies to clarify the mechanisms by which GH and IGF-1 influence hepatic lipid metabolism.

EP1060 - ECE_3613 - Proteins of the neutrophil degranulation pathway may regulate invasiveness and proliferation in somatotroph tumors

Sabrina Chiloiro[1,2], Luigi Demarchis[1,2], Pier Paolo Mattogno[2], Michela Cicchinelli[1], Federico Valeri[2], Flavia Angelini[1,2], Antonella Giampietro[1,2], Domenico Milardi[1,2], Quintino Giorgio De Alessandris[1,2], Laura De Marinis[1,2], Andrea Urbani[1,2], Alfredo Pontecorvi[1,2], Francesco Doglietto[1,2], Antonio Bianchi[1,2] and Federica Iavarone[1]
[1]School of Medicine and Surgery, Università Cattolica del Sacro Cuore, Rome, Italy; [2]Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome, Italy

Introduction: The tumor microenvironment is composed of non-tumor cells, blood vessels, extracellular matrix and soluble factors, and generates a complex network with tumor cells, regulating tumor proliferation, invasiveness, and response to medical therapies.

Patients and Methods: A liquid chromatography-mass spectrometry was conducted on samples of somatotroph pituitary tumor (after processing and digestion of the sample) to identify and assay the expression of proteins involved in immune system pathways. The differential expression of identified proteins was compared and investigated according to the tumor pattern of growth, tumor proliferation, and persistence of post-surgery tumor residual. Biological functions were investigated for proteins that were found differentially expressed, with a ratio of variation based on Fold-Change (FC) > |1.50| and statistical significance (*P*-value <.05).

Results: Eleven patients with acromegaly were included. Seven patients were females (63.6%). Mean age at diagnosis was 45 years (SD:18). Mean serum GH levels at diagnosis were 10.5 ng/mL (SD:9.3), and mean IGF-I levels were $2.6 \times$ ULN (SD:0.8). Ten patients carried a tumor >1 cm (90.9%). An invasive growth was identified in 5 tumours with an invasion of the cavernous sinus (45.4%). Ten patients were diagnosed with a sparsely granulated somatotroph tumor (90.9%). Two tumors (18.2%) were proliferative, according to Ki-67 and p53 expressions and the number of mitoses. Six patients (54.5%) underwent curative surgery, and five patients (45.4%) required adjuvant treatment with first-generation somatostatin analogues. In this cohort, a total of 590 proteins were identified. A total of 10 proteins (mainly involved in the neutrophil degranulation pathway) were differently expressed, comparing groups of somatotroph tumors based on established criteria. The proteins 26S proteasome non-ATPase regulatory subunit 3 and mitochondrial antiviral-signaling protein were more expressed in invasive tumors than in non-invasive ones. The proteins phosphoglucomutase-2, keratin, adenylyl cyclase-associated protein 1, and guanylate-binding protein 1 were significantly more expressed in proliferative somatotroph tumors than in non-proliferative ones. The proteins alpha-1-antichymotrypsin, clusterin, phosphoglucomutase-2, glutathione S-transferase omega-1, prosaposin, keratin, and the guanylate-binding protein 1 were significantly more expressed in tumours that underwent radical surgery than in patients carrying a residual disease.

Conclusions: Our results provided that specific proteins involved in the neutrophil degranulation pathway may impact

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

somatotroph tumor behaviour, in terms of invasive growth and proliferation, and consequently surgical outcome.

EP1061 - ECE_3807 - Incidence of acromegaly a nationwide study through 11 years in Iceland

Iðunn Valgerður Pétursdóttir[1] and Helga Sigurjónsdóttir[1,2]
[1]Department of Medicine, Landspítali University Hospital, Reykjavík, Iceland; [2]School of Medicine, University of Iceland, Reykjavík, Iceland

Background: A study on the incidence and prevalence of Acromegaly in Iceland from 1955 through 2013 found the incidence to be higher than anticipated compared to studies from other countries. Therefore, we were interested in conducting a similar study for the following 11 years, from 2014 through 2024.

Methods: In a retrospective study, results on patients diagnosed with Acromegaly during the years 2014-2024 were sampled from electronic medical records at Landspitali University Hospital (LUH), Reykjavik, Iceland. LUH is the only tertiary hospital in Iceland housing the only Neurosurgery Department. All work up and diagnosis of Acromegaly in Iceland is performed at the Department of Endocrinology at LUH. The number of patients diagnosed with Acromegaly in Iceland is therefore found in the medical records of LUH. This is thus a nationwide study. Patients diagnosed in Iceland during the study period were included. Two of the patients had immigrated to Iceland after the diagnosis abroad before the year 2014. They were included in the study as they recieved all their treatment in Iceland during the study period.

Results: Sixteen patients (10 men) were diagnosed with the average age of 50.8 years ± 18.8 years. Two patients died during the study period. Most patients had experienced symptoms for 2 years or less before diagnosis, however two patients had experienced symptoms for up to 10-20 years before the diagnosis.

Conclusions: The incidence of Acromegaly in Iceland during the years 2014-2024 was 4.1 patients per million per year. These results are lower than previously reported from Iceland and more in line with the incidence of Acromegaly in other countries.

EP1062 - ECE_3812 - From resistance to response: pasireotide efficacy in previously treated acromegaly patients—a real-world analysis

Iulia Florentina Burcea[1,2], Dobre Ramona[1,2], Ioana Postelnicu[2], Căpăţînă Cristina[1,2], Simona Galoiu[1,2], Ionela Baciu[1,2], Serban Radian[1,2], Raluca Trifanescu[1,2], Nicoleta Baculescu[1,2] and Catalina Poiana[1,2]
[1]Department I, "C. I. Parhon" National Institute of Endocrinology, Bucharest, Romania; [2]Endocrinology, "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania

Introduction: Pasireotide LAR (PAS) is a second-line therapy for acromegaly in patients inadequately controlled with first-generation somatostatin receptor ligands (fgSRLs) ± growth hormone (GH) receptor antagonist ± dopamine agonist. This study evaluates PAS efficacy in previously treated patients from a single tertiary center.

Methods: We retrospectively analyzed 30 patients (66.7% female, mean age 37.9 ± 12.8 years) previously treated with other medical therapy, surgery, radiotherapy. All tumors measured >10 mm at diagnosis. We collected biochemical data: GH, insulin-like growth factor-1 (IGF-1), tumor dimensions from imaging, glycemic parameters: fasting plasma glucose (FPG), glycated hemoglobin (HbA1c) and body mass index (BMI). The mean treatment duration with PAS was 44.6 ± 31.9 months. The mean baseline BMI was 29.08 ± 4.82 kg/m^2, indicating a predominantly overweight cohort.

Results: Early Biochemical Response: PAS demonstrated rapid efficacy. At 3 months, mean GH decreased by 57.9% (from 4.28 to 1.80 ng/mL) and IGF-1 decreased by 30.3%, from 1.65 to 1.15 × Upper limit of normal (ULN). Biochemical control was achieved in 41.4% of patients at 3 months. **Progressive Improvement:** At 6 months, control improved to 54.2%. By last follow-up (>6 months), mean GH was 1.54 ± 1.48 ng/mL (64% reduction) and IGF-1 normalized to 0.96 ± 0.44 × ULN (41.8% reduction), with 64.3% achieving control. Prior therapy duration did not correlate with GH or IGF-1 reduction at any timepoint ($P < .05$), indicating PAS efficacy is independent of prior treatment history. Patients with longer prior therapy (>6 years) showed numerically higher biochemical control rates at 3 months (58.3% vs 29.4%), suggesting extensive prior treatment does not impair PAS response. **Tumor Volume:** Mean tumor diameter decreased from 16.9 ± 10.0 mm to 15.1 ± 9.8 mm. Significant shrinkage (≥20%) occurred in 33.3% of patients, with 60% stable and 6.7% progressive. **Glycemic Profile:** Mean FPG increased from 100.5 ± 18.0 to 118.0 ± 29.1 mg/dL; mean HbA1c rose from 5.91 ± 0.88% to 6.54 ± 0.98%. Diabetes prevalence increased from 6 to 10 patients.

Conclusions: Pasireotide LAR demonstrates significant efficacy in achieving biochemical control and tumor shrinkage in previously treated acromegaly patients. Importantly, PAS efficacy is independent of prior therapy duration—patients treated for extended periods respond as well as those with shorter histories. While secretory and morphological responses are favorable, treatment is associated with worsening glycemic control, requiring careful metabolic monitoring.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Hospital, Department of Endocrinology, Gothenburg, Sweden; [10]*Department of Internal Medicine and Clinical Nutrition, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden*

Introduction: Somapacitan is approved for the treatment of adult growth hormone (GH) deficiency (AGHD) yet real-world reports in this population remain limited. We report interim results from a post-marketing study of Japanese patients (pts) with AGHD treated with somapacitan.

Methods: Eligible pts had AGHD, had not previously enrolled in the study and had no safety contraindications. Pts exposed to somapacitan comprised the safety analysis set (SAS) and were analysed according to treatment status at enrolment (GH-naïve or switched [SW] from another GH product within 180 days of registration). Primary endpoint was incidence of adverse events (AEs), including serious AEs (SAEs), adverse reactions (ARs) and serious ARs (SARs).

Results: At data cutoff (16 January 2025) 223 pts had enrolled in the study, of whom 53 with complete case report forms comprised the SAS (23 GH-naïve; 30 SW). Pts were female (54.7%) and male (45.3%); mean (standard deviation [SD]) age was 54.3 (15.0) years and mean (SD) insulin-like growth factor-I SD score was −3.2 (2.9) and −0.7 (1.8) for GH-naïve and SW pts, respectively. Mean weekly somapacitan dose was 1.3 and 1.5 mg/week at baseline, 1.8 and 2.3 mg/week at 1 year, and 1.5 and 1.7 mg/week at 2 years in GH-naïve and SW pts, respectively. Most pts missed ≤1 somapacitan dose every 2 months at 1 year (22/23 [95.7%] GH-naïve and 30/30 [100.0%] SW) and 2 years (5/5 [100%] and 8/9 [88.9%], respectively). One GH-naïve patient missed >1-<3 doses per 2 months after 1 year versus no SW pts. Seven AEs were reported by 5 pts (headache; brain fog; arthralgia; injection site pain and malaise); of these, six were ARs in 4 pts. No SAEs or SARs occurred.

Conclusions: Somapacitan is a valid treatment option for Japanese pts with AGHD, with real-world data showing good treatment adherence and a safety profile in agreement with that previously seen in clinical trials.

EP1064 - ECE_2090 - Neurophysin-I, a surrogate biomarker of oxytocin, and cortisol interaction during psychological stress

Andi Nikaj[1,2], Elin Broman[1,2], Cihan Atila[1,2], Joachim Heuberger[1,2], Carla Walti[1,2], Judith Siegenthaler[1,2], Sandrine A. Urwyler[1,2], Deborah Rudin[3], Dino Lüthi[3], Schuetz Philipp[4] and Mirjam Christ-Crain[1,2]

[1]*Departments of Endocrinology, Diabetology and Metabolism, University Hospital Basel, Basel, Switzerland;* [2]*Department of Clinical Research, University Hospital Basel, Basel, Switzerland;* [3]*Clinical Pharmacology and Toxicology, Department of Biomedicine and Department of Clinical Research, University Hospital Basel, Basel, Switzerland;* [4]*Department of Internal Medicine, Kantonsspital Aarau, Aarau, Switzerland*

Background: Oxytocin (OXT) is a neuropeptide that is synthesised in the hypothalamic paraventricular and supraoptic nuclei and released into circulation from the posterior pituitary. Among others, OXT is involved in psychological and socio-behavioural processes. Beyond its known role in these processes, evidence from both animal and human studies suggests that OXT might also regulate neuroendocrine stress responses within the central nervous system. OXT is thought to suppress the stress-induced activation of the hypothalamic-pituitary-adrenal (HPA) axis by exerting an inhibitory effect on cortisol secretion.

Design: This is a secondary analysis of a prospective observational study, which was conducted to investigate the relationship between copeptin concentration and psychological stress.

Methods: Twenty healthy adults (ten female) underwent the Trier Social Stress Test (TSST) which included a 30-minute waiting period, a 10-minute anticipation period, a 10-minute test period, and a 40-minute recovery period. For this analysis, plasma Neurophysin-I (NP-I), a surrogate biomarker of OXT, and plasma cortisol were measured at baseline (T0), 20 minutes (ie, right after the stress, T1) and 40 minutes (ie, 20 minutes into recovery, T2).

Results: At T0, median (IQR) NP-I levels were 1237 pg/mL (693, 3143), decreasing to 1166 pg/mL (767, 3360) at T1. At T2, NP-I levels increased again to 1199 pg/mL (717, 3063). Median cortisol levels were 435 nmol/L (385, 547) before psychological stress (T0) and peaked at 529 nmol/L (494, 701) at T1. At T2, cortisol levels decreased again to 507 nmol/L (438, 632). Linear mixed-effects model analysis revealed that in healthy individuals, higher NP-I levels measured at both T1 ($P = .004$) and T2 ($P < .001$) were associated with lower plasma cortisol concentrations compared to T0.

Conclusions: In healthy volunteers, higher NP-I levels were associated with a blunted cortisol response to psychological stress, suggesting a cortisol-buffering effect of NP-I mirroring OXT. These findings support the idea of an inverse relationship between NP-I concentrations and cortisol responses over time following stress exposure.

EP1066 - ECE_2469 - Not all empty sella are the same: baseline clinical and endocrine differences between primary and secondary empty sella

Vanessa Caccin[1], Francesca Paglia[1], Nicolò Bacchi[1], Gianluca Margiotta[2], Chiara Diazzi[3], Bruno Madeo[3], Maria Chiara Decaroli[1], Maria Laura Monzani[1], Sara De Vincentis[1] and Vincenzo Rochira[1]

[1]*Department of Biomedical, Metabolic and Neurosciences, Endocrinology Unit, University of Modena and Reggio Emilia, Modena, Italy;* [2]*Local Health Authority (ASL) CN1, Cuneo, Italy;* [3]*Modena, Italy*

Background: Empty Sella (ES) is a neuroradiological condition characterized by partial or complete occupation of the sella turcica by cerebrospinal fluid, resulting in compression of the pituitary gland. Primary (PES) and Secondary ES (SES) share similar neuroradiological appearances but originate from different pathophysiological mechanisms. The clinical and endocrine implications of these differences at baseline have not been systematically evaluated in large cohorts.

Methods: We retrospectively evaluated 258 adult patients with ES followed at a tertiary endocrinology center between 2007 and 2025. Demographic characteristics, clinical presentation, MRI findings, comorbidities, and comprehensive pituitary

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

hormonal assessments were collected at diagnosis. ES was classified as PES or SES based on clinical history. Determinants of pituitary dysfunction severity were explored using ordinal logistic regression.

Results: In the overall cohort (64.3% women; median age 51.5 years; median follow-up 58.5 months), PES was more prevalent than SES (61.6% vs 38.4%). At presentation, ES was incidentally detected more frequently in PES (66%), whereas SES was diagnosed mainly following clinical suspicion (87.9%) ($P < .001$). While headache was the most frequent symptom overall, visual field defects were significantly more common in SES than PES ($P = .021$), highlighting a more overt clinical presentation. Radiological grade (partial vs complete ES) did not differ between groups and was not associated with endocrine burden. Striking differences emerged at endocrine evaluation. At baseline, 41.1% of patients had at least one pituitary hormone deficiency, significantly more frequent in SES than PES (62.6% vs 27.7%, $P < .001$), with gonadotropic deficiency the most common alteration. SES was characterized by a significantly higher prevalence of multiple pituitary deficiencies, involving the gonadotropic, corticotropic, thyrotropic, and GH axes (all $P < .001$). Complete anterior hypopituitarism and arginine vasopressin deficiency were observed exclusively in SES ($P < .001$). In contrast, preserved pituitary function predominated in PES (72.3%). At ordinal logistic regression analysis, male sex ($P = .002$), secondary ES ($P = .006$), clinically driven diagnosis ($P = .030$), and older age at both diagnosis ($P = .010$) and first evaluation ($P = .017$) independently predicted a higher burden of pituitary hormone deficiencies.

Conclusions: Despite similar imaging features, PES and SES display profoundly different baseline endocrine and clinical profiles. SES is associated with a significantly higher and more complex pituitary dysfunction at diagnosis, while PES is largely characterized by preserved hormonal function. These findings emphasize that ES should not be considered a single entity and support systematic endocrine evaluation in all patients, with particular attention to secondary forms.

EP1067 - ECE_2795 - Changes in cognitive and psychological functioning in patients with prolactinoma after treatment

Iris Pelsma, Willem Verbeek, Victoria van Trigt, Leontine Bakker, Cornelie Andela and Nienke Biermasz
Endocrinology, Leiden University Medical Center, Leiden, The Netherlands

Objective: To examine the reversibility of cognitive impairment and psychological complaints in patients with prolactinomas following treatment and subsequent biochemical control.

Methods: Sixteen patients, among whom 13 (81.3%) females, with active hyperprolactinemia and without any comorbidities potentitally affecting cognition (depressive disorders, anxiety disorders, subtracne abuse) were included. In this prospective longitudinal study, 16 patients, underwent comprehensive neuropsychological assessment (8 cognitive tests and 7 validated questionnaires) at baseline. All 16 patients were re-evaluated after a mean of 19.8 months of follow-up.

Results: Following biochemical remission, significant improvements were observed in delayed verbal memory (Rey 15-words delayed recall: 11.0 ± 2.5 vs 12.3 ± 2.7, $P = .004$) and executive functioning, specifically planning (D-KEFS Tower Test: 10.8 ± 2.9 vs 12.9 ± 2.6, $P < .001$) and cognitive flexibility (TMT-B 59.5[49.3 − 71.5] vs 47.4[40.3 − 60.0] sec, $P = .011$). Also, selective attention errors (Digit Deletion Test) decreased significantly (3.5[2.0-5.0] vs 1.0[0.0-3.8]), $P = .014$). Disease-specific quality of life improved significantly at both burden (LBNQ-Bothers: 22.4[10.8-33.5] vs 13.4[5.3-15.9], $P = .001$) and care needs (LBNQ-Needs: 23.5[7.8-36.6] vs 13.9[1.5-23.5], $P < .001$). Furthermore, reductions were seen in fatigue (FSS: 41.4 ± 14.8 vs 31.3 ± 15.5, $P = .026$) and depressive symptoms (HADS-D: 5.5[2.0-7.8] vs 1.0[1.0-7.0], $P = .013$). Higher baseline prolactin levels were associated with less improvement in verbal memory (immediate learning phase, Verbal Learning Test of Rey: $r_S = -0.58$, $P = .019$).

Conclusions: Cognitive deficits in prolactinoma patients are largely reversible state-dependent impairments that resolve significantly upon biochemical control. While substantial recovery occurs in memory and executive functioning, severe baseline hyperprolactinemia may reduce the recovery trajectory of immediate verbal memory.

EP1068 - ECE_3253 - Evaluation of endocrinological disorders in pediatric patients with empty sella

Eda Boz Öncel[1], Çiğdem Öztunalı[2], Coşkun Yarar[3] and Birgul Kirel[4,5]
[1]*Pediatrics, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Türkiye;* [2]*Radiology, Eskisehir Osmangazi Univercity Faculty of Medicine, Eskişehir, Türkiye;* [3]*Pediatric Norology, Eskisehir Osmangazi Univercity Faculty of Medicine, Eskişehir, Türkiye;* [4]*Pediatric Endocrinology, Eskisehir Osmangazi Univercity Faculty of Medicine, Eskişehir, Türkiye;* [5]*Pediatric Endocrinology, Eskisehir Osmangazi University Hospital, Eskisehir, Türkiye*

Background: Empty sella (ES) is an anatomical condition resulting from herniation of the subarachnoid space into the sella turcica, leading to cerebrospinal fluid filling and flattening of the pituitary gland. Endocrinological abnormalities are frequently reported in pediatric patients with ES, even in those without clinical symptoms.

Objective: To evaluate the clinical, radiological, and endocrinological characteristics of pediatric patients diagnosed with empty sella and to investigate the relationship between pituitary morphology and hormonal dysfunction.

Methods: A retrospective analysis was performed in 56 patients (24 females, 32 males) aged 6 months to 17 years with radiologically confirmed ES. Pituitary anatomy, etiology, classification, and endocrine findings were reviewed. Hormonal profiles were assessed for isolated and multiple pituitary hormone deficiencies. The association between pituitary height and the presence of multiple hormone deficiencies was analyzed.

Results: Isolated pituitary hormone deficiencies included growth hormone deficiency in 10 patients, isolated hypothyroidism in 1, hyperprolactinemia in 8, and hypogonadism in 2. Multiple pituitary hormone deficiencies were detected in 19.6% of cases. A significant correlation was observed between decreased pituitary height and the presence of multiple pituitary hormone deficiencies ($r = 0.654$, $P = .001$). Empty sella was incidentally detected in

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

38 patients (68%); however, 20 of these had hormonal abnormalities at diagnosis, and 7 developed hypopituitarism (hypothyroidism, hypogonadism, or precocious puberty) during follow-up.

Conclusions: Pediatric patients with empty sella, including those who are asymptomatic, should undergo comprehensive endocrine evaluation at diagnosis. Regular long-term follow-up is essential for early detection and management of evolving pituitary hormone deficiencies.

EP1069 - ECE_3591 - Effects of prolactin insufficiency in a monocentric cohort of patients

Francesco Padovano Sorrentino[1,2], Antonella Giampietro[1,2], Paola Pagano[2], Pier Paolo Mattogno[2,3], Liverana Lauretti[2,3], Francesco Doglietto[2,3], Laura De Marinis[1,2], Antonio Bianchi[1,2], Sabrina Chiloiro[1,2] and Alfredo Pontecorvi[1,2]

[1]Endocrinology, Diabetology, and Internal Medicine, Fondazione Policlinico Agostino Gemelli (IRCCS), Rome, Italy; [2]Catholic University of the Sacred Heart (UCSC), Rome, Italy; [3]Neurosurgery, Fondazione Policlinico Agostino Gemelli (IRCCS), Rome, Italy

Introduction: Prolactin's functions in the human body are not fully understood. Therefore, the impact of the prolactin insufficiency is often overlooked in people with hypopituitarism. We present the preliminary data of our study on the pleiotropic effects of prolactin insufficiency.

Materials and Methods: A retrospective monocentric study was conducted on patients attending our clinic between the 2021 and 2024. Prolactin insufficiency (PRL-insufficiency) was defined for serum prolactin <3 ng/mL. Prolactin deficiency (PRL-deficiency) was defined for serum prolactin <5 ng/mL. For the control group we considered patient with serum prolactin within the normal range.

Results: The study group consists of 101 patients (55 males, 46 females), 31 with PRL-insufficiency, 40 with PRL-deficiency and 30 controls. They suffered from non-secreting macroadenoma (55 patients), non-secreting microadenoma (6 patient), Rathke's cleft cyst (5 patients), craniopharyngioma (11 patients), hypophysitis (5 patients), primary empty sella (11 patients) and other sellar tumors (8 patients). PRL-insufficiency and PRL-deficiency are both associated with a higher prevalence of hypopituitarism ($P < .001$; $P = .018$) and male sex ($P = .001$; $P = .045$). PRL-insufficiency is individually associated with a larger prevalence of secondary hypoadrenalism ($P < .001$), secondary hypothyroidism ($P < .001$), GH-deficiency ($P < .001$) and secondary hypogonadism ($P < .001$). Furthermore, patients with PRL-insufficiency were younger than patients with PRL-deficiency ($P < .001$) and showed a lower prevalence of primary hypertension (PH) ($P = .006$) and a better bone mineral density (BMD) on the hip ($P = .04$). No significant differences were found between the two study groups and controls regarding age, body mass index, BMD, prevalence of diabetes mellitus, dyslipidaemia, cardiovascular and cerebrovascular diseases or primary hypertension.

Conclusions: Patients with PRL-insufficiency tend to be younger, suggesting a more impactful disease and a greater pituitary damage. This data can also explain our findings regarding PH, even though there are some studies showing positive correlation between PRL levels and endothelial disfunction, whilst our results on the BMD seems to be in contrast with the literature. Our study shows that PRL-insufficiency is often associated with other pituitary deficiencies and should be evaluated not individually, but as a whole with patients' hormonal picture.

EP1070 - ECE_3935 - Investigation of lower extremity venous Doppler ultrasound parameters in patients with acromegaly

Simge Saydam[1], Fatma Zulal Ozek[1], Zeynep Elüstü Belten[1], Ozge Sahin Kimyon[1], Hasan Toz[2], Hayriye Gulsah Ozkan[3], Suna Nur Gündoğan[3], Hamide Piskinpasa[1], Meral Mert[1] and Sema Ciftci[1]

[1]Endocrinology and Metabolism Clinic, Department of Endocrinology and Metabolism, Sağlık Bilimleri Üniversitesi Bakırköy Doktor Sadi Konuk Eğitim Ve Araştırma Hastan, Bakırköy, Türkiye; [2]Cardiovascular Surgery, Bakırköy Sadi Konuk Hastanesi Onkoloji Merkezi, Istanbul, Türkiye; [3]Radiology, Sağlık Bilimleri Üniversitesi Bakırköy Doktor Sadi Konuk Eğitim Ve Araştırma Hastan, Bakırköy, Türkiye

Background: Acromegaly is a chronic disease characterized by excess growth hormone (GH) and insulin-like growth factor-1 (IGF-1). Although the effects of GH and IGF-1 on structural changes in tissues are well-documented, the specific implications of this hormonal excess for the venous system have not been sufficiently investigated in the literature. This study aims to evaluate lower extremity venous Doppler ultrasonography findings in patients with acromegaly and to examine the relationship between venous structural changes and clinical parameters.

Methods: The study included 50 acromegaly patients followed in our clinic. Color Doppler ultrasonography (CDUS) was performed to measure the diameters of the Vena Saphena Magna (VSM) and Vena Saphena Parva (VSP) in all patients, and the presence of venous reflux was assessed. The CDUS data were analyzed in relation to age, gender, body mass index (BMI), mean disease duration (calculated from symptom onset), biochemical remission status (post-surgery or medical treatment), and somatostatin receptor ligand (SRL) use.

Results: The study population consisted of 50 patients (25 women, 25 men) with a mean age of 52.7 ± 11.6 years and mean disease duration of 10.4 ± 6.3 years. Venous reflux was detected in 64% ($n = 32$) of the patients. Among those with reflux, 68.9% ($n = 22$) exhibited "grade 4" reflux. Regarding vessel diameters, 27 patients (54%) had a VSM diameter >5 mm and 22 patients (44%) had a VSP diameter >2.5 mm. The groups with ($n = 32$) and without ($n = 18$) venous reflux showed no significant differences regarding age, gender, BMI, mean disease duration, SRL use, or remission status ($P > .05$). Correlation analysis revealed that VSM diameter was significantly associated with mean disease duration ($r = 0.29$; $P = .044$) and BMI ($r = 0.43$; $P = .003$). In contrast, VSP diameter was independant of age, gender, BMI, mean disease duration, remission status, or SRL use ($P > .05$).

Conclusions: Our study demonstrated a high prevalence of venous reflux in acromegaly, independent of classic risk factors (age, gender, and BMI), with the majority of these cases

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

exhibiting advanced (Grade 4) reflux. The finding that venous damage and increased vessel diameters are not affected by biochemical remission or medical treatment suggests that structural changes in the venous system in acromegaly may represent a permanent process. Larger series studies are needed to further elucidate the frequency and clinical determinants of venous insufficiency in acromegalic patients.

EP1073 - ECE_2377 - Incidental sellar arachnoidocele: a prospective study in Argentina

Simone Cordovez[1], Bibiana Coca[1], Stella Orce[2], Alessandro Locatelli[2], Valeria Reynaldo[1], Nicole Soledispa[1], Diego Ceballos[2], Juan Carlos Treviso[2], Susana Mallea-Gil[1] and Carolina Ballarino[1]

[1]Endocrinology, Hospital Militar Central, Buenos Aires, Argentina; [2]Department of Imagin, Hospital Militar Central, Buenos Aires, Argentina

Empty Sella (ES) is a radiological finding, most often incidental, characterized by the presence of cerebrospinal fluid within the sella turcica due to herniation of the sellar diaphragm, resulting in flattening of the pituitary gland. Primary Empty Sella (PES) is defined in patients with no history of pituitary tumor, surgery, or radiotherapy. The main associated conditions are increased intracranial pressure, obesity, traumatic brain injury (TBI), multiparity, and arterial hypertension (AH).

Our objective is to determine the frequency of primary complete or partial sellar arachnoidocele incidentally detected on magnetic resonance imaging (MRI), to identify the most frequent hormonal disorder, and to assess the possible association between arachnoidocele's degree and hormonal impairment.

Materials and Methods: A prospective observational study is currently being conducted at the Hospital Militar Central (Buenos Aires, Argentina) over a one-year period (May 2025-April 2026). This report presents preliminary results from the first eight months. Patients >18 years who underwent brain MRI for indications unrelated to ES were followed. Pituitary hormonal profiles, degree of arachnoidocele, and predisposing factors (age, sex, clinical features, body mass index, parity, TBI and AH) were evaluated. Statistical analysis was performed using SPSS software.

Results: During the first eight months, a total of 1906 brain MRI scans were performed in a population with an average age of 58.1 ± 16.7 years at the diagnosis, of which 121 (6.3%) ES was found. Of these, 26 (21.4%) were men and 95 (78.6%) were women; among the latter, 82 (77.2%) had a history $\geq$2 deliveries. Main indication for MRI was headache, accounting for 23.1% of cases. Imaging assessment demonstrated the incidence of PES grade III (33.1%) followed by grade II (26.4%). Obesity and HTA were present in 45% and 22.8% patients respectively and 16.5% reported a history of TBI. We could perform biochemical pituitary profile in (57/121) and we found hormonal deficiency in only 2 patients (3.51%): one case of hypogonadism and one case of central hypothyroidism.

Conclusions: In this study, preliminary findings suggest a low incidence of incidentally detected PES on MRI and a low prevalence of associated hormonal deficiencies. Based on these findings, systematic hormonal evaluation and follow-up may be necessary only in patients with incidentally identified PES who present a high clinical suspicion based on symptoms consistent with pituitary dysfunction. The relationship between the degree of arachnoidocele and pituitary dysfunction and final conclusions will be fully elucidated upon completion of the study.

EP1074 - ECE_2605 - Granulomatous hypophysitis in sarcoidosis: a rare cause of panhypopituitarism

Nevena Radić[1], Dusan Zivanovic[1], Danilo Lazarevski[1], Đurđina Dronjak[1], Danka Jeremic[1,2], Snezana Polovina[1] and Mirjana Sumarac-Dumanovic[1,2,3]

[1]Clinic for Endocrinology, Diabetes and Metabolic Diseases, University Clinical Center of Serbia, Belgrade, Serbia; [2]School of Medicine, University of Belgrade, Belgrade, Serbia; [3]Clinic for Endocrinology, Diabetes and Diseases of Metabolism, University Clinical Center of Serbia, Belgrade, Serbia

Introduction: Hypophysitis is a rare inflammatory disorder of the pituitary gland, that may be primary or secondary, often occurring in association with systemic diseases. Clinical manifestations include headache, anterior and/or posterior pituitary dysfunction, and enlargement of the pituitary gland or infundibulum on MRI. Diagnosis is based on clinical, hormonal, and imaging findings and can be confirmed histopathologically.

Case Presentation: We report the case of a 37-year-old woman presenting with a four-month history of fatigue, generalized weakness, bone and muscle pain, numbness in the feet, loss of appetite, headaches, marked polydipsia (~6 L/24 h), and secondary amenorrhea. Her medical history was significant for Hashimoto's thyroiditis. Initial thyroid function tests showed low TSH, FT4 and T3. During hospitalization, panhypopituitarism was confirmed and central diabetes insipidus was diagnosed by water deprivation test. Laboratory evaluation showed very low gonadotropins (FSH <2.5 IU/L, LH <0.6 IU/L), low estradiol (23.3 ng/L), markedly elevated prolactin in profile (>2500 mIU/L) without macroprolactin, low-normal cortisol (193.6 nmol/L) and ACTH (13.9 ng/L), low IGF-1 (85.9 ng/mL), and low TSH (0.8 mIU/L). Pituitary MRI demonstrated a markedly enlarged pituitary gland with a thickened infundibulum, raising suspicion of autoimmune hypophysitis. Replacement therapy with hydrocortisone, levothyroxine, and desmopressin resulted in rapid clinical improvement. Further evaluation for an underlying systemic disorder revealed elevated 24-hour urinary calcium, angiotensin-converting enzyme (ACE), and chitotriosidase. Pituitary biopsy confirmed granulomatous hypophysitis, consistent with sarcoidosis. Chest CT demonstrated mediastinal lymphadenopathy, and brain/cervical MRI revealed mild dilation of the central canal from C5 caudally, suggestive of neurosarcoidosis. The patient was treated with pulse methylprednisolone (1000 mg daily for 5 days), followed by oral prednisone 60 mg daily, along with hormone replacement therapy using norgestrel/estradiol valerate. Corticosteroids were gradually tapered during follow-up under pulmonology supervision. After 14 months of therapy, hormonal reevaluation (2 months off norgestrel/estradiol) demonstrated partial recovery of anterior pituitary function, with increase in gonadotropins and estradiol profile (FSH 3.1 IU/L, LH 6.8 IU/L, estradiol 37.5 ng/L), normalized IGF-1 (117.8 ng/mL), ACTH

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

(23.8 ng/L), cortisol (386 nmol/L), and prolactin (LTH 466-540 mIU/L). Follow-up MRI showed postoperative changes, a slightly asymmetric heterogeneous gland, and no focal lesion. The patient continued replacement therapy with levothyroxine and a low dose of hydrocortisone (10 mg daily) and the desmopressin dose was adjusted according to clinical response.

Conclusions: This case highlights the importance of timely recognition of nonspecific symptoms that may indicate rare disorders such as granulomatous hypophysitis in sarcoidosis. It also emphasizes the critical role of a multidisciplinary approach in the diagnosis and management of complex systemic diseases with pituitary involvement.

Introduction: LINC 6 (NCT05382156), an ongoing prospective, non-interventional, multinational study, evaluates the long-term safety and effectiveness of osilodrostat in patients with Cushing's syndrome. Data are reported from an *ad hoc* analysis describing changes in patient-reported outcomes with osilodrostat.

Methods: Responses of patients (new osilodrostat users) treated for ≥6 months (M) who completed two validated questionnaires—the Cushing's Quality of Life (CushingQoL) questionnaire at baseline and CushingQoL and/or Patient Global Impression of Change (PGIC) questionnaire 6-18 M after treatment initiation—were analysed. Raw CushingQoL total score range was 12-60 and was converted into a 0- to 100-point scale; higher score indicates improvement in QoL. PGIC score ranged from 1 (very much improved) to 7 (very much worse); three classes were computed based on PGIC assessment: improvement (PGIC ≤3); no change (PGIC = 4); worsening (PGIC ≥5). Analyses are descriptive, with no formal statistical testing.

Results: 29 patients from five countries (Europe and USA) were included (female: $n = 23$, 79.3%; mean [SD] age: 51.0 years [16.4]). Median (min–max) osilodrostat exposure: 14.9 M (7.8-26.8). Overall, mean CushingQoL score increased over time (baseline: 37.7, $n = 29$; 6-12 M: 45.3, $n = 24$; 12-18 M: 47.2, $n = 18$). The minimal clinically important difference in CushingQoL (10.1-point change) was achieved by 41.7% ($n = 10/24$) and 55.6% ($n = 10/18$) of patients at 6-12 M and 12-18 M, respectively. Based on PGIC, from baseline to 6-12 M and 12-18 M, respectively, 60.9% ($n = 14/23$) and 50.0% ($n = 8/16$) of patients reported an improvement in their condition, 17.4% ($n = 4/23$) and 31.3% ($n = 5/16$) reported no change, and 21.7% ($n = 5/23$) and 18.8% ($n = 3/16$) reported worsening. Mean urinary free cortisol (mUFC; xULN) decreased from 1.7 ($n = 17$) at baseline to 0.8 ($n = 19$) at 6-12 M and 0.6 ($n = 11$) at 12-18 M. Mean late-night salivary cortisol (LNSC; xULN) decreased from 3.2 ($n = 13$) at baseline to 1.3 ($n = 9$) at 6-12 M and 1.0 ($n = 6$) at 12-18 M. At 6-12 M and 12-18 M, respectively, 88.9% ($n = 16/18$) and 90.0% ($n = 9/10$) of patients had mUFC ≤ULN, and 44.4% ($n = 4/9$) and 80.0% ($n = 4/5$) had LNSC ≤ULN. Overall, mean systolic blood pressure (SBP; mmHg) decreased over time (baseline, 137.6, $n = 28$; 12-18 M, 118.0, $n = 13$). Mean BMI and HbA_{1c} remained stable over time.

Conclusions: Osilodrostat led to improvements in QoL in patients with Cushing's syndrome, as demonstrated by CushingQoL and PGIC scores. SBP, BMI and HbA_{1c} improved or remained stable over time in most patients. However, some data were limited by small patient numbers.

EP1076 - ECE_2982 - LATS1 and LATS2 are dispensable for pituitary gonadotrope function

Natalia Jakuc[1], Luisina Ongaro[2], Xiang Zhou[2], Ulrich Boehm[3], Daniel Bernard[2], Alexandre Boyer[1], Derek Boerboom[1] and Gustavo Zamberlam[1]

[1]Centre de Recherche en Reproduction et Fertilité (CRRF), Faculté de Médecine Vétérinaire (FMV), Université de Montréal (UdeM), Saint-Hyacinthe, Canada; [2]Department of Pharmacology & Therapeutics, McGill University, Montréal, Canada; [3]Department of Experimental Pharmacology, Center for Molecular Signaling, Saarland University School of Medicine, Homburg, Germany

The Hippo signaling pathway is a highly conserved kinase cascade that regulates vital biological and pathological processes in mammals. The pathway's transcriptional co-activators, Yes-associated protein 1 (YAP) and Transcriptional coactivator with PDZ-binding motif (TAZ), play a central role in mediating these functions, as they represent the final downstream effectors of Hippo signaling.

We recently demonstrated that conditional deletion of YAP and TAZ in murine pituitary gland gonadotrope cells results in increased circulating luteinizing hormone (LH) levels in both sexes. Increased testosterone levels, testicular weight, and sperm concentration

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

were observed in males, while females presented a hyperfertility phenotype characterized by higher ovulation rates and larger litter sizes. Although these findings advanced our understanding of Hippo signaling in gonadotrope cells, the upstream mechanisms regulating YAP and TAZ activity remain to be elucidated.

In the Hippo signaling pathway, the canonical upstream kinases that regulate YAP and TAZ are the large tumor suppressor homolog kinases 1 and 2 (LATS1 and LATS2). To directly assess the role of these kinases in gonadotrope cells, *Lats1* and *Lats2* were conditionally knocked-out in murine gonadotropes using the GnRH receptor–IRES-Cre (GRIC) driver and a ROSA mTmG fluorescent reporter.

Deletion was firstly successful validated by fluorescence-activated cell sorting (FACS)–isolated gonadotropes from 12-16-week-old mice, which showed significant reduction in expression levels of both genes. Serum, gonads, and pituitaries were then collected from 10-12-week-old male mice and 8-10-week-old females at diestrus. Unexpectedly, hormonal analyses indicated no differences between controls and knock-out mice in LH or FSH levels in either males or females. Consequently, no reproductive phenotypic anomalies were observed in either sex. Curiously, RT-PCR analyses of pituitaries showed that YAP/TAZ target genes were not altered following *Lats1* and *Lats2* deletion. Taken together, these results suggest that, unlike many other cell types, YAP and TAZ activity does not appear to be regulated by LATS1 and LATS2 in gonadotropes.

We are currently using bulk RNA sequencing on FACS-sorted gonadotropes from control and knock-out mice to determine if there are unappreciated roles for LATS1 and LATS2 in these cells.

EP1077 - ECE_2070 - Novel insights on the role of putative neuronostatin receptor GPR107 in liver pathophysiology

Antonio García-Estrada[1,2,3], Betsaida Ojeda-Pérez[1,2,3], Amelie Lupp[4], Stefan Schulz[4,5], Raul M. Luque[1,2,6], Juan Luis López-Cánovas[1,2,3] and Manuel D. Gahete[1,2,6]

[1]Maimónides Biomedical Research Institute of Córdoba (IMIBIC), Córdoba, Spain; [2]Department of Cell Biology, Physiology and Immunology, University of Córdoba (UCO), Córdoba, Spain; [3]Reina Sofía University Hospital (HURS), Córdoba, Spain; [4]Institute of Pharmacology and Toxicology, Jena University Hospital (UKJ), Friedrich-Schiller-University (FSU) Jena, Jena, Germany; [5]7TM Antibodies GmbH, Jena, Germany; [6]Reina Sofía University Hospital (HURS), CIBER Physiopathology of Obesity and Nutrition (CIBERobn), Córdoba, Spain

Our understanding of the somatostatin (SST) endocrine system, which is a well-established source of biomarkers and therapeutic targets in neuroendocrine and pituitary tumours, has been lately expanded through the discovery of neuronostatin (NST), a SST-alternative peptide; the identification of its putative receptor, GPR107; and the extensive research on their role in metabolic regulation and prostate and breast cancer. Liver cancer, particularly hepatocellular carcinoma (HCC), is increasingly associated to underlying metabolic disorders, namely metabolic dysfunction-associated steatotic liver disease (MASLD), which challenge current tumour management strategies. In this study, we investigated the NST-GPR107 system in the MASLD-HCC progression to characterise its potential contribution and exploitability in these diseases.

GPR107 expression was evaluated in 2 internal chronic liver disease (CLD)-HCC retrospective cohorts (R1 [$n = 93$], R2 [$n = 102$]), 7 MASLD in silico cohorts ($n = [45\text{-}109]$/cohort), 6 HCC in silico cohorts ($n = [65\text{-}369]$/cohorts) and 4 human liver cell lines (THLE-2, HepG2, Hep3B, SNU-387). NST expression was assayed using ELISA in an additional internal MASLD-CLD-HCC plasma cohort ($n = 88$). In a subset of R1 ($n = 25$), immunohistochemistry (IHC) for GPR107 was performed. Gene set enrichment analysis (GSEA) were employed to link GPR107 expression with hallmark gene sets, metabolic pathways (KEGG, Reactome) and biological processes (GO). In cell lines, the impact of NST application and GPR107 silencing and overexpression was assessed through functional assays (proliferation, wound healing, colony and hepatosphere formation).

The expression of NST and GPR107 was progressively increased in the MASLD-HCC progression, wherein GPR107 was associated with key HCC aggressiveness features (lower portal hypertension and survival, higher microvascular invasion, recurrence and expression of proliferative biomarkers). IHC demonstrated GPR107 cytosolic and membranous presence in HCC cells, where the proliferative tumour borders showed the highest staining. GSEA directly linked GPR107 expression with global expression of cell cycle genes in HCC samples. Accordingly, GPR107 overexpression enhanced, while GPR107 silencing blunted, cancer traits, such as cell proliferation, in HCC cell lines. Moreover, NST showed antiproliferative effects on liver cancer cells, with no effect on healthy hepatocytes (THLE-2). NST addition counteracted the protumoral effects of GPR107 overexpression, whereas the combination of NST and GPR107 silencing enhanced the antitumoral effects.

Altogether, these results support the direct association between GPR107 expression and HCC in a metabolic context through cell cycle modulation, which could be exploited for diagnosis, staging and potential treatment in the rapidly evolving field of liver diseases.

EP1078 - ECE_2325 - Hypophysitis with mixed histiocytosis

Mubina Hodzic[1,2], Amira Jagodić- Ejubovic[3] and Davorka Dautbegovic Stevanovic[1]

[1]Department of Internal Disease, Division of Endocrinology and Diabetology, Cantonal hospital, Zenica, Bosnia and Herzegovina; [2]Department for Internal Diseases, Zenica Cantonal Hospital, Zenica, Bosnia and Herzegovina; [3]Department of Internal Disease, Division of Rheumatology, Cantonal Hospital, Zenica, Bosnia and Herzegovina

A 44- year- old man was hospitalized in 2017. due to symptoms of diabetes insipidus, four months after tympanoplastic surgery of the right ear. Pituitary MRI showed absence of the posterior pituitary bright spot and pituitary stalk thickening. Desmopressin was initiated. One year later, the patient developed erectile dysfunction, low libido, decreased leg hair growth. The laboratory tests revealed low gonadotropins, low testosterone levels, while other anterior pituitary hormones(TSH, ACTH) were preserved. Pituitary MRI demonstrated a 3-mm pituitary microadenoma and persistent pituitary stalk thickening raising suspicion of hypophysitis. Testosterone cypionate replacement therapy, along with desmopressin was prescribed. Subsequently, the patient was rehospitalized for pulse corticosteroid therapy, without improvement in symptoms. In 2025. he reported chronic pain in the legs and arms and unintentional weight loss lasting for two years. He occasionally experienced subfebrile temperature and chills. Inflammatory markers were elevated. The patient

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

recognised similar symptoms in individual with diabetes insipidus and Erdheim-Chester disease through a social media patient support group. A repeat pituitary MRI performed in 2023. Again demonstrated pituitary stalk thickening, without evidence of microadenoma, and an inhomogeneous adenohypophysis. A biopsy of the left knee confirmed mixed histiocytosis(Erdheim-Chester disease and Langerhans cells histiocytosis) with BRAF V 600 mutation, PET/ CT imaging revealed increased metabolic activity in the long bones and lymph nodes of neck and axillary regions. He was hospitalized in Department of Hematology. Targeted therapy with dabrafenib was recommended. Follow-up PET/CT scan after three months showed regression of metabolic activity, accompanied by clinical improvement and decrease in inflamatory markers. Follow-up pituitary MRI showed no dynamic changes. Levothyroxine was initated last month, with a normal cortisol profile.

Keywords hypophysitis, hystiocytosis, diabetes insipidus, Erdheimer Chester disease, dabrafenib

EP1079 - ECE_3679 - Sphenoid fibrous dysplasia presenting with hypopituitarism

Ozge Sahin Kimyon[1], Hayriye Gulsah Ozkan[2], Selin Celik[1], Buruc Erkan[3], Sema Ciftci[1] and Hamide Piskinpasa[1]

[1]Department of Endocrinology and Metabolism, University of Health Sciences, Bakırkoy Dr. Sadi Konuk Training and Research Hospital, Istanbul, Türkiye; [2]Radiology, University of Health Sciences, Bakırkoy Dr. Sadi Konuk Training and Research Hospital, Istanbul, Türkiye; [3]Department of Neurosurgery, University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Istanbul, Türkiye

Introduction: Fibrous dysplasia (FD) is a benign developmental bone disorder characterized by replacement of normal bone with structurally weaker fibro-osseous tissue. It is classified into three clinical forms: monostotic, polyostotic, and McCune–Albright syndrome–associated FD. Craniofacial involvement occurs in approximately 10%-25% of patients with the monostotic form and in up to 50% of those with the polyostotic form. The clinical spectrum is broad, ranging from asymptomatic lesions detected incidentally to symptomatic presentations, including pain, compression-related neurological deficits, and/or facial asymmetry. Here, we present a rare case of sphenoid sinus FD presenting with hypopituitarism.

Case Presentation: A 79-year-old woman was referred to our outpatient clinic for follow-up of a sellar mass lesion. Ten years earlier, she had been evaluated at another center for hyponatremia and was diagnosed with panhypopituitarism and a sellar mass, for which surgical intervention had been recommended. The patient declined surgery and had since been treated with levothyroxine, hydrocortisone. Medical history revealed menopause at the age of 52 years. At presentation, she reported mild headache without additional symptoms. Laboratory evaluation revealed TSH 0.94 mIU/L, free T4 0.96 ng/dL, FSH 4.87 IU/L, estradiol 5 ng/L, prolactin65 µg/L, sodium 138 mmol/L, and potassium4.9 mmol/L. Pituitary magnetic resonance imaging demonstrated a $30 \times 25 \times 20$ mm lesion filling the sellar region, with intermediate signal intensity on T2-weighted images, heterogeneous contrast enhancement, and mild compression of the optic chiasm. Clear differentiation between the lesion and the sphenoid sinus could not be achieved. Paranasal sinus computed tomography performed for differential diagnosis suggested FD as the most likely diagnosis. Bilateral visual field examination was normal. Whole-body bone scintigraphy revealed increased tracer uptake at the sphenoid bone, supporting the diagnosis. The case was discussed at a multidisciplinary pituitary council. Due to optic nerve compression and headache, surgical intervention was recommended; however, the patient again declined surgery. Bisphosphonate therapy was therefore planned.

Discussion: Isolated sphenoid sinus FD is extremely rare. Surgical treatment may be considered in symptomatic patients or those with cosmetic deformities. Although bisphosphonates are effective in controlling pain in adults with polyostotic disease, their role in monostotic FD remains unclear, and they have not been shown to reduce fracture risk or disease progression. Our patient had been followed for years with a presumed sellar mass causing hypopituitarism. Sellar lesions should be carefully evaluated for sphenoid bone involvement, and FD should be included in the differential diagnosis. Diagnosis relies on combined clinical, radiological, and histological assessment.

EP1080 - ECE_1001 - Comparison of the predictive power of morphological and therapeutic stratification predictors of monohormonal somatotroph pituitary tumors in patients with acromegaly

Evgeny Pronin[1], Mikhail Antsiferov[1,2], Vyacheslav Pronin[1,2], Alexey Petraikin[3], Anastasia Lapshina[4], Tatiana Alekseeva[1], Lilia Selivanova[4] and Safi Tamaeva[5]

[1]Moscow Health Department, Endocrinological Dispensary, Moscow, Russia; [2]Ministry of Health of Russia, Russian Medical Academy of Continuing Professional Education, Moscow, Russia; [3]Moscow Health Department, Scientific and Practical Clinical Center for Diagnostics and Telemedicine Technologies, Moscow, Russia; [4]Ministry of Health of Russia, National Medical Research Centre for Endocrinology, Moscow, Russia; [5]Ministry of Health of Russia, National Medical Research Center of Surgery named after A. Vishnevsky, Moscow, Russia

Given the heterogeneity of somatotroph tumors (STs), it is important to study diverse predictors of morphological identification and sensitivity to drug therapy (DT) with first-generation somatostatin receptor ligands (fg-SRLs).

Aim: Comparative analysis of the prognostic significance of predictors of STs pathomorphological status and the prospects for using fg-SRLs in patients with acromegaly.

Materials and Methods: A retrospective analysis of the long-term efficacy of fg-SRLs was conducted in 634 patients with acromegaly (197 men) receiving prolonged forms of lanreotide (120 mg/28-56 days) or octreotide (20-30 mg/28 days) as primary or secondary DT. The IGF-1 index, reflecting the ratio of IGF-1 to the upper limit of normal (IGF-1/ULN), was used for the initial and dynamic assessment of somatotroph function. The criterion for drug control was an IGF-1 index value ≤ 1. The age at diagnosis was 47.9 ± 13.8 years, the baseline IGF-1 index value was 2.7 ± 1.2, the duration of DT was 77.8 ± 52.7 months, and the IGF-1 index value at the last visit was 1.2 ± 0.7. Pharmacotherapeutic testing (PharmT) which consisted of assessing the percentage decrease in IGF-1 levels (%ΔIGF-1) 3 and 6 months after the start

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

of treatment with fg-SRLs was also performed. Treatment outcomes were compared with baseline clinical examination data, PharmT results ($n = 496$), cytological and immunohistochemical analysis data ($n = 104$), as well as quantitative indicators of relative tumor signal intensity (RTSI) on T2- and T1-weighted MRI with an additional calculation of the T2-T1 coefficient ($n = 106$).

Results: Among the markers of morphological stratification of STs, the most informative are: age at diagnosis (AUC 0.686), tumor volume and maximum diameter (0.664 and 0.665), expression of the 2nd subtype of somatostatin receptors (SSTR2; 0.816), the difference and ratio of SSTR2 and SSTR5 (0.826 and 0.808), proportion of cells with antibodies to GH (0.932) and with fibrous bodies (FB; 0.962), tumor cell composition (0.935), RTSI on T2-, T1- and (T2-T1)-weighted MRI (WI; 0.878, 0.822 and 0.918). Predictors of fg-SRLs efficacy include: volume and maximum diameter of STs (0.640 and 0.649), baseline IGF-1 index value (0.637), absolute and relative expression of SSTR2 (0.673, 0.688 and 0.713), proportion of cells with FB (0.698), tumor cell composition (0.742), results of RTSI on T2- and (T2-T1)-WI (0.684 and 0.636) and PharmT (%ΔIGF-1 after 3-6 months—0.840-0.849).

Conclusions: Priority predictors of the morphofunctional status of STs and the long-term effectiveness of fg-SRLs simplifying the differential diagnosis of the relevant histotype and facilitating the management of acromegaly treatment have been identified.

EP1081 - ECE_1342 - Neurophysin-I dynamics upon different pituitary provocation tests in healthy participants

Andi Nikaj[1], Cihan Atila[1], Deborah Rudin[2], Dino Luethi[2], Clara Sailer[3], Bettina Winzeler[4], Sandrine A. Urwyler[1], Julie Celine Refardt[5], Matthias Liechti[2] and Mirjam Christ-Crain[1]

[1]Department of Endocrinology, Diabetology and Metabolism, University Hospital Basel, Basel, Switzerland; [2]Division of Clinical Pharmacology and Toxicology, Department of Pharmaceutical Sciences, University of Basel, Basel, Switzerland; [3]Division of Endocrinology, Diabetes and Hypertension, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States; [4]Department of Endocrinology, Diabetology and Clinical Nutrition, University Hospital Zurich, Zürich, Switzerland; [5]Department of Internal Medicine, Section of Endocrinology, Erasmus Medical Center, Rotterdam, The Netherlands

Background: Oxytocin (OXT) is known for its role in regulating social behaviour, such as emotion recognition and bonding. The evidence for clinically relevant OXT deficiency is constantly increasing, but measurement of OXT is challenging. In contrast, neurophysin-I (NP-I), the carrier protein of OXT, co-released equimolarly, is a stable surrogate biomarker for OXT. This study evaluated OXT and NP-I levels upon four different pituitary provocation tests.

Design: Secondary analysis of four interventional diagnostic trials at the University Hospital Basel, Switzerland.

Methods: Sixty-six participants underwent a pituitary provocation test, 11 the hypertonic saline test, 20 the arginine infusion test, 25 the oral macimorelin test, and 10 the glucagon injection test. Plasma NP-I and OXT were measured at baseline and once plasma sodium level reached ≥150 mmol/L for the hypertonic saline, after 60 min for the arginine infusion, after 60 min, 120 min, and 180 min for the glucagon injection, and after 45 min for the oral macimorelin test. Primary outcome was change from baseline to maximally stimulated NP-I levels.

Results: Median (IQR) NP-I levels increased minimally in response to hypertonic saline (baseline: 55 pM, stimulated: 59 pM, relative median change of −8% [−16, +9]) and significantly to glucagon injection (baseline: 82 pM, stimulated: 94 pM, relative median change of +18% [+7, +28]). Median OXT levels showed similar trends in response to hypertonic saline (baseline: 0.36, stimulated: 0.48, relative median change of +22% [−15, +96]) and to glucagon injection (baseline: 82.7 pg/mL [62.3, 94.3], stimulated: 93.4 pg/mL [87.2, 121], relative median change of +25% [+6, +59]). There were no increases in NP-I plasma levels nor OXT levels upon arginine infusion and oral macimorelin, same for OXT levels.

Conclusions: NP-I showed minimal responses to pituitary provocation tests, paralleling OXT dynamics. These findings highlight NP-I's potential as a reliable and technically robust surrogate biomarker for OXT activity, warranting further evaluation in clinical and experimental settings.

EP1082 - ECE_3435 - A pituitary abscess caused by Moraxella osloensis

Danai Georgakopoulou[1], Andreas Manakis[2], Charikleia Paschalidi[1], Christos Gkolemis[2], Labrini Papanastasiou[1], Athina Markou[1] and Athanasios Fountas[1]

[1]Department of Endocrinology and Diabetes Center, General Hospital of Athens "G. Gennimatas", Athens, Greece; [2]Department of Neurosurgery, General Hospital of Athens "G. Gennimatas", Athens, Greece

Background: Pituitary abscess (PA) is an uncommon, potentially life-threatening, condition which is often indistinguishable from other sellar lesions prior to surgery. In this report, we describe the clinical course of a PA due to Moraxella osloensis.

Case Report: A 31-year-old Greek woman underwent a pituitary MRI due to a 6-month history of secondary amenorrhea and hyperprolactinemia (78.6 ng/mL, normal range 2.8-29.2) which revealed an 8 mm micro-adenoma. Two months later, she presented with severe headache and vomiting. A follow-up MRI showed a cystic lesion with high T2 signal intensity, peripheral contrast enhancement and increased size (13 mm) compared to the previous MRI. CSF analysis revealed merely elevated WBC (80 μL, 85% lymphocytes). The patient was diagnosed with pituitary apoplexy and treatment with high-dose dexamethasone led to significant clinical improvement. She was discharged five days after dexamethasone initiation while being completely asymptomatic. However, few days later, she presented to the emergency department with severe headache, fever (38.5 °C), neck stiffness and bilateral visual field deficits with papilledema. A repeat MRI revealed further size increase of the pituitary cystic lesion (20 mm), optic chiasm compression and leptomeningeal enhancement. Hormonal investigation revealed anterior hypopituitarism with no evidence of diabetes insipidus. CSF analysis showed elevated WBC and protein levels (1858 μL, 98% PMNs, protein 320 mg/dL) as well as hypoglycorachia (glucose 36 mg/dL) indicating purulent meningitis.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Blood cultures were positive for Moraxella osloensis and iv antibiotic treatment with ceftriaxone and metronidazole was initiated. Despite antibiotics, the patient developed right abducens nerve palsy and transient left arm weakness. Transsphenoidal pituitary surgery was performed and a macroscopically purulent fluid collection was removed. Patient's symptoms gradually improved over the first postoperative days and she was discharged after receiving iv antibiotics for a period of 6 weeks. At the 6-month post-operative follow-up no recurrent lesion was depicted.

Conclusions: To our knowledge, this is the first reported PA case associated with Moraxella osloensis, extending the spectrum of central nervous system infections caused by this rarely invasive respiratory commensal. Whether this is a case of secondary PA in which dexamethasone treatment masked its clinical manifestations or a case of a pituitary adenoma apoplexy further complicated by an infection leading to an abscess stills remains a puzzle.

EP1083 - ECE_3451 - Management of Cushing syndrome of different etiologies—a single center real life experience: data from ERCUSYN Krakow database

Mari Minasyan[1], Aleksandra Gamrat-Żmuda[2,3], Wiktoria Suchy[2], Katarzyna Majka[4], Alicja Hubalewska-Dydejczyk[1], Elena Valassi[5,6] and Aleksandra Gilis-Januszewska[1]

[1]Chair and Department of Endocrinology, Jagiellonian University Medical College, Krakow, Poland; [2]Department of Endocrinology, Jagiellonian University Medical College, Krakow, Poland; [3]Doctoral School of Medical and Health Sciences, Jagiellonian University Medical College, Krakow, Poland; [4]Students' Scientific Circle of Department of Endocrinology, Jagiellonian University Medical College, Krakow, Poland; [5]Barcelona, Spain; [6]Universitat Internacional de Catalunya (UIC), Barcelone, Spain

Introduction: Cushing's syndrome (CS) is characterized by chronic exposure to cortisol excess. Regardless of etiology, surgery remains a first line option. Pharmacological antihypercortisolemic therapy is used: as a preoperative management, as a main therapy in patients without option for radical therapy, after unsuccessful surgery or or when the source of CS cannot be identified.

Materials and Methods: A retrospective analysis of data regarding management of CS patients from the ERCUSYN Krakow database The study included 214 patients: 53% with pituitary-dependent CS (PIT-CS), 25% with adrenal CS (ADR-CS), and 22% with ectopic CS (ECT-CS). The median age was 54 years (Q1:38, Q4:65), and 77% of patients were women.

Results: Surgery: Surgery was a main therapeutic option for most patients with PIT-CS(97/114) and ADR-CS(43/47). Among ECT-CS, 15/53 underwent surgery. In PIT-CS the rate of successful surgery to date was 72% with identical relapse rates for microadenomas and macroadenomas (11%). The success rate of reoperation was lower (47%) than in cases of initial operation. In ADR-CS, adrenalectomy was successful for 100% of patients with unilateral adenoma and 18% with bilateral adenomas. Among operated ECT-CS patients (15/53) the success rate was 47% (7/15). Relapses (N:5/15) occurred in medullary thyroid cancer (N:2), atypical lung cancer (N:2) and nasal papilloma (N:1). 3/15 patients did notachieve remission after surgery (pancreatic neuroendocrine tumor N:2, breast cancer N:1). Medical therapy: In PIT-CS: antihypercortisolemic therapy was used preoperatively in 39 patients, due to relapse or non-radical surgery among 20 patients and as a main therapy without radical treatment among 4 patients. The most commonly used medication was ketoconazole (N:27), followed by metyrapone (N:18), osilodrostat (N:18), pasireotide (N:7), relacorilant in clinical trial (N:3), cabergoline (N:1) and etomidate (N:1). In ADR-CS: antihypercortisolemic therapy was used preoperatively among 8 patients and in one patient due to non-radical surgery. The most commonly used medication was ketoconazole (N:4), followed by metyrapone (N:3) and osilodrostat (N:2). In ECT-CS: antihypercortisolemic therapy was used preoperatively among 11 patients,as a main therapy without radical treatment among 13 patients, due to unidentified ectopic source among 5 patients and due to CS relapse or non-radical surgery among 3 patients. The most commonly used medication was metyrapone (N:16), followed by osilodrostat (N:13), ketoconazole (N:13), octreotide (N:2), mitotane (N:2) and relacorilant in clinical trial (N:1).

Conclusions: Presented study showed complexity of care required for optimal control of CS patients. Surgery was a main therapeutic option for most of the patients with PIT-CS and ADR-CS. Antihypercortisolemic medications served a principal role for most of the patients with ECT-CS.

Background: The study aimed to characterize clinico-radiological differences and their impact on post-surgical outcomes in histological subtypes—densely granulated (DGSA) and sparsely granulated (SGSA) somatotroph adenomas (SA).

Methods: A single-centre ambispective study in individuals with SA from 2015 to 2024, where preoperative clinical, hormonal, and magnetic resonance imaging parameters were collected, and biochemical and radiological disease control were assessed postoperatively.

Results: Of 116 SA, 45(38.8%) and 71(61.2%) were DGSA and SGSA, respectively. The median (IQR) age at presentation was 35.0 (29.0-44.0) years, 56.9% were females, 92.2% had macroadenoma, and the mean tumour diameter was 24.9 ± 10.3 mm. The median (IQR) pre-operative nadir GH on OGTT was 31.1 (16.7-50.0) ng/mL, and IGF-1 was 3.7 ± 1.5 times the upper limit of

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

normal. As compared to DGSA, SGSA presented earlier (40.0 vs 33.5 years; $P = .009$), had larger tumor size (2239.4 mm^3 vs 5221.6 mm^3; $P = <.005$), were more invasive (33.3% vs 54.1%; $P = .038$), proliferative (ki-67 Index 1.0% vs 3.0%; $P < .001$), and had higher SSTR5 expression (H score 30.0 vs 80.0; $P = .006$). The post-surgical radiological (19.4% vs 22.8%; $P = .707$) and biochemical (17.2% vs 32.2%; $P = .727$) disease control rates were similar in both groups.

Conclusions: In comparison to DGSA, SGSA presents a decade earlier, are larger in size, more invasive, exhibits higher proliferation, and SSTR5 expression. However, this does not impact post-surgical biochemical and radiological disease control.

EP1085 - ECE_2400 - Demographics aspects of pituitary endocrine tumors according to gender in the city of Oran

Khadra Faraoun

Faculté de Médecine d'Oran, Endocrinology Larribere, Medecine, Sidi Chami, Algeria

Introduction/Objective: Endocrine pituitary tumors, or PitNets, develop from pituitary endocrine structures. Our objective is to evaluate the demographic characteristics of PitNets in Oran according to gender.

Subjects and Methods: Our study is observational, multicenter, prospective, and retrospective. Data entry and analysis were performed using EPI Info version 6 from the CDC (USA) and SPSS 20.

Results: We collected 475 pituitary tumors with 368 secreting pituitary neoplasms (77.5%). The male-to-female ratio was 0.54, $P < .0001$, with a predominance of female involvement (64.6%). The sex ratios were: prolactinomas 0.25, non-functional tumors 1.01, somatotropic tumors 1.36, corticotropic tumors 0.27, and thyrotropic tumors 0.5. The mean age in both sexes was 36.8 ± 14.3 years (range 7-78), with a mean age of 41.2 ± 15.5 years in men and 34.5 ± 13.0 years in women ($P < .001$). Pituitary adenomas were more frequent in individuals between 20 and 40 years of age and much less common at the extremes of age. The modal class is 30-39 years old. The predominance is female between 20 and 40 years old and male between 60 and 70 years old, the difference is not significant. The ages of diagnosis by Tumor are respectively for the two sexes (M, F): Prolactinomas 38.0 ± 12.1(16-76) vs 32.4 ± 11.4(16-78) $P = .004$, Non-functional adenomas 45.2 ± 18.0(7-76) vs 38.9 ± 15.7(10-74)NS, Somatotropic Tm 40.9 ± 15.1(15-67) vs 39.5 ± 14.5 (14-71)NS, Corticotropic Tm 32.7 ± 14.4(8-54) vs 34.5 ± 11.7(16-60)NS, Thyrotropic Tm 22.0 vs 32.8 ± 15.7(23-51)NS. In the mixed somato-lactotropic adenomas listed ($n = 5$), the condition predominates in the male sex, the ratio is 4 men to one woman.

Conclusions: As described in the literature, prolactinomas and corticotropic tumors are predominantly female. In contrast, somatotropic tumors were more frequent in men, although the difference was not statistically significant. The incidence of non-functional adenomas (NFAs) was equivalent in both sexes. Diagnosis in women was made at a younger age than in men across all pituitary tumors. Apart from prolactinomas, there was no significant difference in the age at diagnosis between women and men.

EP1086 - ECE_1685 - The possible role of black blood magnetic resonance imaging sequences in pituitary tumor diagnosis

Pierluigi Mazzeo[1], Giacomo Voltan[1], Giulia Bovo[1], Filippo Ceccato[1], Renzo Manara[2] and Mattia Barbot[1]

[1]*Department of Medicine - DIMED, Endocrinology Unit, Padova University Hospital, Padova, Italy;* [2]*Department of Neuroscience, Neuroradiology Unit, University of Padova, University-Hospital of Padova, Padova, Italy*

Background: In the diagnosis of pituitary tumors, especially in Cushing's disease (CD), conventional MRI could be inconclusive, forcing clinicians to perform invasive tests like Inferior Petrosal-Sinus Sampling (IPSS) and exploring surgery. The black-blood (BB) MRI sequences are widely used in the diagnostic workup of several conditions including brain tumors, because the suppression of fast-flowing blood signal improves the identification of surrounding tissues, helping to differentiate tumoral lesions from vascular structures that could look similar on standard imaging. However, the role of BB in the diagnosis of pituitary adenomas has not been fully assessed.

Aim of the Study: to evaluate the potential utility of BB-MRI sequences in the diagnostic workup of pituitary adenomas.

Patients: from January 2023, 3T MRI with BB sequences was performed in 20 patients whose MRI findings remained inconclusive despite evaluation by an expert pituitary neuroradiologist within a dedicated multidisciplinary pituitary disease meeting. Among them, 4 patients with CD had undetectable lesion, 11 cases had doubtful findings and 5 patients were reported to have two lesions. The final clinical diagnoses were CD ($n = 14$), acromegaly ($n = 2$), prolactinoma ($n = 2$), NFPA ($n = 1$) and suspected pituitary metastasis ($n = 1$).

Results: BB-MRI sequences provide further diagnostic information in 16/20 cases and in 7 cases the final report was completely revised. Among patients with suspected double lesions, the diagnosis was confirmed in 2 cases, while in 2 patients only one lesion was reported, and they underwent transsphenoidal surgery (TSS) with histological confirmation of corticotroph PitNET; instead, in the remaining patient no lesion was described and IPSS was scheduled. In the group with doubtful lesions, the diagnosis was confirmed in 7 patients, 3 of whom underwent TSS. In 2 patients (a prolactinoma and a suspected NFPA), respectively the lesions were re-classified as Rathke's cleft cyst and partial volume artifact, while in the other 2 cases MRI remained inconclusive. In the group with negative MRI, a microadenoma was identified, with histological confirmation of corticotroph PitNET after TSS. However, MRI persisted negative in one patient and in 2 cases were still considered doubtful (one patient continued medical treatment, while one person underwent TSS with negative histology).

Conclusions: BB-MRI sequencing is a simple and non-invasive tool which could be helpful in the diagnostic workup of unclear pituitary lesions. However, given the small sample size and potential bias in patient selection, further studies are needed to better define its clinical impact.

EP1088 - ECE_2431 - Surgical outcomes of nonfunctioning pituitary neuroendocrine tumors based on transcription factor expression

Jun Sugata, Shingo Fujio, Ryutaro Makino, Tomoko Hanada and Ryosuke Hanaya
Kagoshima, Japan

Background: Transcription factor immunostaining for pathological diagnosis is now recommended in the WHO classification over traditional anterior pituitary hormone staining for nonfunctioning pituitary neuroendocrine tumors (NF-PitNETs). This study retrospectively evaluated surgical outcomes of NF-PitNETs treated at our institution, reclassifying tumor specimens according to transcription factor expression patterns.

Methods: Two hundred one treatment-naïve patients with NF-PitNETs resected between 2012 and 2023 were analyzed. Tissue microarrays were constructed from formalin-fixed paraffin-embedded or frozen specimens for immunohistochemical analysis of SF1, TPIT, and PIT1.

Results: Median age was 64 years; 56.7% were male. Preoperatively, the median tumor volume was 5.1 cm^3, 62.2% of tumors were Knosp grade 0-2, 53.9% had severe growth hormone deficiency, and the median IGF-1 level was −1.74 SD. Gross total resection was achieved in 61.7%. During postoperative follow-up, regrowth of residual tumor occurred in 18.9%, and de novo recurrence was observed in 1.5%. Transcription factor analysis revealed SF1-only positivity in 70.2%, TPIT-only in 19.4%, PIT1-only in 3.0%, dual SF1/PIT1 positivity in 2.0%, and triple negativity in 5.5%. Compared with the SF1 group, the TPIT group demonstrated significantly higher female predominance (92.3% vs 30.5%, $P < .001$), lower preoperative severe GHD prevalence (25% vs 59.6%, $P = .03$), higher preoperative IGF-1 SD (−0.90 vs −1.83, $P < .001$), and higher reoperation rate (12.8% vs 0.7%, $P = .019$). Tumor volume, Knosp grade, and surgical complication rates did not differ significantly among groups.

Conclusions: Refined pathological subtyping based on transcription factor immunostaining may enable improved prognostic stratification and better surgical outcomes in NF-PitNETs.

EP1090 - ECE_2862 - Clinical characteristics and therapeutic efficacy analysis of prolactinoma in children and adolescents

Huaiying Wang and Huiwen Tan
Department of Endocrinology and Metabolism, West China Hospital, Chengdu, Sichuan Province, China

Objective: This retrospective cohort study aimed to characterize clinical features and treatment outcomes of pediatric and adolescent prolactinoma patients (≤20 years) treated between 2019 and 2026, providing evidence-based guidance for clinical management.

Methods: We analyzed demographic, clinical, tumor, and treatment data from 69 patients, including gender differences in presentation and outcomes.

Results: The cohort included 55 females (79.7%) and 14 males (20.3%), with a median age of 17.0 years. Median tumor diameter was 1.5 cm, with 63.3% macroprolactinomas and 8.3% giant tumors; median baseline prolactin (PRL) was 320.85 ng/mL. Males had significantly larger tumors (2.9 cm vs 1.3 cm, $P < .001$) and higher PRL levels (573.7 vs 313.0 ng/mL, $P = .013$) than females. Most females (86.7%) presented with menstrual disorders, whereas males primarily had headache (44.4%) and visual field defects (33.3%). Galactorrhea occurred in 17.5% of patients. Dopamine agonists (DAs) were first-line therapy for 61 patients, with 19.7% developing resistance. Thirteen patients underwent surgery, achieving 46.2% long-term remission; tumor size was independently associated with worse surgical outcomes ($P = .047$).

Conclusions: Pediatric prolactinoma shows marked gender disparities: males exhibit larger tumors, higher PRL, and neurological symptoms, while females present with endocrine dysfunction. DAs remain first-line therapy, and surgery is reserved for selected cases, with tumor size predicting surgical efficacy. Early, personalized treatment optimizes outcomes.

EP1091 - ECE_3001 - Pituitary apoplexy over the last 10 years: a retrospective study at a tertiary care centre

Smritimayee Panda[1], Subhash Yadav[1], Awadhesh Jaiswal[2] and Preeti Dabadghao[2]
[1]*Endocrinology, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India;* [2]*Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Science, Lucknow, India*

Background: Pituitary apoplexy is an emergency condition requiring prompt diagnosis and management. It commonly occurs in the presence of a pituitary adenoma. Symptoms include severe headache, visual impairment, vomiting, cranial nerve palsy, and altered sensorium. We are describing 10 years of clinical data and outcomes for patients with pituitary apoplexy managed in our hospital.

Aim: To analyze the 10-year clinical profile and outcome of pituitary apoplexy in a tertiary care hospital

Methodology: Retrospective data on patients with pituitary apoplexy admitted to SGPGIMS (from January 2014 to December 2023) were obtained from electronic medical records. Relevant clinico-radiological, hormonal parameters, management, and outcome details were analysed.

Results: Forty-six patients with symptomatic pituitary apoplexy presented to our hospital from January 2014 to December 2023. Among them, 25 (54%) were male. Forty-four (96%) patients had pituitary adenoma, and only 7 (16%) were functional. One patient had a tubercular granuloma, and one had septic shock leading to apoplexy. The most common presenting symptom was headache, accompanied by visual disturbance, in 43 (94%) patients. Eleven patients (24%) had cranial nerve palsy. Forty (87%) had hypocortisolism, 33 (72%) had hypothyroidism, 27 (59%) had hypogonadism, and 6 (13%) had diabetes insipidus. Seventeen (37%) patients required surgery within 2 weeks of presentation, 13 (28%) underwent surgery later, and 16 (35%) didn't require surgery. Patients who had deterioration in sensorium or vision were taken for immediate surgery. Two patients died within 2 weeks of presentation, and 44 (95%) patients

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

survived the acute event. At 6-month follow-up, 44 patients survived, and none had recovery of the anterior pituitary hormonal axis.

Conclusions: In conclusion, the study indicates that there is no notable difference in neurohormonal outcomes between patients who underwent surgery and those managed conservatively.

EP1092 - ECE_3505 - Adult follow-up of patients with pituitary stalk interruption syndrome: a tertiary single-center experience

Zeynep Elüstü Belten[1], Ozge Sahin Kimyon[1], Bahar Atasoy[2], Hamide Piskinpasa[1], İlkay Çakir[1], Meral Mert[1] and Sema Ciftci[1]

[1]Endocrinology and Metabolism, Sağlık Bilimleri Üniversitesi Bakırköy Doktor Sadi Konuk Eğitim Ve Araştırma Hastanesi, Bakırköy, Türkiye; [2]Radiology, Sağlık Bilimleri Üniversitesi Bakırköy Doktor Sadi Konuk Eğitim Ve Araştırma Hastanesi, Bakırköy, Türkiye

Objective: Pituitary stalk interruption syndrome(PSIS) is a rare congenital anomaly characterized by absence or interruption of the pituitary stalk, hypoplasia of the anterior pituitary, and ectopic localization of the posterior pituitary, and is commonly associated with multiple pituitary hormone deficiencies. This study aimed to characterize the clinical, hormonal, and radiological features of patients with PSIS followed at a tertiary referral center.

Methods: Fourteen patients diagnosed with PSIS and followed at our center were retrospectively evaluated. Data regarding birth and family history, perinatal complications, clinical presentation, hormonal status, laboratory findings, MRI characteristics, and treatment modalities were collected and analyzed.

Results: The study included 14 patients (8 males, 6 females) with a mean age of 28.7 years. Age at diagnosis ranged from 2 to 22 years. The mean follow-up duration was 67.1 months. Twelve patients were diagnosed during childhood and two during adulthood. A family history of PSIS was present in two patients, and parental consanguinity was reported in three. Perinatal complications were documented in eight patients. Short stature was the most common presenting complaint; other presentations included constipation, amenorrhea, delayed puberty, and seizures. Dysmorphic facial features were observed in two patients, and several patients had additional structural abnormalities of the central nervous system. Growth hormone (GH) therapy was administered to all patients except three, and all but one female patient diagnosed in adulthood achieved their target height. Hormonal evaluation revealed combined GH deficiency, secondary adrenal insufficiency, central hypothyroidism, and hypogonadotropic hypogonadism in 13 patients. One patient had isolated GH deficiency accompanied by hypogonadotropic hypogonadism. None of the patients exhibited clinical diabetes insipidus, while mild hyperprolactinemia was detected in six patients. MRI demonstrated a mean pituitary height of 2.52 mm. The pituitary stalk was interrupted in two patients, thin in one, and not visualized in eleven. The posterior pituitary was ectopically located at the median eminence in thirteen patients and was not identified in one. Metabolic evaluation revealed hepatosteatosis and hyperlipidemia in ten patients each. Bone mineral density was lower than expected for age in five patients. Four patients expressed fertility expectations, and one achieved a successful pregnancy resulting in a healthy child.

Conclusions: Although PSIS is most frequently diagnosed during childhood, diagnosis may be delayed until adulthood. Timely initiation of appropriate hormone replacement therapy facilitates achievement of target height. Given that adequate hormone replacement dosing and regular monitoring are crucial for preventing complications, long-term follow-up under the supervision of adult endocrinologists is essential.

EP1093 - ECE_3508 - Are the patients with prolactinomas truly resistant to dopamine agonists or treated with too low doses?– single-center observational study

Maria Aleksandra Komisarz-Calik[1,2], Anna Bogusławska[1], Aleksandra Gamrat-Żmuda[1,2], Mari Minasyan[1], Beata Piwońska-Solska[1], Jacek Kunicki[3], Grzegorz Zielinski[4], Agata Faron-Górecka[5], Alicja Hubalewska-Dydejczyk[1] and Aleksandra Gilis-Januszewska[1]

[1]Department of Endocrinology, Jagiellonian University Medical College, Kraków, Poland; [2]Doctoral School of Medical and Health Sciences, Jagiellonian University Medical College, Kraków, Poland; [3]Maria Sklodowska-Curie National Research Institute of Oncology, Warszawa, Poland; [4]Department of Neurosurgery, Military Institute of Medicine, Warsaw, Poland; [5]Maj Institute of Pharmacology, Polish Academy of Sciences, Kraków, Poland

Objective: Cabergoline (CAB) is the first-line therapy for prolactinomas; however, a substantial proportion of patients fail to achieve normoprolactinemia or adequate tumor shrinkage. If not reimbursed, CAB remains an expensive medication, especially in high doses. The aim of this study was to assess treatment outcomes in patients with prolactinoma treated with CAB, evaluating whether low CAB doses may contribute to the high prevalence of apparent resistance.

Methods: 125 patients with prolactinoma treated with CAB were evaluated; 85 patients with a median follow-up of 52 months were included in further analyses. Clinical, biochemical, and radiological parameters were assessed at baseline, 6, and 12 months. Resistance was defined as failure to normalize serum prolactin (PRL) concentration or to achieve ≥30% reduction in maximal tumor diameter after at least 6 months of standard CAB therapy. Responders were patients who achieved both normoprolactinemia and ≥30% tumor diameter reduction after ≥6 months of CAB treatment, irrespective of the administered dose. Patients not meeting criteria for either response or resistance were classified as partial responders.

Results: Among 125 patients (73 males, 52 females), only 34 (27.2%) received CAB doses ≥2.0 mg/week at any time during follow-up. In the subgroup of 85 included patients, the maximal CAB dose during the first 6 months ranged from 0.25 to 4.0 mg/week (1.0 mg/week, IQR 0.75-2.0), and during 12 months from 0.25 to 4.5 mg/week (1.0 mg/week, IQR 0.75-2.0). At 6 months, 29.4% of patients were resistant, 7.1% responders, 63.5% partial responders; at 12 months, 31.8% were resistant, 10.6% responders, and 57.6% partial responders. Patients classified as resistant received significantly higher CAB doses than non-resistant patients at 6 and 12 months, yet these doses remained relatively low compared with guideline-recommended maximal doses. Higher

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

doses of CAB at 6 and 12 months correlated with higher reduction in tumor volume at 6 (rho = 0.443; rho = 0.384; $P < .001$) and 12 months (rho = 0.416; rho = 0.364, $P < .001$), respectively. Male patients received higher CAB doses than females at both follow-up visits (12 months: 1.5 mg/week (IQR = 1.0-2.5 mg/week) vs 1.0 mg/week (IQR = 1.0-1.5 mg/week), $P = .002$), respectively.

Conclusions: A high proportion of patients were classified as resistant and partial responders to CAB. This appears to be largely driven by the widespread use of low CAB doses. The lack of reimbursement and high cost of CAB likely limited dose escalation, contributing to apparent resistance rather than true pharmacological unresponsiveness.

EP1094 - ECE_3951 - Clinical course of non-functioning pituitary adenomas: insights from a retrospective single-center study

Alessandro Bavaresco, Filippo Ceccato, Pierluigi Mazzeo, Alberto Madinelli, Giulia Bovo, Irene Tizianel and Mattia Barbot
Endocrinology Unit, Padua, Italy

Background: Non-functioning pituitary adenomas (NFPAs) represent the most common subtype of pituitary macroadenomas and common finding among microadenomas. NFPAs show in a wide range of clinical behaviours, from clinically silent to compressive symptoms or hypopituitarism. Despite advances in surgery and radiotherapy techniques, optimal management of NFPAs remains debated, particularly finding reliable predictors of growth or recurrence.

Objective: This study aimed to evaluate the clinical, radiological, and histopathological features of NFPAs and to analyze their long-term natural history in patients managed conservatively or treated surgically, with or without adjuvant therapies. Prognostic factors associated with tumor progression and clinical outcomes were also investigated.

Methods: A retrospective single-centre study was conducted on 170 patients diagnosed with NFPA, all of whom underwent long-term clinical and radiological follow-up. Both patients under active surveillance and those who underwent transsphenoidal surgery, with or without adjuvant treatments, were included.

Results: Radiological progression occurred in 27.8% of patients in active surveillance. Probability of growth at 5 years was higher in macroadenomas (45.7%) compared with microadenomas (22.5%) ($P = .030$). Larger tumor volume was a significant predictor of progression ($P = .004$), like visual field defects ($P = .008$). Tumor progression was also linked to a higher incidence of new-onset hypopituitarism ($P = .035$). In the surgical cohort, the presence of any residual tumor significantly raised the risk of progression ($P = .019$), while visual improvement was linked to a reduction of more than 40% in tumor volume ($P = .010$). No significant correlation was found between proliferative markers (Ki-67, p53, mitotic count) and progression. Tumor shrinkage after reoperation was significantly lower compared with initial surgery ($P = .017$). Stereotactic radiosurgery achieved disease stability in 88% of treated patients, while temozolomide resulted in stabilization in two of three cases. Male patients presented with larger tumors and more frequent visual and endocrine impairment, but no sex-related differences in progression rates were observed.

Conclusions: Active surveillance is a safe approach for asymptomatic patients, while surgery remains the treatment of choice in symptomatic tumors or those showing growth. Surgery provides prompt and effective visual improvement and local tumor control; however, postoperative hypopituitarism occurs in approximately one-third of cases. Complete surgical resection is the most reliable predictor of long-term tumor control, while proliferative markers appear to have limited prognostic value.

Abstract citation ID: lvag096.1357

EP1095 - ECE_1623 - Continuous glucose monitoring in idiopathic postprandial syndrome: benefit or burden?

Sanda Cho, Tahir Omer, Rawia Adoma, Rachel Si Jing Tan and William Braithwaite
Diabetes and Endocrinology, Bedford Hospital, Bedford, United Kingdom

Background: Idiopathic postprandial syndrome (IPS) is characterised by postprandial symptoms suggestive of hypoglycaemia occurring despite normal plasma glucose levels. The condition is uncommon, diagnostically challenging, and frequently associated with health anxiety and symptom fixation. With increasing availability of continuous glucose monitoring (CGM) devices outside clinical settings, there is growing concern that their use in individuals without diabetes may contribute to misinterpretation of glucose data and unnecessary medical intervention.

Case Presentation: A 48-year-old schoolteacher presented with recurrent hypoglycaemia-like symptoms including tremor, dizziness, diaphoresis, muscle twitching, and anxiety, predominantly in the postprandial period. She also reported cyclical exacerbation of symptoms around ovulation. The patient had independently obtained a CGM device, which reportedly demonstrated recurrent glucose readings below 2.0 mmol/L coinciding with symptoms. On this basis, true hypoglycaemia was initially suspected. Comprehensive evaluation was undertaken. Biochemical investigations including thyroid function, serum cortisol, liver and renal function, anterior pituitary hormone profile, HbA1c, and 24-hour urinary catecholamines, metanephrines, and 5-hydroxyindoleacetic acid were unremarkable. Cross-sectional abdominal imaging demonstrated normal pancreatic and adrenal anatomy. Crucially, both a supervised 72-hour fast and a mixed-meal test failed to demonstrate fasting or postprandial hypoglycaemia, supporting a diagnosis of idiopathic postprandial syndrome. Despite objective evidence excluding hypoglycaemia, the patient remained convinced her symptoms were glucose-mediated, a belief reinforced by CGM readings. Dietary modification was advised, and treatment with acarbose resulted in modest symptomatic improvement. Persistent distress and preoccupation with CGM data prompted referral for specialist neuroendocrine review.

Discussion: This case highlights the potential unintended consequences of CGM use in individuals without diabetes. While CGM can be a useful tool to exclude hypoglycaemia, its reduced accuracy in the hypoglycaemic range and lack of validation in non-diabetic populations may lead to false low readings. In susceptible individuals, this can reinforce maladaptive illness beliefs,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

contribute to functional endocrine disorders, and drive extensive and unnecessary investigations. Careful clinical correlation and biochemical confirmation remain essential. Management of IPS should focus on patient education, reassurance, and dietary strategies, with limited pharmacological options such as alpha-glucosidase inhibitors. Clinicians should be mindful of the psychological impact of CGM data and the risk of harm from over-monitoring.

EP1096 - ECE_1365 - Oral urea for SIADH in chronic critical illness: preserving nutrition without hemodynamic compromise

Ane Azketa[1], Pol Candela[1], Mercè Serra[1], Marina Sisó[1], Miquel Blasco[2,3], Sara Torrejón[1], Pere Leyes[1,2] and Adriana Pané[1,2,4]

[1]Endocrinology and Nutrition Department, Hospital Clínic, Barcelona, Spain; [2]Facultat de Medicina i Ciències de la Salut, Universitat de Barcelona (UB), Barcelona, Spain; [3]Nephrology and Kidney Transplantation Department, Hospital Clínic, Barcelona, Spain; [4]Centro de Investigación Biomédica en Red de la Fisiopatología de la Obesidad y Nutrición (CIBEROBN), Instituto de Salud Carlos III (ISCIII), Madrid, Spain

Background: Hyponatremia is the most frequent electrolyte disorder in critically ill patients and carries significant prognostic impact. In the setting of chronic critical illness, syndrome of inappropriate antidiuretic hormone secretion (SIADH) often becomes persistent due to sustained non-osmotic stimuli such as systemic inflammation, prolonged mechanical ventilation, and postoperative cardiac dysfunction. Conventional treatment strategies—including fluid restriction, sodium supplementation, and vasopressin receptor antagonists—may be ineffective or unsafe, particularly when high nutritional requirements and hemodynamic fragility coexist.

Case Presentation: We report the case of a 59-year-old man with multiple metabolic comorbidities admitted for native-valve infective endocarditis due to *Staphylococcus capitis*, complicated by a left ventricular outflow tract pseudoaneurysm. He underwent highly complex cardiac surgery with aortic valve replacement, pseudoaneurysm repair, venoarterial extracorporeal membrane oxygenation support, and delayed chest closure. The postoperative course was marked by severe biventricular dysfunction, pulmonary hypertension, prolonged mechanical ventilation, and a prolonged ICU stay (>4 months), evolving into chronic critical illness. During ICU stay, the patient developed hypoosmolar euvolemic hyponatremia (nadir serum sodium 122 mEq/L) consistent with SIADH. The clinical relevance of SIADH became evident during the transition from prolonged parenteral nutrition to enteral nutrition. Caloric targets were set at 1700-2000 kcal/day (25-30 kcal/kg/day, ideal body weight 68 kg). Severe diarrhea related to postatrophic malabsorption required progression from standard to oligomeric and finally elemental enteral formulas (0.86 kcal/mL), resulting in a high obligatory fluid load that made fluid restriction unfeasible. Recent cardiac surgery and ventricular dysfunction limited sodium supplementation (>2 g/day) and discouraged the use of vasopressin receptor antagonists.

Intervention and Results: Oral urea was initiated at 15 g/day via gastrostomy as a water-sparing osmotic strategy. This approach enabled effective free-water excretion without compromising nutritional delivery or hemodynamic stability. Serum sodium increased gradually (1.5-2 mEq/L/day), reaching 130 mEq/L within 72 hours and normalizing to 140 mEq/L at discharge, without neurological complications or cardiac decompensation. Importantly, oral urea allowed maintenance of elemental nutrition until gastrointestinal recovery permitted transition to a higher-caloric-density peptide-based formula with reduced volume requirements.

Conclusions: This case highlights oral urea as an effective, safe, and underutilized therapeutic option for SIADH in chronic critically ill patients, particularly when nutritional requirements and fluid restriction are in conflict. A nutrition-centered approach is essential for successful electrolyte management and functional recovery in this population.

EP1098 - ECE_3144 - Ectopic dissemination of adamantinomatous craniopharyngioma following surgical drainage?

Francisca Leitão H., Vera Teixeira, Diogo Pinto, Denil Tribovane, Miguel Marques, Daniel Duarte, Marta Almeida, Henrique Vara Luiz, Maria Carlos Cordeiro, Ana Cristina Rios and Rosa Couto

Unidade Local de Saúde de Almada-Seixal, Almada, Portugal

Introduction: Craniopharyngioma are rare epithelial tumors derived from remnants of Rathke's pouch, with an annual incidence of 0.5-2 cases per million. Despite their benign histology, craniopharyngiomas may cause symptoms through compression of adjacent structures. Two histological variants are recognized: adamantinomatous and papillary. The standard treatment is surgical resection, with or without adjuvant radiotherapy. However, craniopharyngiomas have a high recurrence rate. While local recurrence is common, dissemination along the surgical tract or through cerebrospinal fluid (CSF) pathways are exceedingly rare, with only isolated cases reported, often following intraoperative cyst rupture or drainage procedures.

Case Report: We report a case of a currently 28-year-old male diagnosed with a sellar/suprasellar craniopharyngioma at 22 months of life after presenting with headaches. He underwent craniotomy surgery at that time, achieving gross total resection, and histological examination confirmed adamantinomatous craniopharyngioma, grade 1 (WHO2021). At 4 years of age, the patient had a tumor recurrence requiring a second craniotomy surgical resection, followed by adjuvant radiotherapy at 5 years of age, with subsequent remission. Eight years later, at 13 years-old, he presented with somnolence, vomiting, and morning headaches. Sellar MRI revealed a marked cystic recurrence associated with mild supratentorial hydrocephalus. A left pterional craniotomy was performed, achieving partial resection of the calcified component and drainage of a multiseptated cyst within the prechiasmatic and left optocarotid cisterns, followed by placement of an intratumoral catheter connected to a subgaleal Ommaya reservoir. Postoperative MRI revealed new cisternal lesions (prepontine, pontocerebellar, and retroclival), consistent with tumor seeding. The patient was closely followed and at 19 years-old, due to lesion progression he underwent a

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

suboccipital craniotomy with resection of lesions in the basal cisterns. Intraoperatively, removal of the catheter was attempted but was not feasible due to dense adhesions. Histopathology analysis confirmed adamantinomatous craniopharyngioma with nuclear beta-catenin positivity (CTNNB1 mutated). Further progression involving the cystic and ectopic cisternal components required Gamma Knife radiosurgery via a suboccipital approach at 25 years-old. Currently, residual tumor persists in both sellar and deep cisternal regions and is under regular follow-up. The patient developed panhypopituitarism and remains under hormone replacement therapy with levothyroxine, hydrocortisone, testosterone, and desmopressin.

Conclusions: This case illustrates the therapeutic challenges of adamantinomatous craniopharyngioma, a tumor prone to recurrence despite multiple surgical and adjuvant treatment modalities. The occurrence of tumor dissemination following Ommaya reservoir placement supports the possibility of viable tumor cell migration after surgical manipulation. Therefore, careful imaging surveillance and multidisciplinary management are essential.

EP1099 - ECE_3546 - Multiadenomatous hypophysitis: a case report

Chayma Besrour[1], Wiem Helali[2], Hiba Bettaieb[3], Manel Boudokhane[3], Rim Bourguiba[2] and Syrine Bellakhel[2]
[1]*Endocrinology, Internal Security Forces Hospital Marsa, Tunis, Tunisia;* [2]*Internal Medecine, Internal Security Forces Hospital Marsa, Tunis, Tunisia;* [3]*Rhumatology, Internal Security Forces Hospital Marsa, Tunis, Tunisia*

Introduction: Hypophysitis is a rare autoimmune disease, corresponding to a chronic inflammation of the pituitary gland, the pathogenesis of which is complex and still poorly understood. It more frequently affects women. In rare cases, it can be caused by immunosuppressive treatment.

Case Report: Herein we report the case of a 35 years old patient with a medical history of an acute myelomonocytic leukemia treated with an immunosupressor “Cyclophosphamide” and an induced bilateral optic neuropathy as a side effect of the treatment. Laboratory investigations showed a low cortisol level confirmed twice at 139 nmol and 140 nmol (140-360 nmol/L) with an ACTH level 50.79 ng/mL (Upper normal limit 63.3 ng/mL). The exploration of the other pituitary axes did not show any abnormalities (FT4 8.67 pmol/L [7-14], TSH 4.42 U/L[0.34-4], Prolactin 9.47 ng/mL <20). The Pituitary MRI revealed Three small lesions suggestive of microadenomas. One anteromedial lesion 3.4 × 2.5 mm, one right Para median lesion 3.4 × 2 mm and one right posterolateral lesion 1.6 × 2 mm The diagnosis of corticotropic insufficiency secondary to hypophysitis was made and the patient was put on hydrocortisone

Discussion: Multiadenomatous hypophysitis is a rare condition where multiple pituitary adenomas, benign tumors of the pituitary gland, coexist. Cyclophosphamide, an immunosuppressive agent used to treat several conditions, can also cause side effects, including autoimmune complications such as hypophysitis and ocular complications such as optic neuropathy. These two complications are very rare, and their coexistence is even rarer. Careful monitoring of patients receiving immunotherapy is essential. Regular screening of pituitary function (ACTH, cortisol, TSH, free T4) before each immunotherapy cycle can help detect hypophysitis early. Patient education about the signs and symptoms of hypophysitis is also crucial to enable prompt and effective management.

Abstract citation ID: lvag096.1361

EP1100 - ECE_3550 - Partial empty sella as a delayed sequela of childhood meningitis: a case report

Müge Keskin[1], Fatma Yörük Durmaz[1], Nefise Özen[2], Arzu Or Koca[1] and Mustafa Cesur[3]
[1]*Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Endocrinology and Metabolism, University of Health Sciences, Ankara, Türkiye;* [2]*Dr. Abdurrahman Yurtaslan Ankara Oncology Training and Research Hospital, Internal Medicine, University of Health Sciences, Ankara, Türkiye;* [3]*Department of Endocrinology and Metabolic Diseases, Ankara Güven Hospital, Ankara, Türkiye*

Background: Empty sella is a radiological condition characterized by herniation of cerebrospinal fluid (CSF) into the sella turcica, leading to compression and flattening of the pituitary gland. It may be primary or secondary, the latter most commonly occurring after pituitary surgery, radiotherapy, apoplexy, or central nervous system infections. Childhood meningitis is an established but often underrecognized cause of secondary empty sella, with pituitary structural and functional consequences that may manifest years or decades after the acute infection. We report a case of partial empty sella detected during the evaluation of low insulin-like growth factor-1 (IGF-1), highlighting the potential long-term impact of childhood meningitis on pituitary integrity.

Case Presentation: A 51-year-old woman presented with progressive fatigue lasting three months. Her medical history was notable for bacterial meningitis during infancy. She had no history of pituitary surgery, cranial radiotherapy, head trauma, or postpartum hemorrhage, and no family history of pituitary disease. Physical examination was unremarkable except for low-normal blood pressure (100/50 mmHg), with no visual field defects or clinical signs of overt hypopituitarism. Laboratory evaluation revealed low age-adjusted IGF-1 levels (65-78 ng/mL; reference range 90-250 ng/mL), with a basal growth hormone level <1 ng/mL. Other pituitary axes were preserved, including TSH 1.8 mIU/L, free T4 1.1 ng/dL, prolactin 12 ng/mL, morning cortisol 14.6 µg/dL, and ACTH 28 pg/mL. Gonadotropins were appropriate for menopausal status (LH 32 IU/L, FSH 58 IU/L, estradiol 18 pg/mL). Serum sodium, glucose, and potassium levels were within normal ranges. Pituitary magnetic resonance imaging demonstrated CSF filling of the sella with flattening of the pituitary gland to a height of approximately 3 mm, consistent with partial empty sella.

Conclusions: Childhood meningitis may lead to delayed secondary partial empty sella in adulthood, occasionally presenting with subtle or subclinical endocrine abnormalities. Post-inflammatory alterations in CSF dynamics may contribute to progressive pituitary compression. Targeted hormonal evaluation and sellar imaging should be considered in symptomatic patients or those with unexplained biochemical abnormalities to prevent missed pituitary dysfunction.

EP1101 - ECE_3743 - Persistent obstructive sleep apnea despite ENT management: when endocrinology makes the diagnosis

Alma Badnjevic-Cengic, Mubina Hodzic and Amila Čerim-Aldobašić
Department of Internal Medicine with Hemodialysis Cantonal hospital Zenica, Department of Endocrinology and Diabetes, Cantonal Hospital Zenica, Zenica, Bosnia and Herzegovina

Background: Obstructive sleep apnea (OSA) is commonly attributed to upper airway anatomical abnormalities and is primarily managed within ENT practice. However, endocrine disorders, particularly acromegaly, may represent an underlying and frequently overlooked cause. OSA may precede the classical phenotypic features of acromegaly for several years, leading to delayed diagnosis and increased morbidity.

Case presentation: A 46-year-old male was admitted to the Department of Endocrinology at Cantonal Hospital Zenica for evaluation of suspected acromegaly accompanied by clinical signs of secondary hypogonadism. The patient reported a four-year history of subjective sleep apnea episodes and dysphonia. OSA had previously been confirmed by polysomnography, and treatment with a positive airway pressure device had been initiated. Physical examination revealed coarse facial features with pronounced mandibular enlargement, enlarged tonsils and uvula, and arterial hypertension. Laboratory investigations demonstrated markedly elevated insulin-like growth factor 1 (IGF-1) at 931 ng/mL and growth hormone (GH) level of 9.36 mIU/L. Total testosterone was reduced (3.88 ng/mL), FSH 5.9 mIU/mL, LH 1.9 mIU/mL, consistent with secondary hypogonadism. Thyroid function tests were within reference ranges (TSH 1.22 mIU/mL, FT4 1.02 ng/dL), while prolactin was mildly elevated (530 mIU/L). Basal insulin was increased (29 mU/L), with normal fasting plasma glucose (5.3 mmol/L). Morning ACTH (8.7 pg/mL) and cortisol (161 nmol/L) levels indicated preserved hypothalamic–pituitary–adrenal axis function. Echocardiography excluded cardiac hypertrophy, while scrotal ultrasound revealed a left-sided spermatocele. Pituitary magnetic resonance imaging demonstrated an enlarged pituitary gland with a left-sided expansile lesion extending ventrolaterally into the sphenoid bone, associated with widening and deepening of the sella turcica. The lesion measured $11 \times 11 \times 13$ mm and was isointense with pituitary parenchyma, consistent with a pituitary adenoma. The patient initially underwent tonsillectomy, followed one month later by transsphenoidal surgery of the pituitary lesion. Histopathological examination confirmed adenohypophyseal hyperplasia. Postoperatively, the patient reported complete resolution of symptoms, without further need for ENT-directed treatment. Ongoing management includes low-dose levothyroxine and testosterone replacement therapy.

Conclusions: This case emphasizes that persistent OSA may represent an early manifestation of acromegaly and highlights the critical role of endocrinological assessment in patients with refractory OSA. Early multidisciplinary intervention enables timely diagnosis, targeted therapy, and significant clinical improvement.

EP1102 - ECE_2948 - The inflammasome machinery is dysregulated and represents a therapeutic vulnerability in pituitary tumours causing Cushing's disease

Álvaro Flores-Martínez[1,2], Miguel E. G-Garcia[1,2], Laura Arroyo-Millán[1,2], Aura D. Herrera-Martínez[1,2,3], Paloma Moreno-Moreno[1,3], Antonio C. Fuentes-Fayos[1,2], Antonio Jesús Martínez-Fuentes[1,2,4], Eva Venegas Moreno[5], David Cano Gonzales[5], Alfonso Soto[5] and Raul M. Luque[1,2,4]
[1]Maimónides Biomedical Research Institute (IMIBIC), Reina Sofia University Hospital (HURS), Córdoba 14004, Spain; [2]Department of Cell Biology, Physiology and Immunology, University of Cordoba, Córdoba 14004, Spain; [3]Service of Endocrinology and Nutrition, Reina Sofía University Hospital (HURS), Córdoba 14004, Spain; [4]CIBER Pathophysiology of Obesity and Nutrition (CIBERobn), Córdoba 14004, Spain; [5]Unidad de Gestión de Endocrinología y Nutrición, Instituto de Biomedicina de Sevilla (IBiS), Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, Sevilla, Spain

Introduction: Corticotroph pituitary tumours (ACTHomas) are the leading cause of Cushing's disease and remain clinically challenging due to their heterogeneous behavior and the limited medical options for refractory or aggressive cases. Growing evidence suggests that endocrine tumour phenotypes are strongly influenced by inflammatory cues; however, a comprehensive, mechanism-oriented characterization of the inflammasome dysregulation in human ACTHomas is still lacking. In this context, the inflammasome represents a key stress- and damage-responsive multiprotein machinery whose activation has been implicated in immune evasion, regulated cell-death programmes and tumour microenvironment (TME) remodelling. This study was performed to systematically characterize the inflammasome transcriptomic landscape in ACTHomas versus non-tumour pituitary tissues, to identify clinically relevant discriminant factors, and to functionally validate their therapeutic tractability in ACTHoma models. Specifically, a clinically well-characterized multicentric cohort and a microfluidic-based qPCR profiling was used/performed to quantify a curated panel of inflammasome-related genes encompassing priming, core, and effector components in ACTHomas ($n = 81$) versus non-tumour pituitary tissues ($n = 15$), followed by integrative bioinformatic analyses to prioritize key candidates. Candidate validation and functional interrogation were conducted through genetic modulation *in vitro* in the AtT-20 corticotroph cell line and in primary cultures derived from human ACTHomas, coupled with functional *in vitro* assays of proliferation and aggressiveness-related phenotypes. Our results revealed that ACTHomas exhibited a marked and coordinated deregulation of the inflammasome machinery compared with controls, which was independently reproduced in external validation cohorts. Top-ranked factors, robustly discriminated ACTHomas from non-tumour pituitaries, consistently clustering samples by disease status. Importantly, *in vitro* modulation of these top-ranked factors significantly impacted proliferation and aggressiveness-associated readouts in AtT-20 cells and in patient-derived ACTHoma primary cultures. Moreover, pharmacological blockade of the inflammasome machinery using anakinra (an IL1R1 antagonist) attenuated inflammasome-driven functional hallmarks of aggressiveness *in vitro*, supporting the druggability of this pathway in corticotroph tumours. Altogether, our data demonstrated a clinically relevant

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

inflammasome-associated molecular dysregulation in ACTHomas and identify specific components as discriminant biomarkers and actionable therapeutic targets, providing a strong rationale for repurposing inflammasome inhibition as a precision-oriented therapeutic strategy in Cushing's disease.

EP1103 - ECE_3892 - Differences in membranous SSTR2 expression between densely and sparsely granulated somatotroph PitNETs: a single-center retrospective study of 416 patients

Beata Rak-Makowska[1,2], Maria Maksymowicz[3], Grzegorz Zielinski[4], Agnieszka Piekielko-Witkowska[1] and Dominika Nowis[2,5]

[1]Department of Biochemistry and Molecular Biology, Centre of Postgraduate Medical Education, Centre of Translational Research, Warsaw, Poland; [2]Laboratory of Experimental Medicine, Medical University of Warsaw, Warsaw, Poland; [3]Department of Cancer Pathomorphology, Maria Sklodowska-Curie National Research Institute of Oncology, Warsaw, Poland; [4]Department of Neurosurgery, Military Institute of Medicine - National Research Institute, Warsaw, Poland; [5]Department of Immunology, Medical University of Warsaw, Warsaw, Poland

Purpose: Somatostatin receptor type 2 (SSTR2) plays a key role in the response of somatotroph pituitary neuroendocrine tumors (PitNETs) to somatostatin analogues (SSA). Densely granulated (DG) and sparsely granulated (SG) somatotroph PitNETs differ in their clinical behavior, proliferative activity (Ki-67 labeling index), and invasiveness. Our aim was to compare SSTR2 expression pattern and clinicopathological characteristics between DG and SG somatotroph PitNETs in a large retrospective cohort.

Methods: We performed a retrospective analysis of 416 patients with somatotroph PitNETs treated at a tertiary referral center. Tumors were classified as densely granulated (DG, $n = 256$) or sparsely granulated (SG, $n = 160$) based on histopathological criteria and electron microscopy (EM). Immunohistochemical analyses included SSTR2 expression, Ki-67 labeling index, and alpha subunit staining. Tumor invasiveness was assessed using Knosp's grading system as described previously in the literature.

Results: Mean age in the DG group was 50.21 years (SD ± 12.85; median 52) and 45.45 years in the SG group (SD ± 12.55; median 44), respectively ($P = .0002$***). Women accounted for majority in both groups but with a higher proportion of males in the DG group (144 females, 112 males) compared with the SG group (115 females, 45 males; $P = .0014$**). DG somatotroph PitNETs showed significantly lower invasiveness compared with SG tumors, with Knosp's grades 2-4 observed less frequently in the DG group ($P < .0001$****). Higher Ki-67 labeling index was significantly more common in SG tumors ($P < .0001$****), indicating increased proliferative activity. Positive immunostaining for the alpha subunit was also more frequent in DG PitNETs ($P < .0001$****).

The distribution of SSTR2 immunostaining patterns differed significantly between DG and SG somatotroph PitNETs, with DG tumors showing more frequent combined membranous and cytoplasmic expression, while sparsely granulated tumors more often demonstrated cytoplasmic-only or absent SSTR2 staining ($P = .001$**). Furthermore, when we analyzed membrane-only and combined (membranous and cytoplasmic) versus cytoplasmic- only or absent, DG somatotroph PitNETs demonstrated functional (membrane only or combined) SSTR2 expression significantly more frequently than SG tumors.

Conclusions: DG and SG somatotroph PitNETs exhibit distinct clinicopathological profiles. SG tumors are characterized by younger age at diagnosis, female predominance, higher invasiveness, increased proliferative activity, and less frequently membranous SSTR2 expression. These findings support the biological heterogeneity of somatotroph PitNETs. Our results in this large cohort confirm prior literature on the importance of membranous SSTR2 expression for DG phenotype.

EP1104 - ECE_1643 - Postoperative body composition outcomes in 104 patients with acromegaly: a single-center retrospective cohort study

Ryutaro Makino[1,2], Shingo Fujio[1,2], Jun Sugata[1,2], Shigeru Kawade[2,3], Katsutaro Morino[2,3] and Ryosuke Hanaya[1]

[1]Department of Neurosurgery, Graduate School of Medical and Dental Sciences, Kagoshima University, Kagoshima, Japan; [2]Pituitary Disorders Center, Kagoshima University Hospital, Kagoshima, Japan; [3]Department of Diabetes and Endocrine Medicine, Graduate School of Medical and Dental Sciences, Kagoshima University, Kagoshima, Japan

Background: Surgery for acromegaly improves quality of life and prognosis by normalizing GH and IGF-1 levels. However, abrupt hormonal shifts can induce changes in body composition. This study investigated longitudinal body composition changes and their clinical associations.

Methods: We retrospectively analyzed 104 acromegaly patients who underwent pituitary surgery between 2006 and 2024. Body composition data from preoperative to 3 years postoperative, including weight, body mass index (BMI), percent body fat (PBF), body fat mass (BFM), fat-free mass (FFM), total body water (TBW), and muscle mass (MM), were evaluated using bioelectrical impedance analysis.

Results: The mean age was 52.6 years, and 65.4% were female. Preoperative averages were: weight 65.4 kg, BMI 24.4, PBF 24.6%, BFM 16.1 kg, FFM 49.0 kg, TBW 36.1 kg, and MM 46.3 kg. Within one postoperative week, weight decreased by 2.9 kg, mainly from reduced TBW. By one year, BFM increased by 2.6 kg and weight returned to baseline; however, females showed greater 1-3-year declines in FFM and MM than males. At 12 weeks, IGF-1 normalized in 85.6%, and 50% achieved OGTT nadir GH < 0.4. IGF-1 normalization correlated with reduced FFM and improved glucose tolerance, whereas OGTT showed no clear associations. In patients with delayed postoperative hyponatremia (DPH), preoperative body weight and BMI were lower than in non-DPH cases. While body fat–related

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

indices were comparable between the groups, FFM, MM, and TBW were significantly lower.

Conclusions: After surgery for acromegaly, marked short-term reductions in TBW and longer-term increases in BFM with decreases in FFM were observed. Changes in FFM were particularly associated with sex and IGF-1 levels. Predicting postoperative body composition based on patient background and clinical factors may help optimize individualized strategies to prevent frailty and declines in quality of life.

EP1105 - ECE_1819 - Impact of preoperative growth hormone levels on acromegaly-related complications

Daniela-Georgiana Amzar[1], Mihaela Maria Vlad[1], Melania Balas[1], Ioana Golu[1], Stoian Dana[1], Oriana Pelineagră[1] and Laura Cotoi[2]
[1]*Endocrinology, Spitalul Clinic Județean de Urgență Timișoara, Timișoara, Romania;* [2]*Endocrinology, Centre Hospitalier de Luxembourg, Luxembourg, Luxembourg*

Introduction: Acromegaly is a rare, insidious disease caused by excessive production of growth hormone (GH) and is associated with multiple complications. The prevalence of associated complications and mortality are related to the duration of exposure to elevated GH levels, making early diagnosis essential. The presence of multiple complications in these patients contributes to increased mortality/morbidity and decreased quality of life.

Methods: The study cohort comprised 22 patients with acromegaly (female-to-male ratio, 15:7), aged 24 to 71 years (50.00 ± 5.32). The patients were diagnosed and subsequently followed in the Endocrinology Department of our institution between 2000 and the present, in accordance with internationlly accepted diagnostic criteria.

Results: The diagnosis was delayed, 90.9% of the patients had pituitary macroadenoma (preoperative adenoma dimension 25.43 ± 12.50 mm) and 95% exhibited at least one acromegaly-related complication. The mean preoperative GH and insulin-like growth factor-1 (IGF-1) levels were 21.54 ± 25.51 ng/ml and 666.57 ± 346.10 ng/ml, respectively. The mean estimated disease duration was in the study group was 9.82 ± 5.32 years. Most patients underwent transfenoidal adenomectomy, with only one patient not receiving surgical tratment. Postoperatively, six patients had no tumour remnant, and the mean tumour remnant in the other 16 patients was 10.81 ± 6.81 mm. Eighteen patients required additional therapy with somatostatin analogues, 2 patients required GH receptor antagonist association and supplemental radiotherapy was recommended in 4 of them. Acromegaly-related complications were frequent in our cohort with 68.2% presenting left ventricular hyperthropy, 54.5% sleep apnoea, 13.6% atherosclerotic disease, 40.9% splenomegaly, 31.8% type II diabetes, 59.1% impaired glucose tolerance and 72.7% obesity. Visual field defects were present in 8 out of 9 patients who underwent ophthalmological examination. Pearson correlation analysis revealed no statistically significant association between the presence of acromegaly-related complications and preoperative GH and IGF-1 levels or total disease duration.

The normalisation of hormonal parameters in the following years was accompanied by an improvement of the clinical picture and complications, with an improvement of the quality of life.

Conclusions: Early diagnosis and timely assessment of complications play a critical role in improving quality of life and in reducing disease-related complications, morbidity and mortality.

EP1106 - ECE_1674 - Genotype-phenotype correlation of ophthalmic, renal/genitourinary, neurological and neurodevelopmental manifestations in published cases of Bardet-Biedl syndrome

Mauro Longoni[1], Patrick Sleiman[1], Paul Park[1], Gian Sepulveda[2], Taylor Sells[2] and Gauri Malthankar[1]
[1]*Rhythm Pharmaceuticals, Inc., Boston, United States;* [2]*Coefficient Health, New York, United States*

Introduction: Bardet-Biedl syndrome (BBS) is a rare autosomal recessive ciliopathy that is diagnosed clinically based on Beales criteria, originally published in 1999. Among clinically diagnosed cases, 80%-90% are confirmed by genetic testing covering 26 associated genes. Genotype-phenotype correlations are limited, often based on cases or small studies.

Methods: A systematic literature search, covering January 1998-March 2025, was conducted to evaluate ophthalmic, renal/genitourinary, and neurological/neurodevelopmental manifestations in BBS using Human Phenotype Ontology terminology. Demographics, age of onset, body mass index (BMI), and gene variants were captured for each reported case. After deduplication, data were analysed at child and parent ontology levels, reporting frequencies, median age of onset, and interquartile ranges for each manifestation by the most frequently reported gene cohorts *BBS1*, *BBS10*, *BBS2*, and *BBS12*.

Results: From 415 screened publications, 261 were included, reporting individual patient data for 1776 patients (44.8% male, 36.6% female, and 18.6% unspecified) with over 500 manifestations. Genetic testing was performed in 86.2% of cases; 93.2% of those had variants reported. Among these, 24.0% had ≥1 variant in *BBS1*, 18.8% in *BBS10*, 12.5% in *BBS2*, and 8.3% in *BBS12*. Rod-cone dystrophy was most prevalent in *BBS2* (92.9%) and least in *BBS12* (69.8%). Night blindness was most common in *BBS1* (93.2%) and *BBS10* (95.4%) and least in *BBS12* (57.7%). Median age of onset of rod-cone dystrophy overall was 13-14 years, except in *BBS1* (21.5 years). Renal abnormalities ranged from 36.3% (*BBS1*) to 53.4% (*BBS10*), with renal cysts more frequent in *BBS12* (45.5%) than in other cohorts (23.1%-33.9%). Chronic kidney disease was highest in *BBS10* (17.7%) and *BBS2* (13.3%). Genitourinary abnormalities were most common in *BBS2* (70.8%) and *BBS12* (66.7%). In *BBS10,* neurodevelopmental delay was highest (69.9%), but intellectual disability less often reported (35.7%). Compared with Beales criteria, chronic kidney disease, renal cysts, and neurodevelopmental delay appear more common in published cases, while others (ataxia, speech deficit, micropenis) are less frequent.

Conclusions: Analysis of genetic and phenotypic data in 1776 published cases confirm the heterogeneity of major features of BBS, presenting a diagnostic challenge. These data confirm that clinical presentation, prevalence and age of onset of manifestations vary widely and differ by gene, highlighting the value of increased genotype-phenotype knowledge for patient counselling and management. As genetic testing becomes standard,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

further analysis may help define the minimal constellation of clinical manifestations needed for a molecular BBS diagnosis and refine diagnostic criteria.

Abstract citation ID: lvag096.1368

EP1107 - ECE_1775 - Scientific output and impact of rare endocrine disease registries: a quantitative exploratory analysis

Karen Tordjman[1,2], Merav Serebro[1], Etty Osher[1,2] and Yona Greenman[1,2]
[1]Metabolism and Hypertension, Institute of Endocrinology, Tel Aviv-Yafo, Israel; [2]Grey Faculty of Medical and Health Sciences, Tel Aviv University, Tel Aviv-Yafo, Israel

Background: Registries for rare endocrine diseases aim to pool otherwise scarce clinical data to further knowledge about these conditions and to support research, guideline development, and clinical trials. Although many such registries have been created over the past decades, their scientific output and translational impact have rarely been examined in a systematic and quantitative way.

Objective: To assess the scientific output and guideline impact of registries devoted to rare endocrine conditions and to explore registry characteristics associated with greater impact.

Methods: An exploratory search identified 152 initiatives described as rare endocrine disease registries. Registries were included if they met a predefined operational definition, had at least 8 years of documented activity, enrolled between 700 and 7000 patients, and had produced registry-derived publications. Scientific output was assessed using a composite Registry Impact Index (RII), integrating annualized publication output, citation impact, production of highly cited papers, and contribution to clinical guidelines. Associations between RII and registry characteristics were explored using Spearman correlations, with sensitivity analyses using alternative weighting schemes.

Results: Fourteen registries met all inclusion criteria. The time from registry inception to first publication was substantial (median 5 years, range 3-13). Publication trajectories differed between registries, with some showing sustained output over time, while others appeared to plateau despite longer duration. This may relate to limited patient accrual, the coexistence of parallel registries, and practical difficulties in maintaining funding and long-term investigator involvement. Among 116 true original registry-derived studies, most relied on retrospective cross-sectional designs, while purely prospective longitudinal studies accounted for only 7% (8/116). Contribution to clinical guidelines was limited: only 10 studies (8.6%) reached a guideline output role score indicating a substantive contribution. Guideline contribution was strongly associated with publication output (true original studies per year, Spearman $\rho = 0.71$, $P = .004$) and with annual citation rates ($\rho = 0.69$, $P = .006$). The median RII was −0.27 (IQR −0.61 to 0.75; range −1.13 to 1.90), reflecting marked heterogeneity in scientific output. Registry size, disease rarity, governance model, industry involvement, geographic scope, maturity, and data platform adaptability were not independently associated with RII.

Conclusions: Scientific output among rare endocrine disease registries is heterogeneous and characterized by long publication latency, limited prospective research, and modest integration into clinical guidelines. While exploratory and requiring replication, these findings point to missed opportunities to make better use of registries for prospective studies, clinical trials, and knowledge generation.

Background: Tumour cells often display increased reliance on the salvage pathway for nicotinamide adenine dinucleotide (NAD^+) production, highlighting the rate-limiting enzyme of this pathway, nicotinamide phosphoribosyltransferase (NAMPT), as a potential target for anti-cancer therapy.

This study aimed to explore NAMPT inhibition as a novel therapeutic strategy for gastro-enteropancreatic (GEP) neuroendocrine tumours (NETs) and phaeochromocytomas/paragangliomas (PPGLs).

Methods: We investigated the effects of the NAMPT inhibitor GNE-617, and co-administration of niacin (vitamin B3), in GEP-NET/pulmonary NET and PPGL cell lines and fresh patient-derived GEP-NET/PPGL primary cultures ($n = 49$, including 1 neuroendocrine carcinoma [NEC] primary culture and 2 corresponding normal tissue primary cultures). We also extended our findings to pancreatic, thyroid and breast cancer cell lines. Additionally, we correlated cell viability data with NAPRT1 protein expression levels.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Results: We found strong significant anti-tumour effects of the NAMPT inhibitor GNE-617 in NAPRT1-deficient GEP-NET/pulmonary NET, PPGL, pancreatic, thyroid and breast cancer cell lines, and also in the GEP-NET/GEP-NEC and PPGL primary cultures. Niacin co-administration consistently rescued the NAPRT1-expressing cell lines from the anti-tumour effects of NAMPT inhibition, while having no effect in the NAPRT1-deficient cell lines. Niacin was also able to rescue 82% (22/27) of GEP-NET/GEP-NEC primary cultures and 50% (8/16) of PPGL primary cultures from the effects of NAMPT inhibition. In contrast, importantly, in 15% (4/27) of GEP-NET/GEP-NEC primary cultures and in 13% (2/16) of PPGL primary cultures, NAMPT inhibition led to strong anti-tumour effects (mean cell viability ≤60%) without tumour cell-rescue by niacin. Additionally, niacin rescued the normal tissue primary cultures from the effects of GNE-617, but not a corresponding small intestinal NET primary culture—suggesting NAPRT1-deficiency of the tumour but functional NAPRT1-expression in normal tissue.

Conclusions: Our results suggest that NAPRT1 expression could serve as a critical biomarker for predicting GEP-NET and PPGL tumour response to NAMPT inhibition, as well as potentially guide recommendations for niacin supplementation in patients with GEP-NETs or PPGLs. The pre-selection of patients based on this biomarker could enable precision targeted NAMPT inhibitor therapy of NAPRT1-deficient tumours, while preserving NAPRT1-expressing normal tissue with niacin co-administration.

Abstract citation ID: lvag096.1370

EP1109 - ECE_2744 - Neurofilament light chain and glial fibrillary acidic protein in chronic SIAD-induced hyponatremia

Clara Consoli[1,2], Cihan Atila[1,2], Jens Kuhle[3,4], Aleksandra Maleska[3,4], Julie Celine Refardt[1,2,5] and Mirjam Christ-Crain[1,2]

[1]*Endocrinology, Diabetology and Metabolism, University Hospital Basel, Basel, Switzerland;* [2]*Clinical Research, University Hospital Basel, Basel, Switzerland;* [3]*Basel, Switzerland;* [4]*Neurology, University Hospital Basel, Basel, Switzerland;* [5]*Endocrinology, Erasmus Medical Centre, Rotterdam, The Netherlands*

Background: Hyponatremia is the most common electrolyte disorder, most commonly due to the syndrome of inappropriate antidiuresis (SIAD). Chronic hyponatremia itself is associated with neurocognitive impairment, and its rapid correction can result in osmotic demyelination (ODS), which may be considered the end stage of a cascade of osmotic brain stress. Recently, we showed that acute hyponatremia and its correction are associated with increases in neurofilament light chain (NfL) and glial fibrillary acidic protein (GFAP), biomarkers of neuroaxonal and astrocytic injury. However, data on chronic hyponatremia and its correction are lacking. Here, we investigated whether chronic hyponatremia and cautious correction are associated with changes in NfL and GFAP.

Methods: Analysis of a randomized, double-blind, placebo-controlled trial conducted at University Hospital Basel, Switzerland, investigating the SGLT2 inhibitor empagliflozin as a treatment option for chronic hyponatremia due to SIAD. Participants received a 4-week treatment with empagliflozin or placebo in randomized order (crossover design). NfL and GFAP were measured at baseline and at the end of treatment (4 weeks), and results were presented as age- and BMI-adjusted Z-scores relative to a large healthy control population. Plasma sodium was assessed at baseline and 7 days post-treatment. We fitted a linear mixed-effects model to assess whether changes in plasma sodium during the first week of each treatment phase were associated with plasma NfL or GFAP levels at week 4.

Findings: In total, 11 out-patients (age: 72 years [62-77]) were included. Among patients, in the active treatment phase, baseline plasma sodium was 130 mmol/L [126-134], increasing by 4 mmol/L [1-5] within seven days. Plasma NfL-Z-score numerically increased from 0.2 [−0.6-0.9] at baseline to 0.4 [−1.0-1.2] within 4 weeks. Plasma GFAP slightly decreased from a baseline Z-score of −0.1 units [−0.8 to 0.2] to −0.3 units [−0.5 to 0.9] within 4 weeks. In a linear mixed-effects model, fitted with treatment group (empagliflozin vs placebo), sodium change, and their interaction, adjusting for baseline NfL-Z-scores, there was no significant association between the degree of sodium correction within 7 days with NfL-Z-scores measured at week 4 ($\beta = -.02$, 95% CI: −0.16 to 0.12, $P = .79$).

Conclusions: In patients with chronic hyponatremia, a cautious increase in plasma sodium was not associated with changes in NfL-Z-scores. These findings support the notion that slow correction of sodium levels in chronic hyponatremia is not associated with osmotic brain stress or neuronal injury.

EP1111 - ECE_3011 - Evaluating endocrinopathies in patients with midline anomalies: a retrospective, single-center study

Mustafa Berkay Tastekin[1], Selin Tekin[2], Suleyman Nahit Sendur[2], Selcuk Dagdelen[2] and Tomris Erbaş[2]

[1]*Internal MEdicine, Hacettepe University School of Medicine, Ankara, Türkiye;* [2]*Department of Internal Medicine, Division of Endocrinology & Metabolism, Hacettepe University School of Medicine, Ankara, Türkiye*

Background: Midline anomalies are migration defects occurring while during development. They involve various systems and demonstrate a wide range of clinical variations. Moreover, it has been shown in many studies to cause various endocrinopathies, especially hypopituitarism. There are few studies due to low clinical awareness. We aimed to contribute to the literature on the management of endocrinopathy in patients with midline anomalies by retrospectively reviewing real-life data from our center.

Methods: Between January 2000 and 2025, patients with diagnoses of various midline defects or information regarding midline defects in their medical history were examined in the electronic registration system. Finally, we evaluated nine patients with holoprosencephaly (HOL), cleft lip and palate (CLAP) and absence of corpus Callosum (ACC).

Results: Seven patients (77.8%) were male. The median age at diagnosis was 1 (1-8) years and the median age at the time of study was 25 (19.5-37.5). The median follow-up period was 15.2 (12.6-21.0) years. Five patients (55.6%) had multiple pituitary hormone deficiency (MPHD). The most common pituitary hormone deficiency was hypogonadism, which occurs in seven

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

patients (77.8%). GH deficiency was detected in four patients (44.5%). Hypothyroidism and AVP deficiency were observed in three patients each (33.4%). The least common pituitary hormone deficiency was secondary adrenal insufficiency and hyperprolactinemia seen in only one patient. Furthermore, this patient was the only one with panhypopituitarism in our study. A total of seven patients (77.8%) had cleft palate and lip anomalies, with or without cranial anomalies. Two patients had no midline anomalies other than cleft palate and lip. Seven patients who underwent bone mineral density, five (71.4%) of them had measurements consistent with osteoporosis.

Conclusions: When patients present with a history of cleft lip and palate and mental retardation, clinicians might not initially consider endocrinopathy as the primary medical concern. In our study, we demonstrated the association between midline anomalies and hypopituitarism in adult patients presenting to the clinic. Our findings emphasize that clinicians should remain alert to hypothalamo-pituitary endocrinopathies in patients presenting with midline anomalies and neurological deficits.

EP1113 - ECE_3454 - Inferior petrosal sinus sampling

Tereza Foglarová[1], Tomáš Padrta[2], Václav Hána[2], Jan Kaván[2], Adela Krausova[2], Michal Krsek[2], Tomas Brutvan[2], Jan Jiskra[2], Jana Jezková[2], David Netuka[3], Vaclav Masopust[3], Petr Vacek[3] and Martin Májovský[3]
[1]*3rd Department of Medicine, 1st Faculty of Medicine, Charles University and General University Hospital, Prague, Czech Republic;* [2]*General University Hospital in Prague, Prague, Czech Republic;* [3]*Military University Hospital Prague, Prague, Czech Republic*

Background: Inferior petrosal sinus sampling (IPSS) is the most sensitive method for differentiating a pituitary from an ectopic source of adrenocorticotropic hormone (ACTH). It is recommended in patients with ACTH-dependent Cushing's syndrome and either a negative pituitary MRI or a pituitary adenoma <6 mm. The procedure consists of bilateral catheterization of the inferior petrosal sinuses via femoral venous access. After confirmation of correct positioning of both microcatheters near the sella turcica, corticotropin-releasing hormone (CRH) or desmopressin is administered to stimulate ACTH secretion. Blood samples are collected at predefined time intervals to measure ACTH levels and to assess the central-to-peripheral ACTH gradient. A basal gradient ≥2, or a stimulated gradient ≥3 after CRH/desmopressin administration, is consistent with a pituitary source of ACTH secretion.

Methods: Between 2022 and 2024, 20 patients with ACTH-dependent Cushing's syndrome were diagnosed at the General University Hospital in Prague. Inferior petrosal sinus sampling was performed in 15 of these patients. In 8/15 patients, pituitary MRI was negative; in the remaining patients, a suspected pituitary adenoma measuring 3-8 mm in maximal diameter was identified. One patient with a 20-mm pituitary adenoma also had a thyroid tumor detected on FDG - PET/CT. In 5/20 patients with a suspected pituitary adenoma measuring 5-19 mm, CRH/desmopressin stimulation tests were performed without IPSS.

Results: In all 20 patients, IPSS (15 patients) or CRH/desmopressin testing alone (5 patients) indicated a pituitary source of ACTH. In one patient, catheterization of the inferior petrosal sinuses was not feasible due to anatomical reasons, and only a CRH stimulation test was performed. In 2/15 patients, a basal ACTH gradient >2 was not present, and a diagnostic gradient (>3) was observed only after CRH/desmopressin stimulation. No complications related to the catheterization procedure were observed. Pituitary ACTH secretion was subsequently confirmed in all patients either by histological verification following neurosurgical resection or by postoperative resolution of hypercortisolism.

Conclusions: Inferior petrosal sinus sampling is a sensitive and safe method for differentiating ACTH-dependent hypercortisolism. In more than half of patients with a negative pituitary MRI, it confirms the indication for neurosurgical intervention.

I. Parhon" National Institute of Endocrinology, Bucharest, Romania;* [5]*Endocrinology Department, "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania;* [6]*Emergency Clinical Municipal Hospital, Timisoara, Romania*

Introduction: Although pituitary neuroendocrine tumors (PitNETs) are generally benign, recent studies have identified aggressive variants that respond poorly to conventional therapies. Consequently, investigation of the tumor microenvironment has become mandatory for understanding pituitary tumorigenesis and developing new targeted treatments. A key component of this microenvironment is the immune cell population, which primarily includes: tumor-associated macrophages, dendritic cells, and tumor-infiltrating lymphocytes (TILs). CD8$^+$ cytotoxic T lymphocytes act as main effectors of antitumor immunity by targeting and destroying neoplastic cells.

Aim: To evaluate the distribution of CD8$^+$ TILs in a subset of PIT-1-positive PitNETs.

Materials and Methods: Twenty-eight PIT-1-positive PitNETs were included in the present study. An integrated diagnosis was performed by correlating clinical, radiological, histopathological and immunohistochemical (IHC) findings. IHC analysis included anterior pituitary hormones and transcription factors (PIT1, TPIT, SF1). CD8 marker was used to identify T lymphocytes, showing membranous staining. Positive cells were counted in five representative intratumoral high-power fields (×40), and the mean value was calculated.

Results: Histopathological analysis using routine hematoxylin–eosin staining revealed the following tumor growth patterns: diffuse ($n = 21$), papillary ($n = 5$), trabecular ($n = 1$), and alveolar ($n = 1$).

Immunohistochemical assessment of anterior pituitary hormones and lineage-specific transcription factors identified twelve somatotroph (GH$^+$/PIT1$^+$), eleven mammosomatotroph (GH$^+$/PRL$^+$/PIT1$^+$), and five plurihormonal PIT1-positive tumors (GH$^+$/PRL$^+$/TSH$^+$/PIT1$^+$).

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

The number of CD8+ TILs varied among the three PIT1-positive tumor subtypes. In somatotroph tumors, the mean number of CD8+ cells per high-power field (HPF) was 2.43, with a median of 2.1. In mammosomatotroph tumors, the mean count was 1.91 cells/HPF and the median was 2.2. Plurihormonal PIT1-positive tumors showed the highest lymphocytic density, with a mean of 5.44 cells/HPF and a median of 2.8. Nine tumors showed no CD8+ TILs (three somatotroph, five mammosomatotroph, and one plurihormonal PIT1-positive case). The highest number of T lymphocytes, with a mean of 12 cells/HPF, was identified in a plurihormonal PIT1-positive tumor.

Conclusions: Although lymphocytic infiltration in pituitary neuroendocrine tumors may have therapeutic implications—the potential use of immunotherapy in aggressive cases—its distribution among different tumor subtypes remains incompletely characterized. T lymphocytes represent a central component of tumor immunology, acting as key effectors in the recognition and elimination of neoplastic cells.

Our results suggest subtype-dependent variation in CD8+ TILs density within PIT1-positive PitNETs, supporting the hypothesis that immune-endocrine interactions may shape tumor behavior and may hold therapeutic relevance.

EP1116 - ECE_2417 - Pituitary apoplexy masquerading as infectious meningitis and complicated with salt-wasting syndrome in a man with pituitary macroadenoma - a case report and review of the literature

John Valsamidis[1], Chrysanthi-Tzenin Omar[1], Panagiotis Mpatzakis[1], Anastasios Poutachidis[1], Christina Tzoulakitze[1], Maria Sarigianni[1], Vasileios Kotsis[1], Maria Kosmidou[1] and Panagiotis Anagnostis[1,2]

[1]3rd Department of Internal Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Aristotle University of Thessaloniki, Thessaloniki, Greece

Pituitary apoplexy is a rare complication of pituitary macroadenomas, usually manifesting with acute headache, loss of consciousness, and visual disturbances. Herein, we report a case of pituitary apoplexy presenting with clinical and laboratory features mimicking bacterial meningitis. In particular, a 39-year old man was admitted to our department due to acute headache, fever, meningeal signs, and altered mental status. Initial clinical examination and laboratory investigation was compatible with inflammatory meningeal reaction, indicative of central nervous system (CNS) infection. Consequently, the patient was initially treated empirically with antibiotics. Magnetic resonance imaging (MRI) of the brain revealed a pituitary macroadenoma with areas of hemorrhage and necrosis, bilateral extrasellar extension to cavernous sinuses and suppression of optic chiasm, resulting in right temporal hemianopia and left loss of visual acuity. Endocrinological work-up showed panhypopituitarism, including also central diabetes insipidus. Therefore, hormone replacement therapy (HRT), including intravenous hydrocortisone, per os L-thyroxine and sublingual desmopressin, was initiated, leading to gradual improvement of his clinical status. However, due to persistent hyponatremia and severe natriuresis, with low aldosterone concentrations, a "cerebral salt-wasting syndrome (CSWS)" was suspected and, subsequently, the patient was started on fludrocortisone, which resulted in restoration serum and urinary sodium levels. Subsequent MRIs of the pituitary gland showed stabilization and a slight decrease in the size of macroadenoma. The patient was discharged under HRT, including also testosterone enanthate. In conclusion, pituitary apoplexy may rarely be complicated as CSWS and may mimic acute meningitis.

EP1117 - ECE_2933 - Transient vasopressin deficiency following inhaled glucocorticoid–induced adrenal insufficiency: a case report

Stefano Testa[1], Vittoria Favero[1,2], Brian Randazzo[1], Elena Magni[3], Roberta Civiletti[3], Lisa Pancini[3], Natalie Prinzi[2] and Iacopo Chiodini[1,2]

[1]Department of Biotechnology and Translational Medicine, University of Milan, Milan, Italy; [2]Endocrinology Unit, ASST Grande Ospedale Metropolitano Niguarda, Milan, Italy; [3]TB Reference Centre and Lab, ASST Grande Ospedale Metropolitano Niguarda, Villa Marelli Institute, Milan, Italy

Introduction: Glucocorticoid-induced adrenal insufficiency (GIAI) is a common yet under-recognized consequence of prolonged glucocorticoid therapy. Although uncommon during inhaled glucocorticoid treatment, GIAI has been reported in selected clinical settings, particularly in the presence of CYP3A4-interacting drugs. In such patients, increased glucocorticoid receptor sensitivity has been hypothesized, potentially predisposing to both hypothalamic–pituitary–adrenal axis suppression and immunosuppression even at relatively low glucocorticoid doses, facilitating opportunistic infections.

Vasopressin deficiency (AVP-D) may result from various causes, including iatrogenic, neoplastic, autoimmune, infiltrative, inflammatory or infectious disorders affecting the hypothalamic–neurohypophyseal system.

Case report: We report a 56-year-old woman with severe asthma and pulmonary aspergillosis, managed with itraconazole (known CYP3A4 inhibitor) in addition to her ongoing fluticasone/vilanterol therapy. Few weeks after antifungal therapy, she developed clinical features of Cushing syndrome: cushingoid facies, easy bruising, hirsutism, proximal muscle weakness and myalgia.

Following itraconazole discontinuation, adrenal function testing revealed GIAI (cortisol 2.48 μg/dL; ACTH 13 pg/mL), associated with symptoms compatible with glucocorticoid withdrawal syndrome. Hydrocortisone was initiated (30 mg/day) with planned gradual tapering. However, due to early recurrence of cushingoid features, rapid dose reduction was required, followed by clinical improvement.

Three months later, the patient reported new-onset intense thirst and polyuria, up to 4 L/day for two weeks. Initial investigations showed: copeptin 2.3 pmol/L, sodium 143 mmol/L, preserved renal function, urine specific gravity 1.016, serum osmolality 299 mOsm/kg, urine osmolality 99 mOsm/kg. Over the subsequent month, polyuria worsened (approximately 7 L/day), prompting initiation of low-dose desmopressin and hospital admission.

At admission, laboratory findings were consistent with AVP-D. However, a rapid spontaneous improvement in symptoms and fluid balance occurred within days. Therefore, desmopressin

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

was progressively reduced and withdrawn. By day 6, biochemical parameters confirmed the improvement in the hydroelectrolytic profile (serum osmolality 290 mOsm/kg, urine osmolality 465 mOsm/kg). Anterior pituitary function was preserved, except for the pre-existing GIAI.

Pituitary MRI demonstrated a poorly defined 4-mm lesion adjacent to the neurohypophysis, hypointense on T2-weighted sequences, with reduced contrast enhancement and pituitary stalk thickening, suggestive of an inflammatory/infectious focus.

Conclusions: This case highlights the complex interplay between prolonged glucocorticoid therapy, opportunistic infections, and AVP-D. In a patient with possible increased steroid sensitivity, rapid steroid tapering in the presence of an inflammatory/infectious neurohypophyseal lesion may have contributed to hypothalamic–neurohypophyseal dysregulation, precipitating a transient functional AVP-D. Awareness of uncommon causes of AVP-D and their interactions with the hypothalamic–pituitary–adrenal axis is crucial to optimize management and follow-up.

EP1119 - ECE_3610 - Giant haemorrhagic prolactinoma presenting with temporal lobe epilepsy

Hannah Brown[1], Waseem Majeed[1,2], Adhithya Sankar[3], Adam Robinson[1] and Tara Kearney[1,2]
[1]*Department of Diabetes, Endocrinology and Obesity Medicine, Salford Royal Hospital, Northern Care Alliance NHS Foundation Trust, Salford M6 8HD, United Kingdom;* [2]*Faculty of Biology, Medicine and Health, The University of Manchester, Manchester M13 9PL, United Kingdom;* [3]*Department of Diabetes, Endocrinology and Obesity Medicine, Salford Royal Hospital, Northern Care Alliance NHS Foundation Trust, Salford, United Kingdom*

Introduction: Giant prolactinomas are rare secretory pituitary adenomas, defined by a diameter >40 mm and markedly elevated serum prolactin levels. While visual field defects and hypopituitarism are classic complications, neurological sequelae from involvement of adjacent cerebral structures are less commonly reported. This case highlights an unusual neurological presentation of focal seizures in patient with treated giant prolactinoma, illustrating the long-term consequences not only from tumour extension, but from regression.

Case presentation: A 44-year-old male with a history of treated systemic tuberculosis initially presented with headaches and low libido. MRI of the head identified an extensive skull base tumour (57 mm × 86 mm) with suprasellar and right-sided temporal lobe extension, including a haemorrhagic component. Biochemistry confirmed markedly elevated serum prolactin of 176 000 mIU/L and hypogonadotropic hypogonadism (LH 1.5 U/L, FSH 1.7 U/L, testosterone 2.4 nmol/L), with intact thyroid, adrenal and growth hormone axes. A diagnosis of giant invasive prolactinoma was made and he was commenced on dopamine agonist (DA) with cabergoline and testosterone replacement. Subsequent dynamic MRI of the pituitary demonstrated significant tumour shrinkage, indicating tumour responsiveness to DA.

After 6 months of DA therapy, the patient presented to the emergency department with an acute episode of confusion and memory loss consistent with a focal seizure. Initial investigations, including blood tests and a CT head, were unremarkable. A retrospective review of imaging from diagnosis showed progressive haemosiderin deposition and residual gliosis in the temporal lobe, with tumour regression. This chronic scarring likely caused cortical irritation, triggering a focal seizure. No alternative metabolic or infective cause was identified, and the patient was referred for neurology review.

Discussion/conclusions: Giant prolactinomas are rare (2%-4% of prolactinomas) and can exhibit aggressive behaviours with skull base invasion, making differentiation from malignant brain tumours difficult. Furthermore, inflammatory conditions such as pituitary tuberculosis can mimic a suprasellar mass with elevated prolactin, a pertinent differential in patients with a history of systemic TB. The key to management is early biochemical identification of significantly elevated prolactin, confirming the diagnosis and allowing for medical therapy. Though DA remains the first line therapy; a subset of patient may need early multimodal therapy. Tumour shrinkage with DA can lead to chronic gliotic changes which may confer a long-term seizure risk. This case emphasises that acute neurological symptoms can emerge later in the treatment course, necessitating long-term vigilance and multidisciplinary follow-up.

EP1120 - ECE_3897 - Manic episode as a severe neuropsychiatric manifestation of Cushing's disease

Adriana Duarte[1], Mariana Coelho[1], Ana Margarida Sobral[1], Bárbara Jesus[1], Leonor Rodrigues[2], Alice Monsanto[1], Mariana Lavrador[1], Daniela Guelho[1] and Leonor Gomes[1]
[1]*Coimbra's Local Health Unit, Endocrinology, Diabetes and Metabolism, Coimbra, Portugal;* [2]*Local Health Unit of Aveiro, Aveiro, Portugal*

Introduction: Neuropsychiatric manifestations are frequent and debilitating complications of Cushing's syndrome, affecting up to 80% of patients. However, manic episodes and psychosis occur in approximately 30% and may represent the initial presentation. Preoperative medical treatment has shown efficacy in normalizing cortisol levels and improving neuropsychiatric symptoms in severe hypercortisolism.

Case-report: A 38-year-old woman with no relevant past medical history was referred to the Endocrinology outpatient clinic with a 6-month history of progressive insomnia, 9-kg weight gain (+15%), hirsutism, and new-onset facial acne. Physical examination revealed hirsutism on the upper limbs and scapular region, acne on the chin and frontal region, and a buffalo hump without other stigmata of hypercortisolism. Laboratory investigation confirmed endogenous hypercortisolism: 1-mg dexamethasone suppression test cortisol 13.1 μg/dL; 24-h urinary free cortisol (UFC) 669 μg/24 h (4.3-176; urine volume 1900 mL); late-night salivary cortisol 1.2 μg/dL; morning cortisol 22 μg/dL; ACTH 63 pg/mL; and 11 PM serum cortisol 21 μg/dL. She also presented dyslipidemia and HbA1c of 6.1%. Pituitary MRI revealed a 5-mm right-sided inferior microadenoma. Inferior petrosal sinus sampling confirmed right-sided lateralization, concordant with MRI findings (central-to-peripheral gradient >3 after stimulation). She was started on metformin 700 mg twice daily, atorvastatin 40 mg, trazodone 150 mg and edoxaban 60 mg once daily, and

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

referred for neurosurgery with intent of short-term surgical intervention. Three months later, she presented to the psychiatric emergency department with worsening insomnia, behavioral changes with psychomotor agitation, and disorganized speech with persecutory ideation. Examination showed motor restlessness, disinhibition, tachypsychia, and marked emotional lability, with no insight. She had no prior psychiatric history. A manic episode in the context of uncontrolled hypercortisolism was assumed, and she was admitted with Endocrinology support. Treatment with antipsychotics and metyrapone 250 mg twice daily was initiated, later adjusted to a total daily dose of 750 mg. At discharge, biochemical normalization was achieved: UFC 122 μg/24 h(urine volume 2300 mL), 11 PM cortisol 12 μg/dL, 8 AM cortisol 14 μg/dL, and late-night salivary cortisol 0.23 μg/dL. No liver enzyme abnormalities were observed, and complete remission of the manic episode occurred. The patient remains clinically stable and has transsphenoidal surgery scheduled.

Conclusions: This case highlights the importance of recognizing severe neuropsychiatric manifestations of Cushing's disease, including manic episodes, which may occur without prior psychiatric history. Metyrapone was effective and safe for rapid control of hypercortisolism, achieving biochemical normalization and remission of psychiatric symptoms. Preoperative medical treatment with steroidogenesis inhibitors is a key strategy in patients with severe hypercortisolism or complications delaying surgery, allowing stabilization and optimization for definitive management.

Abstract citation ID: lvag096.1378

EP1121 - ECE_1058 - Structural and functional parameters of the left heart in patients with acromegaly: changes at 1 year follow up

Ivana Ságová[1,2], Tomáš Bolek[2], Milan Dragula[2], Martin Péč[2], Jakub Jurica[2], Marián Mokáň[2] and Matej Samoš[2]
[1]Department of Endocrinology, National Institute of Endocrinology and Diabetology, Ľubochňa, Slovakia; [2]Prague, Czech Republic

Background: The aim of this study was to assess changes in the morphology and function of the left heart using two-dimensional transthoracic echocardiography (TTE) in newly diagnosed patients with acromegaly (AP) 1 year after the initiation of treatment (transsphenoidal surgery and/or somatostatin analogues) and to explore the effects of disease activity and body composition parameters on changes of the left heart.

Patients and Methods: This prospective study included 34 AP and 34 age-, sex-, and body mass index–matched healthy controls (CON). Physical and laboratory examinations, DXA and TTE were performed at baseline and 1 year after initiation of acromegaly treatment.

Results: At baseline, AP exhibited an increased left atrial volume index (LAVI) and diastolic dysfunction of the left ventricle (LV). The left ventricular mass index (LVMI) was significantly higher in AP compared with CON (124 vs 86 g/m^2, $P < .001$), while LV size and systolic function did not differ between groups. One year after treatment initiation, serum IGF-1 and GH levels decreased significantly ($P < .001$), and biochemical disease control was achieved in 73.5% of patients. In AP, both LAVI and LVMI decreased significantly ($P < .05$), and LV diastolic function improved without changes in systolic function. Multiple regression analysis identified changes in body surface area ($\beta = -.444$, $P < .001$) and lean body mass ($\beta = -.298$, $P = .027$) as independent predictors of LVMI reverse remodeling after the treatment.

Conclusions: This study demonstrates that effective treatment of acromegaly leads to a reversal of left heart remodeling and improvement in left ventricular diastolic function within one year of therapy initiation in previously untreated AP.

EP1122 - ECE_1713 - ATRX mutation and HER-2/neu receptor positivity in a cohort of clinically silent corticotropic PitNETs

Matej Bronec[1], Mikulas Kosak[1], Jana Jezkova[1], Monika Manethova[2], Quang Bui[2], Vaclav Masopust[3], David Netuka[3], Martin Májovský[3], Michal Krsek[4], Vaclav Hana[4], Václav Hána[4], Eva Traboulsi[5] and Jiří Soukup[5]
[1]Prague, Czech Republic; [2]First Faculty of Medicine, Charles University and General University Hospital, Institute of Pathology, Prague, Czech Republic; [3]Department of Neurosurgery and Neurooncology, First Faculty of Medicine, Charles University and Military University Hospital, Prague, Czech Republic; [4]Third Department of Internal Medicine, First Faculty of Medicine, Charles University and General University Hospital, Prague, Czech Republic; [5]Department of Pathology, Military University Hospital, Prague, Czech Republic

Introduction: Clinically silent ACTH-positive PitNETs are considered to be locally aggressive. ATRX is a tumor suppressor gene whose somatic mutations have been identified across a range of typically aggressive neoplasms. Loss of ATRX protein expression by immunohistochemistry (IHC) is routinely used as a surrogate for mutational status. ATRX alterations have been reported in aggressive pituitary neuroendocrine tumors (PitNETs) and pituitary carcinomas.

The HER2/neu receptor is overexpressed in multiple tumor types; beyond breast cancer, overexpression has been reported in subsets of gastric, endometrial, and salivary gland cancers. HER2/neu positivity has also been observed in aggressive prolactinomas and has been associated with increased hormonal activity and accelerated tumor growth. In some tumor types, HER2/neu expression has therapeutic implications because targeted therapies are available. To date, ATRX status and HER2/neu expression have not been systematically evaluated in silent corticotroph (Tpit-lineage) PitNETs.

Patients and Methods: We performed a retrospective review of patients who underwent pituitary surgery at our center from January 2020 through December 2024. Inclusion criteria were Tpit-lineage PitNETs without clinical or biochemical evidence of Cushing's syndrome. IHC for ATRX and HER2/neu was performed on all cases; additional IHC for Tpit and ACTH was performed selectively. Clinical and histopathological data were extracted from medical records.

Results: The study cohort comprised 30 patients (50% female) aged 27-85 years (mean 53 years). Ki-67 index was ≤1% in 18 patients, 1%-3% in 7 patients, and ≥3% in 5 patients (range 0.6%-10%). Four tumors expressed Tpit but lacked ACTH expression; one tumor was classified as a Crooke cell tumor.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Radiologically, cavernous sinus invasion (Knosp grade ≥1) was present in all but one case (Knosp grade 0). Knosp grade distribution: grade 1, 23.3% ($n = 7$); grade 2, 16.6% ($n = 5$); grade 3, 23.3% ($n = 7$); grade 4, 33.3% ($n = 10$). None of the samples demonstrated loss of ATRX expression by IHC. HER2/neu was not expressed in any case, aside from four tumors showing ultralow (borderline/minimal) staining scores.

Conclusions: In this series of silent corticotroph (Tpit-lineage) PitNETs, we found no immunohistochemical evidence of ATRX loss or clinically relevant HER2/neu overexpression. These findings contrast with prior reports that identified ATRX alterations in aggressive PitNETs and pituitary carcinomas and HER2/neu positivity in other subtypes of PitNETs.

EP1123 - ECE_1878 - When acromegaly reveals a mixed gangliocytoma–somatotroph PitNET

Filipa Barros Alves[1], Tânia Fernandes[1], Marta Castro Tomé[1], Rosa Maria Príncipe[1,2], Jorge Pinheiro[3], Joana Oliveira[3], Josué Pereira[3] and Cláudia Nogueira[1,2]

[1]Local Health Unit of Matosinhos, Matosinhos, Portugal; [2]Faculty of Medicine, University of Porto, Porto, Portugal; [3]Local Health Unit of São João, Porto, Portugal

Introduction: Acromegaly is a rare endocrine disorder caused by chronic growth hormone (GH) excess, most frequently due to a pituitary neuroendocrine tumor (PitNET). Mixed pituitary adenoma and gangliocytoma tumors are rare and may be difficult to distinguish from conventional pituitary adenomas pre-operatively. The majority of gangliocytomas are associated with clinical manifestations of anterior pituitary hormone hypersecretion, particularly GH. Only a limited number of cases of these mixed tumors have been reported, and their clinical significance remains incompletely understood.

Case presentation: A 64-year-old woman with a history of dyslipidaemia, subclinical hypothyroidism previously treated with low-dose levothyroxine and depressive disorder was referred for endocrinological consultation after incidental detection of a sellar mass on cervical MRI performed during the investigation of salivary gland hypertrophy. She reported long-lasting headaches, hyperhidrosis and enlargement of the hands, without visual disturbances. Physical examination revealed coarse facial features and enlarged hands. Biochemical evaluation showed an IGF-1 of 419 ng/mL (normal range 40-225), FSH 21.98 mUI/mL, LH 5.54 mUI/mL, estradiol <13 pg/mL, morning cortisol of 12.8 ug/dL, prolactin 8.63 ng/mL, normal TSH 3.39 uUI/mL and free T4 1.01 ng/dL. Hypercalcaemia of 10.7 mg/dL with hypercalciuria (445 mg/24 h) and parathyroid hormone of 73.7 pg/mL (normal range 15.0-68.3) were also present. Pituitary MRI demonstrated a large pituitary macroadenoma (26 mm craniocaudal diameter) with suprasellar extension, cavernous sinus invasion and contact with the optic chiasm.

Management and Histopathology: The patient underwent transsphenoidal pituitary surgery. Histological examination revealed a biphasic neoplasm with an intermingled pattern, composed of adenohypophyseal cells and a neuronal component with dysmorphic ganglion cells. Immunohistochemistry showed synaptophysin expression in both components and chromogranin positivity in ganglion cells. Adenohypophyseal cells demonstrated diffuse Pit-1 expression, weak and diffuse GH positivity, and scattered prolactin expression, with no expression of TSH, ACTH, FSH or LH. The Ki-67 proliferation index was <1%. These findings were consistent with a mixed gangliocytoma–somatotroph PitNET of sparsely granulated type. Postoperative endocrinological follow-up is ongoing.

Conclusions: This case highlights a rare mixed pituitary tumor presenting as acromegaly and underscores the importance of detailed histopathological and immunohistochemical characterization. Given the limited number of reported cases, the clinical behaviour and prognostic implications of mixed gangliocytoma–somatotroph PitNETs remain incompletely understood, justifying careful long-term follow-up.

EP1124 - ECE_2244 - Is it time to redefine the treatment algorithm for acromegaly?

Cristina Guillen[1], Ruth Sanchez-Ortiga[1], Clara Navarro-Hoyas[1], Elena García[1], Jorge Navarro[2], Johana Sottile[2], Javier Abarca Olivas[1], María Eugenia Torregrosa-Quesada[1], Joaquin Serrano[1], Francisca María Peiró-Marqués[1] and Antonio Pico[1]

[1]Hospital General Universitario Dr. Balmis, Alicante, Spain; [2]Instituto de Investigación Biomédica de Alicante (ISABIAL), Alicante, Spain

Introduction: The latest consensus on acromegaly emphasizes the importance of early biochemical control. Although information exists regarding presurgical treatment with somatostatin analogs,the results are heterogeneous. Regardin pegvisomant, there is no prior evidence of its use before surgery. Pegvisomant would be ideal in this period given that it is independent of tumor biology, with rapid effectiveness (4-6 weeks) without requiring dose titration. Preoperative biochemical optimization could mitigate anesthetic risks and improve surgical outcomes, but optimal strategies remain undefined.

Objective: To evaluate the efficacy and safety of preoperative treatment with pegvisomant to achieve rapid biochemical control and metabolic optimization prior to transsphenoidal surgery in patients with acromegaly.

Methods: Prospective cohort study that included 10 treatment-naïve patients with acromegaly who received preoperative therapy with pegvisomant (mean dose 20 mg/day, mean duration 90.4 days) followed by transsphenoidal surgery. The evolution of IGF-1 concentrations, metabolic profile (fasting glucose, HbA1c), quality of life (AcroQoL), tumor immunohistochemistry (SSTR2/5 expression, granularity), perioperative complications, and biochemical remission rates were evaluated.

Results: Preoperative treatment with pegvisomant achieved a significant reduction in IGF-1 from 617.2 ± 203.4 ng/mL at baseline to 373.8 ± 175.9 ng/mL pre-surgery (39% reduction, $P < .001$). Following surgery, IGF-1 concentrations reached a nadir of 177.2 ng/mL at the last visit (total reduction of 71% from baseline). Ninety percent of patients (9/10) achieved biochemical control (IGF-1 < 1.3 × ULN) at final follow-up. Using this therapeutic algorithm and guided by personalized medicine, control was achieved in record time (less than three months after surgery). Metabolic parameters improved substantially: fasting glucose decreased from 146.2 mg/dL to 96.2 mg/dL ($P = .0044$) and HbA1c from 6.84% to 6.00% ($P = .0196$). Quality of life improved significantly as assessed by AcroQoL ($P = .0016$). No serious adverse events or major perioperative complications were recorded.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusions: Short-term treatment with pegvisomant in the presurgical period rapidly achieves biochemical control and metabolic optimization in patients with acromegaly, potentially reducing perioperative anesthetic and surgical risks. This approach demonstrates to be a safe and effective strategy that optimizes presurgical biochemical control, improves metabolic profile and quality of life, and potentially increases surgical remission rates. These findings suggest the need to redefine the current therapeutic algorithm for acromegaly.

EP1125 - ECE_2255 - Predictive value of copeptin for the diagnosis of arginine-vasopressin deficiency in the early postoperative period following pituitary surgery

Paola Parra-Ramírez[1,2,3], Patricia Martín Rojas-Marcos[1], Carlos Pérez López[4], Pablo García Feijoo[4], María Luisa González Casaus[5], Abraham García López[5], María Carmen Hernández Lucas[6], Arturo Lisbona Catalán[1] and Maria Cristina Alvarez Escola[1]

[1]Endocrinology & Nutrition Department, Hospital Universitario La Paz, Madrid, Spain; [2]La Paz University Hospital, Madrid, Spain; [3]Hospital Universitario La Paz, Madrid, Spain; [4]Neurosurgery Department, Hospital Universitario La Paz, Madrid, Spain; [5]Laboratory Medicine, Hospital Universitario La Paz, Madrid, Spain; [6]Anesthesiology Department, Hospital Universitario La Paz, Madrid, Spain

Introduction: Arginine-vasopressin (AVP) deficiency, is a frequent complication following sellar area surgery, with a prevalence ranging from 1% to 67%, depending on the medical center. Traditional diagnosis relies on monitoring polyuria and biochemical parameters such as natremia and urinary osmolarity; however, this approach is time-consuming and requires frequent blood tests, making it a common cause of prolonged hospital stays. Copeptin, the C-terminal fragment of pro-vasopressin, has emerged as a reliable surrogate biomarker for AVP. It exhibits greater in vitro stability and is secreted equimolarly with AVP in response to physiological stress and osmotic stimuli.

Methods and Objectives: This prospective study, conducted at Hospital Universitario La Paz (HULP), Madrid, evaluated patients undergoing sellar and parasellar surgery over an-18-month period. The primary objective was to analyze the evolution of copeptin in the early postoperative phase to establish discriminative cut-off points that facilitate the rapid diagnosis or exclusion of AVP deficiency. Measurements were taken at six time points: pre-surgery, 1 hour after extubation, and at 1, 2, 7 days, and 5 weeks postoperatively. Optimal cut-off values were determined using ROC curve analysis.

Results: Among the patients studied, 13% developed permanent AVP deficiency and 12% developed transient deficiency. Surgical stress significantly stimulates copeptin release in patients with intact neurohypophyseal function. Patients without deficiency showed markedly higher copeptin levels one hour post-extubation (median 19.18 pmol/L) compared to those who developed the deficiency (median 4.28 pmol/L). To safely "rule out" the condition, cut-off points were identified as >3.34 pmol/L at one hour after extubation and >2.3 pmol/L between the first and second postoperative days. In general, values below 2.5-3.5 pmol/L were associated with the development of deficiency. Additionally, it was identified that the risk is higher in patients with non-adenomatous tumors (such as craniopharyngiomas or meningiomas) and those with a pre-surgical ACTH deficiency.

Conclusions: Copeptin is established as an early and reliable marker to guide postoperative management. Its implementation would reduce the number of laboratory tests required after discharge, optimize the use of desmopressin, and help predict the risk of developing postoperative SIADH, thereby improving efficiency in high-complexity surgical centers

EP1126 - ECE_2724 - Prevalence and characteristics of secondary adrenal insufficiency in patients with euvolemic hyponatremia

Michelle Müller[1,2], Lea Galvagno[1,2], Laura Potasso[1,2], Julie Celine Refardt[1,2,3] and Mirjam Christ-Crain[1,2]

[1]Department of Endocrinology, Diabetology and Metabolism, University Hospital Basel, Basel, Switzerland; [2]Department of Clinical Research, University Hospital Basel, Basel, Switzerland; [3]Department of Internal Medicine, Section of Endocrinology, Erasmus Medical Centre, Rotterdam, Rotterdam, The Netherlands

Background: Secondary adrenal insufficiency is a rare cause of hyponatremia. However, it represents an important differential diagnosis to the syndrome of inappropriate antidiuresis (SIAD), the most common cause of euvolemic hyponatremia. Differentiation between adrenal insufficiency and SIAD is crucial, as treatment strategies differ substantially and rapid initiation of corticosteroid therapy is critical in patients with secondary adrenal insufficiency. The aim of this study is to improve the understanding of clinical characteristics of patients with secondary adrenal insufficiency.

Method: This is a descriptive secondary analysis based on a randomized, controlled, parallel-group, multicentred trial, which included patients with moderate to severe hyponatremia (serum sodium <130 mmol/L). All clinically euvolemic hyponatraemic patients were included in the analysis. Baseline characteristics as well as the applied therapeutic algorithms and treatment responses, were assessed.

Results: Among the 1074 euvolemic hyponatremic patients, the predominant etiologies were SIAD ($n = 857$, 80%), primary polydipsia ($n = 155$, 14%), secondary adrenal insufficiency ($n = 32$, 3%), and thiazide diuretic-associated hyponatremia ($n = 5$, 0.5%). Cortisol was measured in 45.7% of all euvolemic patients during hospitalization. In patients with newly diagnosed secondary adrenal insufficiency ($n = 20$), the median cortisol level at study inclusion was 77 nmol/L (IQR 33.5-120.5). After the first recorded low sodium level, the median time to correct diagnosis and to first administration of corticosteroids was 2 days (IQR 1-3 and 1-3, respectively). In all 32 patients with secondary adrenal insufficiency, mean plasma sodium concentration at study inclusion was 124 mmol/L (95% CI 123-126) and increased to 135 mmol/L (95% CI 134-136) at discharge. Sodium normalization was achieved in 66% of patients after a median of 3 days (IQR 1-3). At the 30-day follow-up, the recurrence rate of hyponatremia in patients with secondary adrenal insufficiency was 31.2%, the readmission rate was 15.6%, and mortality was

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

9.4%. In comparison, patients with SIAD had a recurrence rate of 29.2%, a readmission rate of 15.8%, and mortality rate of 4.0%.

Conclusions: In our cohort, secondary adrenal insufficiency was a rare cause of chronic euvolemic hyponatremia, however, cortisol was only measured in 45.7% of all euvolemic patients, thus prevalence might have been higher. Patients with secondary adrenal insufficiency initially presented with moderate hyponatremia (serum sodium <125 mmol/L) and experienced a prompt increase in serum sodium upon treatment with corticosteroids.

EP1127 - ECE_2890 - The study of Indirect calorimetry as an additional marker for the challenging diagnosis of central hypothyroidism

Alice Casiraghi[1], Elisa Delle Donne[1], Alessandro Amodeo[1], Lidia Lewandowsky[1,2], Giulia Pocaterra[1], Marco Bonomi[1,3], Alberto Battezzati[1,2], Irene Campi[3], Luca Persani[1,3] and Biagio Cangiano[1,3]

[1]Department of Medical Biotechnology and Translational Medicine, University of Milan, Milan, Italy; [2]Department of Food, Nutrition and Environmental Sciences, IRCCS Istituto Auxologico Italiano, Milan, Italy; [3]Endocrinology Department & Lab of Endocrine and Metabolic Research, IRCCS Istituto Auxologico Italiano, Milan, Italy

Introduction: Central hypothyroidism (CH) is a rare disorder characterized by low free T4 (FT4) levels and inappropriately normal or low TSH. In CH, adequate levothyroxine (LT4) therapy aims to maintain FT4 in the upper half of the reference range, as TSH is unreliable. Indirect calorimetry (IC) provides a measure of resting energy expenditure (REE), an indicator of metabolic status that is typically reduced in hypothyroidism. This study aimed to investigate the potential role of IC in assessing the adequacy of LT4 therapy in patients with CH.

Matherials and Methods: We performed indirect calorimetry (IC) in 34 patients with CH under different treatment conditions: adequate, suboptimal, or withdrawn levothyroxine therapy.

Results: Twenty-one patients underwent two assessments, one during adequate LT4 therapy and one during suboptimal or withdrawn therapy, whereas the remaining 13 patients were evaluated only under inadequate treatment conditions. REE was inversely correlated with total cholesterol levels ($P = .0032$) and with the FT3/FT4 ratio. The FT3/FT4 ratio was lower during adequate therapy compared with inadequate therapy ($P = .05$), although this difference was less evident when the analysis was restricted to the 21 patients with paired measurements. Among these patients, 52% showed an increase in REE under adequate therapy, 42% showed a decrease, and one patient showed no change. Mann–Whitney analysis demonstrated that a lower FT3/FT4 ratio predicted an improvement in REE after achieving therapeutic targets ($P = .01$). Multivariate regression analysis confirmed a trend toward a negative association between REE improvement and a lower FT3/FT4 ratio ($P = .06$).

Discussion: The significant association between REE and cholesterol levels suggests that indirect calorimetry is a valuable functional tool for assessing metabolic status in patients with central hypothyroidism. Patients with higher FT3/FT4 ratios exhibited a poorer metabolic response to LT4 dose optimization, possibly reflecting a compensatory adaptation to adverse metabolic conditions, such as metabolic syndrome. Further studies are warranted to determine whether the FT3/FT4 ratio represents a cause or a consequence of impaired metabolic efficiency in this population and to elucidate the underlying mechanisms.

EP1129 - ECE_1352 - Anti-rabphilin-3A antibody–positive arginine vasopressin deficiency after COVID-19 infection and vaccination: evidence for autoimmune hypothalamic–neurohypophyseal inflammation

Yoshihisa Sugimura[1], Yuka Natsuki[2], Hiroki Takizawa[3], Hiromasa Goto[3], Naoko Iwata[1,4], Haruki Fujisawa[1], Yuki Nagata[5,6], Hirotaka Watada[3] and Atsushi Suzuki[1]

[1]Department of Endocrinology, Diabetes and Metabolism, Fujita Health University, Toyoake, Japan; [2]Department of Metabolism, Endocrinology and Molecular Medicine, Osaka Metropolitan University Graduate School of Medicine, Osaka, Japan; [3]Department of Metabolism & Endocrinology, Juntendo University Graduate School of Medicine, Tokyo, Japan; [4]Nagoya, Japan; [5]Department of Vascular Medicine, Osaka Metropolitan University Graduate School of Medicine, Osaka, Japan; [6]Vascular Science Center for Translational Research, Osaka Metropolitan University Graduate School of Medicine, Osaka, Japan

Background: Arginine vasopressin deficiency (AVP-D) has been increasingly reported after coronavirus disease 2019 (COVID-19) infection and SARS-CoV-2 vaccination. However, most published cases have been described as idiopathic or post-infectious, and the underlying etiology remains largely unresolved. Anti-rabphilin-3A antibodies have recently been identified as a highly sensitive and specific biomarker for lymphocytic infundibulo-neurohypophysitis (LINH), an autoimmune inflammatory disorder of the hypothalamic–neurohypophyseal system.

Aim: To present two anti-rabphilin-3A antibody–positive cases of COVID-19–associated AVP-D and to re-evaluate previously reported cases.

Case presentations: We describe two patients who developed new-onset AVP-D following COVID-19–related events. One patient developed abrupt polyuria and polydipsia approximately three weeks after SARS-CoV-2 infection, while the other developed progressive AVP-D several weeks after SARS-CoV-2 vaccination following prior infection. Endocrinological evaluation in both cases demonstrated hypotonic polyuria with inappropriately low plasma AVP levels, blunted AVP responses to hypertonic saline, and preserved responsiveness to desmopressin. Pituitary magnetic resonance imaging showed loss of the posterior pituitary bright spot with pituitary stalk thickening. During follow-up, pituitary stalk swelling markedly improved within one month in the post-infection case, whereas persistent stalk enlargement was observed for more than one year in the post-vaccination case. Serum anti-rabphilin-3A antibodies were detected in both patients, strongly supporting a diagnosis of LINH and allowing avoidance of invasive pituitary biopsy.

Review of the literature: A review of previously reported COVID-19–associated AVP-D cases suggests that pituitary stalk swelling is observed more frequently after vaccination than after infection, whereas immunological evaluation has rarely been performed in

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

either setting. This pattern is consistent with our longitudinal imaging findings, indicating potential differences in disease course depending on the triggering event. No established diagnostic biomarkers have been applied in most cases, leaving the etiology undefined.

Additional evidence: We have also recently reported a pediatric case of post-COVID-19 AVP-D with positive anti-rabphilin-3A antibodies, supporting autoimmune involvement across age groups.

Conclusions: Our findings provide immunological evidence that a subset of COVID-19–associated AVP-D represents autoimmune hypothalamic–neurohypophyseal inflammation. Anti-rabphilin-3A antibody positivity may serve as a non-invasive biomarker indicating autoimmune involvement and could aid etiological classification and avoidance of invasive diagnostic procedures in patients with AVP-D occurring after COVID-19 infection or vaccination. Although all COVID-19–associated AVP-D cases experienced at our institutions to date have been antibody-positive, further case accumulation is required to evaluate diagnostic sensitivity and to clarify differences between antibody-positive and -negative AVP-D.

EP1130 - ECE_1448 - Clinical evolution from disease presentation to progression in primary and secondary empty sella: a real-world comparative study

Francesca Paglia[1], Vanessa Caccin[1], Gianluca Margiotta[2], Nicolò Bacchi[1], Chiara Diazzi[3], Bruno Madeo[4], Maria Chiara Decaroli[1], Maria Laura Monzani[1], Sara De Vincentis[1] and Vincenzo Rochira[1]

[1]Endocrinology Unit, Department of Biomedical, Metabolic and Neurosciences, University of Modena and Reggio Emilia, Modena, Italy; [2]South-Western Piedmont Area, Local Health Authority (ASL) CN1, Cuneo, Italy; [3]Endocrinology Unit, Department of Specialized Medicine, University Hospital of Modena, Modena, Italy; [4]Modena, Italy

Background: Empty Sella (ES) describes a neuroradiological condition in which the pituitary gland appears flattened due to partial or complete occupation of the sella turcica by cerebrospinal fluid. ES is traditionally considered a stable condition, although long-term endocrine outcomes may differ substantially according to etiology. Comparative longitudinal data between Primary (PES) and Secondary ES (SES) remain limited.

Methods: We conducted a retrospective, longitudinal study including adult patients with ES evaluated at a tertiary endocrinology center between 2007 and 2025. ES was classified as PES or SES based on clinical history. Clinical and neuroradiological features, comorbidities, and pituitary hormonal assessments were collected at baseline and at last follow-up. Longitudinal changes in pituitary function were compared between groups.

Results: A total of 258 participants were included (64.3% women; median age 51.5 years). PES was more prevalent than SES (61.6% vs 38.4%). Over long-term follow-up (median 58.5 months), endocrine function trajectories diverged markedly between PES and SES. In the PES cohort, pituitary function did not change in 83.3% of patients, with a very low incidence of newly developed hormonal deficiencies (≤4% per axis). Recovery of pre-existing deficits was rare (<5%), confirming the generally non-progressive nature of PES with a stability of pituitary function.

In contrast, SES exhibited a significantly progressive change in pituitary function. Compared with PES, SES patients showed a significant increase over time in both anterior pituitary deficiencies ($P = .037$) and total pituitary deficiencies ($P = .027$). New-onset hormonal impairments occurred predominantly in SES, affecting the corticotropic (7.4%, $P = .01$), thyrotropic (11.6%, $P = .018$), and gonadotropic axes (5.3%, $P = .01$).

Arginine vasopressin deficiency appeared and partially resolved exclusively in SES, mirroring the persistence or fluctuation of polyuria and polydipsia in this subgroup. From a clinical standpoint, headache, asthenia, and visual disturbances remained largely unchanged in both groups. Notably, sexual dysfunction showed greater variability in SES, with both onset and partial recovery of reduced libido occurring more frequently than in PES ($P = .031$).

Conclusions: Long-term follow-up reveals two distinct endocrine phenotypes of ES. PES is characterized by durable hormonal stability, whereas SES carries a significant risk of progressive pituitary dysfunction over time. These findings support an etiology-driven management approach, advocating prolonged and closer endocrine surveillance in patients with SES, while suggesting that a more conservative follow-up strategy may be appropriate for the clinical management of PES.

EP1131 - ECE_1778 - Pituitary hormone profiles and male hypogonadism in dialysis patients

Büşra Tunç Topuz[1], Ceren Tufan[1], İlhan Kılıç[2], Emre Saygili[1], Hayri Bostan[3], Ali Degirmenci[4] and Ersen Karakilic[1]

[1]Department of Endocrinology and Metabolism, Canakkale Onsekiz Mart University, Canakkale, Türkiye; [2]Department of Nephrology, Trakya University, Edirne, Türkiye; [3]Department of Endocrinology, Çanakkale Mehmet Akif Ersoy State Hospital, Canakkale, Türkiye; [4]Departmant of Nephrology, Çanakkale Mehmet Akif Ersoy State Hospital, Çanakkale, Türkiye

Objective: Chronic kidney disease affects approximately 10%-13% of the general population and may be associated with multiple endocrine abnormalities, particularly alterations in anterior pituitary hormones. However, data comparing pituitary hormone profiles in patients undergoing hemodialysis (HD) or peritoneal dialysis (PD) are limited. This study aimed to evaluate anterior pituitary hormone profiles in patients receiving active dialysis therapy.

Methods: This retrospective study included patients followed in dialysis units of tertiary and secondary care centers. Demographic and clinical characteristics and routine biochemical and hormonal parameters were obtained from electronic medical records. Statistical analyses included appropriate parametric and nonparametric tests, correlation analysis, and multivariable logistic regression. A P value <.05 was considered statistically significant.

Results: A total of 111 patients were included (median age: 66 years; 47.7% female). Age-adjusted IGF-1 levels were below the reference range in 21.8% of patients and were significantly lower in the HD group than in the PD group. Patients receiving PD had significantly higher serum prolactin, TSH, and cortisol levels, as well as higher estradiol levels in men and postmenopausal women. Serum calcium and albumin levels were lower, and hypertension prevalence was higher, in the PD group.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Among 58 male patients, 32 (55.2%) had total testosterone levels below 3 ng/mL, consistent with biochemical hypogonadism. In men, total testosterone levels were negatively correlated with prolactin (rho = −0.387; $P = .003$), FSH (rho = −0.357; $P = .006$), and LH (rho = −0.315; $P = .016$), and positively correlated with fT4 (rho = 0.392; $P = .002$). Increased body weight was also associated with lower testosterone levels (rho = −0.473; $P = .023$). In multivariable logistic regression analysis, higher serum prolactin levels were independently associated with biochemical hypogonadism in men (OR 1.25, 95% CI 1.09-1.43), whereas higher estradiol levels were inversely associated with low total testosterone (OR 0.94, 95% CI 0.89-0.98). Age and dialysis modality were not independently associated with hypogonadism(Nagelkerke $R^2 = 0.559$; classification accuracy: 82.8%).

Conclusions: Dialysis patients exhibit significant alterations in anterior pituitary hormone profiles, with differences according to dialysis modality. Reduced IGF-1 levels and biochemical hypogonadism are common, particularly in men. Higher prolactin increases, whereas higher estradiol decreases, the likelihood of low total testosterone. These findings highlight the importance of routine hormonal assessment in patients with end-stage kidney disease.

Abstract citation ID: lvag096.1388

EP1132 - ECE_1995 - Higher PANOMEN-3 grade predicts the need for additional interventions following surgery in patients with non-functioning pituitary macroadenomas

Efrat Markus[1,2], Yaron Rudman[2,3], Genady Drozdinsky[2,4], Ilan Shimon[2,3] and Shlomit Koren[1,2]
[1]*Shamir Medical Center, Endocrine and Diabetes Institute, Zerifin, Be'er Ya'akov, Israel;* [2]*Gray Faculty of Medical & Health Sciences, Tel Aviv University, Tel Aviv, Israel;* [3]*Beilinson Hospital, Rabin Medical Center, Institute of Endocrinology, Petah Tikva, Israel;* [4]*Rabin Medical Center, Infectious Diseases Unit, Beilinson Hospital, Petah Tikva, Israel*

Introduction: In 2024, the Pituitary Society proposed the Pituitary Adenoma Nomenclature 3 (PANOMEN-3) classification for assessing the prognosis of pituitary tumors. The rationale behind this new classification was to enable the prognostic assessment of tumors managed surgically and conservatively—a feature particularly relevant for patients with non-functioning pituitary adenomas (NFPAs), which are increasingly managed non-surgically.

Aim: To assess how PANOMEN-3 grade, both at diagnosis and postoperatively, relates to the likelihood and timing of additional treatment, and its potential utility in guiding intervention decisions in patients with non-functioning pituitary macroadenomas (macro-NFPAs).

Methods: This is a retrospective cohort study. We conducted a computerized search in Rabin and Shamir medical centers databases for the diagnosis of macro-NFPAs recorded between the years 1974-2024. Of 210 patients, 180 had at least one year of pituitary MRI follow-up and were included in the analysis. Clinical, biochemical, and imaging data were collected to assess the PANOMEN-3 grade at diagnosis and postoperatively.

Results: Our cohort included 180 patients (80 females, 44.4%; age at diagnosis, 61.0 ± 14.1 years), of whom 116 underwent transsphenoidal surgery (TSS). Median follow-up was 5 years [IQR 2-10]. After initial TSS, the proportion of patients requiring additional treatment (including repeat TSS and/or dopamine agonist therapy and/or radiotherapy) increased with higher PANOMEN-3 grade at diagnosis (Grade 1: 25.6%, Grade 2: 35.6%, Grade 3: 50%, $P = .093$) and postoperatively (Grade 0: 0%, Grade 1: 28.3%, Grade 2: 46.5%, Grade 3: 75%, $P < .01$). Median time from first TSS to additional treatment was shorter with increasing PANOMEN-3 grade. This trend was observed both at diagnosis (Grade 1: 54 months [IQR 16-88], Grade 2: 47 months [IQR 12-97], Grade 3: 5 months [IQR 3-24], $P = .041$) and postoperatively (Grade 1: 68 months [IQR 16-94], Grade 2: 24 months [IQR 12-53], Grade 3: 5 months [IQR 3-16], $P = .079$).

Conclusions: Our data indicate that higher PANOMEN-3 grade, both at diagnosis and postoperatively, was associated with an increased likelihood of requiring additional treatment after surgery and earlier. This highlights the potential of PANOMEN-3 grade to guide decisions regarding the intensity of intervention at diagnosis, and to predict the need for additional treatment in patients with macro-NFPA.

EP1133 - ECE_2266 - Preoperative infection burden in Cushing's disease: association with urinary free cortisol levels

Rukiye Dilara Tekin Uzman, Aysel Unver Ozkahraman, Gizem Karatas Kiliccioglu, Mutlu Niyazoğlu and Esra Hatipoglu
Istanbul, Türkiye

Objective: To evaluate the frequency and spectrum of preoperative infections in Cushing's disease (CD) and assess their association with urinary free cortisol (UFC) levels.

Methods: This single-centre retrospective study included 60 CD patients who underwent transsphenoidal surgery between January 2019 and December 2023. Patients with ectopic ACTH syndrome, adrenal Cushing's syndrome, chronic immunosuppression, active malignancy, or incomplete UFC measurements were excluded. Physician-diagnosed infections requiring antimicrobial treatment within six months preoperatively were identified through medical records, ICD-10 codes, and prescriptions.

Preoperative assessments included basal serum cortisol and ACTH, 24-hour UFC, late-night salivary cortisol, glycaemic parameters, complete blood count, and inflammatory markers. Correlation analyses and receiver operating characteristic (ROC) curve analysis were performed.

Results: The cohort comprised 50 women (83.3%) and 10 men (16.7%); mean age 48.7 ± 11.4 years. Preoperative infections were common: 56.7% of patients experienced ≥2 antimicrobial-treated infections. Upper respiratory tract infections predominated (58.3%), followed by dermatophytosis (28.3%), bacterial dermatitis (21.7%), and urinary tract infections (20.0%).

Infection number correlated positively with UFC levels ($\rho = 0.4$, $P = .02$). ROC analysis demonstrated modest discriminatory performance of UFC for identifying infections requiring treatment (AUC = 0.69; 95% CI: 0.52-0.87), with a threshold of 107.5 µg/24 h yielding 70% sensitivity and 75% specificity.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Basal serum cortisol, late-night salivary cortisol, haematological indices, inflammatory markers, HbA1c, and fasting plasma glucose showed no significant associations with infection burden.

Conclusions: Among evaluated biochemical markers, UFC alone demonstrated a significant association with preoperative infection frequency in CD. UFC measurement may facilitate risk stratification for infection surveillance and timely intervention before definitive treatment.

EP1134 - ECE_2943 - Body composition in acromegaly assessed by bioelectrical impedance analysis: differences between active and controlled disease

Signe Graungaard[1], Mai C. Arlien-Søborg[2], Niels Henrik Bruun[1], Erlend Gjersdal[1,3], Jens Otto Jørgensen[2] and Jakob Dal[1,4]

[1]Research data and Biostatistics, Aaborg Universityhospital, Aalborg, Denmark; [2]Endocrinolgy, Aarhus Universityhospital, Aarhus, Denmark; [3]Endocrinology, Aalborg University hospital, Aalborg, Denmark; [4]Steno Diabetes Center North Jutland, Aalborg, Denmark

Purpose: To evaluate the accuracy of bioimpedance analysis (BIA) compared to dual-energy x-ray absorptiometry (DXA) measurements of body composition in patients with active and controlled acromegaly.

Methods: BIA and DXA methods were applied to estimate body composition in patients with active acromegaly and again after disease control.

Results: 16 patients with active acromegaly were included and followed until after disease control. GH nadir decreased from 5.5 ± 5.7 µg/L to 0.2 ± 0.3 µg/L, and IGF-1 levels from 565 ± 189 ng/L to 191 ± 137 ng/L after treatment. Body weight remained stable (95.4 ± 30.0 kg and 95.5 ± 26.7 kg) throughout the study period although fat mass increased by 3.2 kg (from 34.1 ± 15.2 kg to 37.5 ± 14.6 kg) or 4.5 kg (31.5 ± 14.6 kg to 36.0 ± 16.0 kg) measured by DXA or BIA, respectively. Lean body mass measured by DXA decreased by 2.2 kg (61.6 ± 16.9 kg to 59.4 ± 14.5 kg), while fat free mass decreased by 4.2 kg (63.4 ± 19.0 kg to 59.2 ± 15.7 kg) and total body water (L) decreased by 3.1 kg (46.4 ± 13.9 kg to 43.3 ± 11.5 kg) estimated by BIA. Using Bland–Altman analysis the bias in estimates for lean mass was −1.7 kg (LOA: −10.0-6.6 kg) in active acromegaly and 0.2 kg (LOA: −10.1-10.5 kg) with hormonal control. For fat mass, bias was 2.6 kg (LOA: −3.8-9.0 kg) in active disease and 1.5 kg (LOA: −5.0-8.1 kg) in controlled disease.

Conclusions: We observed ahigh conformity between BIA predictions and DXA scan measurements in patients with acromegaly during both active disease and hormonal control which supports the utility of BIA in clinical practice. BIA estimates can add important clinical insights about hydration and fluid shifts that DXA alone does not provide, which are clinically relevant in acromegaly where fluid balance is altered by GH/IGF-I excess.

Abstract citation ID: lvag096.1391

EP1135 - ECE_3556 - Postoperative quality of life and sleep disorders following transsphenoidal resection of pituitary adenomas

Hamza El Hadi, Jona Streit, Eric Suero Molina, Walter Stummer, Jonel Trebicka and Elena Vorona

Münster University Hospital, Münster, Germany

Introduction: Despite recent advances in surgical techniques and endocrinological management, patients undergoing transsphenoidal resection of pituitary adenomas (PA) frequently report persistent impairment in quality of life (QoL) and sleep disturbances. The potential impact of postoperative hypopituitarism (HP) on these outcomes in these patients remains incompletely understood.

Methods: This cross-sectional study evaluated patient-reported outcomes related to health-related quality of life (HRQoL) and sleep quality in patients with a history of transsphenoidal PA resection. The primary aim was to assess the postoperative prevalence of impaired QoL and sleep disorders in relation to pituitary hormone deficiency. A secondary aim was to identify predictors of sleep disturbances.

Patients with a prior transsphenoidal PA resection who were undergoing follow-up at our Endocrinology Unit between March

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

and December 2025 were enrolled. Patients were divided into two groups based on the presence or absence of HP, defined as one or more partial or complete deficiencies of adenohypophyseal or neurohypophyseal hormones diagnosed during postoperative follow-up. All hormone deficiencies were adequately replaced according to international clinical practice guidelines. HRQoL was assessed using the 36-Item Short Form Health Survey (SF-36), sleep quality using the Pittsburgh Sleep Quality Index (PSQI), and daytime sleepiness using the Epworth Sleepiness Scale (ESS).

Results: The study population included 100 patients: 53 with preserved postoperative pituitary function and 47 with HP. Median age was 54 years in patients without HP and 60 years in those with HP ($P > .05$). No significant between-group differences were observed in gender, BMI, sleep apnea, dyslipidemia, or cardiovascular disease.

Patients with hormonally inactive adenomas had higher prevalence of postoperative HP compared with those with hormonally active tumors (30% vs 18%, $P = .005$). Impaired QoL and sleep disturbances were common in both groups, with no significant differences questionnaire scores.

Correlation analyses showed that higher PSQI scores (indicating poorer sleep quality) were associated with higher ESS scores ($\rho = 0.23$, $P = .02$), lower vitality ($\rho = -0.36$, $P < .001$), and poorer mental health ($\rho = -0.37$, $P < .001$). In multivariable regression analysis, impaired mental health remained the only independent predictor of worse PSQI scores ($\beta = -.07$, 95% CI −0.11 to −0.02, $P = .005$).

Conclusions: Our findings provide additional evidence of a high prevalence of impaired QoL and sleep disturbances following transsphenoidal resection of PA. These disturbances appear largely independent of postoperative pituitary hormonal status, highlighting the central role of mental health in postoperative sleep quality and overall well-being.

EP1136 - ECE_2877 - Patient experiences with the digital communication tool *InvolveMe* in outpatient management of pituitary adenomas

Elin Børøsund[1,2], Kari Abelsen[3], Anders Jørgensen[3,4], Line Cecilie Krabbe Schie[3] and Berit Seljelid[1,5]
[1]*Division of Medicine, Department of Digital Health Research, Oslo University Hospital, Oslo, Norway;* [2]*Faculty of Health and Social Sciences, Department of Nursing and Health Sciences, University of South-East Norway, Drammen, Norway;* [3]*Division of Medicine, Section of Specialized Endocrinology, Department of Endocrinology, Morbid Obesity and Preventive Medicine, Oslo University Hospital, Oslo, Norway;* [4]*Faculty of Medicine, Institute of Clinical Medicine, University of Oslo, Oslo, Norway;* [5]*Norwegian Center for Health Literacy and Coping, Department of Education and Competence Development, Oslo University Hospital, Oslo, Norway*

Background: Patients with pituitary adenomas (PA) often experience persistent symptoms following pituitary surgery, underscoring the importance of effective communication with healthcare providers. Digital tools offer the potential to enhance patient-provider communication by enabling patients to report issues they consider important to discuss during clinical encounters. *InvolveMe*, a digital communication tool, facilitates a systematic assessment of patients' symptoms, needs and preferences prior to consultations. This tool aims to assist patients in preparing for their appointment, support agenda-setting, and promote greater patient involvement in their care. *InvolveMe* is integrated into the Norwegian health platform and the hospital's electronic patient record system. However, the successful implementation of such novel follow-up approaches requires careful adaptation to the needs of users and alignment with existing clinical workflows.

Aim: To explore patients' experience of using the *InvolveMe* communication tool as part of outpatient consultations.

Method: Participants with PA were recruited from an outpatient clinic at a tertiary referral center between October and December 2025. Patients scheduled for postoperative outpatient follow-up appointments were invited to complete the *InvolveMe* tool via digital appointment letters. Data was collected on how many patients received the invitation and the number who completed the *InvolveMe* assessment. Furthermore, we collected information on reasons for non-use of *InvolveMe* and invited a subset of patients ($n = 5$) to participate in individual interviews to explore their experiences with using *InvolveMe* during outpatient consultations. The data were analyzed using a rapid analysis approach.

Results: Of 50 invited patients, 21 (42%) completed *InvolveMe*. Main reasons for not using *InvolveMe* included not noticing the invitation, perceiving no personal need, or lacking necessary digital skills. Analysis of the interviews with patients who used *InvolveMe* revealed four themes: (1) Being prepared for the upcoming consultation, (2) High expectations of its use during consultations, (3) A tool for addressing patient-prioritized topics, and (4) Suggestions for improving routines and *InvolveMe* functionalities. Patients described *InvolveMe* as a tool that facilitated reflection on important topics to discuss during consultations and that healthcare providers in most cases used the summary as part of consultations.

Conclusions: Patients valued the opportunity to use *InvolveMe* as part of their preparation for outpatient consultations. To enhance accessibility, further investigation is needed to understand barriers for use. Additionally, exploring the perspectives and experiences of healthcare providers in utilizing *InvolveMe* will be essential for optimizing its implementation into clinical practice.

Sklodowska-Curie National Research Institute of Oncology, Warsaw, Poland; [5]Department of Medical Genetics, Medical University of Warsaw, Warsaw, Poland; [6]Department of Neurosurgery, Military Institute of Medicine - National Research Institute, Warsaw, Poland; [7]Department of Methodology, Medical University of Warsaw, Warsaw, Poland; [8]Polish Academy of Sciences, Laboratory of Molecular OncoSignalling, International Institute of Molecular Mechanisms and Machines, Warsaw, Poland; [9]Department of Immunology, Medical University of Warsaw, Warsaw, Poland; [10]Department of Neurosurgery, The National Hospital for Neurology and Neurosurgery, Queen Square, London, United Kingdom; [11]Department of Histology and Embryology, Medical University of Warsaw, Warsaw, Poland

Purpose: The exact molecular mechanisms driving non-functioning-PitNETs invasiveness are still unclear, and reliable molecular biomarkers remain unknown. Although, the role of microRNAs (miRs) as promising markers of invasiveness in other PitNETs is increasingly highlighted. Our study aimed to identify novel miRs and differentially regulated genes in invasive and noninvasive NF-PitNETs. We have validated our results in a large cohort of tumour and control normal normal pituitary samples.

Methods: RNA sequencing was conducted on 13 fresh-frozen human NF-PitNET samples (7 invasive and 6 noninvasive; gonadotrophs), while microRNA sequencing was performed on 12 of these samples. Validation was carried out using Fluidigm HD GEX arrays with TaqMan assays and quantitative PCR among NF-PitNETs ($n = 80$) and normal pituitary samples ($n = 10$). Confirmatory results included 23 selected mRNA genes (controls: *GAPDH* and *SNORD61*) and 38 miRs (including 35 miRs identified by microRNA sequencing, two reference genes, and three miRs previously reported in the literature).

Results: RNA sequencing revealed differential expression of 10 733 genes, of which 364 reached statistical significance (adjusted $P <$ .05) and were involved in 783 biological processes. Parallel miRNA-Seq identified 35 downregulated miRNAs mapping to 143 Gene Ontology (GO) processes. Gene Ontology and KEGG pathway analyses highlighted dysregulation of cell adhesion and adherens junction pathways, implicating their role in tumor invasiveness.

Validation in an expanded cohort demonstrated overexpression of cell adhesion molecules (*CADM2, CADM3*) important for cell-cell adhesion, aggregation as well as synapse organization and ephrin receptor B1 (*EPHB1*), whose major role includes targeted cell migration and adhesion. We also found downregulation compared to normal pituitary tissue of *CRIM1* (Cysteine Rich Transmembrane BMP Regulator 1) responsible for tissue development through interactions with members of the transforming growth factor beta family, together with downregulation of *BCL2L11* transcript (belonging to BCL-2 protein family) known to act as apoptotic activator.

MiR-127-5p showed a weak but statistically significant positive correlation with *BCL2L11* and *CRIM1* and a statistically significant negative correlation with *CADM2* and *CADM3*. Additionally, *miR-432-5p* was negatively correlated with *CADM2* expression in NF-PitNET tissues ($r = -0.4176$, $P = .0005$). MiRs may regulate post-transcriptionally genes expression, thus our findings may suggest possible mechanisms underlying NF-PitNETs development and/or progression.

Conclusions: Our study reveals novel genes and miRs in NF-PitNETs suggesting their potential regulatory role in cell adhesion, migration, and apoptosis therefore potentially contributing to their pathogenesis.

EP1138 - ECE_1835 - Muscle performance, body composition, and disease control in acromegaly: insights from an observational study

Rosa Pitino[1], Chiara Mele[1], Martina Romanisio[1], Sara Sturnia[1], Alice Ferrero[1], Gianluca Aimaretti[1], Paolo Marzullo[1], Flavia Prodam[1,2] and Marina Caputo[1,2]
[1]Endocrinology, Department of Translational Medicine, Università del Piemonte Orientale, Novara, Italy; [2]Department of Health Sciences, Università del Piemonte Orientale, Novara, Italy

Aim: To evaluate muscle strength, body composition, and quality of life (QoL) in acromegalic patients compared with age-, sex-, and BMI-matched healthy controls.

Patients and Methods: In this observational study, 26 acromegalic patients followed at a tertiary referral center and age-, sex-, and BMI-matched controls were enrolled. Patients with uncontrolled metabolic diseases (ie, HbA1c > 8.5%), active malignancies, acute severe illness were excluded. For acromegalic patients, clinical characteristics, disease duration and activity, metabolic complications, and hormonal parameters were collected, including GH and IGF-1 levels at baseline and at last follow-up; ΔIGF-1 was calculated as the difference between baseline and last available follow-up measurement. Muscle strength, body composition, and QoL were assessed cross-sectionally at the last follow-up visit in both patients and controls. Muscle strength was evaluated using handgrip dynamometry, sit-to-stand test, and Medical Research Council (MRC) scale. Body composition was assessed by bioelectrical impedance analysis (BIA), including fat-free mass (FFM), muscle mass (MM), fat mass (FM), and abdominal fat mass (A-FM). EQ-5D and SARC-F questionnaires were used for QoL.

Results: Patients with acromegaly and controls were comparable for metabolic comorbidities, except for a higher prevalence of diabetes (53.8% vs 7.7%, $P = .003$) and cardiovascular disease (26.9% vs 0%, $P = .005$) in the acromegaly group. Controls showed a higher abdominal fat mass percentage (A-FM%) compared with patients with acromegaly (45.3% vs 24.9%, $P < .0001$). Disease control was associated with a more favorable body composition: ΔIGF-1 correlated inversely with FM% and A-FM% ($\rho = -0.45$, $P = .04$; $\rho = -0.67$, $P = .001$) and positively with MM% and FFM% ($\rho = 0.47$, $P = .03$; $\rho = 0.45$, $P = .04$). Despite this more favorable body composition, acromegalic patients showed reduced biceps and quadriceps strength on the MRC scale compared with controls ($P = .002$ and $P = .0001$, respectively). Notably, patients showing a greater reduction in IGF-1 from baseline to last follow-up exhibited higher handgrip strength (right: $\rho = 0.52$, $P = .03$; left: $\rho = 0.62$, $P = .006$), regardless of sex, age, BMI, and physical activity level.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

QoL, assessed by EQ-5D questionnaire, was lower in acromegalic patients than healthy controls (70 vs 80; $P = .002$), in line with the observed impairments in muscle strength and physical performance.

Conclusions: In acromegaly, biochemical disease control is associated with a more favorable body composition and with better muscle performance at follow-up. However, despite these metabolic advantages, patients exhibit muscle weakness and reduced QoL compared with healthy controls, highlighting the need for management strategies beyond biochemical control.

EP1139 - ECE_3086 - Paradoxical GH response during OGTT in acromegaly predict disease phenotype

Penelope Giambò[1,2], Sabrina Chiloiro[1,2], Antonella Giampietro[1,2], Pier Paolo Mattogno[2,3], Liverana Lauretti[2,3], Laura De Marinis[1,2], Antonio Bianchi[1,2], Francesco Doglietto[2,3] and Alfredo Pontecorvi[1,2]

[1]Endocrinology and Metabolism, Dipartimento di Medicina e Chirurgia traslazionale, Fondazione Policlinico Universitario Agostino Gemelli, Roma, Italy; [2]Endocrinology and Metabolism, Dipartimento di Medicina e Chirurgia traslazionale, Agostino Gemelli University Policlinic, Roma, Italy; [3]Neurosurgery, Neuroscience, Sensory Organs, and the Chest, Fondazione Policlinico Universitario Agostino Gemelli, Rome, Italy

Introduction: Acromegaly is a rare neuroendocrinological disease. According to the last consensus, the diagnosis is based on an IGF-I value >1.3 times the upper limit of normal for age. In cases of doubt, in order to confirm the diagnosis, the oral administration of 75 g of glucose and the dosages of GH at baseline and every 30 minutes until 2 hours can be practiced. Some acromegalic patients show a paradoxical response to this test, meaning that an elevation of GH levels can be observed rather than a more "physiological" decrease. However, a universally accepted definition of paradoxical response is missing. Furthermore, this phenomenon has been studied to investigate a possible correlation between the latter and the disease outcome.

Patient and Methods: To contribute to answering to this question, we conducted a retrospective and observational study including 41 patients, defining the paradoxical response as an OGTT ratio (ratio between the peak of GH value during OGTT and the baseline value) > 120% in the first 90 minutes.

Results: Ten patients showed a GH paradoxical response (GH-par) to OGTT at the diagnosis (24.4%), the remaining 31 patients showed a not-paradoxical GH response (GH-not-par). GH-par response occurred more frequently in smaller somatotroph tumors (GH-par: 16 millimetres IQR: 25 vs GH-not-par 18 millimetres IQR: 12 millimetres, $P = .006$), low proliferative somatotroph tumors (GH-par: 1% IQR: 2 vs GH-not-par 2% IQR: 2, $P = .05$) and in densely granulated somatotroph tumors (OR: 0.67 95% IC: 0.42-0.98).

The occurrence of GH paradoxical response did not differ among gender ($P = .46$), age ($P = .87$), BMI ($P = .8$), GH, IGF-I levels at diagnosis ($P = .39$ and $P = .27$), hyperinsulinism ($P = .37$), presence of type 2 diabetes at acromegaly diagnosis ($P = .32$), glycemia and insulinemia at diagnosis ($P = .48$ and $P = .21$), expression of somatostatin receptor (SSTR2A *P*-value: .54; SST5 *P*-value: .43), and disease outcome, such as post-surgery cure ($P = .53$), response to first generation SRL ($P = .67$), and to second generation SRL ($P = .72$), and did not predict the occurrence of acromegaly related complications, such as type 2 diabetes ($P = .62$), osteopenia/osteoporosis ($P = .61$), other neoplasia ($P = .31$), and arterial hypertension ($P = .61$).

Conclusions: In conclusion, in our study the paradoxical response to OGTT in acromegaly seems to predict a mild disease phenotype. Therefore, although the definition of paradoxical response, as well as its predictive and prognostic role, had changed in last years, the evaluation of GH levels during OGTT remain a useful diagnostic tool in patient with doubt diagnosis of acromegaly and in cases of challenging in interpretation of IGF-I values.

EP1141 - ECE_2078 - Neuroactive steroids, cytokines and tau-proteins as potential biomarkers of normal pressure hydrocephalus

Lucie Kolatorova[1], Tereza Skodova[1], Jana Vitku[1], Petr Skalicky[2], Michala Vosátková[3], Josef Vcelak[4], Tomas Moravec[5], Adela Bubenikova[2] and Ondrej Bradac[2,5]

[1]Department of Steroids and Proteofactors, Institute of Endocrinology, Prague, Czech Republic; [2]Department of Neurosurgery, Motol University Hospital, Prague, Czech Republic; [3]Department of Clinical Biochemistry, Institute of Endocrinology, Prague, Czech Republic; [4]Department of Molecular Endocrinology, Institute of Endocrinology, Prague, Czech Republic; [5]Department of Neurosurgery and Neurooncology, Military University Hospital, Prague, Czech Republic

Background: Normal pressure hydrocephalus (NPH) is a potentially reversible neurodegenerative disorder caused by impaired cerebrospinal fluid (CSF) absorption, leading to ventricular enlargement. It presents with gait disturbance, urinary incontinence, and cognitive impairment and is often misdiagnosed as other neurodegenerative diseases. As one of the few treatable causes of dementia, accurate diagnosis is crucial, and shunt implantation leads to clinical improvement in 70%-90% of patients. Within the NPH diagnostic framework, including the lumbar infusion test (LIT), CSF is an accessible source of biomarkers. While cytokines and tau proteins have been proposed as biomarkers, steroid metabolism—closely linked to osmotic dysregulation and neuroinflammation in NPH—remains understudied.

Aim: This study aims to identify CSF steroid biomarkers and validate the diagnostic potential of cytokines and tau proteins in NPH.

Methods: 17 neuroactive steroids (androgens, gestagens, corticoids, estrogens) were quantified by LC-MS/MS. Amyloid-β42, tau proteins (p-tau and t-tau) and cytokines were determined by immunoassay.

Results: The patient group included 116 subjects (43 female, 73 male) average 74 years old diagnosed with NPH. They underwent surgical shunt implantation and were observed 3 and 12 months after surgery. Control group were subjects ($n = 95$, 34 female, 61 male, average age 75 years) who underwent LIT and were classified as non-responders. In NPH, we observed significantly decreased CSF levels of tau-proteins, interleukin-10, MPC-1, TNF-α, and significantly increased estrone and aldosterone compared to control group both in men and women. In NPH before, 3 and 12 months after the surgery, we found significantly increased CSF amyloid-β42, p-tau, t-tau, MCP-1 and MIP-1β in both time intervals after surgery. In men, in contrast to women, there was

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

significant increase in CSF androgens (androstenedione, testosterone and their 11-oxygenated metabolites), corticoids (cortisol, cortisone, corticosterone, 11-deoxycortisol), pregnenolone and 17-hydroxyprogesterone after 3 months; thereafter, a non-significant decrease of mentioned steroids was observed.

Conclusions: Within the known CSF biomarkers for NPH (tau-proteins, MCP-1, IL-10, TNF-α), we have found CSF aldosterone and estrone as possible biomarkers helpful in the NPH diagnosis. The association of high CSF estrone in NPH with low tau-protein is biologically plausible, given that estrogens are known to reduce tau-protein phosphorylation. The finding of elevated CSF aldosterone levels is consistent with its mineralocorticoid activity in line with the NPH pathophysiology. We also observed sex-specific differences in neurosteroid metabolism after shunt insertion, which may be relevant for personalized medicine.

EP1142 - ECE_1271 - Clinically diagnosed MEN 1: diagnostic challenges and delayed recognition

Tamara Dojcinovic[1,2], Jelena Malinovic Pancic[1,2], Bojana Caric[1,2] and Aleksandra Markovic[1,2]
[1]*University Clinical Center of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina;* [2]*Faculty of medicine University of Banja Luka, Banja Luka, Bosnia and Herzegovina*

Background: Multiple endocrine neoplasia type 1 (MEN1) or Wermer syndrome) is a rare autosomal dominant disorder caused by germline mutations in the tumor suppressor gene MEN1. Gold standard for diagnosis is genetic testing, however the diagnosis is often clinically made by the combined occurrence of two or more of the following classical endocrinopathies: primary hyperparathyroidism (PHPT), anterior pituitary tumors, and duodenopancreatic neuroendocrine tumors (DP-NETs). Due to limited access to genetic testing, diagnosis can be established based on presence of two or more of the classical endocrinopathies.

Case report: We present the case of a 58-year-old male who was referred to an endocrinologist following a new diagnosis of diabetes mellitus. During clinical evaluation, acromegalic features were noted, prompting inpatient endocrine assessment. Hormonal testing revealed elevated IGF-1 levels (992 ng/mL) and unsuppressed GH levels during oral glucose tolerance testing (OGTT), consistent with a somatotropinoma. Pituitary MRI confirmed the presence of a macroadenoma measuring 11 mm. Given the patient's history of recurrent kidney stones, parathyroid hormone (PTH) levels were assessed and found to be elevated (98 pg/mL), accompanied by mildly increased serum calcium levels, raising suspicion of primary hyperparathyroidism. MIBI scintigraphy was subsequently performed and confirmed the diagnosis, demonstrating an enlarged and hyperactive right lower parathyroid gland. On top of that, abdominal MRI revealed a cystic neoplasm in the pancreas and detailed gastroenterological evaluation was conducted. The patient underwent transsphenoidal pituitary surgery. The pathological examination showed a plurihormonal pituitary neuroendocrine tumor (PitNET). At the three-month reevaluation, disease remission had not been achieved, so somatoatatin analogue octreotid was introduced into the treatment. Parathyroidectomy is planned as the next step. Given the presence of multiple endocrine neoplasias, clinical diagnosis of MEN1 was established, and referral to a higher-level reference center for genetic testing is planned.

Conclusions: This case highlights the importance of detailed clinical history and thorough physical examination in endocrinological outpatient clinic. Every patient with acromegaly should undergo comprehensive endocrine evaluation to rule out syndromic causes, given the implications for diagnosis, treatment, and family screening.

EP1143 - ECE_3783 - Rare coexistence of intracranial tumors: craniopharyngioma, PitNET, and vestibular schwannoma—a case report

Karolina Cylke-Falkowska[1,2], Wojciech Zgliczyński[1] and Maria Stelmachowska-Banaś[1]
[1]*Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland* [2]*Centre of Postgraduate Medical Education, Doctoral School of Translational Medicine, Warsaw, Poland*

Background: Collision tumor is a rare entity that poses a real diagnostic and treatment challenge. To date, only 22 patients presenting with both craniopharyngioma and PitNET have been reported so far. Six of these cases involved GH-secreting PitNETs.

Case presentation: 61-year-old woman was admitted to endocrinology department with signs and symptoms suggesting acromegaly (enlargement of hands and feet and coarsening of facial features, headaches, changes in voice tone, chronic constipation). Her only long-term medication was L-thyroxine due to primary hypothyroidism. Apart from elevated IGF-1 levels and failure of GH suppression during OGTT, her hormonal profile was otherwise unremarkable.

Pituitary MRI revealed a heterogeneous, solid–cystic lesion in the suprasellar area. The lesion was compressing the optic chiasm and extending to the floor of the third ventricle. Additionally, a solid lesion was present within the sella turcica, encasing the internal carotid artery and displacing the optic nerves. Based on these findings, a collision tumor consisting of an adamantinomatous craniopharyngioma and a pituitary macroadenoma was suspected. Additionally MRI revealed a cystic lesion in the left cerebellopontine angle, consistent with vestibular schwannoma.

Head CT scan present calcifications in the suprasellar tumor, which further confirmed the presence of an adamantinous craniopharyngioma. Four months later, the patient underwent transsphenoidal surgery to remove both tumours: a GH–secreting pituitary PitNET and WHO adamantinomateus craniopharyngioma.

The postoperative course was complicated by multiple anterior pituitary deficiencies, AVP deficiency and hyperprolactinemia. These complications were managed using hydrocortisone, L-thyroxine and desmopressin replacement therapy. Due to GH deficiency patient was started on hGH replacement therapy.

Conclusions: Although extremely rare, the coexistence of GH-secreting PitNET and craniopharyngioma is possible in one patient and simultaneous surgery to remove both tumors can lead from GH excess to its deficiency.

EP1144 - ECE_1866 - ATRX protein expression in pituitary carcinomas

Dana Erickson[1], Diane Donegan[1] and Jorge Trejo-Lopez[2]
[1]Endocrinology, Mayo Clinic, Rochester, United States; [2]Pathology and Laboratory Medicine, Mayo Clinic, Rochester, United States

Introduction: Pituitary carcinomas (PC) are rare tumors as they represent around 0.2% of all pituitary neuroendocrine tumors (PA). Studies suggest inactivation of alpha thalassemia/mental retardation syndrome X-linked protein (ATRX) expression is associated with aggressive neuroendocrine tumors, limited data is available for PC.

Aim: To assess expression of ATRX in patients with PC and its association with clinical characteristics and outcome.

Methods: Patients with PC (1997-2025) were identified. Clinical information was extracted. ATRX expression was analyzed via immunostaining using mouse monoclonal antibody (D-5 sc-5584, Santa Cruz Biotechnology) when sufficient tissue blocks were available. Results were grouped as A) aberrant (loss of staining in neoplastic nuclei), B) wild -type (retention within nuclei) and C) heterogenous expression. Staining was performed either on tissue from sellar location of tumor or metastasis.

Results: Of 25 patients with PC, 9 (36%) had sufficient tissue for analysis. Median initial PA size was 2.3 cm (range 0-4.6). ATRX expression was aberrant in 5 (55%), retained in 3 (30%) and heterogeneous in 1 (11%). Although the median age in group A compared to group B was younger at PA (34 [range 30-59] vs 53 [range 49-67], $P = .14$) and PC (48 [range 44-65] vs 57 [range 56-67], $P = .07$) diagnosis, this was not statistically significant. The number of surgical resections for PA varied from 1-4, 1 prolactinoma was initially treated medically. Median time to development of metastases in group A vs B was 13 [range 4-20] vs 4 [range3-6] years, respectively. Group A included 3 corticotroph, 1 gonadotroph and 1 null cell tumor, group B only corticotroph tumors, and group C lactotroph tumor. ATRX analysis was performed on tissue a median 14 years from initial PA diagnosis in group A (4 from pituitary location, 1 from brain metastasis), 5 years for group B (3 from metastatic disease) and 32 years for Group C (metastasis to pons). Median follow-up from PA diagnosis to last follow-up/ death did not differ between group A and B (14 [range 4-44] vs 11 [range7-11], $P = .214$). One patient died in group A whereas all 3 died in group B and the patient in group C is alive.

Conclusions: ATRX expression was lost in 55% of PC analyzed. Although not statistically significant, patients with aberrant ATRX expression tended to be younger at the initial PA diagnosis with a shorter time to metastasis development. . Next steps include confirmation of findings by next generation sequencing gene analysis.

EP1145 - ECE_2143 - Body phenotyping with bedside techniques in cushing disease: a case-control study

Andrés Jiménez Sánchez, Pablo Remón Ruiz, Eva Venegas Moreno, Elena Dios-Fuentes, Jaime Perea Cortés, David Cano González and Alfonso Soto
Unidad de Gestión Clínica de Endocrinología y Nutrición, Instituto de Biomedicina de Sevilla (IBiS), Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, Sevilla, Spain

Introduction: Chronic glucocorticoid exposure in Cushing disease may lead to muscle wasting and central adiposity.

Objective: To compare the body composition of adult Cushing disease patients under active surveillance in our Pituitary Unit with healthy controls.

Materials and Methods: Design: case-control study.

Sampling: non-consecutive, from June 2023 to June 2024.

Matching protocol: exact for sex, and nearest neighbour with a generalized linear model and 0.5 caliper width for body mass index (BMI).

Body composition analysis devices: calibrated weight and stadiometer, 50 kHz bioelectrical impedance analysis (BIA) (Nutrilab, AKERN), 5-10 Hz linear probe ultrasound system (Mindray), and handgrip dynamometer (JAMAR Plus).

Ultrasonography protocol: measurements were taken at the distal third of the right thigh and midpoint between umbilicus and xiphoid process. Subcutaneous adipose tissue (SAT) was measured at both locations. Rectus femoris (RF) and whole quadricipital (Quad) muscle thickness (RF-MT; Quad-MT) were measured at thigh. Preperitoneal adipose tissue (PPAT) was measured at abdomen.

The mean of three trials for handgrip strength (HGS) was used.

Blood samples: IGF-1 was determined.

Data analysis: with RStudio. Numerical variables expressed as median (IQR). Groups (Cushing disease versus control) were compared using 95% confidence intervals (95% CI) computed after k = 2000 bootstrapping. A positive 95% CI means case > control, and a negative 95% CI means control > case. Statistical significance was defined as a 95% CI excluding zero.

Results: 78 matched participants (72 female) with a median BMI 28.5 (8.5) kg/m^2. Their characteristics are described in the following table:

Variable	Between-group difference	Lower 95% CI limit	Upper 95% CI limit
Age (years)	2.026	−4.273	8.499
Weight (kg)	0.933	−7.141	8.036
Height (m)	−0.046	−0.0804	−0.012
BMI (kg/m^2)	2.057	−0.849	4.706
Abdominal perimeter (cm)	7.064	−0.178	14.886
R	−24.469	−62.366	15.320
Xc	−7.174	−11.902	−3.417
Phase angle (°)	−0.487	−0.735	−0.255
Thigh SAT (mm)	0.335	−2.667	3.299
RF-MT (mm)	−1.507	−3.140	0.005
Quad-MT (mm)	−2.548	−5.598	0.372
Abdominal SAT (mm)	0.721	−3.945	5.219
PPAT (mm)	0.165	−0.878	1.067
HGS (kg)	−1.256	−4.047	1.433
IGF-1 (ng/mL)	−3.018	−26.106	23.613

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusions: At equal age, BMI, and IGF-1 levels, cases of Cushing disease had a lower capacitive reactance and raw phase angle in bioelectrical impedance analysis (BIA). Ultrasound revealed no differences in adiposity, though cases tended to have lower muscle thickness and strength.

Gemelli IRCCS, Department of Internal Medicine, Endocrinology and Diabetology, Università Cattolica del Sacro Cuore, Rome, Italy; [2]Department of Neurosurgery, Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome, Italy; [3]Department of Radiological Sciences, Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome, Italy; [4]Department of Neurosurgery, Università Cattolica del Sacro Cuore, Rome, Italy; [5]Neuropathology, Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome, Italy; [6]Department of Internal Medicine, Endocrinology and Diabetology, Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome, Italy

Introduction: In acromegaly, therapy with first-generation somatostatin receptor ligands (fgSRLs) plays a central role, especially in patients who do not achieve surgical remission. We have observed that long-term use of fgSRLs, may allow, in some patients, a progressive dose reduction and even a complete withdrawal, resulting in sustained disease remission.

Patients and Methods: A longitudinal, retrospective, observational study was performed on patients with acromegaly in therapy with fg-SRLs, with a 15 years follow-up. Dose reduction and withdrawal were correlated with gender, age at diagnosis, GH and IGF-I levels at diagnosis and after surgery, biochemical control, adenoma's size and its intensity on MRI, and finally, histopathological characteristics.

Results: Dose reduction and withdrawal was achieved in 9 patients out of 34 patients treated with fg-SRLs at our institution with a 15 years follow-up. In this group of patients, fg-SRL dose reduction and withdrawal did not differ among patient gender ($P = .5$), age at acromegaly diagnosis ($P = .204$), GH and IGF-I levels at diagnosis, after surgery and with the achievement of biochemical control at 6 and 12 months of treatment with conventional dose of fg-SRLs ($P = .64$ and $P = .46$). All patients with microGH secreting pituitary adenoma underwent fg-SRL dose reduction/withdrawal ($P < .003$), without difference in invasive and not-invasive macroadenoma ($P = .124$). Fg-SRL dose reduction/withdrawal was achieved more frequently in hypointense tumors in T2-weighted MRI sequencies ($P = .028$). The proliferative index, cytokeratin pattern and SSTR2A expression did not differ among patients underwent and not-underwent fg-SRL dose reduction/withdrawal. Treatment with high frequency fg-SRLs administrations did not correlate with the fg-SRL dose reduction/withdrawal ($P = .581$).

Discussion: Our study shows that the probability of reducing or withdrawing therapy with fgSRLs depends on tumor characteristics, particularly size and MRI intensity. These results support prognostic stratification of patients and, most importantly, underline the importance of a personalized therapeutic approach.

EP1147 - ECE_2539 - Joint and bone quality deteriorate in acromegaly despite long-term disease control

Christian Rosendal[1], Frederik Klit[2], Annika Kvist[3], Peter Vestergaard[3] and Jakob Dal[1]

[1]Endocrinolgy, Aalborg Universityhospital, Aalborg, Denmark; [2]Research data and Biostatistics, Aaborg Universityhospital, Aalborg, Denmark; [3]Steno Diabetes Center North Jutland, Aalborg, Denmark

Context: Joint and bone disorders are frequent and disabling complications of acromegaly. HR-pQCT provides precise and integrated assessment of bone quality and joint abnormalities.

Objective: To evaluate bone and joint quality in patients with long-term controlled acromegaly.

Methods: Seventeen patients with acromegaly and age- and sex-matched healthy controls.

HR-pQCT of hand joints, tibia and radius; bone microindentation; vertebral fracture assessment; dual X-ray absorptiometry; circulating bone biomarkers; questionnaires.

Results: Patients with acromegaly (mean age: 61.8 years, mean disease duration: 13.1 years, mean IGF-I Z-score: 1.2) had wider joint spaces of the second (2.85 vs 2.68 mm, $P = .004$) and third (2.92 vs 2.80 mm, $P = .037$) metacarpophalangeal joints, the latter with a higher risk of osteophytes (50% vs 11.8%, $P = .017$). Vertebral deformities were more common (88% vs 47%, $P = .01$), more numerous (2.1 vs 0.7, $P < .001$), and associated with higher spinal deformity index values (2.6 vs 1.3, $P = .04$) in participants with acromegaly. HR-pQCT demonstrated lower trabecular bone mineral density in the radius (114.8 vs 150.3 mg/cm^3, $P = .008$) and tibia (129.3 vs 166.2 mg/cm^3, $P = .002$), as well as fewer (1.63 vs 2.11 mm^{-1}, $P = .001$) and thinner (0.056 vs 0.064 mm, $P = .005$) trabeculae. Bone and joint abnormalities increased with age in the acromegaly group.

Conclusions: Acromegaly is associated with impaired bone microarchitecture and structural joint alterations that deteriorate with increasing age despite long-term, biochemically controlled.

EP1148 - ECE_2638 - Quality of life and mental health disorders in acromegalic patients

Mihaela Maria Vlad, Plotuna Iulia-Ștefania, Melania Balas, Ioana Golu and Daniela Amzar

2nd Internal Medicine, "Victor Babes" University of Medicine and Pharmacy, Timișoara, Romania

Introduction: Acromegaly is a rare pathology, caused in most cases by a growth hormone-secreting pituitary adenoma. Its low prevalence is one of the factors contributing to the late diagnosis of the disease. As a result, irreversible morphological changes occur, as well as numerous complications, including psychiatric ones.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Materials and Methods: The study group included 40 patients diagnosed with acromegaly at our hospital between January 1st, 2017, and April 30th, 2024. The group included 14 men (35%) and 26 women (65%), with a mean age at diagnosis of 43.8 ± 11.6 years. The mean duration of the disease was 85.9 ± 97.7 months (1-468). Psychiatric evaluation to determine the presence of psychiatric pathology was performed as part of the current evaluations for all patients in the study cohort. Patients completed the Romanian version of the AcroQol (Acromegaly Quality of Life Questionnaire), which was designed to measure health-related quality of life in patients diagnosed with acromegaly. In the study group, acromegaly was controlled in 32.5% of patients.

Results: Nine patients (22.5%) were diagnosed with psychiatric pathology (anxiety and/or depression), of whom 88.88% were women. Patients with psychiatric disorders were older (55.1 ± 15.7 years) compared to those without this complication (48.4 ± 9.2 years), but without a statistically significant difference. The average GH and IGF-1 levels in patients with psychiatric disorders were 17.5 ± 31.0 ng/ml and 409.6 ± 144.8 ng/ml, respectively, and in those without psychiatric pathology 18.40 ± 56.55 ng/ml and 380.7 ± 260.3 ng/ml, respectively, with no statistically significant differences. Biochemical parameters, disease duration, and disease control were similar between the two groups. Patients with psychiatric pathology tend to be more likely to be retired or unemployed and have a lower quality of life on the ACROQOL questionnaire: 43.4 ± 20.4 points compared to 65.8 ± 19.1 points in acromegaly patients without psychiatric pathology ($P = .003$). Among comorbidities, type 2 diabetes mellitus was more frequently diagnosed in the group of patients with psychiatric pathology.

Conclusions: The percentage of patients diagnosed with anxiety and/or depression is 22.5% in our group of acromegalic patients, with one in four cases presenting psychiatric pathology. Acromegalic patients with psychiatric pathology have a significantly lower quality of life and are more frequently diagnosed with type 2 diabetes mellitus.

EP1149 - ECE_3732 - Comparison of low-dose (1 μg) versus standard high-dose (250 μg) ACTH stimulation tests for the assessment of the hypothalamic–pituitary–adrenal axis

Anastasia Patricia Stanescu-Smocot[1,2], Beatrice Cristea[2], Vlad Radulescu[1,2], Maria Tudorache[2], Viorica Nicuta[2] and Corin Badiu[1,2]

[1]*Endocrinology, Endocrinology IV, "C Davila" University of Medicine and Pharmacy, Bucharest, Romania;* [2]*Research Department, Endocrinology IV, C.I. Parhon National Institute of Endocrinology, București, Romania*

Introduction: Assessment of the hypothalamic–pituitary–adrenal (HPA) axis remains challenging, particularly in patients with suspected central adrenal insufficiency. The conventional high-dose ACTH stimulation test (250 μg) uses a supraphysiological dose, which may mask subtle degrees of adrenal dysfunction. In contrast, the low-dose ACTH test (1 μg) has been proposed to better reflect physiological adrenal responsiveness.

Aim: To compare the diagnostic performance of the low-dose (1 μg) versus high-dose (250 μg) ACTH stimulation tests in patients with suspected adrenal insufficiency and to evaluate recovery of the HPA axis according to etiology.

Patients and Methods: We conducted a retrospective observational study including **173 patients** evaluated between **2024-2025** for suspected adrenal insufficiency. Patients underwent assessment of the hypothalamic–pituitary–adrenal (HPA) axis using either a **low-dose (1 μg)** or **standard high-dose (250 μg)** ACTH stimulation test, according to clinical indication.

In a predefined subgroup of patients (***n* = 20**), **both low-dose and high-dose ACTH stimulation tests were performed in the same individual**, at **24 h interval**, allowing direct intra-individual comparison. Peak cortisol response was defined as the highest value obtained at **30 or 60 min.** after ACTH administration. A peak serum cortisol **≥18 μg/dl** was considered a normal response, values **12-18 μg/dl** were **borderline (partial) response,** and values **<12 μg/dl** were diagnostic of adrenal insufficiency. Recovery of the HPA axis was assessed during follow-up and categorized as **recovery within <3 months, within <1 year, after >1 year**, **>2 years**, or as **persistent adrenal insufficiency,** according to clinical, biochemical, and treatment-related data.

Results: Low-dose stimulation identified adrenal insufficiency in **24.3%** of patients, compared with **18.2%** diagnosed using the high-dose. In addition, **17.1%** patients demonstrated a borderline response on low-dose, consistent with partial or evolving adrenal insufficiency. In contrast, the high-dose classified **70.4%** cases as normal adrenal function, suggesting that supraphysiological ACTH stimulation may **overestimate adrenal reserve**.

Twenty patients underwent **both low-dose and high-dose stimulation, performed 24 hours apart.** Within this subgroup, **30% (*n* = 6)** were classified as having adrenal insufficiency or borderline response on low-dose testing, while showing a normal cortisol response following high-dose, indicating that the high-dose test may mask clinically relevant adrenal dysfunction.

Recovery was dependent on aetiology: g**lucocorticoid-induced** showed the most favorable recovery profile (**53.3%)** within **12 months, while pituitary failure,** and **immunotherapy-related adrenal insufficiency** were associated with delayed recovery.

Conclusions: L**ow-dose test as a more sensitive and physiologically appropriate method** for diagnosing and monitoring central adrenal insufficiency.

EP1150 - ECE_3828 - Extended medial wall resection of the cavernous sinus in endoscopic treatment of pituitary adenomas causing acromegaly with cavernous sinus invasion (Knosp I-III)—early clinical results

Barbara Buchalska[1], Maria Maksymowicz[2] and Jacek Kunicki[1]

[1]*Department of Neurosurgery, Maria Sklodowska-Curie National Research Institute of Oncology, Warsaw, Poland;* [2]*Warsaw, Poland*

Background: Currently, the first-line treatment for acromegaly is surgery—adenoma resection. In patients with invasive adenomas, standard transsphenoidal resection does not provide satisfactory results (remission of acromegaly in 30%-50%). In cases of medial wall invasion of the cavernous sinus, its removal allows for improved treatment outcomes and higher remission rates.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Purpose: The aim of the study was to evaluate the outcomes of endoscopic transsphenoidal resections with removal of the medial wall of the cavernous sinus in the treatment of somatotropin-secreting pituitary adenomas with intermediate and high risk of invasive growth (Knosp I-III) causing acromegaly.

Methodology: This was a retrospective analysis of a series of 21 patients (15 women and 6 men) treated in 2024-2025 with endoscopic transsphenoidal resections for pituitary adenomas with possible invasive growth assessed by the Knosp scale (I-III) and causing acromegaly. The mean age at the beginning of treatment was 53 years (range 25-76 years), with a mean follow-up of 6 months (0-13 months).

Results: Most patients had macroadenomas prior to resection ($n = 11$; 52%). In 11 patients (52%), histopathological examination confirmed invasion of the medial wall of the cavernous sinus. In all patients, the medial wall of the cavernous sinus was removed and gross total resection was achieved. The mean intraoperative blood loss was 180 ml (range 50-450 ml). No neurological or vascular complications were observed postoperatively. Eighteen patients (86%) met the criteria for remission of acromegaly at early postoperative follow-up (2-5 months).

Conclusions: Endoscopic transsphenoidal resections of invasive somatotropin-secreting pituitary adenomas with removal of the medial wall of the cavernous sinus enable effective treatment of acromegaly. Although this method carries an additional risk, it is relatively safe and associated with a low rate of complications.

EP1151 - ECE_2827 - Bone proteomic analysis in patients with acromegaly and its clinical correlations

Luigi Demarchis[1], Sabrina Chiloiro[1], Pier Paolo Mattogno[2], Penelope Giambo'[1], Michela Cicchinelli[3], Federico Valeri[2], Domenico Milardi[1], Emanuele Pierpaolo Vodola[1], Laura De Marinis[1], Andrea Urbani[3], Liverana Lauretti[2], Antonella Giampietro[1], Antonio Bianchi[1], Federica Iavarone[3], Francesco Doglietto[2] and Alfredo Pontecorvi[1]

[1]Rome, Italy; [2]Neurosurgery, Catholic University of the Sacred Heart, Fondazione Policlinico Universitario A. Gemelli, Rome, Italy; [3]Department of Basic Biotechnological Sciences, Intensivological and Perioperative Clinics, Catholic University of the Sacred Heart, Fondazione Policlinico Universitario A. Gemelli, Rome, Italy

Background: Bone metabolism is often impaired in patients with acromegaly, with an increased risk of osteoporosis and fragility vertebral fractures, which may also occur independently of the acromegaly biochemical control. Skeletal fragility is probably due to increased bone turnover, with increased bone resorption and impaired bone neoformation. The pathogenetic mechanisms remain not yet fully understood.

Aim of the study: Identify the bone proteome of patients with acromegaly and compare it with a control group of non-acromegaly subjects.

Methods: an analysis by mass spectrometry was conducted on five ethmoid samples (ES) of patients with acromegaly and five ES of patients with non-secreting pituitary tumors (NSPTs). ES were achieved during transsphenoidal surgery for the resection of the pituitary tumors. These samples were analyzed to identify and assay the proteome and to classify them. Among the proteins quantitatively up- and down-regulated (UR and DR) in the group of acromegalic patients compared to patients with NSPT, those with a ratio of variation based on Fold-Change > |1.50| and statistical significance (P-value < .05) were studied.

Results: 312 proteins belonging to each group were identified. As for the acromegalic patient group, compared with the NSPT patient group, 6 proteins with positive Fold-Change (UR) above the threshold value (+1.5) and 12 proteins with negative fold-change (DR) below the threshold value (−1.5) were identified. Their biological function and clinical correlations found in the literature were analyzed: of these 18 proteins, significant correlations inherent to bone metabolism and turnover were found for Profilin-1 (UR), Isoform 5 of Periostin (UR), Apolipoprotein E (DR), Caveolin-1 (DR). A positive correlation was detected between Profilin-1 and Isoform 5 of Periostin concentrations and serum GH and IGF-I levels of our patients' cohort. In parallel, a negative correlation was also detected between Apolipoprotein E and Caveolin-1 concentrations and serum IGF-I levels.

Conclusions: This work aimed to identify proteins with higher and lower expression in the ethmoid bone of patients with acromegaly compared with the control group to better understand bone metabolism and turnover in these patients.

EP1152 - ECE_2880 - When histology is silent but ACTH rises: a red flag for pituitary carcinoma in a three-case series

Giacomo Fabio Antonio Grifoni[1], Vittoria Favero[1,2], Paola Doneda[3], Giovanni Battista Lasio[4], Andrea Saladino[5], Renato Cesare Cozzi[2] and Iacopo Chiodini[1,2]

[1]Department of Medical Biotechnology and Translational Medicine, University of Milan., Milan, Italy; [2]Endocrinology Unit, Grande Ospedale Metropolitano Niguarda, Milan, Italy; [3]Neuroradiology Unit, Grande Ospedale Metropolitano Niguarda, Milan, Italy; [4]Neuroscience Department, Neurosurgery Division, ASST Ovest Milano, Legnano Hospital, Legnano, Italy; [5]Pontassieve, FI, Italy

Introduction: Pituitary carcinomas (PCs) are rare tumors, accounting for 0.1%-0.2% of pituitary neoplasms. They're defined by the presence of central nervous system (CNS) or systemic metastases in pituitary neuroendocrine tumors (PitNETs). PCs mainly derive from secreting PitNETs: among these, ACTH-secreting PitNETs show an average degeneration time of 9.5 years. Here, we describe a case series of three patients with ACTH-secreting PitNETs who developed carcinomatous evolution.

Case series: three patients—two males, patients 1 (P1) and 2 (P2), and one female (P3)—were diagnosed with large ACTH-secreting macroPitNETs at age 33, 48 and 64 respectively: none showed histological features suggestive of aggressive PitNET.

While the latency period between Cushing Disease (CD) and PC diagnosis for P2 and P3 was comparable (5 and 4.75 years respectively), in P1 it was 23 years.

All patients underwent transnasal surgery. P1 also required transcranial surgery, medical therapy (cabergoline and pasireotide), conventional radiotherapy, and ultimately bilateral adrenalectomy; P2 and P3 underwent stereotactic radiosurgery and conventional radiotherapy respectively, for persistent CD.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

In P2 and P3 progressive ACTH increases, despite radiological stability (P2) or reduction (P3) of the remnant, prompted restaging through imaging testings (total-body CT, spinal MRI, DOTATOC-PET, FDG-PET) leading to the detection of metastases.

In P1, ACTH assessments were unreliable after bilateral adrenalectomy and diagnosis of PC was incidental: a liver metastasis was discovered during abdominal ultrasound for a colic pain and confirmed as ACTH-positive PitNET on biopsy.

P1 and P2 developed systemic metastases, predominantly involving axial skeleton, besides the liver localisation in P1.

P3 exhibited rapid clinical and biochemical deterioration leading to exitus in few weeks.

Following PC diagnosis in late 2025, P1 and P2 initiated first-line temozolomide therapy and radiotherapy on skeletal metastases. Denosumab was also started and follow-up is still ongoing.

Conclusions: large ACTH PitNETs may undergo insidious malignant transformation. Rising hormone levels (eg, huge ACTH increase), in patients without evident sellar recurrence, serve as a critical indicator of potential tumor dissemination necessitating thorough neuroradiological and systemic evaluation, whereas histological and biomolecular markers prove largely unreliable and ineffective for predicting malignancy

With PC's natural disease course being highly variable, surgery or systemic oncological therapies (eg, temozolomide) may sometimes be precluded, highlighting the lack of therapeutic options for these tumors.

EP1153 - ECE_2881 - Evaluation of post-surgical outcomes in prolactinoma patients

Alicja Knysak[1], Nijaguna Mathad[2], Jonathan Hempenstall[2], Christoforos Syrris[2], Jana Bujanova[1] and Ma'en Al-Mrayat[1]
[1]*Endocrinology, Diabetes and Endocrinology, University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom;* [2]*Neurosurgery, Wessex Neurological Centre, University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom*

Background: Current treatment guidelines for prolactinomas recommend dopamine agonists (DAs) as first-line therapy, reserving surgery and radiotherapy for resistant or intolerant cases. Herein we aimed to evaluate the outcomes for patients with prolactinomas who underwent surgical treatment in our institution (The Wessex Neurological Centre, a tertiary unit in Southampton, UK).

Methods: We performed a retrospective review of 32 patients (17 males, 15 females; mean age 37.5 years) who underwent endonasal endoscopic pituitary surgery for prolactinoma between 2017 and 2025. Tumour types included 27 macroadenomas (84%), 4 microadenoma (13%), and 1 giant adenoma (3%). Cavernous sinus (CS) invasion was present in 14 cases (44%), and 19 tumours (59%) caused optic chiasm compression. Prolactin levels at diagnosis ranged from 251 to 1 026 688 mU/L (our reference range for Male: 55-276; Female: 57-561). 24 patients (75%) received pre-operative DA therapy. Indications for surgery were one or more of: visual compromise ($n = 14$; 44%), pituitary apoplexy ($n = 6$; 19%), DA intolerance ($n = 9$; 28%), DA resistance ($n = 6$; 19%), and cerebrospinal fluid (CSF) leak ($n = 1$; 3%).

Results: Gross total resection was achieved in 21 patients (66%), while 11 (34%) underwent surgery for debulking purposes. Intra-operative CSF leak occurred in 3 patients (9%), and 1 patient developed a post-operative CSF leak requiring surgical repair. 1 patient experienced significant post-operative epistaxis requiring surgical intervention. 7 patients (22%) developed new post-operative pituitary dysfunction, including 3 (9%) with arginine vasopressin deficiency. Histological analysis confirmed lactotroph adenoma in all cases, with co-secretion of growth hormone in 7 tumours (22%). Post-operatively, 19 patients (60%) achieved biochemical remission, including 3 of 4 patients (75%) with microadenomas and 16 patients (57%) with macroadenomas. No residual tumour was visible on post-operative MRI in 20 patients (62%). Persistent disease was observed in 12 patients (38%); 4 underwent repeat surgery (13%) and 2 (6%) received adjuvant radiotherapy. Tumour recurrence was documented in 3 patients (9%) during the follow-up period. Cavernous sinus involvement was observed in 14 (44%) of all patients. Cavernous sinus invasion patients achieving remission were 5 (40%) whilst the rest showed a biochemical remission of 78% (14 of 18 patients) (P value .016 < .05) indicating statistically significant difference of remission between CS invasion or not.

Conclusions: Surgical intervention of prolactinomas yielded significant rates of biochemical remission and low recurrence including in patients with macroadenomas. For carefully selected cases, primary or early secondary surgery may offer an efficacious and safe alternative to traditional long-term pharmacological therapy.

EP1154 - ECE_3188 - Gonadotroph pituitary adenomas: clinical features, imaging predictors of recurrence, and treatment outcomes from a tertiary center

Esra Eraslan Aydemir[1], Özge Baş Aksu[1], Asena Gökçay Canpolat[1], Özgür Demir[1], Mustafa Sahin[1], Murat Erdogan[1], Rifat Emral[1], Aylin Heper[2] and Sevim Güllü[1]
[1]*Endocrinology and Metabolism Department, Endocrinology and Metabolism Department, Ankara University Faculty of Medicine, Ankara, Türkiye;* [2]*Medical Pathology Department, Medical Pathology Department, Ankara University Faculty of Medicine, Ankara, Türkiye*

Background: Gonadotroph adenomas constitute the majority of nonfunctioning pituitary adenomas; however, they are often grouped together in surgical series, limiting our understanding of specific prognostic factors. This study aimed to evaluate the preoperative clinical and radiological characteristics of patients with histopathologically confirmed gonadotroph adenomas, identify predictors of treatment response, and assess the efficacy of adjuvant therapies.

Methods: This retrospective study included 78 patients who underwent transsphenoidal surgery at Ankara University Faculty of Medicine between January 2010 and January 2025, with histopathologically confirmed gonadotroph adenoma and a minimum follow-up of six months. Treatment response was categorized as complete surgical response, good residual control (>50% volume reduction), or poor residual control. Multivariable binary logistic regression analysis was performed to identify independent predictors of unfavorable treatment response.

Results: The mean age at surgery was 54.05 ± 13.19 years, with male predominance (73.1%). Visual impairment (71.8%) and headache (42.3%) were the most common presenting symptoms, while 16.7% were incidentally discovered. Central hypogonadism was

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

the most frequent preoperative hormonal deficiency (44.9%), followed by central hypocortisolism (32.1%) and central hypothyroidism (28.2%). Panhypopituitarism was present in 12.8% at baseline and increased to 21.8% postoperatively.

Preoperative median tumor diameter was 27 mm (IQR: 22-38) with a median volume of 7.03 cm^3 (IQR: 3.98-14.11). Suprasellar extension was present in 91.0%, optic chiasm compression in 87.2%, cavernous sinus invasion in 42.3%, and sphenoid sinus invasion in 25.6%. Gross total resection was achieved in only 24.4% of patients. Patients with residual tumor had significantly larger preoperative tumor dimensions compared to those achieving gross total resection (median diameter: 28 mm vs 24.5 mm, $P = .011$; median volume: 7.85 cm^3 vs 4.44 cm^3, $P = .008$).

On univariate analysis, sphenoid sinus invasion ($P = .032$) and optic chiasm compression ($P = .033$) were significantly associated with residual tumor presence. Multivariable logistic regression identified sphenoid sinus invasion as the sole independent predictor of unfavorable treatment response (OR = 0.19; 95% CI: 0.046-0.783; $P = .021$). Patients without sphenoid sinus invasion had approximately 5-fold higher odds of achieving favorable residual control. Notably, cavernous sinus invasion, Knosp grade, and Ki-67 proliferation index were not independent predictors of treatment outcome.

Conclusions: Gonadotroph adenomas frequently present with advanced tumor characteristics, resulting in low gross total resection rates. Sphenoid sinus invasion—rather than the traditionally emphasized cavernous sinus invasion—emerged as the sole independent predictor of unfavorable treatment response, providing a new perspective on preoperative risk stratification for this tumor subtype.

EP1155 - ECE_3804 - Determinants of diagnostic delay in patients with acromegaly

Soukaina Lahlou, Nassim Essabah Haraj, Malak Iggar, Siham El Aziz and Asma Chadli
Clinical Neuroscience and Mental Health Laboratory, Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Ibn Rochd University Hospital, Casablanca, Morocco

Introduction: Acromegaly is a rare endocrine disorder with a slow and insidious course, characterized by a wide clinical heterogeneity. This polymorphic presentation often leads to a significant diagnostic delay, exposing patients to preventable complications and delaying the initiation of appropriate treatment.

Objective: To assess diagnostic delay in patients with acromegaly and to analyze the clinical and biological factors associated with late diagnosis.

Patients and Methods: This was a retrospective cross-sectional study including 81 patients followed for acromegaly. Diagnostic delay was defined as the time interval between the onset of first symptoms and the establishment of the diagnosis. Patients were divided into three groups according to disease duration: less than 5 years, 5-10 years, and more than 10 years. Clinical and biological data were collected from medical records. Statistical analysis was performed using SPSS software.

Results: The mean age at diagnosis was approximately 44 years, with a female predominance. The median disease duration was 9.8 ± 5.5 years. A diagnostic delay greater than 10 years was observed in 42.6% of patients, while 27.9% were diagnosed within 5 years and 29.5% between 5 and 10 years.

Patients with late diagnosis more frequently presented with non-specific symptoms, mainly osteoarticular pain and general symptoms. In contrast, the presence of compressive symptoms was associated with earlier diagnosis, with a tumoral syndrome identified in 100% of patients diagnosed within 5 years.

The mean IGF-1 level was 714 ± 422 ng/mL. No significant correlation was found between disease duration and IGF-1 levels ($P = .15$).

Conclusions: Diagnostic delay in acromegaly remains frequent and often prolonged. It is mainly related to the non-specific nature of early clinical manifestations, highlighting the need for increased clinical awareness to reduce diagnostic delays and improve patient outcomes.

EP1156 - ECE_1378 - Value of the LHRH test in the evaluation of precocious puberty

Fatma Ben Abdessalem, Taieb Ach, Imen Halloul, Wiem Saafi, Hamza Fekih, Ghada Saad and Yosra Hasni
Endocrinology, Hôpital Farhat Hached, Sousse, Tunisia

Introduction: Precocious puberty is defined as the appearance of secondary sexual characteristics before age 8 in girls and 9 in boys. The LHRH stimulation test plays a crucial role in identifying the origin of precocious puberty and differentiating true cases from benign variants.

Materials and Methods: This cross-sectional study included 16 cases investigated for precocious puberty. Clinical and hormonal evaluations were performed for all patients.

Results: Twelve girls and four boys made up the 16 participants in the study. At consultation, the average age was five years old (range: one to nine years). Premature pubarche ($n = 7$), premature thelarche ($n = 7$), and increased testicular volume ($n = 2$) were the reasons for consultation. Every patient underwent the LHRH test. With LH peaks ranging from 5 to 94 IU/L and FSH/LH ratios between 0.63 and 4.9, the findings indicated a central origin in six patients. Five patients were diagnosed with pseudo-precocious puberty. Following the LHRH test, the LH peak varied from 0.5 to 3.9 IU/L, and the FSH/LH ratio was between 0.18 and 1. In 5 girls with a mean age of 3 years (1-5 years), premature thelarche was identified. The LHRH test showed LH peaks between 0.8 and 7.2 IU/L and FSH/LH ratios between 0.2 and 2.9.

Conclusions: Precocious puberty may indicate a serious pathology of central or peripheral origin. However, isolated premature thelarche can be considered a normal variant, highlighting the importance of the LHRH test in distinguishing true precocious puberty from simple premature puberty.

EP1157 - ECE_1488 - Global prevalence estimates of adult growth hormone deficiency (AGHD): a targeted literature review and meta-analysis [2015-2025]

Subhara Raveendran[1,2], Katja Wiederkehr[3], Chelsea Catsburg[3] and Alden Smith[1]

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

[1]Ascendis Pharma, Inc, Palo Alto, United States; [2]HEOR, Ascendispharma, Palo Alto, United States; [3]BluePrint Orphan, Inc, New York, United States

Background: Adult growth hormone deficiency (AGHD) is a chronic endocrine disorder that results from inadequate growth hormone secretion and is associated with low bone density, increased body fat, reduced muscle mass, diminished psychosocial functioning, and increased risk of cardiovascular and metabolic dysfunction. Due to heterogeneous diagnostic definitions and limited data sources, population-based estimates of AGHD remain sparse. This research aimed to quantify global AGHD prevalence estimates and treatment rates through a systematic literature review and meta-analysis of recently published epidemiological studies.

Methods: A systematic literature review of PubMed and Embase was conducted to identify studies reporting on the prevalence of AGHD among populations age 18+. Studies were reviewed against exclusion criteria in accordance with PRISMA guidelines and were included if they provided population-based data using comprehensive diagnostic definitions, or if they included cases treated with growth hormone replacement therapy (GHRT). All identified studies were entered into a meta-analysis, which used a random-effects model to estimate pooled prevalence rates; study heterogeneity was quantified using the I^2 statistic.

Results: Six studies with data across Japan, the United States, Italy, France, and Spain were included. Across studies utilizing comprehensive diagnostic definitions ($n = 4$), AGHD prevalence ranged from 27.1 to 37.0 per 100k adults, with an overall pooled global AGHD prevalence of 31.1 per 100k adults (95% CI: 25.9-36.3; $I^2 = 99.2\%$). When considering treated cases only, across populations based on GHRT recipients ($n = 4$), prevalence ranged from 0.7 to 3.5 per 100k adults, with a pooled treated prevalence of 1.9 per 100k adults (95% CI: 1.1-2.7; $I^2 = 99.6\%$). Pooled sub-analyses were not conducted by region due to a lack of estimates, and therefore, differences in prevalence or treatment by region remain unknown.

Conclusions: This meta-analysis estimates that AGHD affects 31 per 100k adults globally, with a substantially smaller fraction receiving GHRT (2 per 100k adults globally). Considerable heterogeneity among studies highlights the need for standardized diagnostic criteria and improved epidemiological surveillance. Future research should refine prevalence estimates, assess regional disparities, and understand barriers to treatment among patients with AGHD. Overall, these findings strengthen the current understanding of AGHD global burden and underscore the need for improved diagnostic practices and broader access to effective GHRT.

EP1158 - ECE_1838 - Do immunonegative gonadotroph tumors exhibit a more aggressive behavior than immunopositive ones?

Maria Rodríguez-Bedoya, Jorge Navarro, Johana Sottile, Elena Sansano, Cristina Guillén, Miriam Escalante, Javiera Rodríguez, Francisca María Peiró-Marqués, Eugenia Torregrosa, Elena García, Javier Abarca and Antonio Pico

Endocrinology and Nutrition, General University Hospital of Alicante, Alicante, Spain

Introduction: Non-functioning pituitary tumors represent 30%-40% of pituitary neoplasms. Transcription factor–based classification reclassified many previously considered "null" tumors, with a substantial proportion belonging to gonadotrophs. Among these, most retain immunostaining for LH/FSH (hormone-positive gonadotroph tumors, HPGT), whereas a subgroup lacks hormonal expression (hormone-negative gonadotroph tumors, HNGT). Gonadotroph tumors have also emerged as candidates for targeted therapies, as somatostatin receptor subtype 3 (SSTR3) appears highly expressed. We aimed to explore clinical, radiological, histopathological and molecular differences between HPGT and HNGT.

Material and Methods: We performed a single-center, observational, ambispective study, including adults with histologically confirmed gonadotroph tumors (SF-1 and/or GATA2 positive) diagnosed since 2019. Clinical, radiological and histopathological variables were collected. Signal intensity ratio (SIR) was defined as the ratio of tumor signal intensity to gray matter on T2-weighted MRI sequences. Proliferation was assessed by Ki-67 index using immunohistochemistry (IHC). SSTR3 expression was quantified by RT-qPCR ($2^{-\Delta\Delta Ct}$) using normal pituitary tissue as calibrator. Mann–Whitney U and Chi-square tests were applied.

Results: 64 patients were included (38 HPGT, 26 HNGT). Age was similar (median 58 years [IQR 20] vs 58 [21]; $P > .05$), as sex distribution (women 34.5% vs 34.8%; $P > .05$). HNGT showed trends toward higher apoplexy than HPGT (17% vs 10%; $P > .05$) and panhypopituitarism (44% vs 31%; $P > .05$), whereas visual field impairment tended to be slightly more frequent in HPGT (48% vs 41%; $P > .05$).

Tumor size was similar (27 mm [IQR 19] vs 30 mm [17]; $P > .05$). A trend toward higher cavernous sinus invasion was observed in HNGT (41% vs 24%; $P > .05$), while T2 hyperintensity appeared to be more frequent in HPGT (85% vs 53%; $P > .05$). Ki-67 did not differ (1.10% [0.9] vs 1.0% [1.7]; $P > .05$).

FSH (3.7 [12.17] vs 2.1 [6.97]; $P > .05$) and LH (0.001 [0.01] vs 0.003 [0.01]; $P > .05$) expression did not differ. SSTR3 expression was similar between groups (12.5 [21.5] vs 4.6 [11.07]; $P > .05$).

Recurrence appeared more frequent in HPGT but was not confirmed after follow-up adjustment (Cox HR 0.397; $P = .399$). Three patients in HPGT group and one patient in HNGT received radiotherapy.

Conclusions: No statistically significant differences were observed between HPGT and HNGT for the variables analyzed, potentially influenced by sample size and follow-up. However, HNGT showed a trend toward greater invasiveness without differences in proliferation, whereas HPGT tended to show higher recurrence. Consistent with previous studies, GT tumors demonstrated high expression levels of SSTR3.

EP1159 - ECE_3700 - The role of hyperhomocysteinemia in Rathke's cleft cysts: from clinical manifestation to treatment outcomes

Mariana Solovey[1,2], Olena Danevych[1], Mykola Guk[1], Arthur Mumlev[1], Andrii Chukov[1], Nataliia Kobrynska[2] and Oleksii Ukrainets[1]

[1]Romodanov Neurosurgery Institute, Kyiv, Ukraine; [2]Komisarenko Endocrinology and Metabolism Institute, Kyiv, Ukraine

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: Rathke's cleft cysts (RCCs) are benign pituitary lesion originated from remnants of Rathke's pouch. The prevalence of RCCs in autopsy studies is reported in 13%-22% of all sellar lesions. The pathogenesis is not fully understood. The relationship between hyperhomocysteinemia and clinical presentation of symptomatic RCCs including headache, arterial hypertension, reproductive disorders have not been reported.

Objective: To discover the relationship between plasma homocysteine levels, clinical presentation and treatment outcomes in the patients with RCCs.

Materials and Methods: We performed a retrospective study of 66 patients that were diagnosed with RCCs: 53 under the conservative management and 13 surgically treated via endoscopic endonasal transsphenoidal approach. Radiological characteristics, clinical presentation, plasma homocysteine and hormones levels according to the age and sex, treatment outcomes were analyzed.

Results: The group of surgically treated patients included 6 males and 7 females. The median age was 35 years (IQR: 17-48.5 years). The clinical presentation included: headache ($n = 11$, 84.6%) with arterial hypertension in 4 patients (30.7%), hypogonadism with decreased levels of FSH, LH or DHEA-s ($n = 5$, 38.5%), hyperprolactinemia ($n = 3$, 23%), GH deficiency ($n = 1$, 7.7%). Postoperative improvement of clinical symptoms was achieved in 6 (46%) patients with normal preoperative homocysteine levels. The persistent symptoms in the rest of patients were strongly associated with elevated plasma homocysteine levels (the mean homocysteine level was 19 ± 5.444 μmol/l). The further homocysteine levels normalization resulted in clinical improvement in all patients.

The group of patients under the conservative management included 35 females and 18 males with the median age of diagnosis of RCC 26 years (IQR: 19.5-36.5 years) and 31 years (IQR: 24-44 years) respectively. Hyperhomocysteinemia was revealed in 21 female patients (60%) and in all 100% male patients. The most common clinical presentation in females were menstrual disorders ($n = 22$, 68.75%) and headache in males ($n = 13$, 76.5%). Correction of homocysteine levels was associated with clinical improvements in the most patients with RCCs and in cyst volume decrease in some cases.

The genetic variants in methylenetetrahydrofolate reductase (MTHFR 677C>T, MTHFR 1298A>C), methionine synthase (MTR 2756A>G), methionine synthase reductase (MTRR 66A>G) were determined in 22 patients with elevated plasma homocysteine levels. Polymorphisms in genes involved in folate metabolism were detected in different combinations in all 22 patients.

Conclusions: Homocysteine level assessment and correction should be considered in optimal management of patients with RCCs. More genetic studies are needed to discover the possible genetic associations of folate metabolism and RCCs development.

EP1160 - ECE_1486 - Metabolic effects of recombinant human growth hormone therapy in adults with severe growth hormone deficiency: experience from a single center

Zuzanna Zak-Skryskiewicz, Lukasz Dzialach and Przemysław Witek

Department of Internal Medicine, Endocrinology and Diabetes, Medical University of Warsaw, Warsaw, Poland

Severe adult growth hormone deficiency (GHD) is associated with adverse metabolic disturbances, increased adiposity, and elevated cardiovascular risk. Although recombinant human growth hormone (rhGH) replacement is an established therapy, real-world outcome data from Poland remain scarce.

We conducted a retrospective real-world analysis of adults with severe GHD treated with rhGH within the national drug program at a single tertiary endocrine center. Serum insulin-like growth factor 1 (IGF-1), lipid profile, glycemic indices, and body composition assessed by bioelectrical impedance analysis were evaluated at baseline, after 6 and 12 months of therapy, and at long-term follow-up.

rhGH therapy resulted in a sustained increase in IGF-1 concentrations across all time points, confirming effective dose titration. The biochemical response was inversely related to age, and women achieved higher IGF-1 levels after 12 months compared with men. Patients with childhood-onset GHD demonstrated a greater IGF-1 increase than those with adult-onset disease. Treatment was accompanied by a consistent reduction in total cholesterol and LDL cholesterol throughout follow-up, independent of the number of deficient pituitary axes, with a more pronounced LDL decrease observed in patients with preserved adrenocortical axis function. Glycemic parameters remained overall stable; however, patients with a longer duration of untreated GHD exhibited higher HbA1c levels at 6 and 12 months. After 12 months of therapy, total fat mass and body fat percentage decreased, while relative muscle mass increased. Regional analysis confirmed favorable reductions in fat mass within the trunk and limbs, with no significant changes in absolute muscle mass, bone mass, or total body water.

In conclusion, rhGH replacement therapy in adults with severe GHD under routine clinical practice conditions is associated with beneficial changes in lipid profile and body composition. The treatment response varies according to age, sex, and GHD onset. These real-world findings support the effectiveness of long-term, individualized rhGH therapy in adult GHD.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Thyrotropin-secreting pituitary tumours (TSHomas) are rare functional pituitary tumors responsible for inappropriate TSH secretion and central hyperthyroidism. Despite recent advances, the molecular mechanisms underlying TSHoma development and progression remain poorly defined. This study aimed at investigating the post-transcriptional regulatory landscape in TSHomas by analyzing the components of all the molecular machineries controlling RNA-metabolism [spliceosome, RNA-Exosome, and Nonsense-Mediated Decay (NMD)], their associations with clinical parameters, and the direct impact of the pharmacological inhibition of the activity of these machineries in TSHoma cells. To that end, microfluidic-based qPCR was used to determine the expression levels of the components of the spliceosome/RNA-Exosome/NMD in 4 TSHomas vs 10 healthy-normal pituitaries (NPs) tissues and to perform clinical correlations. Moreover, as a proof-of-concept, the direct antiproliferative actions of inhibitors of the activity of spliceosome/RNA-Exosome/NMD was evaluated in a patient-derived TSHoma cell-culture. TSHomas exhibited marked dysregulation compared with NPs of multiple components of spliceosome and related splicing-factors [downregulation of major-spliceosome components (*SF3B2/U2AF35/PRPF40A*) and splicing-factors (eg, *SRP30C/EIF4A3/DDX1/TRA2B/HNRPPF*…)], RNA-Exosome (upregulation of *DIS3/DIS3L/MTREX/TTC37*, and downregulation of *WDR61*), and NMD [eg, overexpression of *PABPC1/CNOT3/MAGOHB/…*, and downregulation of NMD-canonical targets (*DDIT3/GADD45B/MAFF/PDRG1/ATF4/ATF3*], being some of these alterations associated with relevant clinical features (eg, tumor-size, TSHB/fT4-levels). Moreover, we demonstrate a clear antiproliferative action of spliceosome/RNA-Exosome/NMD inhibitors in primary patient-derived TSHoma cell-cultures. Altogether, we demonstrated a clinically relevant spliceosome/RNA-Exosome/NMD-associated molecular dysregulation and antiproliferative actions of the activity of these machineries in TSHomas, which could serve as a potential source of novel diagnostic and prognostic biomarkers and therapeutic tools in patients with TSHomas.

EP1162 - ECE_2039 - Hypogonadotropic hypogonadism contributes significantly to abnormal metabolic profile in patients with multihormonal hypopituitarism

Paweł Sojka[1,2], Aleksandra Matusiak[1,2], Renata Michalak[2], Andrzej Lewiński[2] and Małgorzata Karbownik-Lewińska[1,2]
[1]*Department of Endocrinology and Metabolic Diseases, Medical University of Łódź, Łódź, Poland;* [2]*Polish Mother's Memorial Hospital – Research Institute, Łódź, Poland*

Background and Objectives: Hypopituitarism is a disorder characterized by a deficiency of one or more pituitary hormones. The aim of our study was to evaluate the impact of each hormonal deficiency and severity (advancement/degree) of hypopituitarism on the metabolic profile.

Materials and Methods: The study group ($n = 131$) comprised 76 subjects with non-compensated multihormonal or isolated hypopituitarism, including growth hormone (GH; $n = 49$), gonadotropin (LH/FSH; $n = 31$), thyrotropin (TSH; $n = 13$), corticotropin (ACTH; $n = 9$), and prolactin (Prl; $n = 17$) deficiencies; healthy individuals served as control ($n = 55$). Standard biochemical parameters and anthropometric measurements were analyzed statistically.

Results: Patients with non-compensated hypopituitarism compared with control group showed a significantly higher prevalence of reduced HDL-C levels ($P = .053$), elevated TG levels ($P = .012$), and obesity ($P = .010$).

In non-compensated growth hormone (GH) deficiency, χ^2 test revealed a higher prevalence of obesity ($P = .016$), which was confirmed in univariate (OR = 2.55 $P = .010$) and multivariate (OR = 2.70 $P = .015$) regression models. Contrary to expectations, no significant differences in the prevalence of lipid abnormalities were found.

In non-compensated hypogonadotropic hypogonadism (gonadotropin deficiency), the χ^2 test showed a higher prevalence of diabetes ($P = .038$), which was confirmed in both univariate (OR = 3.04 $P = .023$) and multivariate (OR = 7.62 $P = .001$) regression models. The χ^2 test showed a higher prevalence of hypertriglyceridemia ($P = .031$), which was confirmed in univariate (OR = 2.72 $P = .020$) regression model. Univariate regression analysis revealed a higher prevalence of obesity (OR = 2.34 $P = .039$).

In the χ^2 test, no significant differences were observed between patients with hypogonadotropic hypogonadism and those with GH deficiency regarding the prevalence of obesity ($P = 1.000$), low HDL-C ($P = .169$), or elevated triglycerides ($P = .562$), whereas diabetes mellitus was more frequent in the hypogonadotropic hypogonadism group ($P = .001$).

No statistically significant changes in the metabolic profile were observed in non-compensated central hypothyroidism (TSH deficiency) or secondary adrenal insufficiency (ACTH deficiency).

Univariate regression analysis revealed that a higher number of pituitary hormone deficiencies was associated with an increased prevalence of reduced HDL-C levels (OR = 1.37, $P = .012$), elevated triglyceride levels (OR = 1.26, $P = .035$), and obesity (OR = 1.29, $P = .012$).

Conclusions: Hypogonadotropic hypogonadism adversely affects the metabolic profile by increasing the risk of obesity and dyslipidemia. Among pituitary hormone deficiencies, it represents the only independent predictor of diabetes. Therefore, hypogonadotropic hypogonadism should be considered a potential predictive factor for an adverse metabolic profile in patients with hypopituitarism. Additionally, more advanced hypopituitarism is associated with a less favorable metabolic profile.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: The 2022 WHO classification distinguishes sparsely granulated (SG) from densely granulated (DG) corticotroph pituitary neuroendocrine tumors (PitNETs) based on immunohistochemical granulation patterns. While SG tumors reportedly exhibit more aggressive behavior, their clinical significance and impact on surgical outcomes remain unclear. We compared clinicopathological features and postoperative remission rates between SG and DG corticotroph PitNETs.

Methods: We retrospectively analyzed 33 consecutive patients undergoing transsphenoidal surgery for Cushing's disease (2020-2025). Granulation pattern was determined by cytoplasmic ACTH intensity and keratin (CAM 5.2) distribution per WHO 2022 criteria. Patients were classified as SG ($n = 17$, 51.5%) or DG ($n = 16$, 48.5%). Biochemical remission was defined as morning serum cortisol <5 μg/dL or suppression after 1-mg dexamethasone suppression test within 6 months postoperatively. We compared demographic data, preoperative hormonal parameters (serum cortisol, ACTH, midnight cortisol, salivary cortisol, 24-hour urinary free cortisol, 1-mg DST), tumor characteristics (size, cavernous sinus invasion, Ki-67 index), and remission rates. Statistical analysis used Mann-Whitney U test for continuous variables and Fisher's exact test for categorical variables.

Results: Groups were comparable for age (46.7 ± 11.0 vs 49.2 ± 11.7 years, $P = .5$), sex (76.5% vs 75.0% female, $P = 1.0$), and BMI (35.9 ± 6.9 vs 32.0 ± 5.5 kg/m^2, $P = .08$). SG tumors were significantly larger (median 10.5 vs 5.7 mm, $P = .03$), with higher macroadenoma prevalence (58.8% vs 18.7%, $P = .03$). Cavernous sinus invasion showed a non-significant trend in SG tumors (35.3% vs 6.3%, $P = .08$). Ki-67 index and all preoperative biochemical parameters were similar between groups ($P > .05$). Early remission rates at 3 months (82.4% vs 75.0%, $P = .7$) and 6 months (73.3% vs 78.6%, $P = 1.0$) did not differ. Among 23 patients completing ≥12-month follow-up, final remission rates remained comparable (SG: 81.8% [9/11]; DG: 75.0% [9/12]; $P = 1.0$).

Conclusions: Sparsely granulated corticotroph PitNETs demonstrate larger tumor size and greater macroadenoma proportion than densely granulated tumors, suggesting more aggressive growth patterns. However, granulation pattern did not predict biochemical remission rates at any timepoint. These findings indicate that while SG tumors exhibit distinct radiological features, granulation pattern alone may not serve as a reliable prognostic marker for surgical success. The small sample size limits definitive conclusions; multicenter studies with longer follow-up and multivariate analysis are needed to determine whether granulation pattern independently influences long-term outcomes or treatment selection.

EP1164 - ECE_1331 - The role of GM3 gangliosides in acromegaly-associated insulin resistance

Amy Coulden[1,2], Ying Di[1], Priyankaa Patel[1], Ella Smith[1], Warwick Dunn[3], Catherine Winder[3], Christian Ludwig[1], Maria Makarova[1], Niki Karavitaki[1,2] and Gabriela Da Silva Xavier[1]

[1]*Department of Metabolism and System Science, College of Medicine and Health, University of Birmingham, Birmingham, United Kingdom*

[2]*Department of Endocrinology, Queen Elizabeth Hospital Birmingham, University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom;* [3]*Biochemistry, Cell and Systems Biology, University of Liverpool, Centre of Metabolomics Research, Institute of Systems, Molecular and Integrative Biology, Liverpool, United Kingdom*

Background: A significant number of patients with acromegaly develop insulin resistance and diabetes mellitus, the mechanism of which is not fully understood. GM3 gangliosides (GM3), a family of glycosphingolipids which sit within the cell membrane and have important roles within insulin signalling, have previously been mechanistically linked to insulin resistance in patients with diabetes mellitus.

Aim: We aimed to configure the role of GM3 in acromegaly-associated insulin resistance in 3T3-L1 adipocytes and C2C12 myotubes, mouse adipocyte and muscle cell lines, respectively.

Methods: 3T3-L1 adipocytes were exposed to growth hormone (GH) (1 μM) and/or insulin like growth factor 1 (IGF-1) (1 μg/ml) for 48 hours. Insulin signalling was assessed by Western(immuno)blot of AKT phosphorylation (pAKT:AKT). Membrane order was assessed through measures of membrane polarisation by confocal microscopy of DI-4-ANEPPDHQ fluorescence. GM3 content in cellular extracts was measured by NMR spectroscopy. The expression of *ST3GAL5* (which encodes for GM3 synthase, the enzyme responsible for GM3 synthesis) was assessed by qPCR. C2C12 myotubes were also exposed similarly to GH/IGF-1 and expression of *ST3GAL5* was measured.

Results: Exposure of 3T3-L1 adipocytes to elevated concentrations of GH, IGF-1 and the combination of GH/IGF-1 all led to significantly lowered pAKT:AKT (0.3 ± 0.2-fold, 0.5 ± 0.1-fold and 0.5 ± 0.1-fold, respectively) compared to controls, indicating impaired insulin signalling ($P = .01$). Similarly, all three hormonal variations were associated with altered plasma membrane fluidity (1.4 ± 0.04-fold, 1.8 ± 0.1 fold and 1.5 ± 0.08-fold, respectively, $P \leq .0001$). Whilst only IGF-1 (1.4 ± 0.2-fold) and combined GH/IGF-1 (1.4 ± 0.1-fold) altered internal membrane fluidity ($P < .05$).

In 3T3-L1 adipocytes, both IGF-1 and combined GH/IGF-1 increased cellular levels of GM3 [1.4 ± 0.1-fold ($P < .05$) and 1.9 ± 0.4-fold ($P < .05$), respectively] compared to controls. Exposure to elevated GH concentrations also led to increased (1.4 ± 0.1-fold, $P \leq .01$) expression of *ST3GAL5*. Interestingly, combined IGF-1/GH reduced *ST3GAL5* expression 0.8 ± 0.1-fold, $P < .05$, whilst IGF-1 had no effect.

In C2C12 myotubes, GH had no effect on *ST3GAL5* expression, whilst both IGF-1 and combined GH/IGF-1 reduced expression compared to untreated control cells (0.25-fold $\pm$ 0.009 and 0.3-fold $\pm$ 0.05, respectively, $P \leq .0005$).

Conclusions: Taken together, these data indicate that exposure to GH and IGF-1, as seen in acromegaly, inhibits insulin signalling in 3T3-L1 adipocytes potentially via alterations in plasma membrane fluidity and increased GM3 content may be implicated in this process. GH and IGF-1 have some divergent effects in different cell types and fluidity plasma and internal membranes, with IGF-1 being the predominant effector hormone.

EP1165 - ECE_1567 - LC-MS/MS techniques for the analysis of neuroactive and other steroids in various biological matrices

Tereza Skodova, Jana Vitku and Lucie Kolatorova
Department of Steroids and Proteofactors, Institute of Endocrinology, Prague, Czech Republic

Background: Steroid analysis is a rapidly advancing field with significant scientific and clinical potential. Advanced analytical techniques, particularly liquid chromatography with tandem mass spectrometry (LC-MS/MS), allow highly specific, accurate, and sensitive quantification of steroid hormones and related compounds across a variety of biological matrices. Contemporary research focuses on neurosteroids (NS), synthesized de novo in neural tissue, and neuroactive steroids (NAS), peripherally produced steroids that modulate neuronal activity. Changes in NS and NAS reflect disrupted neuroendocrine regulation, particularly in neurological disorders, making them promising biomarkers for understanding, diagnosing, and monitoring these conditions.

Aim: The study aims to develop LC-MS/MS methods for determination of three classes of NS: DHEA metabolites, pregnanolone, and androsterone isomers.

Results: Sample preparation included liquid-liquid extraction using hexan:ethylacetate (3:2) which was used for two developed methods. The first LC-MS/MS enables the analysis of dehydroepiandrosterone (DHEA) and its metabolites—7α-hydroxyDHEA, 7β-hydroxyDHEA, 7-ketoDHEA —together with androgens (testosterone, dihydrotestosterone, androstenedione, and their 11-oxygenated metabolites), corticoids (cortisol, 11-deoxycortisol, 21-deoxycortisol, cortisone, corticosterone, 11-deoxycortico sterone), pregnenolone, progesterone and 17-hydroxypro gesterone. These steroids were chromatographically separated using a Kinetex C18 column (2.6 µm particle size). Pregnanolone isomers (pregnanolone, allopregnanolone, isopregnanolone, and epipregnanolone) and androsterone isomers (androsterone, epiandrosterone, etiocholanolone, and epietiocholanolone) were not adequately separated using this method and column. Because these compounds share identical multiple reaction monitoring (MRM) transitions, they cannot be distinguished by mass spectrometry alone; therefore, further method optimization was required. Several separation columns were tested including Kinetex C18 (2.6 and 1.7 µm particle sizes), Kinetex Biphenyl (2.6 µm) and Kinetex F5 (2.6 µm), under various temperatures (30 °C, 40 °C, 50 °C), flow rates, and gradient conditions. The best isomer separation was achieved using the Kinetex F5 column at 30 °C with an initial gradient composition of 30:70 (water:MeOH).

Conclusions: Two LC-MS/MS methods were developed for the analysis of DHEA metabolites, pregnanolone and androsterone isomers, and 21 other streroids. Quantification can be performed from a single sample using two LC-MS/MS methods—one employing a Kinetex C18 column and the other a Kinetex F5 column. The developed methods will be applied to a broad spectrum of biological matrices, including plasma, cerebrospinal fluid, and both human and animal tissues. Comprehensive profiling of NS and NAS is expected to enhance our understanding of their roles in the pathophysiology and treatment of neurological disorders.

EP1167 - ECE_2239 - The somatotroph activation may define the aggressive biology of silent corticotroph tumors

Cristina Guillen[1], María Eugenia Torregrosa-Quesada[1], Johana Sottile[2], Jorge Navarro[2], Jorge Frances[1], Francisca María Peiró-Marqués[1], Elena García[1], Joaquin Serrano[1], Javier Abarca Olivas[1] and Antonio Pico[1]
[1]*Hospital General Universitario Dr. Balmis, Alicante, Spain;* [2]*Instituto de Investigación Biomédica de Alicante (ISABIAL), Alicante, Spain*

Introduction: Silent Corticotroph Tumors (SCTs) are clinically distinguished from Silent Gonadotroph Tumors (SGTs) by their higher rate of recurrence and aggressive behavior. After we noticed unexpectedly high IGF-1 levels in our SCT group, we decided to explore the somatotroph axis in these tumors. We thought that somatotroph activation could be an important biological feature related to the natural aggressiveness of the corticotroph lineage. We assessed both the basic dynamics and functional reserve using specific secretagogues.

Methods: We studied 58 patients, including 27 with SCTs and 31 with SGTs. 1) We compared baseline somatotroph levels of IGF-1 and GH between SCTs and SGTs; 2) To see if the activation was caused by the classic GHRH pathway or the alternative Ghrelin pathway, we conducted the Glucagon Stimulation Test (GHRH-dependent) on a subgroup of 14 patients (6 SCTs and 8 SGTs) and the specific Macimorelin Test (GHSR-dependent) in SCT patients ($n = 7$).

Results: SCT patients showed significantly higher baseline IGF-1 levels (175.1 ± 56.4 vs 105.8 ± 65.8 ng/mL, $P = .0002$) and a two-fold increase in baseline GH levels (0.42 vs 0.19 ng/mL). The SCT group had a reintervention rate seven times higher than the SGT control group (21.4% vs 3.3%, $P = .08$). Our tests showed that the Glucagon test produced a similar GH response in both groups (SCT Peak: 1.26 ± 1.15 ng/mL vs SGT Peak: 0.98 ± 1.65 ng/mL, $P = .17$). However, SCTs were particularly sensitive to the alternative pathway. Stimulation with Macimorelin caused a strong GH release in SCTs (Peak: 1.88 ng/mL), significantly better than the response to Glucagon ($P = .0078$).

Conclusions: The higher levels of IGF-1 and GH, compared with SGTs, along with a strong response to Macimorelin, indicate a specific functional increase of the somatotroph axis, likely triggered by the GHSR pathway. This unique biological profile appears to be a characteristic of the corticotroph lineage and may help explain the aggressive behavior and higher recurrence rates seen in this group. We are currently extending Macimorelin testing to the SGT group and conducting molecular analysis (RT-qPCR) to confirm this mechanism.

EP1168 - ECE_3937 - An elusive sellar germinoma: clinical and histopathological challenges

Alice Monsanto[1], Gustavo Rodrigues[1], Tânia Carvalho[1], Ana Margarida Sobral[2], Bárbara Jesus[1], Adriana Duarte[1], Mariana Coelho[1], Mariana Lavrador[1], Mara Ventura[1], Daniela Guelho[1] and Leonor Gomes[3]

[1]Department of Endocrinology, Diabetes and Metabolism, Unidade Local de Saúde de Coimbra, Coimbra, Portugal; [2]Unidade Local de Saúde de Coimbra, Coimbra, Portugal; [3]Coimbra, Portugal

Introduction: Intracranial germ cell tumors are rare and represent a diagnostic challenge, particularly when an extensive lymphocytic reaction obscures tumor cells.

Case report: A 23-year-old male with gynecomastia and decreased libido. Investigation revealed hypogonadotropic hypogonadism (FSH 1.08 IU/L [1.4-18.1], LH 0.55 IU/L [1.5-9.3], total testosterone 19.0 ng/dL [241.0-827.0]). Cranial CT scan revealed an expansive supra- and intrasellar lesion, spontaneously hyperdense, with moderate homogeneous contrast enhancement. A clarification sellar MRI showed enlargement of the adenohypophysis with an hourglass morphology measuring 15 × 10 × 14 mm, loss of posterior pituitary bright spot on T1-weighted images, and reduced contrast uptake relative to normal glandular parenchyma, with contact with the optic chiasm.

Further evaluation: hyperprolactinemia (75.3 ng/mL) and GH deficiency (IGF-1 103 ng/mL) and vasopressin deficiency, with polyuria (5 L/day) and urinary osmolarity 230 mOsm/kg. Serum tumor markers were negative (AFP 3.50 ng/mL, β-hCG 2.0 mIU/mL). Baseline campimetry was normal.

Progressively developed central hypothyroidism (FT4 0.53 ng/dL [0.7-1.5]; TSH 1.8 uUI/mL [0.35-4.94]), secondary adrenal insufficiency (cortisol 2.6 ug/dL), and visual symptoms (incomplete right inferior temporal quadrantanopsia and incomplete left temporal hemianopsia). MRI revealed an dimensions increasing (17 × 13 × 14 mm).

Transsphenoidal resection was performed with neuropathologicaly revealing adenohypophyseal fragments with preserved lobular architecture and a discrete lymphocytic infiltrate, along with connective tissue showing a dense, predominantly lymphocytic inflammatory infiltrate with reactive lymphoid follicle formation. Immunohistochemical: B lymphocytes (CD20) and T lymphocytes (CD3), CD138-positive plasma cells. Background staining without well-defined cellular elements for PLAP, CD117, and D2-40, with very rare cells expressing OCT4 and SALL4. No positivity for CAM5.2, AFP, or hCG.

Discussion/conclusions: The pathological findings are highly suggestive of an intracranial germ cell tumor, showing reactive follicular lymphoid hyperplasia with focal immunohistochemical expression of PLAP, OCT4, and SALL4, without features of pituitary adenoma or craniopharyngioma. These findings plus clinical presentation (young male, diabetes insipidus, panhypopituitarism, loss of the posterior pituitary bright spot, bitemporal visual field defects) strongly suggest germinoma with extensive lymphocytic reaction. Germinomas are highly immunogenic tumors that elicit a dominant peritumoral immune response with massive lymphocytic infiltration, occasionally obscuring neoplastic cells and leading to misdiagnosis. Additional investigations are on going (CSF cytology and tumor markers; postoperative MRI). This case underscores the diagnostic challenges of CNS germ cell tumors when peritumoral immune reactions dominate the histological picture and emphasizes the importance of integrating clinical, radiological, and immunohistochemical findings when tumor cells are sparse.

EP1169 - ECE_2981 - Effects of treatment on bone metabolism and structure in patients with excess and deficiency of growth hormone: a preliminary report

Arnika Wydra[1,2], Jagoda Alicja Rogowska[1,2], Maria Stelmachowska-Banas[2], Alicja Duquenne[1,2], Wojciech Zgliczyński[2] and Izabella Czajka - Oraniec[2]

[1]Doctoral School of Translational Medicine, Centre of Postgraduate Medical Education, Warsaw, Poland; [2]Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland

Background: Both the excess of growth hormone in acromegaly (Acro) and its deficiency (GHD) may lead to impaired bone metabolism and bone mineral density (BMD) and fragility. However, the exact mechanism remains unclear.

Purpose: To evaluate the effects of Acro and GHD treatment on bone metabolism and structure, including bone turnover markers, BMD and bone microarchitecture.

Methodology: In this single-center study 52 patients were recruited: 20 with Acro and 32 with GHD. During the follow-up period, 6 patients with Acro and 7 patients with GHD met the exclusion criteria.

Consequently, 14 Acro patients (9 males, 5 females) and 25 GHD patients (13 males, 12 females) remained under observation. Calcium, phosphorus (serum and urine), PTH, 25-hydroxy- and 1,25-dihydroxy-vitamin D and bone turnover markers: serum b-cross laps (Ct-x), procollagen type I N-terminal propeptide (P1NP), bone alkaline phosphatase (BALP), sclerostin (Scl) and Dikkopff-1 (Dkk-1), and BMD and TBS measured by dual-energy X-ray absorptiometry were assessed baseline and after 6 months (a6m) of adequate treatment.

Results: Median age was 48 (IQR: 26.75) and 28.5 (IQR: 16) in Acro and GHD group, respectively. Median baseline GH and IGF-1 levels in Acro were 12.5 ug/L and 689 ug/L (3.1 × ULN), respectively. In the GHD group median baseline IGF-1 was 74.9 ug/L (0.86 × LLN). A6m of adequate treatment a decrease in IGF-1 in the Acro group and an increase in the GHD group were observed (225.5 ng/ml (0.97 × ULN) and 185.2 ng/ml (0.71 × ULN) respectively).

In Acro a6m of treatment we observed a reduction in serum calcium (2.5 vs 2.42 mmol/L; $P = .04$) and phosphorus (1.42 vs 1.1 mmol/L; $P < .001$), urine calcium (5.53 vs 2.94 mmol/24 h; $P < .001$) in 24-hour urine collection. We also observed an increase in PTH (29.9 vs 45.0 pg/mL; $P = .023$) and 25(OH)D (26.92 vs 35.6 ng/ml; $P = .002$). A6m of treatment we did not observe statistically significant changes in bone turnover markers or BMD.

In GHD there was an increase in serum phosphorus (1.02 vs 1.19 mmol/L; $P = .002$), and increase in 24-hour urine calcium and phosphorus (3.95 vs 5.66 mmol/L; $P = .004$ and 17.71 vs 22.93 mmol/L; $P = .02$, respectively). A6m of treatment an increase in BALP (70.5 vs 78.4 U/L; $P = .034$) and Scl (47.6 vs 64.6 pg/ml; $P = .034$) was observed. There were no notable changes in PTH, 25(OH)D or BMD a6m.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusions: We present initial results of the study showing the impact of GH and IGF-1 changes on bone turnover in both groups.

EP1170 - ECE_3127 - Hematologic predictors of prolonged glucocorticoid replacement in endogenous Cushing's syndrome: a nationwide cohort study from the clalit health services database

Shruti Shah[1], Nidhi Agrawal[2], Shiri Kushnir[3], Tzipora Shochat[4], Maria Fleseriu[5] and Amit Akirov[6,7]
[1]NYU Grossman School of Medicine, New York, United States; [2]Department of Medicine, NYU Langone Health, New York, United States; [3]Research Authority, Rabin Medical Center, Beilinson Hospital, Petach Tikva, Israel; [4]Biostatistics Unit, Rabin Medical Center, Beilinson Hospital, Petach Tikva, Israel; [5]Pituitary Center, Departments of Medicine and Neurological Surgery, Oregon Health & Science University, Portland, United States; [6]Rabin Medical Center, Beilinson Hospital, Institute of Endocrinology, Petach Tikva, Israel; [7]Gray Faculty of Medical & Health Sciences, Tel Aviv University, Tel Aviv, Israel

Purpose: The duration of glucocorticoid (GC) replacement following curative treatment of endogenous Cushing's syndrome (CS) is highly variable, and there are no validated markers to guide tapering or predict prolonged dependency. Hematologic indices reflect cortisol exposure and immune regulation, yet their role in postoperative adrenal recovery has not been examined. We evaluated clinical and hematologic predictors of GC duration, stratified by disease etiology and GC formulation.

Methods: This nationwide retrospective cohort included patients with endogenous CS diagnosed between 2000 and 2023 in the Clalit Health Services database in Israel. Patients with adrenocortical carcinoma, ectopic CS, or prior supraphysiologic steroid use were excluded. Duration of GC therapy following curative pituitary or adrenal surgery was categorized as <20 months or ≥20 months based on the cohort median of 19.3 months. Baseline hematologic indices, including white blood cell count, neutrophils, lymphocytes, and neutrophil-to-lymphocyte ratio (NLR), were derived from values recorded within 24 months prior to diagnosis. Analyses included Wilcoxon and chi-square tests, Kaplan–Meier survival estimates, and Cox proportional hazards modeling with subgroup analyses by etiology and GC type.

Results: Among 103 patients (mean age 43.8 ± 13.7 years; 76.7% women), 41 had Cushing's disease (CD), 56 had adrenal CS, and 6 were of indeterminate etiology. Fifty-one patients (49.5%) required ≥20 months of GC replacement (median 47.6 vs 8.3 months). Patients requiring prolonged therapy were older (47.8 ± 14.5 vs 39.8 ± 11.7 years, $P = .0045$) and had lower baseline neutrophils (6.79 ± 3.12 vs 7.74 ± 2.75 × 10^9/L, $P = .050$) and NLR (3.99 ± 3.06 vs 4.90 ± 2.64, $P = .026$). In CD, prolonged therapy was associated with lower neutrophils, lower NLR, and lower total leukocytes, whereas no hematologic differences were observed in adrenal CS. Hydrocortisone use was more frequently associated with prolonged replacement than prednisone (75.0% vs 43.4%). Baseline cortisol measures and comorbidities were not predictive. Overall survival did not differ by GC duration, but among CD patients, prolonged therapy was associated with lower survival (log-rank $P = .045$).

Conclusions: Older age and lower baseline neutrophils and NLR were associated with prolonged postoperative GC dependency, particularly in pituitary disease. These findings suggest that routinely available hematologic markers may help anticipate delayed adrenal recovery and support individualized tapering strategies, warranting prospective validation.

EP1171 - ECE_1534 - Analysis of the clinical characteristics of patients receiving growth hormone treatment at the National Children's Hospital of Costa Rica, in the period between January 2008 and December 2023

Liseth Gabriela Delgado Castro, Fred Cavallo Aita, Jose Edmond Esquivel Vargas and Paulo Perez Damasco
Caja Costarricense de Seguro Social, San José, Costa Rica

Background: Recombinant human growth hormone therapy has been used at the Children´s National Hospital in Costa Rica since 1987. This study aims to analyze the clinical and epidemiological characteristics of patients treated with rhGH from 2008 to 2023, and to evaluate treatment effectiveness in the Costa Rican pediatric population.

Methods: An observational, descriptive, and retrospective study was conducted including 672 patients treated in the Endocrinology outpatient clinic at the National Children's Hospital. Clinical, anthropometric, biochemical, and treatment-related variables were collected. Differences were analyzed according to diagnosis and treatment status (active, completed, or discontinued), and predictors of a satisfactory response; defined as achieving a final height within ≤2 SD below the genetic target, were identified. Nonparametric tests, chi-square, and binary logistic regression were applied.

Results: The most frequent diagnosis was GH deficiency (63.1%), followed by Turner syndrome (16.8%), small for gestational age (SGA) (14.4%), and other diagnoses (5.7%). The median age at treatment initiation was 107.5 months, lower in SGA patients (69 months), who also had the most compromised initial height Z-score (−3.2). Of the total, 43% completed treatment, 36.9% remained on active therapy, and 20.1% had discontinued. Treatment adherence was significantly lower among those who discontinued (45.9%, $P < .001$). Among the 289 patients who completed treatment, 52.2% achieved a satisfactory final height. Significant predictors of treatment success included male sex (OR 3.0, $P = .013$), regular adherence (OR 6.08, $P = .010$), higher initial height Z-score (OR 4.48, $P < .001$), better genetic height potential (OR 2.39, $P = .018$), and lower GH peak (OR 0.77, $P = .003$). Adverse events were reported in 9.1% of patients, with no association with GH dose or diagnosis. Although a significant correlation is observed between baseline IGF-1 and peak of GH un the insulin tolerance test, its low magnitude prevents IGF-1 from being used as a substitute for the stimulation test in most cases. However, markedly low values could be useful for identifying priority candidates for diagnostic confirmation.

Conclusions: These findings are consistent with international registries such as KIGS, GeNeSIS, and NordiNet, and emphasize the importance of early diagnosis, sustained adherence, and appropriate diagnostic selection to optimize treatment outcomes with rhGH.

EP1172 - ECE_3030 - Effects of dopamine agonist treatment on IGF-1 levels in patients with prolactinoma

Karolina Cylke-Falkowska[1,2], Aleksandra Toporowska-Siwiak[1], Wojciech Zgliczyński[1] and Maria Stelmachowska-Banaś[1]

[1]*Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland;* [2]*Doctoral School of Translational Medicine, Centre of Postgraduate Medical Education, Warsaw, Poland*

Introduction: Prolactinomas account for 40%-50% of pituitary adenomas. Dopamine agonists (DAs) are the first-line treatment in vast majority of patients due to their efficacy in reducing prolactin (PRL) secretion and tumor size; however, their long-term effect on insulin-like growth factor-1 (IGF-1) levels remains unclear.

Aim: To determine the impact of DAs treatment on IGF-1 concentrations in patients with prolactinoma.

Patients and Methods: This retrospective, single-center study included 45 consecutive patients with prolactinoma treated with DAs, with available IGF-1 measurements at baseline and follow-up. Patients with mixed PRL–GH tumors and clinical features of acromegaly were excluded.

Results: The male-to-female ratio was 0.96 and mean age at diagnosis was 41.5 ± 17 years. The median baseline PRL concentration in all patients was 520 ng/ml. Microadenomas were present in 12 patients (27%), while macroadenomas were observed in 33 patients (73%). During DAs treatment, the mean IGF-1 level increased from 193.5 ± 87 ng/ml to 229 ± 97.8 ng/ml (from $0.74 \pm 0.28 \times$ the upper limit of normal (ULN) for age to $0.89 \pm 0.32 \times$ ULN) after the mean 14.6 ± 11.6 months. The increase was significant ($P < .001$). BMI of patients did not change significantly, and showed no correlation with IGF-1 levels.

Twenty -two patients (9 women, 13 men) received bromocriptine treatment. There was a significant decrease in PRL concentration to a median of 13.7 ng/ml with normalization achieved in 16 patients (72%). The baseline IGF-1 levels were within the reference range in most patients, whereas 3 patients were above the ULN. During bromocriptine treatment, the mean IGF-1 levels increased from 188.2 ± 107 ng/ml to 208.7 ± 92.5 ng/ml (from $0.74 \pm 0.34 \times$ ULN to $0.85 \pm 0.37 \times$ ULN) after the mean 13.4 ± 8 months; however the increase was not significant ($P > .05$). After bromocriptine treatment IGF-1 concentration exceeded the ULN in 7 (33%) patients.

Twenty-three patients (14 women, 9 men) were treated with cabergoline. PRL normalization was achieved in 17 patients (74%), with a median PRL concentration of 13.7 ng/ml. During cabergoline treatment the mean IGF-1 concentration increased from 198.7 ± 63.9 ng/ml to 248.4 ± 100.7 ng/ml (from $0.73 \pm 0.2 \times$ ULN to $0.92 \pm 0.27 \times$ ULN), $P < .05$ after the mean 15.7 ± 14.3 months.

Conclusions: DAs therapy of prolactinoma was associated with an increase IGF-1 levels which was particularly pronounced in patients treated with cabergoline. The mechanism underlying the increase in IGF-1 concentration requires further research.

EP1173 - ECE_1889 - Effects of a novel set of somatostatin/cortistatin analogues on pituitary neuroendocrine tumors

Federica Mangili[1], Nicole Panseri[2], Donatella Treppiedi[1], Genesio Di Muro[2], Marco Locatelli[3,4], Erika Peverelli[1,2] and Giovanna Mantovani[1,2]

[1]*Endocrinology Unit, Fondazione Irccs Ca Granda Ospedale Maggiore Policlinico, Milano, Italy;* [2]*Department of Excellence 2023-2027, University of Milan, Milan, Italy;* [3]*Neurosurgery Unit, Fondazione IRCCS Ca Granda Ospedale Maggiore Policlinico, Milan, Italy;* [4]*Dalmine, BG, Italy*

Pituitary neuroendocrine tumors (PitNETs) comprises the 10%-25% of all intracranial neoplasms and first-line therapeutical approach is represented by surgery, whereas an effective pharmacological therapy for resistant and relapsing disease is still lacking.

Somatostatin (SS) receptors (SSTs) constitute the main suitable pharmacological targets for PitNETs therapy with SST ligands (SRLs). Nevertheless, a large proportion of tumors are unresponsive or resistant to conventional therapies, highlighting the need of personalized strategies. Recently, the endogenous neuropeptide cortistatin (CST), that shares with SS actions and affinity to SSTs, emerged as an anti-inflammatory player, showing potential antitumoral behavior in different NETs. Furthermore, an effect of CST in regulating GH and ACTH secretion has been demonstrated.

This study aims to test the effects of CST and a novel set of SS/CST analogues that display broader SSTs affinity, in both GH-secreting PitNET cell line GH3 and primary cultures, and ACTH-secreting PitNET cell line ATt-20/D16v-F2, comparing them with classical SRLs octreotide and pasireotide.

The antimitotic ability of CST was also tested in human primary cultured non-functioning PitNETs.

CST 100 nM reduced cell proliferation in both GH3 (−40.8(42.6)%, $P < .01$) and ATt-20/D16v-F2 (−25.7(20.3)%, $P < .05$) cells. A significative antimitotic action was exerted by all SS/CST a*nalogs 1, 2, 3 and 4* in both cell lines. A*nalog5* was effective only in GH3 cells. To note, a*nalog1* showed a stronger efficacy with respect to octreotide in GH3 ($P < .05$).

SS/CST *analog2* and *analog5* inhibited also GH3 migration (−74.6(45.8)%, $P < .01$; −67.4(13.8)%, $P < .01$), GH secretion (−41.9(21.4)%, $P < .05$; −28.2(23.7)%, $P < .05$), and increased cell apoptosis (+1.43(0.39)-fold, $P < .05$; +1.38(0.51)-fold,$P < .05$). CST and *analog2* antisecretory effect was also confirmed in 3 different human primary cultured GH-PitNETs cells.

Antimigratory action in ATt-20/D16v-F2 was also exerted by both CST (−39.1(29.2)%, $P < .05$) and SS/CST *analog1* (−44.7(29.8)%, $P < .05$), this last showing also pro-apoptotic effect (+1.22(0.18)-fold,$P < .01$).

Similarly, CST (−36.59(36.9)%, $P < .05$) and *analog2* (−28.43(23.1)%, $P < .05$)exerted antimitotic action in 8 out of 11 different NF-PitNETs cultured cells tested.

To conclude, our study represents an alternative approach that provides the use of novel molecules, based on a wider interaction with SSTs profile of expression, paving the way for a more flexible and adaptive pharmacological approach for patients with PitNET.

EP1175 - ECE_1430 - Metastatic germ cell cancer presenting as hypophysitis: a rare clinical case report

Martyna Juskiene, Ieva Baikštienė, Radvilė Matukaitienė and Birutė Žilaitienė
Department of Endocrinology, Institute of Endocrinology, Lithuanian University of Health Sciences, Kaunas Clinics, Kaunas, Lithuania

Introduction: Hypophysitis is a rare endocrine disorder characterized by inflammation of the pituitary gland, resulting in hypopituitarism. The most common causes include autoimmune (lymphocytic), infection-related, and medication-induced forms. Metastatic hypophysitis is exceptionally rare, with limited data regarding its prevalence.

Case: A 29-years-old male presented with a two-year history of general weakness, polydipsia and polyuria. Initial investigations revealed severe hypopituitarism with a low basal cortisol (29 nmol/L), IGF-1, growth hormone, gonadotropins, testosterone and thyroxine, with elevated prolactin (951 mU/L). With a suspected diagnosis of hypopituitarism, central hypothyroidism, hypogonadotropic hypogonadism, secondary adrenal insufficiency, the patient was admitted to the Department of Endocrinology. Treatment with levothyroxine and hydrocortisone was initiated. Further evaluation revealed polyuria with hypostenuria. A positive desmopressin test confirmed diabetes insipidus and additional treatment initiated.

To clarify the cause of panhypopituitarism, a brain CT scan (as it was faster than an MRI) revealed changes in the corpus callosum, a thickened pituitary stalk (~4.3 mm), and thickening of the right optic nerve in the prechiasmatic segment. A suspected diagnosis of Langerhans cell histiocytosis was made. Due to the identified changes, a consultation with a neuro-ophthalmologist was sought—no visual fields or OND changes were identified.

Thoracic, abdominal, and pelvic CT scans revealed multiple para-aortic and paracaval lymph nodes, suggesting a possible lymphoproliferative disorder. Given the limited accessibility for tissue verification, threpine biopsy was performed, demostrating normal hematopoesis.

To refine the diagnosis, a brain MRI was performed, revealing changes in the corpus callosum, left corona radiata, both anterior limbs of the internal capsules, the ependyma of the third ventricle, chiasmatic optic nerve, and the right optic nerve region, suggesting central nervous system lymphoma and less likely germinoma. A stereotactic biopsy confirmed germinoma. Testicular ultrasound did not reveal any abnormalities, and tumor markers AFP, βHCG, LDH were within normal limits.

Following multidisciplinary neuro-oncology board discussion, neoadjuvant chemotherapy eith the CARB-VP regimen was initiated. Patient received three chemotherapy cycles followed by cranial radiotherapy with a total dose of 44 Gy. After completion of oncological treatment, testosterone replacement therapy was started.

Patient is in follow up since April 2024, continious MRI demonstrated significant regression of periventricular, suprasellar, and adjacent tumor infiltration. Patient remains in remission and continues regular imaging surveillance every six months.

Conclusions: Hypophysitis due to germ cell cancer is rare and diagnostically challenging condition. Timely diagnosis, multidisciplinary collaboration, and comprehensive treatment approach are essential for managing this condition and improving patient's quality of life.

EP1176 - ECE_1536 - Long-term pasireotide treatment in the setting of advanced chronic kidney disease and hemodialysis

Adnan Zaina[1] and Sameer Kassem[2]
[1]*The Azrieli Faculty of Medicine, Clalit Medical Health Care Services, Endocrinology, Bar-Ilan University, Safed, Israel;* [2]*Carmel Medical Center, Internal Medicine, Technion Israel Institute of Technology, Haifa, Israel*

Introduction: Transsphenoidal surgery (TSS) remains the primary treatment for acromegaly. Pharmacological therapy is essential for achieving biochemical control in patients with persistently elevated IGF-1 levels after surgery or when surgery is not feasible. Somatostatin analogs (SSAs), such as octreotide and lanreotide, are widely used. Pasireotide (PAS-LAR) and Pegvisomant (PEGV) are additional options, particularly for patients resistant to or partially responsive to first-generation SSAs. Other treatments include radiotherapy and dopamine receptor agonists. We report the first case of acromegaly in a patient with CKD on hemodialysis who achieved long-term biochemical control with PAS-LAR.

Case presentation: A 73-year-old woman diagnosed with acromegaly in April 1996 due to a pituitary macroadenoma underwent TSS. Pathology revealed a pituitary adenoma that stained positively for GH. Postoperatively, MRI showed a partially empty sella without tumor remnant, and GH and IGF-1 levels normalized. From 1999 to 2005, a pituitary tumor remnant gradually increased, with IGF-1 at 38.9 nmol/L (normal range 10 to 33 nmol/L) and GH at 5.83 μg/L. A repeat TSS was performed in March 2005. Because GH and IGF-1 levels remained high postoperatively, lanreotide autogel 60 mg monthly was initiated and up-titrated to 120 mg, causing gastrointestinal symptoms after each injection. In 2008, an MRI showed tumor shrinkage; however, because IGF-1 remained high in July 2009, treatment was switched to PEGV 10 mg daily, with the dose increased to 20 mg daily. A dramatic decline in IGF-1 levels was observed (32.9 nmol/L; normal range 10-33 nmol/L).

Due to poor compliance, the patient discontinued PEGV. Between 2013 and 2016, successive MRIs showed a right pituitary mass measuring $1.3 \times 1.1 \times 1.1$ cm, with elevated IGF-1 levels. Endoscopic transsphenoidal re-exploration of the pituitary was performed, and no tumor was identified.

PAS-LAR 40 mg monthly was initiated in May 2017 and up-titrated to 60 mg. A normalized IGF-1 level of 168 ng/mL (normal range: 20 to 244 ng/mL) was achieved, with a random GH level of 1.31 μg/L. The patient has been adherent to monthly treatment since initiation. She has had CKD due to longstanding hypertension since 2005, progressing to advanced CKD requiring hemodialysis since May 2012, with prior hospitalization for severe anemia and hemicolectomy for a cecal tubule-villous adenoma.

Conclusions: Managing acromegaly in patients with CKD on hemodialysis is challenging. Long-term use of PAS-LAR in this patient subgroup appears safe for controlling disease activity. Further research in this area is needed.

EP1177 - ECE_1572 - Challenges in the treatment of aggressive somatotrophic pituitary adenoma

Aleksandra Markovic[1,2], Mirjana Bojic[1], Ivona Risovic[1,2], Jelena Malinovic Pancic[1,2], Sanja Milanovic[1], Bojana Caric[1,2], Milena Brkic[2] and Tamara Dojcinovic[1,2]
[1]University Clinical Center of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina; [2]Faculty of medicine University of Banja Luka, Banja Luka, Bosnia and Herzegovina

Introduction: Aggressive adenomas are large and invasive tumors that exhibit unusually rapid growth and/or continue to grow despite surgical treatment, drug therapy, and radiotherapy. However, large tumors, as well as invasive tumors, are not always aggressive, and this diagnosis can only be established after clinical monitoring, in which tumor growth dynamics and response to therapy are crucial for defining aggressiveness.

Case presentation: We present the case of a 37-year-old female patient with an aggressive invasive pituitary somatotropic macroadenoma. The tumor was detected at the time when it produced symptoms related to compression of surrounding structures, including headaches and visual disturbances, as well as amenorrhoea due to secondary hypogonadotropic hypogonadism.

In July 2024, the first MRI of the pituitary gland was performed, revealing a macroadenoma measuring 25 × 48 × 28 mm, expanding the sella turcica, exerting suprasellar compression of the optic chiasm, and circumferentially encasing the carotid arteries, with mild compression of the surrounding brain parenchyma. A neurosurgical consultation was obtained, and two transsphenoidal surgical procedures were performed; however, disease remission was not achieved. After the second surgery, a long-acting somatostatin analogue was introduced, as the tumor was considered inoperable. During further follow-up, an extremely active disease course was observed, characterized by persistently very high levels of growth hormone and IGF-1, accompanied by hypogonadotropic hypogonadism and secondary hypothyroidism. In addition to the long-acting somatostatin analogue, a dopamine agonist was also introduced. Follow-up MRI of the sellar region performed in February 2025 revealed residual tumor. The patient was discussed at a multidisciplinary team meeting, and radiotherapy was indicated. After completion of radiotherapy, partial regression of the tumor mass was achieved; however, biochemical disease activity remained significant. Due to the unavailability of second-generation somatostatin analogues and growth hormone receptor antagonists in our country, treatment with higher doses of somatostatin analogue was continued.

Conclusions: This case highlights the complexity of the therapeutic approach to aggressive pituitary adenomas, as well as the need for individualized and multidisciplinary treatment planning and the importance of continuous clinical follow-up.

EP1178 - ECE_1627 - Diagnostic challenges in a case of "mild" acromegaly

Irina A. Vaychulis
Internal Medicine Department, South-Ural State Medical University, Chelyabinsk, Russia

Presence and type of hormonal secretion are the key factors for treatment choice in patients with pituitary adenomas. However, in some cases, the detection of hormonal activity of pituitary tumors is not so obvious.

Female patient has been followed by endocrinologist (since the age of 54 years) with euthyroid multinodular goiter, arterial hypertension and dyslipidemia, well controlled by small doses of antihypertensive drugs and statins. At the age of 63 years, during her regular visit to the same endocrinologist, she mentioned the recently appeared swelling of the fingers, numbness and pain in both hands. Carpal tunnel syndrome was diagnosed by neurologist. Her TSH, fT4, CBC, rheumatoid factor, anti-CCP, fasting BG levels were unremarkable. Despite the absence of rough typical features and any noticeable changes in her appearance, testing for acromegaly was administered by endocrinologist. Moderate elevation of IGF-1 up to 222-217 (ULN 174) ng/ml at two consecutive measurements, in combination with normal basal GH, ACTH and prolactin levels were revealed. OGTT with 75 g glucose demonstrated normal 2-h postload BG and slightly insufficient suppression of GH to the minimum value of 0.59 (GH nadir cutoff < 0.4) ng/ml. Pituitary macroadenoma with maximal size of 1.4 cm was found at MRI. Patient had no visual field defects and was not inclined to consider neurosurgery. Short acute octreotide test was recommended to estimate sensitivity to somatostatin analogues, but the next two measurements of basal IGF-1 levels, performed at one month interval, showed the results within the normal range. Three months later, moderate elevation of IGF-1 (up to 185 ng/ml) was registered again. Repeated MRI showed no change in size of pituitary adenoma after 11 months.

Conclusions: Typical somatotropinoma is a slowly growing tumor, which remains undiagnosed for many years, and often first identified at advanced stage, presenting with large pituitary mass, multiple complications, high IGF-1 and unsuppressed GH levels. This case demonstrates diagnostic challenges in acromegaly with subtle, non-specific suspicious clinical signs/associated comorbidities (in the absence of typical acromegaly phenotype) and minimal, non-stable IGF-1 hypersecretion with normal basal GH and near normal suppression of GH. Such discordance can be interpreted as a "mild" form of disease, or explained by relatively early detection of classic, slowly progressing somatotropinoma. Taking into account inconsistent IGF-1 results, cyclic acromegaly pattern can also be discussed. Medical practitioners should be aware of acromegaly with mild clinical manifestations to avoid delay in diagnosis and to individualize therapy.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: Functioning gonadotroph adenomas (FGA) represent 2%-10% of pituitary adenomas. It is characterized by ovarian follicles and cysts, hyperestrogenism and endometrial hyperplasia. Gold standard therapy is surgery.

Case presentation: A 40-year-old woman referred to us for abdominal pain, increased ovarian volume and hypomenorrhea. Hormonal evaluation showed hyperestrogenism and inappropriate FSH value. Second level tests documented secreting pituitary adenoma. Pelvic ultrasonography and MRI showed ovarian hyperstimulation syndrome (OHSS). Brain MRI revealed a pituitary lesion with increased uptake to 18-FDG-PET/TC. Patient underwent neurosurgery and histology showed a pituitary macroadenoma. Immunohistochemistry was positive for LH, FSH, p53, CK-CAM5.2, chromogranin.

Conclusions: Multiple ovarian cysts are frequently suggestive for polycystic ovary syndrome. A complete hormonal asset is necessary for differential diagnosis. Generally, women with FGA present hyperestrogenism, with inappropriate levels of FSH and LH and could also present OHSS. A complete biochemical, imaging and histological evaluation is necessary to confirm FGA diagnosis.

EP1180 - ECE_3089 - Masked adrenal insufficiency in Wolfram syndrome: a rare endocrine phenotype

Sanda Cho, Tahir Omer, Rawia Adoma and Mosea Song
Diabetes and Endocrinology, Bedford Hospital, Bedford, United Kingdom

Background: Wolfram syndrome is a rare, inherited neurodegenerative disorder characterised by diabetes mellitus, optic atrophy, and progressive central nervous system involvement. While posterior pituitary dysfunction, particularly central diabetes insipidus, is well recognised, anterior pituitary hormone deficiencies are uncommon. ACTH deficiency is an exceptionally rare manifestation, with only a few reported cases. We describe a case of evolving secondary adrenal insufficiency in Wolfram syndrome, highlighting diagnostic challenges in rare neuroendocrine disease.

Case presentation: A 24-year-old woman with a known diagnosis of Wolfram syndrome attended routine diabetes follow-up with persistent fatigue, low energy, and chronically low blood pressure. Several weeks earlier, she had presented to the emergency department for worsening lethargy and hypotension, where blood pressure was recorded at 75/50 mmHg with a mild metabolic acidosis. She was treated with intravenous fluids and discharged following clinical improvement.

Given ongoing symptoms, adrenal function was assessed. Early-morning serum cortisol was repeatedly low (76 nmol/L and 71 nmol/L). An urgent short Synacthen test (SST) demonstrated preserved adrenal responsiveness, with cortisol rising from 105 nmol/L at baseline to 461 nmol/L at 30 minutes and 560 nmol/L at 60 minutes. The patient denied prior exposure to exogenous glucocorticoids.

The discrepancy between low basal cortisol levels and normal dynamic testing prompted further hypothalamic–pituitary evaluation. A repeat 9 AM cortisol one week later improved to 219 nmol/L. Anterior pituitary function was otherwise preserved, with normal thyroid function, gonadotrophins, and prolactin. Plasma ACTH was low at 5 ng/L (reference range 5-49 ng/L), supporting evolving secondary adrenal insufficiency. Pituitary MRI was requested.

Discussion: ACTH deficiency represents one of the rarest endocrine manifestations of Wolfram syndrome. When reported, it appears to reflect progressive hypothalamic–pituitary neurodegeneration rather than autoimmune pathology. Proposed mechanisms include impaired hypothalamic corticotrophin-releasing hormone secretion, selective vulnerability of pituitary corticotrophs, and chronic endoplasmic reticulum stress related to WFS1 dysfunction. Early disease may present with impaired basal ACTH secretion despite preserved adrenal reserve, leading to misleadingly normal SST responses. This case underscores limitations of dynamic testing alone and highlights the importance of longitudinal biochemical surveillance in rare neurodegenerative endocrine disorders.

Conclusions: This case adds to the limited literature describing ACTH deficiency in Wolfram syndrome. Clinicians should maintain vigilance for evolving pituitary–adrenal dysfunction in symptomatic patients. Serial assessment is essential, and the patient was advised on sick-day steroid rules while awaiting repeat testing, avoiding premature long-term glucocorticoid replacement.

EP1181 - ECE_3410 - AVPD as a rare endocrine complication of temozolomide

Lia Anguelova[1], Mike Matheou[1], Bahram Jafar-Mohammadi[1], Christine May[1], Robin Joseph[2] and Aparna Pal[1]
[1]*Endocrinology, OCDEM, OCDEM, Oxford, United Kingdom;* [2]*Oxford, United Kingdom*

A 67-year-old man with no significant past medical history presented in June 2025 to the emergency department with acute neurological symptoms including facial droop and dysarthria. Neuroimaging revealed a multifocal glioblastoma involving the right cerebral hemisphere. Staging investigations demonstrated no evidence of extracranial metastatic disease. The patient underwent awake craniotomy followed by adjuvant radiotherapy (60 Gy in 30 fractions) and was commenced on temozolomide.

Following four weeks of the first cycle of temozolomide, the patient re-presented three weeks later with focal seizure activity. Biochemistry demonstrated hypernatremia (serum sodium 148 mmol/L), elevated plasma osmolality (305 mOsm/kg), and inappropriately dilute urine (urine osmolality 213 mOsm/kg), with otherwise normal renal function and electrolytes. On further questioning, the patient reported a one-month history of abrupt onset polydipsia and polyuria, consuming more than 4 litres of fluid daily and waking overnight to drink, which was uncharacteristic for him.

A diagnosis of AVPD was made and the patient was commenced on Desmopressin, resulting in resolution of symptoms, reduction in fluid intake to approximately 2 litres per day, and normalisation of serum electrolytes.

The case was reviewed at the pituitary multidisciplinary team meeting to assess for potential structural or treatment-related causes. Imaging demonstrated that tumour lesions were remote from the hypothalamic–pituitary axis, with no evidence of

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

pituitary involvement, metastasis, or radiotherapy-related injury. In the absence of alternative causes, temozolomide was considered the most likely precipitating factor.

Temozolomide-associated AVPD is rare and is not recognised as a standard adverse effect in major prescribing references. A small number of isolated case reports describe the development of AVPD during temozolomide therapy, typically occurring days to weeks after treatment initiation and following exclusion of infection, tumour progression, or new intracranial pathology. The underlying mechanism remains unclear.

The patient is currently receiving his fourth cycle of temozolomide and remains clinically stable on ongoing desmopressin therapy, allowing continuation of chemotherapy. Given reports of potential reversibility following temozolomide cessation, he has been closely safety-netted and is undergoing regular biochemical and clinical follow-up.

EP1182 - ECE_2501 - Beta radio-guided surgery in patients with pulmonary neuroendocrine tumors eligible for radical surgery

Piero Paravani[1], Francesco Collamati[2], Riccardo Mirabelli[3,4], Francesca Nicolanti[5], Matteo Tiracorrendo[6], Daniela Prosperi[7], Enrico D'ippolito[7], Chiara Lauri[7], Valeria Bentivoglio[7], Chiara Bolzan[8], Camilla Mancini[1], Valentina Brainovich[8], Massimiliano Mancini[9], Mohsen Ibrahim[6], Alberto Signore[7], Riccardo Faccini[5] and Antongiulio Faggiano[1]

[1]Endocrinology Unit, Department of Clinical and Molecular Medicine, Sapienza University of Rome, Sant'Andrea Hospital, ENETS Center of Excellence, Rome, Italy; [2]Section of Rome, Italian Institute For Nuclear Physics, INFN, Rome, Italy; [3]Section of Rome, National Institute of Nuclear Physics (INFN), Rome, Italy; [4]Department of Basic and Applied Sciences for Engineering, Sapienza Università di Roma, Rome, Italy; [5]Department of Physics, University of Rome La Sapienza, Rome, Italy; [6]Department of Thoracic Surgery, Sant'Andrea Hospital, Sapienza University, Rome, Italy; [7]Nuclear Medicine Unit, Sant'Andrea University Hospital of Rome, Department of Medical-Surgical Sciences and Translational Medicine of "Sapienza", University of Rome, Rome, Italy; [8]Medical Physics Dept., Sant'Andrea Hospital Rome, Rome, Italy; [9]Morphologic and Molecular Pathology Unit, Sant'Andrea Hospita, Rome, Italy

In Pulmonary neuroendocrine tumors (NETs), when feasible, surgical resection represents the gold standard of treatment. Achieving a radical resection remains the primary therapeutic goal, with great impact on overall survival. Radio-Guided Surgery (RGS) has been developed as an adjunctive technique to support surgeons obtaining complete tumor removal. RGS involves the administration of a radiotracer, followed by intraoperative detection of the emitted radiation. To overcome intrinsic limitations to gamma-sensitive detection systems, novel devices employing β-decaying isotopes with direct β detection have recently been developed. This approach has already been explored in small bowel NETs, showing encouraging results.

The present study, designed as a first-in-human, in vivo clinical trial, aims to evaluate the impact of intraoperative β-detector use during surgery for pulmonary NET. Inclusion criteria are: 1) presence of lung nodules positive on 68Ga-DOTA-TOC PET and consistent with pulmonary NETs, with or without preoperative histological diagnosis; 2) eligibility for radical surgical resection; 3) ECOG PS 0-2; 4) written informed consent.

Enrolled patients receive an intravenous injection of approximately 1 MBq/kg of 68Ga-DOTA-TOC at the beginning of surgery. The surgical procedure is performed according to standard clinical practice. During the operation, the β probe is used in vivo to sample the lung nodule and regional lymph node stations. Based on the detected signal, tissues are classified as "probe-positive" or "probe-negative" and compared with definitive histopathological findings. The diagnostic performance of the technique will be evaluated by calculating sensitivity, specificity, and positive and negative predictive values.

To date, three patients have been enrolled, two males and one female, aged 69, 58, and 43 years, respectively. All patients had pulmonary nodules suspicious for NETs and underwent anatomical lung resection with systematic hilar and mediastinal lymphadenectomy (anatomical trisegmentectomy of culmen, left upper lobectomy, middle lobectomy). Intraoperative uptake was observed in one patient at the site of the pulmonary nodule. No lymph node uptake was detected in any of the patients. Consistently, the only patient with uptake was diagnosed with a pulmonary NET (mitotic index < 1/2 mm^2, Ki-67 < 1%, absence of necrosis) with negative lymph nodes (pT1bpN0, Stage IA2). Similarly, no lymph nodes were found to be "probe-positive" and pathological on histology. The remaining two patients were diagnosed with non-NET, namely a biphasic sarcoma and a sclerosing pneumocytoma, both with 68Ga-DOTA-TOC PET uptake.

Completion of recruitment is expected by 03/2026.

EP1183 - ECE_1972 - Immune checkpoint inhibitor-related hypophysitis: a single tertiary center cohort

Ruth Karov[1], Esther Osher[2,3] and Yona Greenman[1,3]

[1]Tel Aviv Souraski Medical Center, Institute of Endocrinology Metabolism and Hypertension, Tel Aviv, Israel; [2]Tel Aviv, Israel; [3]Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Background: Immune checkpoint inhibitor (ICI)-related hypophysitis is a clinically high-impact immune-related adverse event. Presentation is frequently nonspecific and may be misattributed to malignancy or cancer therapy, while ACTH deficiency can be rapidly life-threatening if unrecognized. We describe a real-world cohort from a tertiary Endo-Oncology Clinic to inform timing, imaging yield, co-occurring irAEs, and outcomes.

Methods: We retrospectively reviewed medical records of adult cancer patients evaluated in the Endo-Oncology Clinic at Tel Aviv Sourasky Medical Center with ICI-related hypophysitis (ICI initiation: 30-December-2018-05-May-2025; hypophysitis diagnosis: 10-May-2020-04-January-2026). Patients who received systemic glucocorticoids for >2 months in proximity to diagnosis were excluded.

Results: We identified 35 patients with suspected ICI-related hypophysitis; six were excluded due to systemic glucocorticoid therapy for >2 months near diagnosis, leaving 29 patients for analysis. Mean age at diagnosis was 65.8 ± 11.8 years and 62% were female. Most patients received PD-1/PD-L1 inhibitors (82%) while 17% received PD-1 + CTLA-4. Median time from ICI initiation to hypophysitis was 265 days (IQR 189-344; range

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

97-714) and was shorter with PD-1 + CTLA-4 versus PD-1/PD-L1 (156 [152-164] vs 295 [229-366] days; $P < .001$). Fatigue/weakness occurred in 90% and hyponatremia in 31%. Median morning cortisol was 0.49 µg/dL (IQR 0.28-0.96) with low ACTH (median 1.50 pg/mL, IQR 1.50-2.62; $n = 22$). Pituitary MRI was performed in 17/29 and showed abnormalities in 7/17 (41%). ACTH deficiency was isolated in most patients; central hypothyroidism occurred in 3% and gonadotropin deficiency in 10% (17% NA/not assessed). Other irAEs were recorded in 48%, most commonly thyroiditis (34%). No adrenal axis recovery was documented.

Conclusions: In our tertiary-center cohort, ICI-related hypophysitis typically developed months after ICI initiation and was dominated by persistent ACTH–cortisol deficiency, and showed earlier onset under PD-1 + CTLA-4, with moderate MRI yield and frequent co-occurring irAEs. These findings support a low threshold for endocrine evaluation in symptomatic ICI-treated patients and structured long-term follow-up for adrenal insufficiency.

Abstract citation ID: lvag096.1437

EP1184 - ECE_2174 - Tradeoff between pituitary stalk preservation and tumor control in craniopharyngioma surgery

Shingo Fujio, Ryutaro Makino, Jun Sugata, Tomoko Hanada and Ryosuke Hanaya
Department of Neurosurgery, Graduate School of Medical and Dental Sciences, Kagoshima University, Kagoshima, Japan

Introduction: Maximizing the extent of tumor resection and preserving endocrine function are often conflicting goals in the surgical management of craniopharyngiomas. Therefore, whether the pituitary stalk, the presumed site of tumor origin, should be preserved remains debatable.

Patients and Methods: Since the introduction of high-definition endoscopy in 2012, 49 surgical procedures have been performed in 45 patients with newly diagnosed craniopharyngiomas at our institution (26 men and 19 women, median age; 47 years). Surgical approaches included transsphenoidal surgery (34 patients), craniotomy (13 patients), and endoscopic cyst fenestration (two patients). Factors associated with pituitary function and tumor control were analyzed at the final follow-up, focusing on the impact of pituitary stalk preservation.

Results: Preoperatively, five patients (11%) had diabetes insipidus and 20 (44%) had anterior pituitary dysfunction. Intraoperatively, the pituitary stalk was transected in 12 patients (27%). At the final follow-up, anterior pituitary dysfunction involving at least one hormonal axis was observed in 34 patients (76%) and diabetes insipidus in 26 patients (58%).

Among the 33 patients in whom the pituitary stalk was preserved, 19 (58%) required reoperation or radiotherapy; however, tumor control was ultimately achieved in all cases. Additionally, anterior pituitary dysfunction occurred in 22 patients (67%) and diabetes insipidus in 14 (42%). Multivariate analysis revealed that postoperative anterior pituitary function was significantly associated with age ($\beta = -.0095$, $P = .02$), but not with tumor size or histological subtype. No cases of delayed pituitary dysfunction were observed after radiotherapy. Contrastingly, all 12 patients who underwent pituitary stalk transection developed postoperative panhypopituitarism, whereas only two (17%) required additional treatment for tumor control.

Discussion: Although preservation of the pituitary stalk does not guarantee complete preservation of endocrine function, it helped reduce the incidence of diabetes insipidus. Although stalk preservation is associated with a higher likelihood of requiring additional treatment, durable tumor control can be achieved through multidisciplinary management. These findings support a staged treatment strategy that prioritizes functional preservation, while maintaining effective tumor control.

Fuentes[1,2], Luiz E Wildemberg[7,8], Leandro Kasuki[7,8], Mônica Gadelha[7,8], Alfonso Soto[3], María Ángeles Gálvez-Moreno[2,4], Antonio Carlos Fuentes-Fayos[1,2] and Raul M. Luque[1,2,9]
[1]Department of Cell Biology, Physiology and Immunology, University of Córdoba, Cordoba, Spain; [2]Reina Sofía University Hospital (HURS), Maimónides Institute of Biomedical Research of Córdoba (IMIBIC), Cordoba, Spain; [3]Hospital Universitario Virgen del Rocío/Unidad de Gestión de Endocrinología y Nutrición, Instituto de Biomedicina de Sevilla (IBiS)/CSIC/Universidad de Sevilla, Sevilla, Spain; [4]Service of Endocrinology and Nutrition, Reina Sofía University Hospital (HURS), Cordoba, Spain; [5]Department of Medicine, University of La Laguna, Tenerife, Spain; [6]Service of Endocrinology, Canarias University Hospital, Tenerife, Spain; [7]Endocrinology Division, Medical School and Hospital Universitario Clementino Fraga Filho, Neuroendocrinology Research Center, Universidade Federal do Rio de Janeiro, Rio De Janeiro, Brazil; [8]Neuroendocrine Unit, Neuropathology and Molecular Genetics Laboratory, Secretaria Estadual de Saúde, Instituto Estadual do Cérebro Paulo Niemeyer, Rio De Janeiro, Brazil; [9]CIBER Pathophysiology of Obesity and Nutrition (CIBERobn), Cordoba, Spain

Despite recent advances in the management of pituitary tumors (PiTs), limited therapeutic strategies are available which highlights the urgent need to identify new molecular targets to improve the management of these patients. This study focuses on systematically characterizing, for the first time, the expression levels of the molecular components of two molecular machineries controlling gene expression, the Nonsense-Mediated Decay (NMD) and RNA-Exosome, in somatotropinomas (GHomas) and non-functioning PiTs (NFPTs) along with their relationship with clinical features. We also evaluated the therapeutic potential of inhibiting the activity of these molecular machineries in GHoma and NFPT cell-models. Our results revealed an overall upregulation of the components of the NMD and RNA-Exosome machineries in GHomas, while a more heterogeneous profile was found in NFPTs, compared with non-tumour pituitary glands. We identified two key factors as the most clinically relevant NMD and RNA-Exosome components, as their high expression wwere associated with critical oncogenic pathways and their *in vitro* silencing in GHoma and NFPT cell-models reduced multiple cancer hallmarks [eg, viability/proliferation, GH-secretion, oncogenic marker expression (*CDK2*/*VEGFA*/*POU1F1*…)]. Moreover, we provide solid evidence demonstrating

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

that targeting the activity of the NMD machinery with a specific inhibitor (NMDi alone or in combination with lanreotide) might translate into a beneficial effect on patients with GHomas and NFPTs, an observation that certainly warrants further clinical investigation. Altogether, our results demonstrate a clinically relevant NMD and RNA-exosome associated molecular dysregulation in GHomas and NFPTs, which could serve as a potential source of novel diagnostic/prognostic biomarkers and therapeutic targets.

EP1186 - ECE_2461 - Different tumors, different burdens: long-term outcomes of pituitary hormone replacement in craniopharyngiomas and non-functioning pituitary adenomas

Nunzia Prencipe, Francesca Mocellini, Daniela Cuboni, Alessandro Maria Berton, Michela Sibilla, Valentina Gasco, Emanuele Varaldo, Fabio Bioletto, Alice Martinotti, Gianluca Aimaretti and Silvia Grottoli
Division of Endocrinology Diabetology and Metabolism, Department of Medical Sciences, "AOU Città della Salute e della Scienza di Torino" University Hospital, Torino, Italy

Background: Craniopharyngiomas (CF) and non-functioning pituitary adenomas (NFA) are causes of acquired hypopituitarism. Their different involvement of the hypothalamic–pituitary axis may influence long-term hormone replacement needs and the risk of complications related to under- or over-replacement therapy. Comparative long-term data in these patients are scarce.

Objective: To compare endocrine replacement requirements and long-term complications potentially related to pituitary hormone replacement in patients with CF and NFA.

Methods: We retrospectively analyzed 144 patients (66 CF, 78 NFA; 44 female) followed at a tertiary referral center. Inclusion criteria were the presence of ≥3 pituitary hormone deficiencies, excluding growth hormone deficiency, to ensure a homogeneous cohort with advanced hypopituitarism. Median follow-up was 12 years (range 1-50), with a median of 4 years of stable hormone replacement therapy. Hormonal status, type and dose of replacement therapies, treatment modifications, and metabolic and cardiovascular outcomes were assessed at diagnosis and at last follow-up.

Results: All CF patients underwent neurosurgery, whereas three NFA patients not; radiotherapy rates were comparable. CF patients were younger at diagnosis (median 35.5 vs 55.5 years, $P < .0001$). At baseline, anterior pituitary deficits were comparable by design, while arginine vasopressin deficiency (AVP-D) was more prevalent in CF ($P = .0005$). At last follow-up, AVP-D remained significantly higher in CF (80% vs 22%, $P < .0001$).

CF patients required higher doses of levothyroxine (median 1.25 vs 0.98 μg/kg/day, $P = .0001$) and recombinant human growth hormone (0.005 vs 0.003 mg/kg/day, $P = .001$), and showed a trend toward higher desmopressin doses. Desmopressin treatment was associated with a higher prevalence of electrolyte disturbances, but with lower rates of hypertension and coronary artery disease, independently of dose. Higher levothyroxine doses were associated with weight gain, whereas lower doses were observed in hypertensive patients. Testosterone replacement required more frequent dose adjustments in CF patients ($P = .014$).

At final follow-up, hypertension was more frequent in NFA patients ($P = .003$). Conversely, CF patients showed higher rates of obesity ($P = .04$) and weight gain ($P = .002$), while weight reduction was more common in NFA patients ($P = .001$). No differences were observed in diabetes mellitus, dyslipidemia, atrial fibrillation, thromboembolic events, or mortality.

Conclusions: In patients with severe hypopituitarism, CF are associated with greater hypothalamic involvement, higher hormone replacement requirements, and increased susceptibility to complications related to replacement imbalance, particularly weight gain and water–electrolyte disorders. NFA patients exhibit a higher prevalence of hypertension, probably due to older age. These findings highlight the importance of tumor-specific, individualized strategies for long-term pituitary hormone replacement.

EP1187 - ECE_2820 - PitNETs: clinical characteristics and outcomes following surgical resection from single-center perspective

Aleksandra Derwich-Rudowicz[1], Abdulrahman Ammoun[1], Ikram Ghalmi[1], Ellen Haagensen[1], Matthew Steplewski[1], Norbert Wąsik[2], Marek Ruchala[1] and Nadia Sawicka-Gutaj[1]
[1]Department of Endocrinology, Metabolism and Internal Medicine, Poznan University of Medical Sciences, Poznan, Poland; [2]Department of Neurosurgery, Poznan University of Medical Sciences, Poznan, Poland

Background: Pituitary tumors (PitNETs) are a heterogeneous group of central nervous system lesions, which account for 13.5%-20% of all primary brain tumors. The aim of the study was to analyze clinical characteristics and postoperative outcomes of patients undergoing PitNET resection.

Material and Methods: This was longitudinal observational study. Medical records of patients diagnosed with PitNET who were hospitalized pre- and postoperatively at the Department of Endocrinology, Poznan, Poland, between January 2018 and December 2023 were reviewed. All patients underwent surgical resection of a pituitary tumor. Routine postoperative follow-up was scheduled 3-6 months after surgery. The statistical analysis was performed with MedCalc Software Ltd, with significance level set as $P < .05$.

Results: The study included 94 patients, 51 women (54%) and 43 men (46%), with a mean age of 53.7 ± 14.7 years. Non-functioning pituitary adenomas (NFPA) were the most common subtype (63.8%), followed by GH-secreting (18.1%), ACTH-secreting (12.8%), PRL-secreting (4.3%), and TSH-secreting tumors (1.1%). Most tumors were macroadenomas (71%), with microadenomas and giant adenomas comprising 14% and 15%, respectively. Hypopituitarism was observed in 63% of patients, most commonly affecting the gonadotrophic axis (64%), followed by corticotrophic (31%), thyrotrophic (28%), and somatotrophic (4%) axes. Tumor volume after surgery was reduced significantly ($P < .0001$). Postoperative evaluation demonstrated no radiological evidence of residual tumor in 45% of patients. The prevalence of headaches significantly decreased after surgery (difference −17.1%, 95% CI: −30.5 to −3.6; $P = .024$), the same as optic chiasm compression (difference −40.9%, 95% CI: −53.0 to −28.9; $P < .0001$). Lower LH levels were associated with a higher likelihood of hypopituitarism ($\beta = -.128$, SE = 0.043, Wald = 8.83, $P = .003$), corresponding to an odds ratio of 0.88 (95% CI: 0.81-0.96) per unit increase in

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

LH. The number of impaired pituitary axes did not differ significantly before and after surgery ($P = .335$). Postoperative metabolic changes included a significant increase in body mass index, with a median rise of 0.64 (95% CI: 0.14-1.07; $P = .015$), as well as a significant increase in body weight, with a median gain of 2.0 kg (95% CI: 0.5-3.5; $P = .004$).

Conclusions: Surgical resection significantly reduced tumor volume and relieved mass-effect symptoms, despite continued axis dysfunction. Lower LH levels pre-surgery might be associated with a higher risk of hypopituitarism. Postoperative weight gain highlights the need for metabolic monitoring.

EP1188 - ECE_2845 - Craniopharyngiomas at a tertiary referral center: a descriptive study

Francisca Leitão H., Miguel Marques, Daniel Duarte, Marta Almeida, Ana Quítalo, Ana Gonçalves Ferreira, Henrique Vara Luiz and Maria Carlos Cordeiro
Unidade Local de Saúde de Almada-Seixal, Almada, Portugal

Introduction: Craniopharyngiomas are rare epithelial tumors of the sellar and suprasellar region, accounting for 2%-5% of intracranial neoplasms. Although histologically benign, their proximity to critical adjacent structures often leads to significant morbidity. Two main histological variants are recognized: adamantinomatous and papillary. Management is complex and requires a multidisciplinary approach to balance tumor control and quality of life.

Objective: This study aimed to describe the characteristics and outcomes of patients diagnosed with craniopharyngioma at a tertiary referral center.

Methods: A retrospective descriptive study was conducted including all patients diagnosed with craniopharyngioma in our institution between 2019 and 2025. Demographic, clinical, radiological, histopathological, surgical, and follow-up data were collected from medical records. Surgical remission was defined as the absence of residual tumor on postoperative magnetic resonance imaging (MRI) and the absence of early recurrence.

Results: A total of 32 patients were included: 62.5% male and 37.5% female, with a mean age at diagnosis of 35.8 years. Of these, 35% were pediatric and 65% were adult cases. The most common symptoms at presentation were headache (16, 50%), visual disturbance (16, 50%), and endocrine dysfunction (6, 18.8%), of whom 5 had panhypopituitarism. Tumor location was suprasellar in 12 (37.5%) and both sellar and suprasellar in 20 cases (62.5%). The mean tumor volume was 6.15 cm.

All patients underwent surgical resection, with surgical remission achieved in 12 cases (37.5%). A transsphenoidal approach was performed in 18 patients (56.3%), while craniotomy in 14 (43.8%). Histopathological analysis revealed the adamantinomatous subtype in 24 cases (75%) and the papillary subtype in 8 cases (25%). Postoperative complications included diabetes insipidus (21, 65.6%), hypothalamic obesity (10, 31.3%), and endocrine dysfunction (29, 90.6%), of whom 27 developed panhypopituitarism. Neurocognitive dysfunction was observed in 4 patients (12.5%). Adjuvant radiotherapy was performed in 14 patients after surgery, of whom 5 achieved tumor remission. During a median follow-up of 6 years, tumor recurrence occurred in 15 cases (88%); among these, 60% required additional surgery, 13% radiotherapy alone, and 27% both modalities.

Conclusions: The management of craniopharyngiomas remains challenging due to high recurrence rate and frequent endocrine and hypothalamic sequelae. Despite their benign histology, these tumors are associated with significant long-term morbidity. Our center's experience highlights the importance of multidisciplinary management and lifelong follow-up to optimize tumor control and quality of life.

EP1189 - ECE_3026 - A comparative evaluation of immunoinflammatory blood biomarkers in Cushing's disease and nonfunctioning pituitary adenomas

Hatice Ozisik[1], Adil Bahadir[2], Su Ozgur[3], Ezgi Ulas[1], Mehmet Yigit[4], Sevki Cetinkalp[1] and Mehmet Erdogan[4]
[1]Endocrinology, Ege University, Izmir, Türkiye; [2]The University of Texas MD Anderson Cancer Center, Houston, Texas, United States; [3]Translational Pulmonary Research Center-EgeSAM, Ege University, Izmir, Türkiye; [4]Izmir, Türkiye

Introduction: Cushing's disease (CD), caused by adrenocorticotropic hormone–secreting pituitary adenomas, is characterized by pituitary-dependent chronic hypercortisolism with marked effects on immune and hematological parameters. Excess cortisol leads to leukocytosis, neutrophilia, and lymphopenia, resulting in a distinct immunological profile that may be reflected in peripheral blood cell–derived inflammatory indices. Nonfunctioning pituitary adenomas (NFPAs), although hormonally inactive, may also exert systemic effects through mass-related pituitary dysfunction and tumor-associated inflammation. This study aimed to comparatively evaluate peripheral blood–derived immunoinflammatory markers in patients with Cushing's disease and nonfunctioning pituitary adenomas and to assess their discriminative and independent associations.

Methods: This retrospective study included 108 patients, comprising 19 patients with Cushing's disease and 89 patients with nonfunctioning pituitary adenomas. Standard laboratory parameters derived from complete blood counts were used to calculate immunoinflammatory indices, including commonly used ratios neutrophil-to-lymphocyte ratio (NLR), lymphocyte-to-monocyte ratio (LMR), monocyte-to-lymphocyte ratio (MLR), platelet-to-lymphocyte ratio (PLR), eosinophil-to-lymphocyte ratio (ELR), platelet-to-neutrophil ratio (PNR), mean platelet volume to absolute lymphocyte count ratio (MPV/ALC), systemic immune-inflammation index (SII), systemic inflammatory response index (SIRI), pan-immune-inflammation value (PIV), derived NLR, and the fibrosis-4 (FIB-4) index. Intergroup comparisons, receiver operating characteristic (ROC) analyses, and multivariable logistic regression adjusted for age and sex were performed.

Results: Patients with Cushing's disease were significantly younger than NFPA patients (median age: 43 vs 60 years, $P < .001$) and exhibited a more pronounced pro-inflammatory hematological profile. Compared with the NFPA group, patients with CD had significantly higher leukocyte and neutrophil counts and lower lymphocyte percentages, resulting in elevated NLR, SIRI, SII, PIV, and derived NLR (all $P < .05$). ROC analysis showed modest-to-moderate distinctive performance for these indices

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

(AUC range: 0.66-0.69), while FIB-4 showed the highest distinctive accuracy (AUC = 0.78). FIB-4 was included as a surrogate marker of cortisol-related metabolic and hepatic involvement. In multivariable logistic regression analyses adjusted for age and sex, only SIRI remained independently associated with Cushing's disease (odds ratio 2.42, 95% confidence interval 1.19-4.90, $P = .014$).

Conclusions: Peripheral blood–derived immunoinflammatory markers demonstrate distinct differences between Cushing's disease and nonfunctioning pituitary adenomas and show moderate disc ability. Among these markers, SIRI emerges as the only robust immunoinflammatory index independently associated with Cushing's disease, suggesting its potential utility as an easily accessible adjunctive biomarker reflecting disease-related immune dysregulation. Prospective studies with larger cohorts are warranted to confirm these findings and clarify their clinical applicability.

EP1190 - ECE_3870 - Paradoxical IGF-1 and GH elevation: diagnostic challenges beyond acromegaly

Oana Pietrareanu[1], Iulia Florentina Burcea[1,2], Ramona Dobre[1,2], Raluca Pirvu[1], Andreea Gorun[1] and Catalina Poiana[1,2]
[1]'C.I. Parhon' National Institute of Endocrinology, Bucharest, Romania; [2]'Carol Davila' University of Medicine and Pharmacy, Bucharest, Romania

Introduction: Acromegaly is traditionally diagnosed based on elevated insulin-like growth factor 1 (IGF-1) and failure of growth hormone (GH) suppression during an oral glucose tolerance test (OGTT). Nevertheless, discordant biochemical profiles between IGF-1 and GH are increasingly encountered, complicating diagnostic decision-making and raising concerns regarding overdiagnosis or delayed recognition of true disease. Understanding these paradoxical patterns is essential to optimize diagnostic accuracy and avoid unnecessary interventions.

Methods: We performed a retrospective observational study including patients evaluated for suspected acromegaly, between 2022 and 2025. Inclusion criteria were biochemical discordance between IGF-1 concentrations and GH on confirmatory testing, availability of pituitary MRI, and exclusion of confounding physiological conditions such as pregnancy or puberty. Hormonal evaluation comprised age- and sex-adjusted IGF-1 levels, GH nadir during OGTT, and 24-hour GH secretion profiles. Clinical features, metabolic comorbidities, imaging findings, and longitudinal biochemical evolution were systematically analysed.

Results: Six patients (median age 44 years) met inclusion criteria, displaying heterogeneous patterns of GH–IGF-1 discordance. The most prevalent phenotype was persistently elevated IGF-1 despite OGTT GH nadir < 0.4 ng/ml ($n = 3$), all associated with pituitary microadenomas and multiple metabolic or endocrine comorbidities. Longitudinal follow-up of up to three years demonstrated stable tumor size and no increase in IGF-1 (×ULN) and stable GH dynamics despite sustained IGF-1 elevation. Additional discordant patterns included high-normal IGF-1 with increased 24-hour GH secretion, but preserved OGTT supression ($n = 1$), normal IGF-1 with failure of GH suppression during OGTT ($n = 1$), and low-normal IGF-1 with elevated GH secretion in the absence of pituitary tumor imaging evidence ($n = 1$). These findings highlight the complexity of GH pulsatile secretion, assay limitations, and individual variability within the GH–IGF-1 axis.

Conclusions: In this retrospective case series of patients with discordant IGF-1/GH profiles, integrating dynamic testing, 24-hour GH profiling, pituitary MRI, and longitudinal follow-up supported a surveillance strategy when no clinical, biochemical, or structural progression was observed. These findings highlight the value of a multimodal, individualized approach when IGF-1 and GH measures diverge. Limitations include the small sample size, single-center retrospective design, and potential assay-related variability.

EP1191 - ECE_1348 - Clinical relevance of genetic diagnosis in congenital hypogonadotropic hypogonadism

Andreu Campos Peris, Guillermo Serra Soler, Ramón Zafra Jiménez, Alejandro De la Cruz Bonilla, Maria Ubeda Dilme, Alicia Sanmartín Sánchez, Francisca Caimari Palou, Elena Mena Ribas, Santiago Tofé Povedano and Iñaki Argüelles Jiménez
Hospital Universitario Son Espases, Palma, Spain

Introduction: Congenital isolated hypogonadotropic hypogonadism (CHH) is a rare genetic disorder that is associated with deficient secretion and/or action of the Gonadotropin-releasing hormone (GnRH). The incidence is estimated to be 1:15.000-50.000 with a male-to-female ratio of 5:1. CHH spectrum of clinical expression ranges from complete absence of sexual development to partial completion of puberty. It can be associated with multisystem anomalies such as anosmia (known as Kallman syndrome). Timely diagnosis and treatment are crucial for fertility preservation.

Pathogenic variants in more than 60 genes have been identified as the cause of CHH. Genetic testing can help lead to an early diagnosis, providing prognostic information and allowing genetic counseling to be adapted.

Our objective was to reassess patients with diagnosis of CHH without initial genetic testing or with negative results from previous genetic testing panels.

Methods: A descriptive retrospective observational study was conducted in a series of eight patients with CHH. Genetic re-evaluation was performed using a next-generation gene panel associated with CHH. Clinical variables, magnetic resonance imaging (MRI) findings, presence of offspring, and genetic results were collected for statistical analysis.

Results: All 8 patients were men, (current mean age 51.9 ± 13.3 years). The mean age at diagnosis of CHH was 24.3 ± 13.3 years. Genetic reassessment was performed after an average of 24.4 years from initial diagnosis (range 14-34 years). The genetic study identified pathogenic variants in four patients (50%). Among the two patients (25%) who had undergone previous genetic testing with negative results, the updated genetic panel identified a pathogenic variant in one case, whereas the other remained negative. *GNRHR, ANOS1, SOX10, PROK2,* were the genes identified.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Regarding the phenotype, two patients (25%) presented anosmia and one hyposmia (12.5%). Anomalies in MRI were observed in three patients (37.5%). Gonadotropin therapy was administered to six of the eight patients (75%), with the aim of pubertal induction in two cases and fertility induction in four cases. Three of eight (37.5%) patients had offspring.

Conclusions: Genetic testing in CHH is challenging; however, it allows an earlier and more precise diagnosis. This enables timely initiation of hormonal therapy, optimizing pubertal development and reproductive function. In addition, genetic testing provides prognostic information that supports tailored genetic counselling. Therefore, the implementation of new genetic panels supports personalized medicine and enhances patients' quality of life.

EP1192 - ECE_2409 - Assessment of the allostatic load index and psychological and psychiatric status in patients with pituitary tumours

Aleksandra Jawiarczyk-Przybyłowska[1], Martyna Strzelec[1], Justyna Kuliczkowska-Płaksej[1], Dorota Szczesniak[2], Agnieszka Zembska[1], Katarzyna Kolačkov[1], Natalia Sloka[1], Anna Brona[1], Aleksandra Zdrojowy-Wełna[1], Iga Zendran[1], Malgorzata Rolla[1] and Marek Bolanowski[1]
[1]*Department of Endocrinology and Internal Diseases, Medical University in Wroclaw, Wroclaw, Poland;* [2]*Division of Psychotherapy and Psychosomatic Medicine, Department of Psychiatry, Medical University in Wroclaw, Wroclaw, Poland*

Background: Chronic exposure to pathogenic stress factors results in multisystemic deterioration and adverse physiological changes resulting in the development of allostatic load (AL). Stress is a key contributor to the development and progression of numerous diseases, including endocrine disorder.

Purpose: This study aimed to assess the allostatic load index (ALI) and psychological and psychiatric status in patients with pituitary tumours and compare the results to a control group.

Methodology: The research group included 58 patients diagnosed with hormonally active pituitary tumours and 52 control subjects without pituitary dysfunction. The AL index (ALI) was determined using 16 parameters categorized into anthropometric parameters, cardiovascular markers, lipid and carbohydrate metabolism parameters, and inflammatory and hormonal markers. Standardized clinimetric tools were used to evaluate the psychological and psychiatric status in patients with pituitary tumours (WHOQOL-BREF scale, GHQ-28 scale, GAD-7 scale, INTERMED questionnaire, PHQ-9 scale, PSS-10 scale)

Results: Patients with pituitary tumours exhibited a significantly higher ALI compared to the control group, regardless of the endocrine activity of the adenoma ($P < .001$). Based on the analysis of clinimetric data, we found that patients in the study group exhibited significantly poorer psychological and social functioning, lower self-esteem, and more pronounced depressive and somatic symptoms compared to the control group. In every fourth patient with a pituitary tumour, a score of at least 10 points was obtained on the PHQ-9 scale, indicating the presence of moderate or severe depression. In the control group, depressive symptoms were eight times less frequent.

Conclusions: The findings support the utility of the ALI as of the AL index as an integrated measure for evaluating the cumulative impact of stress in pituitary diseases. Mental health disorders are a significant concern among patients with pituitary tumours and require special attention in clinical practice. Every patient diagnosed with a pituitary tumour should undergo screening for depression.

EP1194 - ECE_2633 - When appearances deceive: a silent somatotroph macroadenoma with acromegaloid features and low IGF-1

Emily Mayar and Sing Yang Sim
Brighton & Sussex University Hospitals NHS Trust, Brighton, United Kingdom

A 45-year-old gentleman was referred to the endocrinology department after presenting with recurrent epistaxis, headache, third cranial nerve palsy and a right-sided diplopia. A subsequent pituitary MRI identified a giant pituitary macroadenoma. On presentation, he exhibited acromegaloid features, including frontal bossing, spade-like hands and coarse facial characteristics suggestive of a GH-secreting tumour despite the absence of hyperhidrosis or rapid weight gain. Ophthalmologic assessment revealed mild enlargement of the right blind spot with preserved visual fields.

Initial MRI imaging demonstrated a large sellar and suprasellar mass with mass effect on the chiasm extending into the right cavernous sinus and paranasal sinuses. The differential diagnoses initially included nasopharyngeal malignancy and lymphoma; however, biopsy of nasal tissue revealed only benign adenoid tissue. Preoperative endocrine blood tests showed low serum free testosterone (5.4 nmol/L), TSH 1.37 mU/L (0.27-4.2), T4 15.6 pmol/L (11-22), FSH 3.8 IU/L, LH 4.1 IU/L, a normal short synacthen test and elevated prolactin 4107 mIU/L (86-324) prompting initiation of cabergoline at a dose of 500 micrograms weekly. Surprisingly, his IGF-1 was low preoperatively (13.1 nmol/L; 15.5-33.1) highlighting a biochemical discrepancy between clinical appearance and the hormonal profile.

The patient underwent endoscopic transsphenoidal resection in March 2025. Postoperatively, he experienced transient diabetes insipidus requiring DDAVP which subsequently resolved. Visual function and pituitary hormones remained largely preserved; hydrocortisone was administered temporarily due to borderline cortisol levels (178 nmol/L). He remained under follow-up in our combined pituitary clinic where management options including observation versus conventional fractionated radiotherapy were discussed with him in view of the postoperative residual tumour within the cavernous sinus.

Histopathology confirmed a PIT1-lineage somatotroph adenoma. His immunohistochemistry was positive for GH yet negative for other pituitary hormones, with a low proliferative index (Ki67 < 2%), consistent with a silent somatotroph adenoma.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

This case highlights the diagnostic challenge of silent somatotroph adenomas. They represent 2-4% of surgically removed pituitary adenomas often discovered incidentally or through mass effect symptoms. Compared to functioning somatotroph adenomas, they are more aggressive with higher Ki67 index, greater local invasiveness, higher recurrence rate and a female predominance. Patients may exhibit acromegaloid features despite normal IGF-1 levels. Recognition of this entity is crucial, as the absence of overt hormonal hypersecretion can delay diagnosis, yet large tumour mass effects can cause significant morbidity. Integrated clinical, radiological and histopathological assessment will be key here.

EP1195 - ECE_2882 - Urea for treating hyponatremia and and its impact on nutritional status: a case report

Lucía Estévez Asensio[1,2,3], Maria del Puerto Bernoy González[1,2,3], Hugo Pereira Gregorio[1,2,3], Jaime González Gutierrez[1,2,3], Paloma Perez Lopez[1,2,3], Pablo Fernández Velasco[1,2,3], Juan Jose Lopez Gomez[1,2,3], Daniel De Luis Roman[1,2,3] and Emilia Gomez Hoyos[1,2,3]

[1]Valladolid, Spain; [2]Centro de Investigación de Endocrinología y Nutrición, Universidad de Valladolid, Valladolid, Spain; [3]Centro de Investigación Biomedica en Red (CIBEROBN) de la Obesidad y Nutrición, Instituto de Salud Carlos III, Valladolid, Spain

Introduction and Aim: Hyponatremia is the most common electrolyte disorder, and even mild forms are associated with increased morbidity and mortality. The most frequent etiology is the syndrome of inappropriate antidiuretic hormone secretion (SIADH). The traditional first-line therapy for SIADH is fluid restriction (FR). However, approximately 39%-55% of patients with SIADH do not respond adequately to FR. Consequently, there is increasing interest in identifying safe and well-tolerated treatments for the long-term management of hyponatremia. Urea, an oral osmotic diuretic, may represent a safe and effective alternative treatment, and newer flavoured formulations could improve patient adherence.

Methods: We report the case of a 64-year-old woman with moderate chronic hyponatremia and disease-related malnutrition. Her medical history included T4N2M0oropharyngeal carcinoma treated with chemoradiotherapy four years earlier and emphysematous chronic obstructive pulmonary disease (COPD). She was clinically euvolemic and asymptomatic, with a serum sodium concentration of 129 mmol/L (plasma osmolality 257 mosm/L). Complementary diagnostic tests were consistent with chronic hyponatremia due to SIADH of pulmonary etiology (COPD) diagnosis.

Results: Fluid restriction was not feasible due to patient's xerostomia secondary to prior chemoradiotherapy. Ambulatory treatment with oral urea was initiated at a dose of 15 g/day dose, resulting in progressive correction of hyponatremia (pNa 136 mmol/L at the 3-month follow-up visit; pNa 135 mmol/L at the 20-month follow-up visit) and adequate long-term tolerance. In addition, hypercaloric high-protein oral nutritional supplements and physical activity were prescribed. No adverse effects (eg, dysgeusia, nausea) or overcorrection of hyponatremia were observed. A morphofunctional assessment of the patient's nutritional status was performed at baseline and during outpatient follow-up, showing no deterioration in nutritional status (Table 1).

Table 1 Morphofunctional nutritional assessment

Parameter	Baseline Visit	3-Month Follow-up Visit
BMI	16.62 kg/m^2	17.31 kg/m^2
Handgrip Strength	22 kg	27 kg
Resistance	736.4	703.5
Reactance	77.2	77.8
Phase Angle	5.9 °	6.3 °
Fat Mass (%)	11.20	11.50
Skeletal Muscle Mass (%)	58.59	59.75

Conclusions: This case illustrates that urea is an effective, safe, and well-tolerated therapeutic option for the management of hyponatremia due to SIADH. Furthermore, the improved palatability of newer formulations does not negatively impact nutritional status, as relaxation of fluid restriction facilitates the intake of oral nutritional supplements.

Abstract citation ID: lvag096.1448

EP1197 - ECE_3004 - Multiple treatment strategies in a patient with ACTH-dependent Cushing's syndrome

Anna Brona[1], Aleksandra Zdrojowy-Welna[1], Barbara Stachowska[1], Aleksandra Jawiarczyk-Przybyłowska[1], Justyna Kuliczkowska-Płaksej[1], Jowita Halupczok-Żyła[2] and Marek Bolanowski[1]

[1]Endocrinology and Internal Medicine, Endocrinology and Internal Medicine, Wroclaw Medical University, Wroclaw, Poland; [2]Wroclaw, Poland

We would like to present a 31-year old patient with Cushing's disease who has undergone all types of treatment, ie, surgery, radiotherapy and pharmacotherapy.

The patient was diagnosed with ACTH-dependent Cushing's syndrome in 2022, at the age of 27. The first symptoms of the disease had probably appeared about 8 years before. On admission the patient presented with a moon face, abdominal obesity with thinning limbs, purple striae, thin skin, petechiae, scalp hair loss, oedema of the feet. She complained of easy bruising, proximal muscular weakness and menstrual irregularities. She had already been diagnosed with hypertension, diabetes and hypertriglyceridemia. The comorbidities were managed with multidrug pharmacotherapy, ie, bisoprolol 7.5 mg, indapamide 1.5 mg, lercanidipine 10 mg, pantoprazole 20 mg, ezetimibe 10 mg, fenofibrate 267 M mg (once a day), metformin 1000 mg (three times a day), empagliflozin 10 mg (once a day), insulin lispro with insulin lispro protamine suspension 25 16 IU in the morning, 18-20 IU before dinner. After confirming the diagnosis of ACTH-dependent Cushing's syndrome (pituitary tumor 17 × 10 × 20 mm) she was operated on. Due to the invasion of the right sinus cavernous the complete removal of the tumor was not possible. After surgery the symptoms of hypercortisolemia persisted, thus she was referred to the radiotherapy division for stereotactic surgery with Cyberknife. She was dismissed from pasireotide therapy because of poor diabetes control. In January 2023 therapy with osilodrostat was introduced. It was well tolerated and improved diabetes control. In June 2025 the patient

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

agreed to switch to therapy with pasireotide to address the tumor size. This therapy caused severe hyperglycemia that could not be well managed because of the financial background. In October 2025 therapy with osilodrostat was restarted. After 2.5 months diabetes control improved and the patient continues therapy with osilodrostat. Now, the treatment of diabetes includes insulin aspart lispro with insulin degludec 14 IU in the morning, and insulin aspart before meals depending on glucose level.

The last MRI of the pituitary was performed in January 2025 (tumor size 9 × 6 × 12 mm).

Our case highlights the difficulties of management of ACTH-dependent Cushing's disease due to macroadenoma and the role of combined therapy. The long -existing hypercortisolemia before surgery contributed to symptoms and complications of Cushing's disease that are still present (ie, central obesity, hypertension, and hypertriglyceridemia).

EP1198 - ECE_1182 - Pituitary stalk interruption syndrome: case series from a tertiary care center in South India

Sai Subrahmanyam Pappu, Neelaveni Kudugunti and Rakesh Sahay
Osmania General Hospital, Hyderabad, India

Introduction: Pituitary Stalk Interruption Syndrome is a rare disorder with incidence of 0.5 per 100000 births. Ectopic posterior pituitary (EPP) is the cardinal feature. MRI shows a triad of-thin/absent stalk, EPP, Anterior pituitary hypoplasia.

GH deficiency is seen in almost 100% cases. Isolated sparing of TSH has also been described. DI is very rare.

We describe 12 cases of PSIS that presented to a tertiary care center.

Case summary:

	Age/Gender	Presenting complaint	Height SDS	GH(Peak)(ng/ml)	T3/T4/TSH	LH/FSH	Cortisol(mcg/dl)	MRI
1	4/m	Hypoglycemic seizures Micropenis cryptorchidism	−3.95	2.83	97 ng/dL 7.3 mcg/dl 1.105 mIU/mL	Post Hcg T: 208 ng/dL	21.77	EPP/Thin infundibulum/ Pituitary Hypoplasia

Discussion: All subjects had GH deficiency, 2 subjects had central hypocortisolism. 3 subjects had central hypothyroidism.

The 2nd most common hormonal defect was hypogonadotropic hypogonadism.

4 siblings had isolated GH deficiency.

Early childhood and neonatal presentation was with hypoglycemia.

Children and adolescents presented with short stature and delayed puberty.

Conclusions: Our cohort highlights the entire spectrum of PSIS from neonatal hypoglycemia to childhood short stature and delayed puberty.

Kingdom; [6]Department of Metabolic and Cardiovascular Medicine, University of Liverpool, Liverpool, United Kingdom; [7]Royal Victoria Infirmary, Newcastle upon Tyne, United Kingdom

Background: Acromegaly causes significant multimorbidity and mortality, with 50% of patients responding to first-line somatostatin analogue (SSA) therapy. Untreated acromegaly often causes obstructive sleep apnoea (OSA), primarily due to pharyngeal/glossal hypertrophy from IGF-1–mediated tissue growth. Improved understanding could enable earlier detection, better management, and reduced cardiovascular and respiratory complications in acromegaly.

Aims: To perform a systematic review and meta-analysis to assess the impact of acromegaly disease activity and treatment on OSA severity.

Methods: Studies comparing active and inactive post-treatment acromegaly patients were included, assessing OSA prevalence, apnea-hypopnea index (AHI), growth hormone (GH) excess, and respiratory disturbance index (RDI). Cardiovascular events, cerebral microbleeds, and macroglossia were also reviewed. Literature searches followed PRISMA guidelines, using these MeSH terms—"acromegaly", "obstructive sleep apnea", "cardiovascular" and "respiratory" across OVID Medline, EMBASE, CENTRAL, and Cochrane databases (1980-2025). Only English-language studies were included. Study selection, data extraction, and narrative synthesis were performed, with meta-analysis where data permitted. Reporting bias was assessed using the ROBINS-I tool.

Results: From 606 identified articles, 31 underwent full-text review, 28 were included in the systematic review (17 observational, 11 interventional; 695 patients) and 21 in the meta-analysis. OSA prevalence remained high in post-treatment acromegaly (active = 44.0%-87.5% vs inactive = 14.0%-58.0%). Meta-analysis showed moderate mean AHI (~15-20 events/hour) for active and inactive disease, with 40%-65% exhibiting moderate-to-severe OSA. Central sleep apnoea occured in 10% of patients but correlated with higher GH/IGF-1 levels. Sleep quality was often poor, with 60%-70% reporting daytime somnolence; although screening tools underestimated severity compared with polysomnography sleep studies (PSG). Acromegaly OSA was driven by oropharyngeal soft-tissue hypertrophy, macroglossia, uvular/soft-palate thickening, tonsillar enlargement, and lateral pharyngeal wall thickening, which correlate with OSA severity and not serum IGF-1 levels. Cardiovascular complications included resistant hypertension, left ventricular hypertrophy, and arrhythmias detected during sleep studies. However, major adverse cardiovascular events (MACE) such as myocardial infarction, stroke, and death were not reported. Therefore, consistent OSA severity predictors included male sex, older age, longer disease duration, higher BMI, and craniofacial/soft-tissue hypertrophy, whereas biochemical disease activity (serum IGF-1 concentrations) showed inconsistent associations.

Conclusions: Cross-sectional meta-analysis found no significant difference in OSA prevalence or AHI between active and inactive disease. However, longitudinal studies showed significant reductions in AHI and OSA severity following surgical or medical control, particularly within the first year. Persistent OSA despite treatment highlights the need for repeat OSA assessments for those with ongoing symptoms despite acromegaly treatment.

EP1200 - ECE_1684 - The utility of anti-rabphilin-3A antibody measurement in autoimmune hypothalamic-pituitary inflammation

Naoko Iwata, Momoka Inoue, Yusuke Kato, Jun Yoshida, Tetsuro Tsumura, Haruki Fujisawa and Yoshihisa Sugimura
Nagoya, Japan

Background: Pituitary inflammation is a chronic inflammatory disorder of the pituitary gland caused by autoimmune, systemic diseases, medications, infections, and other factors. It includes lymphocytic adenohypophysitis, lymphocytic infundibulo-neurohypophysitis (LINH), IgG4-related hypophysitis (IgG4-RH), and immune-related adverse events (irAE) induced by immune checkpoint inhibitors (ICI) in pituitary gland. However, reliable non-invasive diagnostic markers, particularly for posterior pituitary involvement, remain limited. We previously identified anti-rabphilin-3A antibodies as a diagnostic marker for LINH and reported the involvement of rabphilin-3A in the disease pathogenesis. This study evaluated the clinical utility of measuring anti-rabphilin-3A antibodies in pituitary inflammation other than LINH.

Case 1: A 52-year-old male. He had experienced frequent urination for several years. In August 2023, he started chemotherapy with FOLFOX + Pmab for sigmoid colon cancer with multiple liver metastases. From October 2023, he developed dry mouth and polyuria with polydipsia. Endocrine evaluation revealed preserved anterior pituitary function, while the hypertonic saline loading test showed low AVP response. Pituitary MRI showed no enlargement of the pituitary gland or pituitary stalk, with loss of posterior pituitary bright spot. Based on these findings, idiopathic arginine vasopressin deficiency (AVP-D) was diagnosed. Anti-rabphilin-3A antibodies were positive.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Case 2: An 84-year-old male developed joint pain and anorexia in May 2025. Endocrine evaluation including the stimulation tests demonstrated decreased secretion of anterior pituitary hormones and AVP-D. Pituitary MRI showed enlargement of the pituitary gland and pituitary stalk, with blurred T1WI and homogeneous contrast enhancement. Serum IgG4 was elevated at 190.1 mg/dL. Pituitary stalk thickening improved after hydrocortisone therapy, leading to a diagnosis of suspected IgG4-RH. Anti-rabphilin-3A antibodies were positive.

Case 3: A 62-year-old male. Nivolumab therapy initiated in January 2017 for lung squamous cell carcinoma. In April 2018, he developed generalized fatigue. Laboratory tests revealed severe hyponatremia, prompting further endocrine evaluation. Endocrine evaluation revealed isolated ACTH deficiency as an irAE. Serum IgG4 was normal. MRI showed no enlargement of the pituitary gland or pituitary stalk. AVP-D was absent. Anti-rabphilin-3A antibodies were negative.

Discussion: In our study, anti-rabphilin-3A antibodies were positive in cases of idiopathic AVP-D and suspected IgG4-RH, but negative in ICI-induced isolated ACTH deficiency without AVP-D. These findings suggest rabphilin-3A may be involved in autoimmune mechanisms underlying AVP-related hypothalamic-posterior pituitary disorders, including idiopathic AVP-D and IgG4-RH. Measuring anti-rabphilin-3A antibodies may aid in distinguishing these disorders from tumors. Conversely, ICI-induced pituitary dysfunction without AVP-D may involve autoimmune mechanisms targeting antigens other than rabphilin-3A.

EP1201 - ECE_2150 - Intracranial dissemination in aggressive immature PIT-1 lineage pituitary tumor: a consequence of repeated transcranial surgery?

Aysel Unver Ozkahraman[1], Rukiye Dilara Tekin Uzman[1], Huseyin Karatay[2], Ebubekir Akpinar[3,4], Buruc Erkan[3,4], Mutlu Niyazoğlu[1,4] and Esra Hatipoglu[1]

[1]Department of Endocrinology and Metabolism, University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Istanbul, Turkey; [2]Department of Pathology, University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Istanbul, Turkey; [3]Department of Neurosurgery, University of Health Sciences, Basaksehir Cam and Sakura City Hospital, Istanbul, Turkey; [4]Pituitary Disorders Research Center, University of Health Sciences, Istanbul, Turkey

Introduction: Immature PIT-1 lineage pituitary neuroendocrine tumors (PitNETs) are rare, high-risk neoplasms recognized in the World Health Organization 2022 classification. We present a case requiring five surgeries and multimodal treatment, ultimately developing intracranial dissemination.

Case Presentation: A 40-year-old woman presented nine years ago with menstrual irregularity. Hormonal evaluation revealed hypogonadotropic hypogonadism, central hyperthyroidism (FT4: 2.30 ng/dL [N: 0.93-1.7], FT3: 8.3 pg/mL [N: 2.0-4.4], TSH: 6.53 μIU/mL [N: 0.27-4.20]), and secondary adrenal insufficiency (PRL and IGF-1 were normal). Pituitary MRI demonstrated a 43 mm sellar mass. First transsphenoidal surgery (TSS) revealed PIT-1 positivity with diffuse prolactin (PRL) immunoreactivity and focal TSH staining. Adrenal function recovered postoperatively.

Six months later, a 25 mm residual tumor prompted transcranial resection, showing PRL expression (60%) with negative TSH staining, the tumor was endocrinologically non-functioning. Five months later, tumor regrowth to 37 mm necessitated a third TSS; pathology showed PRL positivity with Ki-67 of 5%. Octreotide therapy failed to achieve tumor control.

Three years later after the third surgery, tumor progression to 55 mm with Knosp grade 4 invasion and recurrence of central hyperthyroidism were noted. Transcranial resection revealed PIT-1, GATA-3, PRL positivity with Ki-67 of 15%, consistent with immature PIT-1 lineage PitNET. Gamma Knife and cabergoline were initiated.

Three years later, while the sellar tumor regressed, a new frontal lobe mass measuring ($21 \times 23 \times 30$ mm), isointense on T1- and T2-weighted sequences, was identified. Endocrine evaluation revealed non-functioning status. Resection revealed PIT-1 positivity, patchy PRL expression, Ki-67 of 18%, and 15 mitoses per 10 high-power fields. Systemic imaging including Gallium-68 labeled DOTA-Tyr3-octreotate positron emission tomography/computed tomography excluded distant metastasis, supporting intracranial tumor dissemination. Conventional radiotherapy was administered following this fifth surgery.

One year after the final surgery, the patient remains hormonally and clinically stable with no recurrence on cabergoline 1 mg weekly maintenance therapy.

Discussion: Immature PIT-1 lineage tumors are aggressive PitNETs with complex endocrine presentations. Central hyperthyroidism, as observed in our patient, is a recognized hormonal manifestation. Despite consistent prolactin immunopositivity, hyperprolactinemia was never observed, highlighting immunohistochemical-hormonal discordance. The progressive Ki-67 increase from 5% to 18% underscores malignant potential. Repeated transcranial approaches may have contributed to dissemination via subarachnoid exposure. This case emphasizes close surveillance, multimodal treatment, and careful surgical approach selection in aggressive PitNETs.

Keywords immature PIT-1 lineage tumor, central hyperthyroidism, intracranial dissemination, aggressive pituitary tumor

EP1204 - ECE_3109 - Evaluation of serum IL-1β levels in acromegalic patients with hepatic steatosis

Hatice Ozisik[1], Adil Bahadir[2], Tarik Inci[3], Su Ozgur[4], Sinem Aslan[3], Melih Bektas[3], Ezgi Ulas[3], Mehmet Yigit[3], Nazlican Seren[3], Erhan Canbay[3], Gaye Hamarat[3], Gökçen Ünal Kocabaş[3], Banu Sarer Yurekli[3], Nur Selvi Gunel[3] and Eser Yildirimi Sozmen[3]

[1]Endocrinology, Ege University, Izmir, Turkey; [2]The University of Texas MD Anderson Cancer Center, Houston, TX, United States; [3]Izmir, Turkey; [4]Translational Pulmonary Research Center-EgeSAM, Ege University, Izmir, Turkey

Introduction: Acromegaly is a chronic endocrine disorder caused by excessive secretion of growth hormone (GH) and insulin-like growth factor-1 (IGF-1), and is frequently associated with metabolic complications, including hepatic steatosis. Hepatic involvement in acromegaly is considered a manifestation of metabolic syndrome and may progress to fibrosis, commonly assessed using non-invasive indices such as the Fibrosis-4 (FIB-4) score. Although chronic low-grade inflammation has been proposed as a contributing mechanism in acromegaly-related metabolic dysfunction, the role of circulating inflammatory mediators remains incompletely understood. This study aimed to

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

evaluate inflammatory markers in patients with acromegaly and controls to explore their relationship with hepatic and metabolic parameters.

Methods: A total of 90 participants were included: 48 patients with acromegaly (53.3%) and 42 healthy controls (46.7%). Demographic characteristics, hormonal and metabolic parameters, and abdominal ultrasonography findings were recorded. Serum interleukin-1 beta (IL-1β) and nuclear factor kappa B (NF-κB) levels were measured using enzyme-linked immunosorbent assay. Patients with acromegaly were additionally evaluated according to disease activity (controlled vs uncontrolled). Group comparisons were performed using non-parametric statistical methods. Correlation analyses and exploratory receiver operating characteristic (ROC) analyses were conducted.

Results: Patients with acromegaly were older than controls (median 54 vs 45 years, $P < .001$), while sex distribution was similar ($P = .343$). Markers of metabolic burden were higher in the acromegaly group, including fasting glucose ($P = .009$) and HbA1c levels ($P < .001$). The FIB-4 index was significantly elevated in patients with acromegaly (median 0.94 vs 0.63, $P < .001$), and ultrasonographic hepatic steatosis was more frequent ($P = .030$).

Serum IL-1β levels were significantly lower in patients with acromegaly compared with healthy controls (median 866 vs 2006 pg/mL, $P < .001$). NF-κB levels were also significantly lower in the acromegaly group ($P = .013$). Overall correlation analyses demonstrated weak associations between IL-1β and hepatic or hormonal parameters, which were not consistently maintained in subgroup analyses. In ROC analysis, IL-1β showed good distinctive ability for distinguishing acromegaly from controls (AUC = 0.80), whereas FIB-4 demonstrated modest performance (AUC = 0.72). The ability of FIB-4 to distinguish controlled from uncontrolled acromegaly was limited (AUC = 0.68).

Conclusion: Despite increased hepatic and metabolic burden in acromegaly, circulating inflammatory markers did not indicate classical inflammatory activation. This pattern may reflect immunomodulatory effects of chronic GH/IGF-1 excess rather than a conventional pro-inflammatory state. Given the age difference between groups, findings should be interpreted with caution. These results highlight the complexity of immune–metabolic interactions in acromegaly.

EP1205 - ECE_2331 - Assessment of sex-specific urinary steroid changes induced by ketoconazole in Cushing's syndrome

Arturo Vega-Beyhart[1], Qiang Zhao[1], Gregori Casals[1], Marta Araujo Castro[2], Mireia Mora[1], Aida Orois[1], Cintia Santillan[1] and Felicia Alexandra Hanzu[1]
[1]*Endocrinology and Nutrition, Hospital Clínic De Barcelona, Barcelona, Spain;* [2]*Endocrinology and Nutrition, Hospital Universitario Ramón Y Cajal, Madrid, Spain*

Background: Sex differences in ketoconazole (KTZ) pharmacodynamics have been demonstrated in animal models, but not in humans. In Cushing's syndrome (CS), sex-specific effects of KTZ on urinary steroid profiles remain unexplored. This study evaluated whether intrapersonal KTZ-induced urinary steroid reductions differ by sex.

Methods: Adults (>18 years) with active CS from Hospital Clínic de Barcelona providing one adequate 24-h urine sample during untreated disease and one during KTZ maintenance (≥400 mg/day for ≥3 months) were included. Urinary free cortisol (UFC) and 34 urinary steroids were quantified using GC–MS. Absolute and percentage intrapersonal reductions (baseline – treatment) were calculated for each metabolite, and fold changes (FC) for steroid classes. Changes were compared between females and males to evaluate sex-specific effects of KTZ.

Results: 23 patients were included (12 females; 11 males). Age at inclusion was comparable (females: 44 ± 12; males: 47 ± 15 years old). KTZ doses did not differ (females: 400 [200-600] mg/day vs males: 400 [400-600] mg/day; $P = .20$). Patients achieving UFC below ULN during treatment was similar between sexes (35% in females vs 37% in males). However, a trend toward greater UFC reduction was observed in males (42% [19%-80%], 142 µg/day [6-397]) compared with females (24% [15%-51%], 22 µg/day [10-94]; $P = .13$).

Several metabolites exhibited divergent changes, increasing in females while decreasing in males. This pattern was observed for b-cortol (females: +42% [3-170] vs males: −20% [5-35]; $P = .006$), tetrahydrocortisone (females: +32% [4-165] vs males: −29% [2-60]; $P = .021$), and 5α-tetrahydrocortisol (females: +76% [13-201] vs males: −13% [−22 to 20]; $P = .021$). Moreover, several metabolites showed significantly greater reductions in males than in females, including 5α-tetrahydrocorticosterone (−35% [7-65] vs −18% [5-34]; $P = .022$), 11β-hydroxyandrosterone (−65% [33-77] vs −24% [10-60]; $P = .032$), 20β-dihydrocortisol (−43% [15-77] vs −20% [15-38]; $P = .043$), and 16α-hydroxy-DHEA (−72% [52-89] vs −5.7% [2-68]). No metabolite had significantly greater reduction in females. Finally, FC of glucocorticoid-derived compounds class differed significantly with an overall reduction in males (0.89 [0.75-1.27]) and an increase in females (1.26 [0.91-1.92]; $P = .013$).

Conclusion: Ketoconazole induces sex-specific urinary steroid responses in Cushing's syndrome, with greater glucocorticoid reductions observed in males.

Abstract citation ID: lvag096.1455

EP1207 - ECE_3847 - Pituitary adenoma with hyperprolactinemia and hyperandrogenism-associated menometrorrhagia in a 28-year-old woman: a case report

Salome Batsashvili[1], Ana Avkopashvili[2] and Maia Rekhviashvili[3]
[1]*Endocrinology, European University, Aversi Clinic, Tbilisi, Georgia;* [2]*Endocrinology, Aversi Clinic, Tbilisi, Georgia;* [3]*First Medical Clinic, Tbilisi, Georgia*

Introduction: Pituitary adenomas are a common cause of hyperprolactinemia and may lead to clinically significant reproductive dysfunction through disruption of the hypothalamic–pituitary–gonadal axis. This case highlights the interaction between pituitary and reproductive endocrine disorders and emphasizes the importance of integrated endocrine evaluation in patients with persistent menstrual dysfunction.

Case Presentation: A 28-year-old woman with a history of autoimmune thyroiditis (diagnosed at age 11) and vitiligo presented with fatigue, dyspnea, generalized weakness, dizziness, reduced exercise tolerance, and menometrorrhagia. Additional symptoms included recurrent headaches, hair loss, and hirsutism. Hematological assessment confirmed chronic iron-deficiency

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

anemia with profound ferritin depletion. Obstetric history included two pregnancies delivered via cesarean section; the patient denied a history of miscarriages. Family history was significant for thromboembolic disorders.

The patient's body mass index was within the normal range. Laboratory evaluation revealed elevated DHEA sulfate and free testosterone levels, consistent with hyperandrogenism, along with persistent hyperprolactinemia. Other hormonal investigations, including thyroid function tests, cortisol, and gonadotropins, were within normal limits. Adrenal imaging was performed as part of the hyperandrogenism workup. A vascular abnormality was detected during evaluation, and the patient was referred for angiologic assessment. Pituitary imaging was subsequently performed and confirmed a pituitary microadenoma measuring 2.8 × 2.5 mm. Notably, the patient had no prior diagnosis of pituitary pathology.

The patient was managed with a multidisciplinary approach involving endocrinology, gynecology, and hematology. Iron deficiency anemia was treated with iron replacement therapy, with monitoring of hemoglobin and ferritin levels. Given hyperprolactinemia in the setting of pituitary microadenoma, dopamine agonist therapy was initiated. Gynecologic management was planned to control ongoing menometrorrhagia and prevent recurrent iron depletion, with individualized assessment considering the patient's family history of thromboembolic disorders. Clinical follow-up with repeat hormonal assessment and surveillance pituitary imaging was arranged.

Conclusions and Perspectives: This case emphasizes that pituitary microadenoma–associated hyperprolactinemia can be the central driver of complex reproductive endocrine dysfunction in young women. When accompanied by clinically significant hyperandrogenism, marked by hirsutism, hormonal imbalance may contribute to persistent menometrorrhagia and lead to chronic iron-deficiency anemia with substantial functional impairment. Early recognition of pituitary-related endocrine disturbance and systematic evaluation of coexisting hyperandrogenic states are essential to ensure timely treatment and improve long-term outcomes through coordinated multidisciplinary care.

EP1210 - ECE_3539 - Steroidomic profiling in women with multiple sclerosis

Radmila Kancheva[1,2], Eva Kubala Havrdová[3], Ludmila Kancheva[1], Marta Velíková[1], Josef Vcelak[4], Radek Ampapa[5], Michal Židó[6], Ivana Štětkářová[6], Jana Libertínová[7], Michala Vosátková[8] and Martin Hill[1]

[1]Institute of Endocrinology, Steroid Hormones and Proteohormones, Prague, Czech Republic; [2]Institute of Endocrinology, Prague, Czech Republic; [3]Department of Neurology, First Faculty of Medicine, Charles University, Prague, Czech Republic; [4]Molecular Endocrinology, Institute of Endocrinology, Prague, Czech Republic; [5]Jihlava Hospital, MS Center, Jihlava, Czech Republic; [6]Department of Neurology 3FM CU and UHKV, Third Faculty of Medicine, Charles University, Prague, Czech Republic; [7]Second Faculty of Medicine, Charles University, MS Center, Prague, Czech Republic; [8]Clinical Biochemistry, Institute of Endocrinology, Prague, Czech Republic

Multiple sclerosis (MS) is a chronic inflammatory and neurodegenerative disease of the central nervous system that predominantly affects women of reproductive age. Steroid hormones and their metabolites exert profound immunomodulatory, neuroprotective, and neuromodulatory effects and may influence both susceptibility to MS and disease progression. However, a comprehensive and systematic characterisation of circulating steroid profiles in women with MS has been lacking. This study aimed to perform an extensive steroidomic analysis in women with MS in order to identify disease-associated alterations in steroid biosynthesis and metabolism.

Using a gas chromatography–tandem mass spectrometry platform, complemented by immunoassay for estradiol, a broad spectrum of unconjugated and conjugated steroids was quantified in serum samples from women with MS prior to disease treatment and from age-matched healthy controls. In addition to steroid concentrations, multiple molar ratios were calculated to reflect the activity of key steroidogenic enzymes and pathways, including those involved in adrenal, gonadal, and neurosteroid synthesis.

Women with MS exhibited an overall trend towards lower circulating levels of unconjugated steroids, particularly neuroprotective and immunomodulatory ones, while conjugated steroids were relatively preserved. This resulted in significantly increased ratios of conjugated to unconjugated steroids, suggesting altered steroid sulfation. Disturbances were observed along the pathway to cortisol synthesis, with evidence of impaired conversion of pregnenolone and 17-hydroxypregnenolone, alongside elevated cortisol and cortisone levels consistent with overactivation of the hypothalamic–pituitary–adrenal axis. Additionally, reduced levels of estradiol, androgens, progesterone metabolites, and key neuroactive steroids such as allopregnanolone were detected, indicating compromised neurosteroidogenesis.

Despite generally reduced steroid levels in patients compared with controls, positive correlations were found between several steroid concentrations and clinical indices of disease severity, suggesting the presence of counter-regulatory mechanisms activated during disease progression. Together, these findings demonstrate widespread alterations in the steroidome of women with MS and support a contributory role of disrupted steroid metabolism in MS pathophysiology. Steroidomic profiling may therefore provide valuable insights into disease mechanisms and hold potential for biomarker development.

EP1211 - ECE_3181 - Clinical and genetic aspects of growth hormone deficiency in children: the role of VDR polymorphisms

Mariana Ryznychuk[1] and Olena Bolshova[2]

[1]Bukovinian State Medical University, Chernivtsi, Ukraine; [2]SI "V.P. Komisarenko Institute of Endocrinology and Metabolism of the National Academy of Medical Sciences of Ukraine", Kyiv, Ukraine

In recent years, vitamin D (vit. D) and the vitamin D receptor gene (*VDR*) have attracted considerable scientific interest due to their involvement not only in calcium–phosphorus homeostasis but

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

also in growth regulation. Vitamin D is known to influence the differentiation of somatotroph cells in the pituitary gland, hepatic production of insulin-like growth factor 1 (IGF-1), and physiological processes of cartilage remodeling. The *VDR* gene contains several polymorphic variants, among which BsmI (rs1544410), TaqI (rs731236), and ApaI (rs7975232), located in the 3′ untranslated region, are the most extensively studied. These polymorphisms may modulate VDR expression and mRNA stability, thereby affecting the biological activity of vitamin D.

The aim of this study was to assess the effect of combined VDR gene polymorphisms (BsmI, TaqI, and ApaI) on hormonal, metabolic, and biochemical parameters in children with growth hormone deficiency (GHD).

Materials and Methods: The study included 42 children with confirmed GHD. Genotyping of *VDR* polymorphisms was performed using PCR followed by restriction fragment length polymorphism analysis and agarose gel electrophoresis.

Results: The most frequent combined genotype was the heterozygous variant (G/A + T/C + A/C), observed in 55.56% of patients, whereas the homozygous pathological genotype (A/A + C/C + A/A) was the least common (16.66%). Children carrying the pathological homozygous genotype demonstrated the lowest basal and stimulated growth hormone levels, indicating a more pronounced hormonal deficiency. Decreased serum 25(OH)D concentrations were identified in all genotype groups. Vitamin D deficiency predominated in children with the normal genotype, while insufficiency was more frequently observed in carriers of heterozygous and homozygous variants.

Correlation analysis revealed significant associations between vit. D levels and IGF-1, growth hormone, body mass index, bone age, and height standard deviation score (Ht-SDS). In children with the homozygous pathological genotype, a strong inverse relationship between IGF-1 and Ht-SDS was detected. Biochemical blood parameters, including calcium, phosphorus, creatinine, urea, and cholesterol, did not differ significantly between genotype groups and remained within normal reference ranges. Regression analysis confirmed a significant influence of bone age on IGF-1 and stimulated GH levels, as well as a close association between IGF-1 and stimulated GH.

Conclusions: Analysis of *VDR* genotypes demonstrated that the GATCAC combination was the most prevalent among children with GHD (55.56%). These findings highlight the substantial contribution of genetic factors to the pathogenesis of GHD and support the feasibility of personalized diagnostic and therapeutic approaches.

EP1212 - ECE_1144 - The role of Epithelial Mesenchymal Transition (EMT) modulators in giant invasive Pituitary Neuroendocrine Tumors (PitNets); is there a real connection?

Gamze Akkus[1], Erdem Ince[2], Eralp Cetinalp[2], Puren Yucel[2], Merve Avluklu[3], Aslı Boz[2] and Seyda Erdogan[2]
[1]Endocrinology, Cukurova University, Adana, Turkey; [2]Cukurova University, Adana, Turkey; [3]Adana, Turkey

Backgorund: Epithelial Mesenchymal Transition is a process that changes the cell from an epithelial to mesenchymal phenotype driven by a network transcription factors. Although it is well known the role of EMT markers in other solid tumors such as ovarian, breast and small cell lung cancers. There has been a paucity in the literature regarding the possible role of EMT markers in invasive pituitary tumors

Methods: We evaluate the expression of EMT-related markers (E-CAD, N-CAD, SNAI1, SNAI2 and TWIST) in fifty invasive PitNets. To clarify relation between the expression of these markers and clinical characteristics or remission rates of PitNets is main purpose of our study.

Results: Among the 50 patients included in the study, 24 (48%) were male and 26 (52%) were female, with a mean age of 51.1 ± 14.2 years. Endocrine remission was achieved in 24 patients (48%), and tumor size was equal to or greater than 4 cm in 22 patients (44%). While 15 ($n = 30\%$) of the PitNets were as null cell adenomas, the others were as GH-secreting ($n = 11$, 22%), prolactinoma ($n = 9$, 18%) and gonadotroph adenomas ($n = 15$, 30%). GAPDH was used as an internal control for normalization of gene expression levels. Although the ΔCt values of E-CAD, N-CAD, SNAI1, and SNAI2 showed statistically significant differences among groups ($P < .001$), the relative expression levels calculated by the $2^{-\Delta\Delta Ct}$ method did not differ significantly ($P > .05$). No significant differences in gene expression were observed according to the presence or absence of endocrine remission ($P = .244$, $P = .614$, $P = .595$, $P = .573$, and $P = .808$, respectively).

Conclusion: We could not demonstrate the associations between E-CAD, N-CAD, SNAI1, SNAI2, and TWIST gene expression and clinical course or endocrine remission of giant invasive PitNets functional or nonfunctional. Further studies with large sample size may be needed for in-depth understanding this physiopathological mechanism.

EP1213 - ECE_2256 - The telomerase/shelterin system is impaired in acromegaly and Cushing´s disease: potential pathophysiological relevance

Ignacio Gil-Duque[1,2,3], Miguel E. G-Garcia[1,2,3], Ana De La Rosa-Herencia[1,2,3], Aura D. Herrera-Martínez[2,3,4], David Cano Gonzales[5], Miguel Ángel Núñez-Santos[1,2,3], Manuel D. Gahete[1,2,3], Álvaro Flores-Martínez[1,2,3], María Ángeles Gálvez-Moreno[2,3,4], Alfonso Soto-Moreno[5], Antonio C. Fuentes-Fayos[1,2,3] and Raul M. Luque[1,2,6]
[1]Córdoba, Spain; [2]Maimónides Institute of Biomedical Research of Córdoba (IMIBIC), Reina Sofia University Hospital, Córdoba, Spain; [3]Reina Sofía University Hospital (HURS), Córdoba, Spain; [4]Service of Endocrinology and Nutrition, Reina Sofía University Hospital (HURS), Córdoba, Spain; [5]Unidad de Gestión de Endocrinología y Nutrición, Instituto de Biomedicina de Sevilla (IBiS), Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, Sevilla, Spain; [6]CIBER Pathophysiology of Obesity and Nutrition (CIBERobn), Córdoba, Spain

Pituitary Tumours (PiTs) present significant challenges in diagnosis and treatments due to their heterogeneity and complex pathophysiology and endocrine comorbidities. Current therapies (i.e., surgery, radiotherapy, and/or pharmacological treatment) frequently become ineffective over time, leading to low quality of life and recurrence rates. Therefore, identifying alternative medical tools for these rare pathologies is crucial. In this context, the alteration of the telomerase/shelterin molecular complexes

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

has been associated with cancer pathophysiology and progression; however, their role in PiTs remains poorly understood. Here, we uncovered a profound dysregulation in the expression of key components of the telomerase/shelterin systems in growth-hormone and adrenocorticotropic-hormone producing PiTs [GHomas ($n = 50$) and ACTHomas ($n = 19$), respectively] versus non-tumour pituitary tissues ($n = 10$), and identified critical dysregulated components associated with key clinical features (i.e., sinus invasion, visual alteration, cephalea, etc.). Moreover, we demonstrated that the inhibition of the telomerase activity (using BIBR1532) in primary patient´s derived cell-cultures and available cell-line models (GH3 and AtT-20) might serve as a potential therapeutic tool by reducing cell-proliferation and stem-cell capacity through the modulation of key oncogenic processes, including GH/ACTH synthesis, cell-cycle, and DNA Damage Repair (DDR) pathways. Notably, we also demonstrated that BIBR1532, in combination with somatostatin-analogues, exerted a synergic anti-proliferative effect in GH3 and AtT-20 cells. Altogether, our results demonstrate a profound and clinically relevant telomerase/shelterin-associated molecular dysregulation in GHomas and ACTHomas, which could serve as a potential source of novel diagnostic/prognostic biomarkers and therapeutic targets, offering a new avenue to improve the management of patients with these PiTs.

EP1214 - ECE_1257 - Impact of intensive iron chelation on pituitary iron load and endocrine recovery in transfusion-dependent thalassemia major: a structured review

Ashraf Soliman, Shayma Ahmed, Mohamed Yassin, Fawziya Alyafei, Nada Alaaraj and Noor Hamed
Pediatric Endocrinology, Hamad Medical Center, Doha, Qatar

Background: Transfusion-dependent β-thalassemia major (TDT) leads to progressive iron accumulation in endocrine organs, with the anterior pituitary among the earliest affected. Pituitary iron overload contributes to hypogonadotropic hypogonadism, GH deficiency, delayed puberty, and glycemic dysregulation. Although MRI permits non-invasive assessment of pituitary iron, the reversibility of endocrine dysfunction with intensive chelation remains incompletely characterized.

Objective: To evaluate the impact of intensive iron chelation on pituitary iron burden, endocrine function, and glucose homeostasis in TDT patients, emphasizing age-related variability in recovery.

Methods: A structured review of MRI-based pituitary iron studies from 1990-2025 was conducted. Nine eligible longitudinal and cross-sectional studies (458 patients, ages 7-32 years) reporting pre- and post-chelation endocrine outcomes and pituitary T2/T2*/R2 measurements were analyzed.

Results: Across all studies, pituitary iron overload correlated strongly with impaired hypothalamic–pituitary–gonadal (HPG) and GH–IGF-1 axis function. **Noetzli et al.** demonstrated that increased R2 values predicted hypogonadism, reduced pituitary volume, and attenuated LH/FSH responses. **Christoforidis et al.** reported concurrent reductions in GH peak responses and pubertal delay in adolescents with high pituitary iron.
Endocrine Recovery: Intensive chelation—including high-dose deferoxamine, combined deferoxamine–deferiprone, or escalated deferasirox—produced measurable improvements in hormonal function:

- **Gonadotropins:** Up to **37%** of patients showed improved LH/FSH responses, and **21%** demonstrated pubertal progression following 2-3 years of intensification.
- **GH–IGF-1 axis:** Multiple studies reported increases in IGF-1 levels and improved GH secretory profiles after chelation, particularly in younger patients (<12 years), consistent with partial restoration of somatotroph activity.
- **Prolactin:** Mild PRL increases were observed in some series, suggesting recovering pituitary reserve.

Glycemic Outcomes: Intensive chelation was also associated with improved glucose metabolism:

- **Farmaki et al.** documented significant reductions in fasting glucose, improved insulin sensitivity, and decreased frequency of impaired glucose tolerance after achieving near-normal total body iron.
- Patients with high baseline pancreatic iron showed partial normalization of OGTT responses after 2-4 years of combined chelation.
- Glycemic recovery was strongly age-dependent, with younger patients experiencing greater reversibility.

Age Dependence: Across all analyses, endocrine recovery was far more pronounced in children and adolescents than adults; structural pituitary atrophy in older individuals limited full normalization.

Conclusions: Intensive iron chelation substantially reduces pituitary iron burden and can restore components of the HPG, GH–IGF-1, and glycemic regulatory axes—especially when initiated early. Early MRI surveillance and timely escalation of chelation are critical for preserving long-term endocrine and metabolic health in TDT.

EP1215 - ECE_2009 - Hidden liver involvement in acromegaly: a non-invasive assessment of metabolic dysfunction–associated steatotic liver disease

Rosa Pitino[1], Chiara Mele[1], Martina Romanisio[1], Sara Sturnia[1], Alice Ferrero[1], Laura Veneto[2], Gianluca Aimaretti[1], Cristina Rigamonti[2], Paolo Marzullo[1], Flavia Prodam[1,3] and Marina Caputo[1,3]
[1]Endocrinology, Department of Translational Medicine, Università del Piemonte Orientale, Novara, Italy; [2]Division of Internal Medicine, Department of Translational Medicine, Università del Piemonte Orientale, Novara, Italy; [3]Department of Health Sciences, Università del Piemonte Orientale, Novara, Italy

Background and Aim: Acromegaly is associated with multiple metabolic complications; however, its relationship with metabolic dysfunction-associated steatotic liver disease (MASLD) remains poorly defined. This study aimed to assess the prevalence and severity of MASLD and liver fibrosis in acromegalic patients and to explore their association with hormonal burden, disease characteristics, and metabolic comorbidities.

Patients and Methods: In this monocentric observational study, 26 acromegalic patients (F:M 1.6:1; median age 62 years) were

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

evaluated. Clinical data, disease duration and activity, metabolic complications, and hormonal parameters (GH, IGF-I at baseline and follow-up, and ΔIGF-1 from baseline to last follow-up) were collected. The probability of liver fibrosis was assessed using the Fibrosis-4 index (FIB-4), applying age-adjusted cut-off (>1.3 in ≤65 years and >2.0 in older ones). All patients underwent vibration-controlled transient elastography (VCTE), assessing the Controlled Attenuation Parameter (CAP) for steatosis, Liver Stiffness measurement (LSM) and Spleen Stiffness measurement (SSM). Steatosis was defined as a CAP value >248 dB/m. LSM values <10 kPa, in the absence of other clinical or imaging signs, were considered to rule out compensated advanced chronic liver disease (cACLD). SSM <21 kPa excluded clinically significant portal hypertension (CSPH), according to Baveno VII criteria.

Results: Most patients (80.8%) had undergone pituitary surgery and disease remission was achieved in 42.3% of patients at last follow-up. Among patients with active disease, 46.2% were treated with SSRLs, 3.8% with cabergoline, and 7.7% with pegvisomant. Metabolic complications were frequent, including secondary diabetes (53.8%), dyslipidemia (69.2%), and hypertension (50.0%). Median FIB-4 value was 1.34 (IQR 1.11-1.98), with 38.5% of patients exceeding age-related cut-offs. Median CAP was 244 dB/m (IQR 221-297), and steatosis diagnosed in 42.3% of patients (severe 30.8%). Median LSM was 4.4 kPa (IQR 3.7-4.9), with 23.1% of patients showing LSM between 5 and 9.9 kPa. None of the patients had cACLD. Median SSM was 19.1 kPa (IQR 15.9-27.6). MASLD was diagnosed in 38.4% of patients. Baseline IGF-I levels were correlated with CAP values ($\rho = 0.63$; $P = .002$), indicating an association between steatosis and hormonal burden.

Conclusions: MASLD is highly prevalent in acromegalic patients and should be considered among metabolic complications. The association with baseline IGF-I supports a link between chronic hormonal excess and ectopic fat accumulation.

EP1216 - ECE_2664 - A masquerader in the sella: cavernous sinus ICA aneurysm causing panhypopituitarism

David Lopez-Lazaro[1], Shebina Liz Mathews[1], Muhammad Sohail Akhtar[1,2] and Cornelius Fernandez James[3]

[1]Diabetes & Endocrine, Pilgrim Hospital Boston(United Lincolnshire Hospitals NHS Trust), Boston, United Kingdom; [2]Diabetes & Endocrinology, Boston, United Kingdom; [3]Boston, United Kingdom

Introduction: We present a sellar lesion which was later identified to be an internal carotid artery (ICA) aneurysm. Although the pituitary function was normal at presentation, the patient developed symptomatic panhypopituitarism after four years. This highlights the importance of long-term endocrine surveillance in these patients.

Case Presentation: An 87-year-old lady presented in 2021 with headache and right 6th nerve palsy. CT head revealed a sellar/suprasellar lesion with right parasellar extension, initially suspected as a macroadenoma, but subsequent MRI Pituitary followed by CT angiography confirmed it as a bilateral cavernous sinus ICA aneurysm (right 15 × 19 mm; left 10 × 9 mm), with significant mass effect on the pituitary gland. Her pituitary profile was normal at that time (Cortisol 372 nmol/L, TSH 2.6 mIU/L, FT4 14.6 pmol/L, FSH 45.3 IU/L, IGF-1 11.4 nmol/L, prolactin 373 mIU/L). She was managed conservatively after neurosurgical input.

Repeat CT angiography in 2023 showed progression of the right ICA aneurysm (25 × 15 mm), with a relatively stable left ICA aneurysm (14 × 10 mm). In 2025, she presented with COVID-19 pneumonia and hyponatraemia (Sodium 125). Endocrine workup showed evidence of panhypopituitarism (Cortisol 47 nmol/L, ACTH <5 ng/L, TSH 0.83 mIU/L, FT4 2.9 pmol/L, IGF-1 2.1 IU/L, Prolactin 455 mIU/L). She responded well to hydrocortisone and levothyroxine replacement.

Discussion: Hypopituitarism is most commonly caused by sellar or parasellar tumours. Vascular lesions like ICA aneurysms are an important differential diagnosis of hypopituitarism, as they could mimic non-functioning pituitary macroadenomas. Early detection avoids potentially disastrous complications resulting from manipulation of such aneurysms during transsphenoidal or other pituitary operations. Cavernous segment (C4) ICA aneurysms account for only a small number (2%-9%) of all intracranial aneurysms. They account for <0.17% of all hypopituitarism cases. The hypopituitarism is usually permanent even after surgical interventions. Chronic mass effect from vascular lesions can cause delayed panhypopituitarism over the years. The mechanisms for delayed hypopituitarism include persistent mechanical compression, microvascular compromise, local inflammation and the pituitary microenvironment changes caused by the mass effect from the vascular lesion.

Conclusion: Chronic mass effect from vascular lesions can lead to delayed panhypopituitarism over the years. Lifelong endocrine follow-up is crucial for patients with any sellar mass causing anatomical displacement of the pituitary gland. Early recognition and timely neurosurgical intervention are important in preventing life-threatening endocrine crisis and neurological complications.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: Hyperprolactinemia is one of the most common examples of hormonal imbalance in females with empty or partial empty sella. This imbalance is associated with suppressed dopamine secretion, resulting from intrasellar structures being compressed by the suprasellar cistern. The aim of this study was to assess factors that potentially increase the risk of hyperprolactinemia in women.

Material and Methods: We conducted a prospective analysis, including pituitary magnetic resonance imaging and blood hormone level testing, in 34 women with empty or partial empty sella turcica.

Results: Hyperprolactinemia was observed in four patients (11.8%). Univariate logistic regression analysis demonstrated a significant relationship between patients' body weight (OR 0.84 [0.708-0.997]; $P = .045$) and hyperprolactinemia, with no such relationship shown by other evaluated parameters: pituitary craniocaudal diameter [mm] (OR 1.741 [0.646-4.695]; $P = .27$), pituitary anterior–posterior diameter [mm] (OR 0.637 [0.333-1.217]; $P = .172$), pituitary right–left diameter (OR 0.891 [0.666-1.193]; $P = .439$), pituitary volume [mm^3] (OR 1.001 [0.991-1.011]; $P = .828$), stalk displacement (OR 0.801 [0.765-6.175]; $P = .801$), age (OR 0.884 [0.781-1.001], $P = .05$), or body mass index (OR 0.597 [0.338-1.053]; $P = .075$).

Conclusions: Females with a lower body weight and empty or partial empty sella may be more prone to developing hyperprolactinemia and, therefore, require regular clinical and hormonal assessments.

EP1219 - ECE_2202 - Diabetic ketoacidosis as the first manifestation of acromegaly in an 18-year-old patient: a case report

Katerina Stefanaki[1], Konstantinos Barkas[2], Stefania Magkou[3], Ioannis Boutsikos[4], Paraskevi Kazakou[4], Panagiota Zacharaki[1], Olympia Michalopoulou[4] and Stavroula A. Paschou[1]

[1]Department of Clinical Therapeutics, Endocrine Unit and Diabetes Center, National and Kapodistrian University of Athens, Alexandra Hospital, Athens, Greece; [2]Department of Neurosurgery, National and Kapodistrian University of Athens, G.H Nikea-Piraeus "St. Panteleimon", Athens, Greece; [3]Medical School, National and Kapodistrian University of Athens, Athens, Greece; [4]Department of Clinical Therapeutics, National and Kapodistrian University of Athens, Alexandra Hospital, Athens, Greece

Background: Diabetic ketoacidosis (DKA) is an endocrinological emergency defined by hyperglycemia, anion gap metabolic acidosis and ketosis, while it often constitutes the earliest presentation of diabetes mellitus (DM). Acromegaly represents a rare endocrine disease characterized by excessive production of growth hormone (GH), typically caused by a GH-secreting pituitary adenoma. This disease is most frequently diagnosed between the fourth and fifth decades of life, presenting with a wide range of manifestations, including acral enlargement, soft tissue edema, facial feature deformities, and acrochordons. DM constitutes a frequent complication of acromegaly, predominantly attributable to GH–induced insulin resistance. By contrast, diabetic ketoacidosis represents an uncommon sequela in individuals with acromegaly and coexisting T2DM.

Case Report: We present a case of an 18-year-old Caucasian man who arrived at the emergency department of our clinic with decreased level of consciousness, increased blood pressure, tachypnea (Kussmaul pattern), and tachycardia. For the past three days, the patient had experienced multiple episodes of vomiting and diarrhea without prior medical history. On physical examination, multiple abscesses were found on trunk, scapular and right axillary region, cystic acne, and skin fistulas. Admission blood tests confirmed metabolic acidosis (pH = 6.91, pCO2 = 8 mmHg, HCO3 = 3 mmol/L, Glu = 582 mg/dL, Cl = 110 mmol) with increased anion gap (30) and ketonemia [serum ketones = 6 mmol (<0.6 mmol/l)]. Although the patient was managed successfully based on the established guidelines for DKA, he failed to regain consciousness. Brain CT and MRI revealed a sizable (3.9 cm × 3.3 cm × 3.7 cm) heterogeneous mass in the posterior cranial fossa suggestive of pituitary macroadenoma. Anti-staphylococcal therapy was administered, and abscesses were surgically drained. Endocrine investigation primarily identified elevated levels of ACTH, IGF, GH, cortisol, and increased C-peptide. The patient was referred for neurosurgical management, followed by the subtotal excision of the mass. Histopathology revealed a well-differentiated neuroendocrine tumor expressing GH and ACTH. Post-operatively, the patient exhibited panhypopituitarism with diabetes insipidus and he received hydrocortisone, levothyroxine, testosterone and desmopressin. Insulin and metformin therapy were subsequently initiated for glycemic management.

Conclusions: Although DKA is a rare complication in patients with T2DM and acromegaly, the uniqueness of the present case lies in the occurrence of DKA in an 18-year-old patient with undiagnosed acromegaly, initially suspected of having T1DM. The intricate nature of this case provides a meaningful opportunity to reflect on diagnostic and therapeutic challenges.

EP1220 - ECE_3603 - An unusal presentation of Crooke cell adenoma

Joana Vinhais[1], Beatriz R. Pereira[1], Ana Cláudia Martins[1], David Verissimo[1], Catarina Ivo[1], Mafalda Marcelino[1], Dolores Passos[1], Luis Lopes[1], Dalia Forte[2], Amets Sagarribay[2], João Jácome de Castro[1] and João Nunes Silva[1]

[1]Serviço de Endocrinologia, Hospital das Forças Armadas, Lisboa, Portugal; [2]Serviço de Neurocirurgia, ULS São José, Lisboa, Portugal

Introduction: Crooke cell adenomas (CCA) are a rare subtype of corticotroph pituitary adenomas. CCA are usually invasive macroadenomas and can present with Cushing's disease or can be clinically asymptomatic.

Case Report: A 54-years-old male without relevant past medical history was referred to our endocrinology outpatient clinic after a pituitary macroadenoma was detected on CT performed due to complaints of sinusitis. CT revealed a sellar mass with supra- and infra-sellar extension, marked enlargement of sella turcica, and bone erosion, consistent with macroadenoma. Patient denied headaches or visual changes but reported periocular oedema and tearing for four months, easy bruising and decreased libido. He denied erectile disfunction or weight change. Physical examination showed mild facial plethora,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

periocular oedema and conjunctival hyperaemia, ecchymosis of the upper limbs, and normal BMI (24.9 kg/m^2). Visual fields evaluation by confrontation were normal. Blood work showed glycemia 92 mg/dL, Na+ 144 mmol/L (136-145), K+ 5.3 mmol/L (3.5-5.5), cortisol 26.3 µg/dL (3.7-19.4), ACTH 161 pg/mL (<46), IGF-1 164 ng/mL (55-248), TSH 0.6 uUI/mL (0.350-4.940), fT4 1.27 ng/dL (0.8-1.76), total testosterone 2.4 ng/mL (2.54-8.53), LH 1.63 mUI/mL (0.57-12.07), FSH 4.6 mUI/mL (0.95-11.95), Prolactin 10.6 ng/mL (3.46-19.40).

Pituitary MRI confirmed a well-defined macroadenoma with infra-, supra- and latero-sellar extension (predominantly to the left). There was remodelling of the sellar floor, involvement of sphenoidal sinus, posterior fossa and the prepontine cistern, and compression of the optic chiasma, anterior diencephalon and third ventricle.

The patient was referred for evaluation in neurosurgery department, however, three days later he developed new-onset diplopia and headache. Ophthalmologic evaluation in the emergency department revealed left abducens nerve paresis and CT showed stability of the tumour.

Given the rapid clinical evolution, salivary and 24 h-urinary cortisol were not performed. One week later transsphenoidal surgery was performed and histological diagnosis was Crooke cell adenoma, positive for PIT 1, Chromogranin A, cytokeratin CAM 5.2, and weakly positive for ACTH with Ki-67 <3%.

Conclusion: This atypical presentation of CCA with periocular oedema and conjunctival hyperaemia, likely resulted from compression of venous structures, highlighting the invasive nature of these adenomas. Although these tumours may retain some corticotroph function, reflected by weak ACTH and chromogranin A positivity, their clinical manifestations are often dominated by mass effect rather than hormone excess.

EP1221 - ECE_1718 - Etiology and clinical profile of patients with endogenous Cushing Syndrome: a single center experience

Shahini Winson Gnanathayalan, Manilka Sumanatilleke and Uditha Bulugahapitiya
Endocrinology and Diabetes, National Hospital of Sri Lanka, Colombo, Sri Lanka

Introduction: The clinical presentation of Cushing Syndrome (CS) is variable and non-specific in many cases. Prompt clinical suspicion is the essence not to miss the diagnosis of genuine Cushing syndrome and to avoid extensive evaluation in pseudo-Cushing states (non-neoplastic hypercortisolism).

Objective: To assess clinical characteristics of Cushing syndrome diagnosed at Endocrine department, National Hospital Sri Lanka

Methods: We performed a retrospective evaluation of 20 patients with CS, diagnosed during September 2022—March 2024.

Results: Twenty adult patients (15 females, 5 males, age 21-60 years, mean age with SD 39.6 ± 13 years) were diagnosed to have CS during this period. Seventeen cases (85%) were ACTH dependent (Cushing Disease (CD) – $n = 15$, ectopic Cushing syndrome (ECS) – $n = 2$) while 3 (15%) were ACTH independent (Adrenocortical carcinoma (ACC) – $n = 2$, primary pigmented nodular adrenal disease – $n = 1$). Pituitary macroadenoma was seen in 40% of CD cases. The cases of ECS were secondary to thymic-carcinoid tumor and olfactory-neuroblastoma.

The most common presenting complaints in CD were abdominal obesity with weight gain followed by a new onset or worsening of diabetes mellitus or hypertension. One young male was diagnosed to have CD when he was evaluated for fragility fracture of hip. Persistent severe symptomatic hypokalemia was the first clue to evaluate toward the possibility of CS in both patients with ECS. Among cases of ACC, one presented with generalized monomorphic acne and the other one had adrenal incidentaloma. Typical cushingoid appearance was present in all patients with CD but absent in both patients with ECS and in one patient with ACC. At least one clinical feature with the highest discriminatory value (facial plethora – 35%, easy bruising- 35%, thin skin – 45%, proximal muscle weakness – 60%, wide purple striae – 50%) was present in 90% of the patients. Other features supporting the diagnosis were acne (26%), hyperpigmentation (30%), hirsutism and menstrual irregularities.

Conclusion: The possibility of CS should be considered in patients with unexplained hypokalemia even in the absence of cushingoid features. Proper examination for the presence of highly discriminatory clinical features is helpful to know the pretest probability of CS.

Abstract citation ID: lvag096.1467

EP1222 - ECE_2023 - Multifocal paraganglioma in Von Hippel-Lindau syndrome: a diagnostic conundrum unfolded through multimodal investigation

Maimoona Nawaz, Rachel Brindle, Waseem Majeed and Adhithya Sankar
Manchester, United Kingdom

Introduction: We present a diagnostically complex case of multifocal phaeochromocytoma and paraganglioma (PPGL), initially suggestive of metastatic disease. Further evaluation revealed a unifying diagnosis of Von Hippel-Lindau (VHL) syndrome.

Case Presentation: A 42-year-old female with no personal or family history of PPGL presented with flank pain and urinary symptoms. CT imaging revealed a 4.3 cm atypical right adrenal lesion. Endocrinology review noted episodic hypertension, sweating, and palpitations. Biochemistry showed elevated plasma normetadrenaline (5.51 nmol/L) and metadrenaline (0.34 nmol/L). Alpha blockade with doxazosin was initiated.

Functional imaging (MIBG, FDG PET, somatostatin receptor scintigraphy) confirmed pheochromocytoma. Additional lesions included a 1 cm left para-aortic mass, a non-avid left adrenal nodule (likely adenoma), and a right retrothyroidal neck lesion—all showing uptake on functional imaging. Thyroid ultrasound revealed a U5 lesion, raising concern for metastatic PPGL.

Cytology of the neck lesion confirmed a head and neck paraganglioma. Further imaging identified benign liver haemangioma and bilateral renal parapelvic cysts, prompting genetic testing. Genetic analysis revealed a heterozygous pathogenic VHL mutation: NM_000551.3:c.250G>A; p.(Val84Met), confirming the diagnosis of VHL syndrome. A heterozygous pathogenic VHL mutation was found, making multifocal PPGL more likely. However, the distribution of neuroendocrine lesions was still concerning for metastatic PPGL. Patient underwent uncomplicated laparoscopic right

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

adrenalectomy. Histology confirmed pheochromocytoma with classic Zellballen architecture, chromogranin and synaptophysin positivity, and a low Ki-67 index (<2%), consistent with benign behaviour. Persistently elevated normetanephrines led to excision of the left para-aortic lesion, with histology confirming paraganglioma and biochemical normalization. Surveillance imaging remains unremarkable, excluding metastatic disease.

Discussion: VHL syndrome is a rare autosomal dominant disorder associated with multifocal neuroendocrine tumours. Though sporadic VHL mutations are rare, clinical awareness can aid diagnosis. PPGL in VHL mostly presents as benign multifocal disease but in rare cases can be metastatic.

EP1223 - ECE_2110 - An endocrine double act: a double-edged neuroendocrine tumour—insulinoma with ectopic ACTH secretion

Theingi Zaw[1] and Aye Nyunt[2,3]
[1]Diabetes and Endocrine Department, Glan Clwyd Hospital, Rhyl, United Kingdom; [2]Diabetes and Endocrinology, Rhyl LL18 5UJ, United Kingdom; [3]Endocrinology, Glan Clwyd Hospital, Rhyl, United Kingdom

Introduction: The global incidence of neuroendocrine tumours (NETs) is increasing. Among these, pancreatic neuroendocrine tumours (pNETs) are one of the most common subtypes, with an estimated incidence of approximately 1 per 100 000 population.[1] Insulinomas, although rare, are the most common functional pNETs, with an annual incidence of 1-4 cases per million.[2] We describe a unique case of a previously diagnosed metastatic insulinoma that later developed ectopic ACTH secretion, highlighting the dynamic hormonal behaviour and heterogeneity of NETs.

Case: A 58-year-old man was diagnosed in 2021 with a non-resectable, metastatic, well-differentiated grade 1 pancreatic NET with liver metastases, functioning as an insulinoma. He received four cycles of peptide receptor radionuclide therapy (PRRT), followed by lanreotide and Everolimus due to disease progression.

In early 2024, approximately 4 months prior to hospital admission, he developed bilateral legs oedema accompanied by an unexpected improvement in hypoglycaemic symptoms. He subsequently presented with persistent hypokalaemia, hypocalcaemia and acute psychosis, complicated by type 1 respiratory failure secondary to resistant to intravenous correction of electrolytes requiring intensive care unit admission.

Biochemical evaluation revealed severe hypokalaemia with severe metabolic alkalosis. These findings raised suspicion for hypercortisolism as the underlying cause of the electrolyte disturbance.

Serum cortisol was profoundly elevated at 2951 nmol/L, with a concomitantly high ACTH level of 389 ng/L. CT imaging of the head demonstrated a normal pituitary gland. Additional findings showed markedly elevated calcitonin level of 9290 ng/L.

Given the background of metastatic pancreatic NET and the absence of pituitary pathology, the unsuppressed ACTH secretion was most consistent with ectopic ACTH production. The patient was commenced on metyrapone following multidisciplinary discussion with the NET team. This resulted in significant improvement in hypokalaemia and neuropsychiatric symptoms, allowing successful discharge. He is currently maintained on a block-and-replace regimen with metyrapone and hydrocortisone.

Discussion: The majority of pancreatic NETs produce a single hormone and present with a corresponding hormonal syndrome. However, a minority of tumours may develop secondary hormone secretion at a later stage. Emerging evidence suggests that NETs may demonstrate hormonal plasticity, with the potential to alter or acquire new hormone-secreting profiles as the disease progresses.[3]

This case underscores the importance of recognising the heterogeneity of neuroendocrine tumours and maintaining a high index of suspicion for new or evolving hormonal syndromes, particularly in the context of disease progression. Hormonal co-secretion or phenotypic switching can occur at any stage. It is significantly associated with increased mortality.

EP1224 - ECE_3614 - Everolimus in lung neuroendocrine tumors: statin-associated myopathy risk and potential PFS benefit of concomitant lipid-lowering therapy

Maurizio Martiradonna, Flaminia Russo, Virginia Zamponi, Rossella Mazzilli and Antongiulio Faggiano
Endocrinology Unit, Department of Clinical and Molecular Medicine, Sant'Andrea Hospital, ENETS Center of Excellence, Sapienza University of Rome, Rome, Italy

Everolimus, an oral mTOR inhibitor approved for progressive lung neuroendocrine tumors (RADIANT-4), frequently induces metabolic effects such as hyperglycaemia and dyslipidaemia. In transplant medicine, coadministration of statins with mTOR and/or calcineurin inhibitors is known to increase the risk of statin-associated muscle toxicity due to pharmacokinetic interactions involving CYP3A4, P-glycoprotein and hepatic OATP1B1, which raise systemic statin exposure. However, evidence in oncology is scarce.

We report preliminary data from a retrospective study of patients with lung neuroendocrine tumors (NET) on chronic statin therapy who started antitumor everolimus therapy. Five patients have been included: four treated with everolimus at standard dose of 10 mg daily, who were receiving rosuvastatin 10 mg (n.3) and atorvastatin 40 mg (n.1), and one treated with low-dose everolimus 5 mg daily who was receiving rosuvastatin 5 mg. Among the four patients on standard doses, all had normal baseline CK (median 85 U/L; range 77-123; ULN 168). CK elevations occurred in all patients within 1-3 months. Two exceeded clinically relevant thresholds: one on rosuvastatin increased from 123 to 730 U/L at 1 month (4.3× ULN); one on atorvastatin rose from 110 to 311 U/L at 3 months (1.9× ULN) and, after dose escalation to 80 mg for LDL control, reached 903 U/L at 6 months (5.4× ULN). The remaining two patients showed milder increases (<4× ULN: 77→234 U/L and 85→217 U/L) and were prophylactically switched to non-statin lipid-lowering agents (ezetimibe, bempedoic acid). Notably, the fifth patient on low doses maintained CK within normal limits, suggesting a possible dose-dependent interaction. In addition, progression-free survival (PFS) was compared in 10 patients with lung NET treated with everolimus, divided according to concomitant use of lipid-lowering therapy (statin or non-statin; $n = 5$) versus no lipid-lowering therapy ($n = 5$). Median PFS was higher in the lipid-lowering therapy group (12 months) than in the no lipid-lowering therapy group (6 months), with a statistically significant difference ($P = .03$).

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Although limited by small numbers, these preliminary findings suggest that everolimus may potentiate statin-associated myopathy in lung NET patients, complicating dyslipidaemia management. At the same time, lipid-lowering therapy in patients with lung NET treated with everolimus appears to be associated with superior PFS, suggesting a possible favourable role in oncological outcomes.

EP1225 - ECE_1606 - Early-stage Cushing's disease in adolescence revealed by progressive loss of circadian ACTH and cortisol regulation

Data Kekutia[1,2], Shota Janjgava[1,3] and Elen Giorgadze[1,3]
[1]National Institute of Endocrinology, Tbilisi, Georgia; [2]Tbilisi State University, Tbilisi, Georgia; [3]Ivane Javakhishvili Tbilisi State University, Tbilisi, Georgia

Introduction: Cushing's disease is relatively rare in adolescence and often presents with slowly progressive and subtle changes in biochemical parameters. Interestingly, there is not always marked hypercorticism or convincing imaging findings in the early stages of the disease.

Case Presentation: A 16-year-old boy presented with progressive fatigue, headache, insomnia (with inversion of the sleep-wake cycle), mood swings, constipation, dry skin, mild weight gain, and purple striae on the shoulders. There was a history of childhood inflammatory disease of the spinal cord, during which systemic glucocorticoid therapy was administered. Mild signs of Cushingoid physiology were detected, without significant growth retardation.

Investigations: Hormonal studies demonstrated a disruption of the circadian rhythm of the hypothalamic-pituitary-adrenal axis, as manifested by a disproportionately elevated nocturnal level of adrenocorticotropic hormone (ACTH) (~35 pg/mL; reference: <19 pg/mL) and significant nocturnal secretion of cortisol. The presence of endogenous hypercorticism was confirmed by an elevated level of free cortisol in 24-hour urine, determined by the LC-MS/MS method (~103 μg/24 h; normal: 11-70). Serial laboratory studies over a year showed a progressive increase in ACTH levels from the upper limit of normal to a markedly elevated morning level (~84 pg/mL), with suppression of the nocturnal level, accompanied by loss of diurnal variation in cortisol and elevated cortisol levels. These changes were accompanied by mild but persistent hyperprolactinemia and hypergonadotropinemia (LH and FSH), suggesting multihormonal hypersecretion of the pituitary gland. Electrolytes were within normal limits. Abdominal imaging showed normal adrenal anatomy without focal lesions, ruling out adrenal-dependent Cushing's syndrome. High-resolution magnetic resonance imaging of the pituitary gland with dynamic contrast revealed heterogeneous hypersecretion of the adenohypophysis and a small hypovascular lesion measuring 1.5 mm in the left lobe, suggesting a microadenoma, although the reliability of the result was limited due to motion artifact.

Management and Follow-up: The patient underwent detailed endocrinological monitoring and pharmacological therapy. Dynamic changes in biochemical data allowed the diagnosis of pituitary-induced ACTH-dependent Cushing's syndrome, which is consistent with Cushing's disease.

Conclusion: The present case demonstrates that Cushing's disease in childhood can occur against the background of initially normal cortisol levels, with progressive disruption of circadian rhythms and increased ACTH. This emphasizes the need for cyclical hormonal analysis, the most accurate assessment of urinary cortisol, and detailed pituitary examination to differentiate Cushing's disease from pseudo-Cushing's conditions.

EP1227 - ECE_2032 - Clinical characteristics and therapeutic outcomes of patients with acromegaly in Alexandria—Egypt: a retrospective study

Ahmed Abdelhameed Osman[1], Eman Zaky Ahmed Abdelaziz Azzam[1], Mahmoud Aly Abbassy[2] and Asmaa Abdelsalam Elsherbiny[1]
[1]Endocrinology Unit, Department of Internal Medicine, Alexandria Faculty of Medicine, Alexandria, Egypt; [2]Faculty of Medicine, Department of neurosurgery, Alexandria University, Alexandria, Egypt

Introduction: Acromegaly, though a rare disease is a debilitating disease with variable outcomes when it comes to different therapeutic modalities. We conducted a retrospective study of 22 patients with acromegaly attending Endocrinology outpatient clinic at the Alexandria main university hospital with the aim of characterizing different clinical presentations, therapeutic modalities and outcome.

Results: The study population had a mean age of 35 years at the time of diagnosis, with a slight male predominance (54.5%). The most common primary presentations were headache (68.2%) and acral enlargement (63.6%). Significant comorbidities included hypertension (45.5%), obstructive sleep apnea (45.5%), and hyperprolactinemia (40.9%). Patients needed a mean of 2.91 doctors to establish the diagnosis of acromegaly. Most patients (95.5%) underwent transsphenoidal surgery (TSS) as a primary treatment.

Following treatment, there was a significant reduction in median GH levels from 17.25 ng/mL at baseline to 2.26 ng/mL at 6 months ($P < 0.001$). Similarly, IGF-1 levels decreased from a median of 691.0 ng/mL to 276.0 ng/mL over the same period ($P < .001$). MRI findings showed a significant reduction in mean lesion size from 3.01 cm at baseline to 2.20 cm at 6 months ($P < .001$). By the end of the study, 22.7% of patients were considered cured, while 77.3% remained ongoing treatment.

Conclusion: Therapeutic interventions, primarily surgical, significantly improved biochemical markers (GH and IGF-1) and reduced tumor size in this study. However, a high percentage of patients required multi-modal second and third-line therapies to manage residual disease. The findings emphasize the need for early diagnosis and a comprehensive, long-term management strategy to address persistent comorbidities and improve clinical outcomes for acromegalic patients.

EP1228 - ECE_3748 - Tamoxifen in combination with low dose pasireotide improves both acromegaly control and glucose metabolism

Klaus Badenhoop and Jürgen Reusch
Endocrinology, Deutsches Endokrinologisches Versorgungszentrum, DEVZ, Frankfurt/Main, Germany

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

A now 70-year old female patient was diagnosed with acromegaly due to a STH secretinng macroadenoma in 2002. Neurosurgical removal did not correct STH hypersecretion and led to partial hypopituitarism. The patient was not amenable to further operation nor to radiotherapy. Conservative management was undertaken with pegvisomant which normalised IGF-1 levels, while hydrocortisone and L-thyroxine were supplemented for adequate adrenal and thyroid function. Since the patient was reluctant to inject pegvisomant daily for further long periods of her life she was offered monthly treatment with pasireotide. This new treatment was partially successful for reducing but not normalising IGF-1. However the patient developed type 2 diabetes mellitus (HbA1C 7.8%) under the dose of pasireotide 40 mg/month. After consulting another endocrinologist she was offered treatment with tamoxifen as an off-label drug. The tamoxifen dose was started with 20 mg/d. The combination with pasireotide gradually reduced IGF-1, allowing a dose reduction of pasireotide after IGF-1 had normalised. Due to vertigo attacks and falls the tamoxifen dose had to be reduced to 10 mg/d. Under this daily dose the patient is now without vertigo. Pasireotide (10 mg) is injected at bimonthly intervals with normalised IGF-1. Diabetes control is optimal with a last HbA1C of 6.3% under metformin 500 mg twice daily.

The case illustrates the potential of tamoxifen adjunct therapy in treatment resistant acromegaly. An individualised combination regimen lowers untoward side effects of pasireotide while safeguarding endocrine stability

EP1229 - ECE_3684 - Sex-related differences in Cushing's syndrome: a single-center cohort study

Elena Sofia Blanca[1], Giordana Siracusano[1], Carla Paola Costa[1], Ylenia Alessi[2], Angela Alibrandi[3], Salvatore Cannavò[4] and Francesco Ferraù[4]
[1]Endocrine Unit, University Hospital of Messina, Messina, Italy; [2]Department of Biomedical, Dental and Morphological and Functional Imaging Sciences, University of Messina, Messina, Italy; [3]Sant'Agata di Militello (ME), Italy; [4]Department of Human Pathology of Adulthood and Childhood, University of Messina, Messina, Italy

Introduction: Cushing's syndrome (CS) is a rare, debilitating endocrine disorder caused by chronic glucocorticoid excess, predominantly affecting women, leading to multisystem morbidity. Evidence highlights sexual dimorphism in tumor behavior and genetic background, possibly influencing disease onset, severity and outcomes. Nevertheless, the influence of gender on clinical presentation and prognosis remains debated. This study investigated, within a single-center cohort, sex-related differences in phenotypic, anthropometric, clinical-biochemical features, at diagnosis (D) and at last follow-up in patients undergone remission (R).

Methods: Seventy-nine patients with CS (55 females; mean age 39.41 ± 15.7 years; female-to-male ratio 2.3:1) were followed for 71.1 ± 6.7 months. Data collected included clinical features, anthropometrics, biochemical parameters (urinary free cortisol [UFC, expressed as multiples of the upper limit of normal, ULN], serum cortisol after a 1-mg overnight dexamethasone suppression test [DST], serum midnight cortisol (μg/dl), adrenocorticotropic hormone [ACTH], glucose levels, HbA1c, electrolytes, IGF-1 (standard deviation score)), comorbidities (hypertension, diabetes mellitus [DM], dyslipidemia, osteopenia/osteoporosis, vertebral fractures [VF], psychiatric disorders, cardiovascular [CV] events, central hypothyroidism/hypogonadism, growth hormone [GH] deficiency). Data were stratified and compared by gender.

Results: In the group of patients evaluated at D, 61 patients had Cushing's disease (CD), 12 adrenal adenomas, and 6 ectopic CS. Males more frequently presented diabetes (40% vs12.7%, $P = .009$) and CV events (22.2% vs 2.3%, $P = .010$). Central hypothyroidism was more common in women (18.0% vs 0.0%, $P = .037$), while easy bruising showed a trend toward female predominance (85.7% vs 40.0%, $P = .059$). Remission was achieved more frequently in women (94.5% vs 75.0%, $P = .033$).

In R group, men showed more frequently proximal myopathy (14.3% vs 0.0%, $P = .024$), diabetes, dyslipidemia, and cardiovascular events (42.9% vs 11.8%, $P = .016$; 85.7% vs 33.3%, $P = .001$; 15.4% vs 0.0%, $P = .044$, respectively).

In the comparison between group D and R, BMI ($P = .01$), waist circumference ($P = .063$) and moon facies ($P = .031$) improved in men. Conversely, women showed significant reductions in BMI ($P = .015$), waist circumference ($P = .011$) and HbA1c ($P = .005$).

Conclusion: This study highlights significant sex-related differences in Cushing's syndrome. Men presented with more severe features, including higher rates of diabetes, and cardiovascular complications, while women had a greater prevalence of central hypothyroidism. At last follow-up, women experienced higher remission rates, both genders showed improvements in anthropometric parameters, with women also demonstrating reductions in glycated hemoglobin, whereas men faced increased risks of myopathy and cardiometabolic issues. Recognizing sex-specific patterns can improve diagnostic accuracy and support personalized management.

EP1230 - ECE_1244 - Pituitary stalk interruption syndrome (case report)

Maria Chrysoula Tatarida Palla, Marika Kokkorou, Andreas Bampilis, Galateia Stathori, Michalis Magklis, Myrsini Chamakioti, Agapi Karkampouna, Mina Koutrouli, Eleni Papanikolaou and George Chrousos
Endocrine Unit, National and Kapodistrian University of Athens, Athens, Greece

Background: Pituitary Stalk interruption syndrome (PSIS) is a rare congenital disorder defined by the MRI triad of a thinned or absent pituitary stalk, underdevelopment of the anterior pituitary gland, and an ectopic or non-visualized posterior pituitary. Clinical presentation varies, and although most cases manifest in early childhood, later onset of pituitary hormone deficiencies has been described.

Case Presentation: A 35-year-old male presented with long-standing fatigue. His medical history was notable for late-onset pituitary insufficiency diagnosed at age 10. Prior to that time, growth and developmental milestones were normal. Shortly after a tonsillectomy, he developed high fever (up to 40 °C), followed by a comatose state that required hospitalization. Endocrine evaluation revealed combined anterior pituitary hormone deficiencies, and replacement therapy with hydrocortisone, levothyroxine, and testosterone was initiated. At age 14, growth hormone (GH) therapy was added and continued for six years, resulting in attainment of mid-parental target height.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

MRI of the sellar region demonstrated a hypoplastic anterior pituitary gland, a thin and right-displaced pituitary stalk, and an ectopic posterior pituitary located beneath the hypothalamus—findings characteristic of pituitary stalk interruption syndrome.

Recent laboratory assessment reconfirmed combined anterior pituitary hormone deficiencies, including growth hormone (GH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), adrenocorticotropic hormone (ACTH), and thyroid-stimulating hormone (TSH). Hyperprolactinemia was also identified, consistent with reduced hypothalamic dopaminergic inhibition. Posterior pituitary function has remained intact. Bone mineral density testing revealed osteopenia.

The patient had experienced inadequate symptom control on conventional doses of hydrocortisone, prompting transition to modified-release hydrocortisone (Efmody®), which resulted in improved biochemical stability. GH therapy was also reinitiated after a period of discontinuation by patient preference. Following these adjustments, the patient demonstrated marked improvement in clinical symptoms as well as overall quality of life.

Conclusion: This case highlights a rare presentation of late-onset congenital hypopituitarism due to PSIS, underscoring the need for clinical vigilance in children with acute decompensation after physiological stress and the importance of long-term endocrine follow-up into adulthood. Efmody replacement contributed to improved sense of wellbeing.

EP1231 - ECE_2301 - High stress on the frontline: psychological impact and HPA axis changes in intensive care unit workers during COVID-19

Emre Durcan[1], Serdar Sahin[1], Hande Mefkure Ozkaya[1], Senol Turan[2], Oktay Demirkıran[3], Dildar Konukoglu[4], Fahrettin Kelestimur[5] and Mustafa Sait Gonen[1]

[1]Division of Endocrinology and Metabolism, Department of Internal Medicine, Cerrahpaşa Faculty of Medicine, Istanbul University-Cerrahpaşa, Istanbul, Turkey; [2]Department of Psychiatry, Cerrahpaşa Faculty of Medicine, Istanbul University-Cerrahpaşa, Istanbul, Turkey; [3]Department of Anesthesiology and Resuscitation, Cerrahpaşa Faculty of Medicine, Istanbul University-Cerrahpaşa, Istanbul, Turkey; [4]Department of Medical Biochemistry, Cerrahpaşa Faculty of Medicine, Istanbul University-Cerrahpaşa, Istanbul, Turkey; [5]Department of Endocrinology, Yeditepe University, Medical School, Istanbul, Turkey, Istanbul, Turkey

Objective: During the COVID-19 pandemic, healthcare workers faced intense psychological stressors, including increased workload, fear of transmitting the virus to family members, and social isolation. These stressors were especially pronounced among intensive care unit (ICU) workers due to continuous close contact with infected patients, potentially affecting the hypothalamic–pituitary–adrenal (HPA) axis. This study aimed to evaluate the psychological impact of pandemic-related stress and associated HPA axis changes among ICU workers.

Materials and Methods: This prospective, single-center study included ICU healthcare workers caring for COVID-19 patients, ICU workers with no contact with COVID-19 patients, and healthy controls. Sociodemographic characteristics, job position, working hours, and ICU experience were recorded. Psychological status was assessed using the Beck Depression Inventory (BDI), Beck Anxiety Inventory (BAI), and PTSD Checklist-5 (PCL-5). Vital signs were measured, and morning blood samples were collected for pituitary hormone analysis. A 1-μg low-dose ACTH stimulation test was performed in all participants.

Results: A total of 106 participants were included: 43 COVID ICU workers, 35 non-COVID ICU workers, and 28 healthy controls. Groups were comparable regarding COVID-19 exposure risk, ICU working hours, and prior ICU experience. COVID ICU workers had a higher pulse rate than non-COVID ICU workers, while blood pressure was similar. Total psychological scale scores showed no significant differences between ICU workers caring for COVID-19 patients and those who did not. However, based on the PCL-5 cutoff, PTSD prevalence was higher among COVID ICU workers (51.7% vs 24%, $P = .035$), whereas depression and anxiety prevalence did not differ by BDI or BAI cutoffs. Basal and peak cortisol levels following ACTH stimulation were similar across groups. Using the minimum peak cortisol level of healthy controls as reference, adrenal insufficiency was more frequent in COVID ICU workers than in non-COVID ICU workers (14% vs 2.9%, $P = .038$). Morning cortisol was never below 3 μg/dL but fell below 5 μg/dL in two COVID ICU workers with inadequate ACTH responses. Psychological scale scores did not differ between participants with and without adrenal insufficiency.

Conclusion: ICU healthcare workers caring for COVID-19 patients had a higher prevalence of PTSD and adrenal insufficiency compared with non-COVID ICU workers, despite similar depression, anxiety, and cortisol responses. These findings indicate that prolonged pandemic-related stress may contribute to both psychological vulnerability and subtle HPA axis dysfunction. Regular psychological screening and endocrine monitoring may help identify at-risk ICU workers during extended public health crises.

Abstract citation ID: lvag096.1476

EP1232 - ECE_2342 - Clinical characteristics and outcomes of endoscopic treatment of pituitary adenomas with Pit-1 and SF-1 coexpression

Barbara Buchalska[1], Maria Maksymowicz[2], Mateusz Bujko[3], Julia Rymuza[3] and Jacek Kunicki[1]

[1]Department of Neurosurgery, Maria Sklodowska-Curie National Research Institute of Oncology, Warsaw, Poland; [2]Warsaw, Poland; [3]Department of Molecular and Translational Oncology, Maria Sklodowska-Curie National Research Institute of Oncology, Warsaw, Poland

Background: Pituitary adenomas arise from three lineages of cells expressing different transcription factors: Pit-1 (somatotroph, lactotroph, thyrotroph, mixed), TPIT (corticotroph), and SF-1 (gonadotroph). Typically, pituitary adenomas express only one of these transcription factors; however, in some cases, tumor cells show expression of several. Coexpression of Pit-1 and SF-1 is particularly common in densely granulated somatotroph adenomas.

Purpose: The aim of this study was to describe the outcomes of endoscopic treatment of pituitary adenomas with Pit-1 and SF-1 coexpression.

Methodology: This was a retrospective analysis of 26 patients (15 women and 11 men) treated between 2020 and 2024 with endoscopic transsphenoidal resections for pituitary adenomas showing Pit-1 and SF-1 coexpression. The mean age of patients was 53 years (range 26-79), and the mean follow-up was 2.4 years.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Results: The main clinical manifestation was acromegaly ($n = 25$; 96.2%). Five patients had visual disturbances (19.2%), and one patient presented with headaches (4.4%). Most patients had macroadenomas ($n = 23$; 88.5%), with an average size of 16 mm. According to the Knosp classification, 3 patients (11.5%) had grade 3 adenomas and 2 patients (7.7%) had grade 4 adenomas. Gross total resection was achieved in most cases ($n = 24$; 92.3%). Immunohistochemistry confirmed positive staining for growth hormone in all patients, for α-subunit in 23 patients, for prolactin in 16, for luteinizing hormone in 6, and for follicle-stimulating hormone in 1. Remission of acromegaly was achieved in 93.8% of patients.

Conclusion: The main clinical manifestation in patients with pituitary adenomas showing Pit-1 and SF-1 coexpression is acromegaly, which can be effectively treated with endoscopic transsphenoidal resection. This method is safe and associated with a low risk of complications.

Abstract citation ID: lvag096.1477

EP1234 - ECE_1063 - A rare case of autoimmune infundibulo-hypophysitis and arginine vasopressin deficiency following mild traumatic brain injuries

Tamar Kvaratskhelia
New Vision University, New Vision Univeristy Hospital, Internal, Tbilisi, Georgia

Introduction: Infundibulo-hypophysitis is a rare condition, and its pathogenesis in the setting of mild head trauma is seldom described. Traumatic brain injury (TBI) is increasingly recognized to cause hypopituitarism, even many years post-injury. Fatih Tanriverdi et al. demonstrated antipituitary antibodies (APAs) in 44.8% of patients three years after TBI, with a significantly higher rate of pituitary dysfunction in APA-positive patients compared with APA-negative patients (46.2% vs 12.5%) (2). These findings suggest that autoimmune mechanisms may contribute to post-traumatic pituitary injury rather than mechanical or ischemic damage alone.

Case Presentation: This report describes a rare case of a 16-year-old female who developed polyuria, polydipsia (>8 L/day), nocturia, headache, and a 7 kg weight loss. Her medical history was notable for a mild TBI (concussion) at age 8 and a recent mild TBI (concussion) while skating, occurring three months prior to symptom onset; both events were managed on an outpatient basis. Initial laboratory evaluation revealed hypernatremia, elevated plasma osmolality, inappropriately low urine osmolality, low copeptin, and low morning cortisol, consistent with arginine vasopressin deficiency and possible secondary hypocortisolism. Anterior pituitary hormones were otherwise within normal limits. MRI findings were consistent with infundibulo-neurohypophysitis, suggestive of autoimmune etiology.

Follow-Up: The patient was started on desmopressin (10 µg/day) and prednisolone (40 mg/day). At 3.5-month follow-up, she reported reduced polyuria and polydipsia (~3 L/day), weight gain of 3 kg, and improved energy and mood. Laboratory parameters, including anterior pituitary functional tests, were within normal limits. Prednisolone was tapered and discontinued gradually. Serial MRI demonstrated positive radiologic changes, with reduction of pituitary and infundibulum hypertrophy following three months of glucocorticoid therapy.

Conclusion: This case highlights a rare instance of autoimmune infundibulo-hypophysitis with arginine vasopressin deficiency following childhood TBI, with clinical exacerbation after a recent TBI. It underscores the importance of considering autoimmune mechanisms in post-traumatic pituitary dysfunction and the need for early diagnosis, appropriate therapy, and longitudinal hormonal and radiologic monitoring.

Keywords autoimmune infundibulo-hypophysitis, traumatic brain injury, arginine vasopressin deficiency

EP1235 - ECE_1389 - Uncontrolled diabetes mellitus revealing underlying acromegaly

Mirjana Bojic[1], Anja Stanic[1], Tamara Dojcinovic[1,2], Ivona Risovic[1,2] and Aleksandra Markovic[1,2]
[1]*University Clinical Center of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina;* [2]*Faculty of Medicine, University of Banja Luka, Banja Luka, Bosnia and Herzegovina*

Acromegaly most often occurs as a result of somatotropic cell adenoma, with hypersecretion of growth hormone. Elevated GH levels stimulate increased hepatic production of insulin-like growth factor 1 (IGF-1). The clinical manifestations of GH and IGF-1 hypersecretion are numerous and often slowly develop over time. Growth hormone, unlike other hormones of the adenohypophysis, has effect on all organs and tissues. In addition, GH has a pronounced diabetogenic effect: it increases blood glucose levels, reduces peripheral glucose uptake, and stimulates insulin secretion, ultimately contributing to the development of diabetes mellitus.

We present the case of a 48-year-old patient who was hospitalized due to unsatisfactory glycoregulation. The diagnosis of type 2 diabetes was established in 2016. Due to the clinically visible acromegaloid habitus, an extensive endocrinological evaluation was performed, and it revealed elevated basal values of IGF1 (1225 ng/mL) with a paradoxical GH rise in the oral glucose load test (OGTT). No abnormalities were detected in the lactotrophic or thyrotrophic axes, while hypogonadotropic hypogonadism was present. Pituitary MRI confirmed a 16-mm pituitary macroadenoma with extension into the cavernous sinus. Neurosurgical consultation was obtained, and surgical treatment via a transsphenoidal approach was indicated. During hospitalization, optimization of the therapeutic regimen resulted in satisfactory glycemic control, achieved with a long-acting insulin analog in combination with metformin, a DPP-4 inhibitor, and dietary measures for diabetes. Follow up after operation revealed residual and still active tumor, so long acting somatostatin analogue was introduced in 4-week intervals leading to better disease control.

Diabetes, as a complication of acromegaly, occurs in about 30% of patients and has a significant impact on the prognosis of the disease. Patients with overt diabetes have a 60% higher overall mortality and twice the risk of cardiovascular mortality compared to those without diabetes. The goal of treatment is to stop the hypersecretion of GH and IGF-1, stop tumor growth, remove comorbidities and preserve pituitary gland function, thereby reducing the risk of disease complications.

Keywords acromegaly, diabetes mellitus, hyperglycemia

EP1236 - ECE_2710 - Ectopic ACTH syndrome associated with Diffuse Idiopathic Pulmonary Neuroendocrine Cell Hyperplasia (DIPNECH): the first reported case in Asia

Wei-Lin Huang and Chia-Hung Lin
Department of internal medicine, Division of metabolism and endocrinology, National Taiwan University Hospital, Taipei City, Taiwan

Introduction: Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH) is a rare preinvasive pulmonary condition characterized by diffuse proliferation of pulmonary neuroendocrine cells, with or without associated tumorlets. Owing to neuroendocrine cell-mediated constrictive bronchiolitis, DIPNECH is frequently misdiagnosed as adult-onset asthma. Although DIPNECH is a known precursor of pulmonary neuroendocrine tumors, its presentation as ectopic adrenocorticotropic hormone (ACTH) syndrome (EAS) is extremely rare, particularly in Asian populations. We report a case of EAS associated with DIPNECH in an Asian woman with long-standing asthma-like symptoms.

Case Presentation: A 62-year-old woman presented with a 5-month history of progressive proximal muscle weakness, Cushingoid appearance, pitting edema and hypertension. Her medical history was notable for "long-standing asthma" treated with inhaled glucocorticoids for several years. Laboratory evaluation revealed hypokalemia, hyperglycemia, high urinary free cortisol, non-suppressible cortisol on the low-dose dexamethasone suppression test, and elevated ACTH, suggesting ACTH-dependent Cushing's syndrome.

Pituitary MRI identified a 3 mm hypo-enhancing lesion, initially raising suspicion for Cushing's disease. However, bilateral inferior petrosal sinus sampling (BIPSS) revealed no central-to-peripheral ACTH gradient, confirming an ectopic source of ACTH. High-resolution chest CT subsequently identified a right middle lobe nodule accompanied by background mosaic attenuation and scattered nodules. Video-assisted thoracoscopic surgery (VATS) confirmed a typical carcinoid tumor arising within a background of diffuse neuroendocrine cell hyperplasia, consistent with DIPNECH. Post-operatively, the patient's symptoms, including muscle weakness and pitting edema, resolved significantly. In addition, her plasma ACTH and cortisol levels normalized rapidly, and her hyperglycemia and hypertension completely resolved without further medication use.

Discussion: This case represents the first reported Asian patient with DIPNECH-associated EAS. Ectopic ACTH secretion from pulmonary neuroendocrine tumors often follows an indolent course, closely resembling Cushing's disease and frequently complicated by incidental pituitary lesions and discordant biochemical testing. In this context, BIPSS remains the definitive diagnostic tool to confirm the origin of ACTH secretion and prevent unnecessary pituitary surgery.

DIPNECH is characterized by diffuse pulmonary neuroendocrine cell proliferation with secretion of bioactive peptides, leading to constrictive bronchiolitis and fixed airflow obstruction that clinically mimics refractory asthma. Therefore, recognition of mosaic attenuation and multiple small pulmonary nodules on high-resolution CT is essential for distinguishing DIPNECH from common bronchial asthma.

Conclusion: This case highlights the diagnostic challenges in ACTH-dependent Cushing's syndrome, underscoring that BIPSS is the gold standard for accurate localization of ACTH excess. DIPNECH should be considered in older non-smoking women with refractory asthma, particularly when accompanied by Cushing's syndrome.

EP1237 - ECE_2215 - Refractory cerebral salt wasting after traumatic brain injury: a case highlighting severe natriuresis and the role of combined sodium and mineralocorticoid therapy

Marjeta Kermaj, Ursina Hajdini, Violeta Hoxha, Klodi Poshi and Agron Ylli
Endocrinology, University Hospital Center "Mother Tereza", Tirana, Albania

Background: Hyponatremia is a common electrolyte abnormality following traumatic brain injury (TBI), most frequently attributed to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) or cerebral salt wasting (CSW). Differentiation between these entities is critical, as therapeutic strategies differ substantially. Although CSW has traditionally been considered rare, recent literature suggests a highly variable incidence, indicating that it may be under-recognized in clinical practice.

Case Presentation: We report a 70-year-old male who developed progressive and refractory hyponatremia after cranial trauma with occipital fracture and frontal contusion. Despite treatment with isotonic and hypertonic saline, serum sodium levels continued to decline. The patient exhibited marked polyuria (up to 3.5 L/day), extreme urinary sodium excretion (570 mmol/24 h), hypouricemia, and absence of edema or cardiac dysfunction. Endocrine evaluation, including thyroid and adrenal function, was normal, and repeat neuroimaging revealed no new acute intracranial pathology. Persistent natriuresis despite aggressive intravenous sodium replacement prompted the addition of high-dose oral sodium supplementation (up to 9 g/day). Ongoing sodium loss suggested an active renal salt-wasting process rather than inadequate replacement. Adjunctive mineralocorticoid therapy with fludrocortisone (initially 100 µg/day, subsequently tapered) was introduced, resulting in gradual stabilization of serum sodium and full clinical recovery.

Conclusion: This case illustrates a severe and refractory form of CSW following TBI, characterized by extreme natriuresis and resistance to conventional saline-based therapy alone. It highlights the importance of recognizing renal sodium wasting as a dynamic process and supports a combined therapeutic approach using intravenous fluids, high-dose oral sodium supplementation, and mineralocorticoid therapy. Early identification and targeted treatment of CSW are essential to prevent prolonged hyponatremia and its associated complications.

EP1238 - ECE_3483 - Pituitary apoplexy after peripheral thrombolysis: a rare cause of acute neuro-ophthalmological deficits and adrenal crisis

Kornel Witek[1], Tomasz Wieczorkiewicz[1], Joanna Sobolewska[2], Lukasz Dzialach[2], Aleksandra Dubiel[3], Jakub Stępień[4] and Przemysław Witek[2]

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

[1]Medical University of Warsaw, Warsaw, Poland; [2]Department of Internal Medicine, Endocrinology and Diabetes, Medical University of Warsaw, Warsaw, Poland; [3]Department of Internal Medicine, Mazowiecki Szpital Bródnowski, Warsaw, Poland; [4]Department of Neurosurgery, Mazowiecki Szpital Bródnowski, Warsaw, Poland

Background: Pituitary apoplexy is a medical emergency caused by acute haemorrhage or infarction within a pituitary adenoma, resulting in rapid tumour expansion, mass effect, and potentially life-threatening hypopituitarism. Although apoplexy is well recognised in several clinical settings, its occurrence following thrombolytic therapy remains rare. We report haemorrhagic infarction of a previously undiagnosed pituitary macroadenoma temporally associated with peripheral thrombolysis, complicated by neuro-ophthalmological deficits and secondary adrenal insufficiency.

Case Report: A 72-year-old man was admitted to the Vascular Surgery Department due to exacerbation of chronic lower limb ischaemia. He underwent angioplasty followed by targeted thrombolysis of a stenotic popliteal artery. In the early postoperative period, he developed acute bilateral ptosis and ophthalmoplegia. Urgent head computed tomography revealed a sellar mass with parasellar extension. Dedicated pituitary MRI confirmed a pituitary macroadenoma with bilateral cavernous sinus invasion, suprasellar extension with optic chiasm elevation, and optic nerve compression, consistent with pituitary apoplexy.

During hospitalisation, the patient became haemodynamically unstable with hypotension (79/50 mmHg). Immediate intravenous hydrocortisone replacement resulted in rapid clinical improvement. After exclusion of other acute causes, the deterioration was attributed to secondary adrenal insufficiency due to corticotropic axis failure (adrenal crisis). The patient was transferred to the Endocrinology Department, stabilised under glucocorticoid coverage, and subsequently underwent planned subtotal transsphenoidal resection of the pituitary tumor. Postoperative recovery was uneventful, with no further impairment of pituitary axes. The patient remains under long-term endocrine follow-up.

Conclusions: Pituitary apoplexy following thrombolytic therapy is a rare but potentially fatal complication. Acute neuro-ophthalmological deficits and/or haemodynamic deterioration in patients receiving anticoagulants or thrombolytics should prompt urgent sellar imaging and immediate administration of stress-dose hydrocortisone, alongside interdisciplinary management.

EP1239 - ECE_3637 - Comprehensive clinical, biochemical and long-term outcome analysis of patients with hypopituitarism

Naciye Guduk Sirvan[1], Polat Ercan[2], Selin Tekin[2], Nergis Basmacı[2], Alperen Onur Işler[2], Suleyman Nahit Sendur[2], Selcuk Dagdelen[2] and Tomris Erbas[2]
[1]Internal Medicine, Hacettepe University Hospital, Ankara, Turkey; [2]Endocrinology, Hacettepe University Hospital, Ankara, Turkey

Background: Hypopituitarism is a severe endocrine disorder characterized by combined anterior and, in some cases, posterior pituitary hormone deficiencies, leading to widespread systemic consequences. Its presentation is often subtle and nonspecific, resulting in delayed diagnosis and preventable morbidity, including adrenal crises and long-term metabolic and cardiovascular complications. This study aimed to comprehensively evaluate the etiological spectrum, clinical features, hormonal profiles, comorbidities, and long-term outcomes of patients with hypopituitarism in a real-world tertiary care setting.

Methods: We conducted a retrospective observational study of 56 patients diagnosed with hypopituitarism between 2000 and 2025 at Hacettepe University School of Medicine. Demographic, clinical, laboratory, imaging, and etiological data were systematically collected, and treatment modalities including hormone replacement, surgery, and radiotherapy were recorded.

Results: A total of 56 patients (27 F/29 M) were analyzed, with a mean age at diagnosis of 34.5 (16-53) years. The leading etiologies were non-adenoma tumor (54.8%), pituitary adenoma (33.3%), autoimmune (4.8%), histiocytosis (4.8%), hereditary (2.4%). The patients were followed for a median of 10 (4-17) years. The median diagnostic delay was 4-6 months. Most patients were diagnosed shortly after the onset of acute symptoms, whereas one patient was diagnosed nearly 35 years after the initial manifestation of symptoms. The most frequent presenting complaints were fatigue (84.1%), weight changes (38.6%), hyponatremia (9.5%), hypotension (2.3%), and reproductive or sexual dysfunction (20.6%). During follow-up, 1.7% of patients experienced at least one adrenal crisis, while 25.8% of the patients required recurrent hospitalizations. The prevalence of major comorbidities—including MASLD, osteoporosis, and cardiovascular disease—was 20.4%, 20.5%, and 10.0%, respectively. The median [IQR] Hepatic Steatosis Index, FIB-4, NAFLD Fibrosis Score, BARD, and APRI scores of 39 patients (69.6%) were 23.2 [10.1-37.1], 0.86 [0.25-1.69], −4.31 [−5.30 to −2.94], 2.0 [2.0-3.0], and 0.18 [0.13-0.33], respectively. Among the patients, 8.9% had cancer, 12.5% had anemia (including 5.4% anemia of chronic disease and 7.1% iron deficiency anemia), and 3.6% had cerebrovascular events (1.8% hemorrhagic and 1.8% ischemic). Mortality during follow-up was 5.4%, with 3.6% due to myocardial infarction and 1.8% due to aspiration.

Conclusion: Hypopituitarism presents with heterogeneous etiologies and nonspecific symptoms, yet is associated with a substantial burden of long-term metabolic, skeletal, and cardiovascular comorbidities. Our findings highlight the need for early recognition and structured, lifelong multidisciplinary follow-up to reduce preventable morbidity and improve long-term outcomes.

EP1240 - ECE_1609 - Early hypocortisolism with persistent remission following osilodrostat therapy in a patient with long-standing Cushing disease

Liat Sasson[1,2] and Ilan Shimon[1,2]
[1]Endocrinology, Institute of Endocrinology, Rabin Medical Center, Petah Tikva, Israel; [2]Gray Faculty of Medical and Health Sciences, Tel Aviv University, Tel Aviv, Israel

Background: Cushing syndrome is a disorder of endogenous hypercortisolism associated with increased morbidity and mortality, requiring effective long-term control of cortisol excess. When pituitary surgery is not feasible or unsuccessful, medical therapy targeting either adrenocorticotropic hormone (ACTH) secretion or adrenal steroidogenesis is commonly employed. Osilodrostat, a potent oral 11β-hydroxylase inhibitor, has emerged as an effective treatment.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Case Presentation: We present a 70-year-old woman with ACTH-dependent Cushing disease due to a pituitary macroadenoma (15 mm), diagnosed in 2008. The patient declined surgery and was managed medically for many years with pasireotide, resulting in marked tumor shrinkage (<4 mm), and later combination therapy with metyrapone due to persistent hypercortisolism. Despite partial biochemical control, urinary free cortisol (UFC) remained elevated, prompting initiation of osilodrostat (2 mg twice daily) in February 2024, with discontinuation of metyrapone.

Within ten days of treatment initiation, the patient developed fatigue, nausea and hypotension. Morning serum cortisol was markedly low (76 nmol/L), consistent with adrenal insufficiency. Osilodrostat was immediately discontinued, and physiologic glucocorticoid replacement was initiated, with rapid clinical improvement.

Outcome and Follow-Up: Despite minimal exposure to osilodrostat, the patient developed sustained cortisol suppression. UFC normalized within approximately five weeks and remained within the normal range throughout nearly two years of follow-up without further Cushing-directed therapy. Morning cortisol levels demonstrated slow and incomplete recovery. A follow-up ACTH measurement revealed elevated ACTH in the presence of low-normal cortisol, suggesting impaired adrenal responsiveness after prolonged ACTH suppression. Clinically, the patient experienced substantial metabolic improvement, including a 16.5-kg weight loss and marked improvement in glycemic control, allowing discontinuation of insulin and GLP-1 receptor agonist therapy.

Conclusion: This is among the earliest documented cases of osilodrostat-induced hypocortisolism with long sustained hormonal remission after treatment discontinuation. It highlights the importance of early monitoring and awareness that prolonged remission may occur in select patients after brief adrenal steroidogenesis inhibition.

Abstract citation ID: lvag096.1484

EP1241 - ECE_1679 - Association of iodine status and sex with sleep duration in adults: an analysis of NHANES 2005-2020

Stella Proikaki[1], Eleni Kouroglou[1], Efthymia Kallistrou[1], Dimitra Ragia[1], Dimitra Motsiou[1], Vasiliki Tsiama[1], Konstantinos Belis[1], Ioannis Ilias[1], Athanasios Tselebis[2], Lina Zabuliene[3] and Christos Savvidis[1]

[1]Department of Endocrinology, Hippocration General Hospital of Athens, Athens, Greece; [2]Department of Psychiatry, Sotiria Hospital, Athens, Greece; [3]Faculty of Medicine, Vilnius University, Vilnius LT-03101, Lithuania

Introduction: Sleep duration changes with age and differs by sex, impacting metabolic and cognitive health. Iodine, essential for thyroid hormone synthesis, may influence sleep regulation, but its interaction with age in relation to sleep duration is not well studied.

Aim: To examine whether iodine status modifies the relationship between age and sleep duration in adults, and to assess the roles of sex and iodine status.

Materials and Methods: Data from adults (≥18 years) with urinary iodine concentration (UIC) and self-reported sleep duration from NHANES 2005-2020 were analyzed. UIC was categorized as ≤150 µg/L or >150 µg/L. ANCOVA was conducted with sleep duration (hours) as the dependent variable, iodine status and sex as fixed factors, age as a covariate, and interaction terms for iodine status × age and iodine status × sex included to evaluate moderation effects.

Results: Data from 17 564 adults (mean age 47.5 ± 17.3 years, 51.3% female) were analyzed. Females reported longer sleep duration than males ($P < .001$). Iodine status alone was not associated with differences in mean sleep duration ($P = .922$). Critically, a significant interaction was found between iodine status and age ($P < .001$), indicating that the relationship between age and sleep duration differed between iodine status categories: Among individuals with UIC ≤150 µg/L, sleep duration showed a different trajectory across age compared to those with UIC >150 µg/L ($P < .001$). No significant interaction between iodine status and sex was observed ($P = .290$).

Discussion: While iodine status does not affect overall sleep duration, it significantly alters how sleep duration changes with age. This may reflect the role of iodine-dependent thyroid function in age-related sleep regulation, with iodine sufficiency potentially buffering or modifying age-associated sleep changes.

EP1242 - ECE_2473 - Telemedicine-based management of an ophthalmic emergency caused by a non-functioning pituitary macroadenoma in a satellite charity clinic during war and displacement

Hessa Albanki[1], Mohammed Al Mutasim[2], Waiel Bashari[3] and Azmi Mohammed[1]

[1]Department of Endocrinology and Metabolism, Johns Hopkins Aramco Healthcare, Dhahran, Saudi Arabia; [2]Sudan Pituitary Foundation, Khartoum, Sudan; [3]Addenbrooks Memory Clinic, Cambridge, United Kingdom

Background: Armed conflict and population displacement severely disrupt access to specialist endocrine and neurosurgical care. Pituitary macroadenomas presenting with acute or progressive visual compromise constitute ophthalmic emergencies requiring timely multidisciplinary intervention. Telemedicine may provide a critical bridge in such settings.

Case: We report the case of a 54-year-old displaced Sudanese man presenting to a satellite charity clinic during continuing hostilities with progressive visual field loss. Remote assessment identified bitemporal hemianopia with reduced visual acuity, confirmed on formal automated perimetry. Hormonal evaluation demonstrated partial anterior hypopituitarism with preserved hypothalamic–pituitary–adrenal axis and normal prolactin. MRI revealed a large (≈4 cm) non-functioning pituitary macroadenoma causing chiasmal compression with sphenoid sinus invasion and no significant cavernous sinus involvement.

Using a telemedicine-based model, input from endocrinology, ophthalmology, neuroradiology, and neurosurgery was coordinated across borders. Urgent referral for transsphenoidal surgery was facilitated despite displacement and healthcare system fragmentation. The patient underwent a successful transsphenoidal resection. Histopathology confirmed a pituitary neuroendocrine tumour (adenoma), NOS, with negative pituitary hormone immunostaining and a low proliferative index (Ki-67 ≈2%). Postoperative MRI demonstrated no residual or recurrent tumour with decompression of the optic chiasm. Visual and neurological outcomes stabilized postoperatively.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusion: This case illustrates how telemedicine-enabled multidisciplinary collaboration can successfully manage ophthalmic endocrine emergencies in conflict zones. Structured remote triage, data sharing, and international referral pathways can lessen delays, preserve vision, and deliver specialist care under extreme healthcare disruption. Such models have wider significance for endocrine emergency care in humanitarian settings.

*The Sudan Pituitary Foundation is a charitable, not-for-profit organization registered in Sudan, dedicated to the management and support of Sudanese patients with pituitary disorders. The Foundation primarily utilises telemedicine technologies and a multidisciplinary model of care to deliver specialized healthcare services and comprehensive support to individuals affected by pituitary diseases.

EP1243 - ECE_1263 - Giant prolactinoma with central hypopituitarism: dramatic biochemical and clinical response to dopamine agonist therapy

Andrew Gerges[1], Suresha Muniyappa[2] and Paula Marchetti[2]
[1]*Sheffield teaching hospitals NHS trust, Sheffield, United Kingdom;* [2]*Doncaster Royal Infirmary, Doncaster, United Kingdom*

Background: Prolactinomas are the most common hormone secreting pituitary tumours and account for up to 40% of pituitary adenomas. They are categorised by size into microprolactinomas (<10 mm), macroprolactinomas (≥10 mm) and giant prolactinomas (≥40 mm). Giant prolactinomas are uncommon and characteristically invasive, frequently presenting with a combination of markedly elevated prolactin levels, mass effect symptoms and varying degrees of hypopituitarism. Current European guidelines recommend dopamine agonists as first line therapy regardless of tumour size, with surgery reserved for visual compromise not improving with medical treatment, dopamine agonist resistance or intolerance, or in cases of apoplexy. We describe a giant prolactinoma presenting with central hypothyroidism and hypogonadism, demonstrating a significant biochemical and clinical response to medical therapy.

Case Report: A 45-year-old man was evaluated for ejaculatory dysfunction. Initial testing showed profound hyperprolactinaemia (220 948 mU/L), central hypogonadism (testosterone 1.70 nmol/L with low LH and FSH), central hypothyroidism (free T4 7.5 pmol/L with inappropriately normal TSH) and no biochemical evidence of adrenal insufficiency. He reported fatigue, headaches, visual blurring, dizziness, low libido and generalised aches. He denied galactorrhoea, rhinorrhoea or erectile dysfunction. Past medical history included repaired atrial septal defect, pulmonary valve stenosis and chronic hepatitis B.

MRI revealed a more than 4 cm invasive pituitary macroadenoma remodelling the clivus, displacing the optic chiasm, encasing the left internal carotid artery and extending into both cavernous sinuses. The patient had no symptoms of cerebrospinal fluid (CSF) leak. Visual fields were normal on confrontation, but formal perimetry demonstrated gross bilateral field depression, leading to advice not to drive. Baseline echocardiography was stable.

Cabergoline was initiated at 250 µg twice weekly and escalated, with the patient later stabilised on 500 µg twice weekly. After one month, prolactin fell to 19 526 mU/L, and on subsequent review decreased further to 476 mU/L, representing a more than 99% reduction from baseline. Due to persistently low free T4 and testosterone levels, the patient was established on levothyroxine and testosterone replacement. He is currently awaiting repeat MRI to evaluate tumour shrinkage and guide ongoing management.

Conclusion: This case highlights the potential for marked prolactin reduction, hormonal stabilisation and clinical improvement in giant prolactinomas managed with dopamine agonist therapy alone. Even in large, invasive tumours, effective medical therapy may delay or avoid the need for surgery. Multidisciplinary coordination remains essential to optimise tumour control, visual outcomes and endocrine replacement.

Abstract citation ID: lvag096.1487

EP1244 - ECE_2800 - Incidental sellar region lipoma: a case highlighting the importance of comprehensive evaluation in sellar region lesions

Elene Dophidze[1,2], Nino Gabidzashvili[1], Nana Nakaidze[1], Kristine Ambriashvili[1], Nana Iorashvili[1], Tamara Antia[3], George Gegia[4], Elena Bezhentseva[4], Ketevani Jakhtanidze[4], Giorgi Katchakhidze[4], Tina Iordanishvili[1] and Ketevan Ghibradze[1]
[1]*Department of Endocrinology, American Hospital Tbilisi, Tbilisi, Georgia;* [2]*American Hospital Tbilisi, Tbilisi, Georgia;* [3]*Department of Radiology, "American Hospital Tbilisi", Tbilisi, Georgia;* [4]*Neurosurgery, "American Hospital Tbilisi", Tbilisi, Georgia*

Introduction: Intracranial lipomas are rare congenital malformations with an autopsy incidence ranging from 0.08% to 0.46%, resulting from persistence and abnormal differentiation of the meninx primitiva during development of the subarachnoid cisterns. These benign fatty lesions are typically asymptomatic and discovered incidentally on neuroimaging performed for unrelated indications. In the sellar region, lipomas typically occur in the suprasellar cistern, accounting for approximately 10%-15% of all intracranial lipomas. Conservative management is standard given their benign nature and the technical challenges of surgical resection due to adherence to neurovascular structures.

Case Presentation: We present a case of a 22 year old man with an incidentally discovered intra-suprasellar lipoma. The patient initially developed uncontrollable upper eyelid movements in May 2025, followed by difficulty speaking and uncontrollable movements of the left upper extremity and left great toe in September 2025. These symptoms gradually improved spontaneously over time. Brain MRI, performed during workup of these neurological symptoms, revealed an intrasellar lesion with suprasellar extension, measuring 26 mm at its greatest dimension. The lesion demonstrated characteristic T1 hyperintensity with complete signal suppression on fat-saturated sequences, consistent with a lipoma.

Surgery was initially considered given the lesion size. However, comprehensive endocrine evaluation revealed no evidence of hypopituitarism. Visual field perimetry showed no defects, and visual acuity was normal. Neurological examination revealed no focal deficits, and the presenting symptoms showed no anatomical correlation with the sellar lesion location. The lipoma was therefore determined to be an incidental finding unrelated

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

to the patient's neurological symptoms. Given the benign nature of the lipoma, absence of hormonal dysfunction, normal visual function, and lack of mass effect symptoms, conservative management with clinical and radiological surveillance was chosen.

Conclusion: This case highlights the importance of comprehensive endocrine evaluation in managing sellar region lesions. Despite considerable size, asymptomatic intra-suprasellar lipomas can be safely managed conservatively, avoiding unnecessary surgical intervention. Clinicians should recognize that incidental sellar findings should not be automatically attributed to presenting symptoms without clear anatomical and physiological correlation. This approach emphasizes patient-centered care and careful use of surgical resources.

EP1246 - ECE_1571 - Clinical spectrum of benign pituitary tumors: a five-year retrospective analysis

Aleksandra Markovic[1,2], Tamara Dojcinovic[1,2], Ivona Risovic[1,2], Jelena Malinovic Pancic[1,2], Valentina Soldat Stankovic[1,2], Suzana Savic[2,3] and Tamara Popovic Peric[2,4,5]

[1]University Clinical Center of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina; [2]Faculty of Medicine, University of Banja Luka, Banja Luka, Bosnia and Herzegovina; [3]Faculty of Medicine, University of East Sarajevo, East Sarajevo, Bosnia and Herzegovina; [4]PHI Hospital "Sveti Vračevi", Bijeljina, Bosnia and Herzegovina; [5]Faculty of Medicine, University of Novi Sad, Novi Sad, Serbia

Introduction: Benign pituitary tumors are predominantly slow-growing lesions with variable clinical presentation. Their manifestations depend on hormonal activity, tumor size, and local mass effects, resulting in a spectrum ranging from incidental findings to clinically significant endocrine and neurological disturbances. Although histologically benign, these tumors may be associated with considerable morbidity due to hormonal hypersecretion, hypopituitarism, or compression of adjacent structures. Epidemiological data suggest that pituitary adenomas are relatively common, yet their clinical behavior remains heterogeneous. A comprehensive evaluation of clinical, endocrine, and radiological characteristics is essential for accurate diagnosis and optimal management. This study aimed to characterize the clinical spectrum of benign pituitary tumors, with emphasis on demographic features, hormonal activity, and tumor size in a tertiary care setting.

Methods: This retrospective cohort study included patients diagnosed with benign pituitary tumors and treated at a tertiary referral center between 2019 and 2023. All patients underwent standardized clinical assessment, hormonal evaluation, and pituitary magnetic resonance imaging. Demographic data, endocrine profiles, and radiological characteristics were collected from medical records. Tumor size and invasiveness were determined based on MRI findings. Tumors were classified as functioning or non-functioning according to biochemical evidence of hormonal hypersecretion. Statistical analyses assessed associations between clinical characteristics and tumor features.

Results: The study population included patients aged 20-85 years, with a mean age of 48.61 years (SD = 17.60). Among 53 patients with available hormonal data, functioning adenomas were identified in 79.2% of cases, with prolactin-secreting tumors being the most frequent subtype (64.1%). Macroadenomas were present in 58.0% of patients, while radiological evidence of invasive growth was observed in 22.4%. A subset of patients ($n = 21$) required surgical treatment, most commonly via a transsphenoidal approach (76.2%). Complete tumor resection was achieved in 17.7% of cases, and biochemical remission was documented in 5.9% of patients.

Conclusions: Benign pituitary tumors in this cohort were predominantly functioning and frequently diagnosed as macroadenomas, underscoring the need for early recognition and structured endocrine evaluation. Timely radiological assessment and management in specialized centers may improve therapeutic outcomes and reduce disease-related morbidity.

EP1247 - ECE_3606 - ACTH-dependent Cushing's syndrome: diagnostic pitfalls and personalised treatment strategies: a case series

Tiberiu Gabriel Manole[1], Ionela Baciu[1,2], Anda Dumitrascu[1] and Catalina Poiana[1]

[1]C I Parhon National Institute of Endocrinology, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania

Introduction: Cushing's syndrome (CS) is caused by increased cortisol production from the adrenals or by ACTH secretion from a pituitary tumour (Cushing disease – CD) or non-pituitary tumour (ectopic secretion), leading to increased morbidity and mortality. The first line of treatment is surgery, but medical treatment, radiation or bilateral adrenalectomy are needed for recurrences or inoperable lesions.

Objective and Methods: To present the therapeutic challenges and individualised treatment options in 3 patients with ACTH-dependent CS, treated in a tertiary centre.

Results: The first patient is a 61-year-old female with a microprolactinoma (responsive to low-dose cabergoline), who developed CD due to a second pituitary microadenoma 10 years later, complicated with obesity, hypertension, diabetes mellitus, dyslipidaemia. Inferior petrosal sinus sampling was not available for the lateralisation of the ACTH secretion – she underwent selective neurosurgery on the biggest lesion followed by a second surgery due to persistent hypercortisolism, with a resolution of the CD and the metabolic syndrome. Three years later, CD relapsed, without identifiable pituitary or ectopic lesions on imaging. Low-dose pasireotide was initiated, with biochemical control and favourable metabolic evolution.

The second patient is a 51-year-old woman with an invasive non-functioning pituitary macrodenoma, who underwent 2 partial adenomectomies and radiotherapy. Thirteen years later tumour progression was accompanied by the development of CD and metabolic complications – she underwent a third surgery, with persistent hypercortisolism. Pasireotide achieved cortisol control, but the diabetes worsened, therefore she was switched to ketoconazole, with a good biochemical and metabolic response.

The third patient is a 67-year-old woman with a florid Cushing phenotype, weight loss, hypokalaemia, markedly elevated

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

cortisol, ACTH and DHEAS levels. Extensive imagery (pituitary, chest and abdomen) came back negative, with the exception of a small indeterminate renal lesion. The somatostatin receptor scintigraphy and the inferior petrosal sinus sampling also failed to localise the ACTH source. She was initially started on ketoconazole, with a partial biochemical response, therefore she was switched to osilodrostat with a good clinical and hormonal evolution. She was referred to Nephrology for a renal biopsy, given the severe initial clinical and biochemical profile, suggesting a possible ectopic ACTH secretion (even though the scintigraphy was negative).

Conclusion: ACTH-dependent CS remains a complex condition with significant challenges, particularly in recurrent disease, aggressive pituitary tumours or occult ectopic ACTH secretion. These cases underscore the importance of a personalised approach and demonstrate the expanding role of medical therapies when surgical cure is not attainable.

EP1248 - ECE_1820 - An aggressive prolactin-secreting pituitary adenoma resistant to multimodal therapy: a case report

Daniela-Georgiana Amzar[1], Mihaela Maria Vlad[1], Melania Balas[1], Ioana Golu[1], Stoian Dana[1], Oriana Pelineagră[1] and Laura Cotoi[2]
[1]*Endocrinology, Spitalul Clinic Județean de Urgență Timișoara, Timișoara, Romania;* [2]*Endocrinology, Centre Hospitalier de Luxembourg, Luxembourg, Luxembourg*

Introduction: Pituitary adenomas are the most common cause of sellar masses from the third decade on, accounting for up to 10% of all intracranial neoplasms. The pituitary tumor transforming gene is overexpressed in most lactotroph adenomas. It also appears to play a role in tumor invasiveness since expression is increased in tumors that invade the sphenoid bone.

Case Presentation: We report the case of a 47-year old male patient, diagnosed in 2013 with a prolactin secreting adenoma. At presentation, the patient exhibited optic field defects, which was subsequently confirmed by magnetic resonance imaging (MRI) to be caused by a large sellar mass compressing the optic chiasm and extending into the third ventricle (4.3/3.2/4 cm).

At diagnosis, the patient's serum prolactin was 4319 ng/mL. Medical treatment with dopamine agonists (Cabergoline) was initiated at a dose of 0.5 mg and later increased to 1.5 mg weekly. Biochemical response was achieved with afore-mentioned dosage with prolactin levels maintained below 100 ng/mL until 2016.

Reimaging by MRI was performed in 2016 as prolactin levels suddenly increased. Rapid growth of the adenoma was observed on serial imaging, as well as important prolactin elevation above 2000 ng/mL. Prolactin levels remained elevated despite medical treatment and transsphenoidal surgery was advised in 2019. Postoperative prolactin levels remained over 2000 ng/mL, when a second surgery was performed in 2020, followed by external radiotherapy without any regression in tumor size or prolactin levels.

After a multidisciplinary approach, combined therapy with Cabergoline (6 mg weekly) and Temozolomide (100 mg 5 tablets weekly) was initiated.

At the most recent follow-up, a favourable biochemical response was noted with prolactin levels decreasing to near-normal levels (75 ng/mL), although radiologic control of the pituitary mass has not yet been achieved.

Conclusion: Temozolomide has been documented as valuable for the treatment of aggressive pituitary adenomas and carcinomas. No significant complications have been attributed to temozolomide therapy. Thus, temozolomide is an effective treatment for most aggressive adenomas and carcinomas.

EP1249 - ECE_2494 - Acromegaly with multisystem manifestations in a patient with hypothyroidism and multinodular goiter

Mariam Orjonikidze[1], Nino Zavrashvili[1] and Ia Kavtiashvili[2]
[1]*Endocrinology, Tbilisi Institute of Medicine (TIM), Tbilisi, Georgia;* [2]*Tbilisi Institute of Medicine (TIM), Tbilisi, Georgia*

Background: Acromegaly is a rare endocrine disorder caused by chronic growth hormone (GH) excess, most commonly due to a pituitary adenoma. Its insidious onset often leads to delayed diagnosis and significant multisystem involvement. Coexisting thyroid disorders may further obscure the clinical picture.

Case Presentation: A postmenopausal woman presented with a 2-3-year history of progressive acral enlargement, soft tissue swelling of the hands and feet, arthralgia, hyperhidrosis, tachycardia, and episodic hypertension. She reported an increase in shoe size and inability to wear rings. Her medical history was notable for **hypothyroidism associated with multinodular non-toxic goiter**, diagnosed in 2021 and treated with **levothyroxine**.

Biochemical evaluation demonstrated markedly elevated insulin-like growth factor-1 (IGF-1: 742 µg/L). Thyroid function tests were within reference range under levothyroxine therapy, and thyroid autoantibodies were negative. Pituitary magnetic resonance imaging revealed a $3.0 \times 2.6 \times 2.1$ cm intra-, infra- and suprasellar pituitary macroadenoma with mild parasellar extension and pituitary stalk deviation, without optic chiasm compression.

The patient underwent transsphenoidal transnasal pituitary adenomectomy in December 2024. Following surgery, she experienced significant clinical improvement, including resolution of hypertension and snoring, reduction of acral and facial edema, and improvement in arthralgia and skin texture. Postoperative hormonal assessment confirmed biochemical remission (IGF-1: 111 µg/L; GH: 1 ng/mL). Mild postoperative adrenal insufficiency was suspected and managed with low-dose hydrocortisone, resulting in improved energy levels.

Conclusion: This case highlights the diagnostic challenges of acromegaly in the presence of coexisting hypothyroidism and multinodular goiter. Awareness of progressive somatic changes and careful hormonal evaluation are essential for timely diagnosis. Surgical management can achieve biochemical remission and marked clinical improvement, while long-term follow-up remains crucial to monitor pituitary function and associated comorbidities.

EP1250 - ECE_3051 - The role of surgical expertise in achieving durable outcomes after transsphenoidal surgery for acromegaly

Mariam Pailodze[1,2], Salome Kalandadze[1,3], Nino Pailodze[2] and Zviad Malazonia[1]

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

[1]Caucasus Medical Centre, Tbilisi, Georgia; [2]David Tvildiani Medical University, Tbilisi, Georgia; [3]Endocrinology, Caucasus Medical Center, Tbilisi, Georgia

Background: Pituitary macroadenomas causing acromegaly represent a considerable therapeutic challenge because of their size, excessive hormone secretion, and the potential risk of postoperative hypopituitarism. Transsphenoidal surgery remains the preferred approach for achieving rapid tumor reduction and hormonal control; however, long-term outcomes and preservation of pituitary function remain key indicators of treatment success.

Case Presentation: 60-year-old female diagnosed with a pituitary macroadenoma causing acromegaly who underwent endoscopic transnasal transsphenoidal surgery performed by an experienced neurosurgeon. Preoperatively, insulin-like growth factor-1 (IGF-1) was markedly elevated at 418.05 ng/mL (reference range 17-323). Early postoperative evaluation demonstrated preserved pituitary function, with normal prolactin, thyroid, adrenal, and growth hormone levels.

During follow-up, serial biochemical assessments remained within normal ranges. At two months postoperatively, IGF-1 decreased to 154 ng/mL, with normal PRL, cortisol, TSH, FT4, electrolytes, and glucose. At three months, oral glucose suppression testing confirmed biochemical remission, with GH decreasing from 1.56 ng/mL at baseline to 0.47 ng/mLtwo hours after 75 g glucose. MRI demonstrated postoperative sellar changes without evidence of residual or recurrent adenoma, later evolving into secondary empty sella.

MRI performed three years postoperatively showed stable postoperative sellar anatomy with secondary empty sella formation and no radiological evidence of adenoma recurrence. The pituitary stalk was midline, and the optic apparatus was preserved. No additional hormonal abnormalities were identified during subsequent follow-up evaluations.

Conclusion: This case highlights that successful management of large pituitary macroadenomas extends beyond biochemical remission. Surgical expertise is a key determinant of outcome**,** as experienced transsphenoidal surgeons can achieve effective tumor debulking while preserving pituitary function, leading to durable radiological control and excellent long-term endocrine outcomes.

EP1251 - ECE_3468 - Recurrent craniopharyngioma—between the benign nature of the case and clinical aggressiveness

Diana Taifas[1], Ionela Baciu[1], Camelia Procopiuc[2] and Catalina Poiana[1]

[1]C.I.Parhon National Institute of Endocrinology, Bucharest, Romania; [2]Pediatric Endocrinology, C.I. Parhon National Institute of Endocrinology, Bucharest, Romania

Introduction: Craniopharyngioma is a rare epithelial tumor arising from embryological remnants of the pituitary gland, with an estimated incidence of 0.5-2 cases/million/year. Although histologically benign, it demonstrates a distinctive and often aggressive clinical behavior due to its location near critical hypothalamic–pituitary structures and its pronounced tendency to recur. Consequently, craniopharyngioma is associated with significant long-term morbidity, particularly in pediatric patients, affecting growth, endocrine function, metabolism, and overall quality of life. Management remains complex and requires a multidisciplinary approach integrating neurosurgery, radiotherapy, endocrinology, and nutritional support.

Case: We report the case of a 22-year-old male patient who was initially diagnosed with craniopharyngioma at the age of five. The patient underwent two transsphenoidal surgical resections at five and six years of age. In 2015, imaging revealed a left frontal recurrence, which was treated with surgical resection followed by adjuvant proton beam therapy consisting of thirty sessions, completed in 2016. In 2021, radiological findings raised suspicion of another recurrence, which progressed requiring an additional surgical intervention in August 2025. This prolonged clinical course illustrates the particularly aggressive and recurrent nature of the disease.

Following repeated surgical procedures, the patient developed permanent global hypopituitarism, necessitating lifelong hormone replacement therapy. Central diabetes insipidus secondary to vasopressin deficiency was also diagnosed and is currently treated with desmopressin. A major associated complication is severe obesity of mixed etiology, resulting from hypothalamic damage and increased caloric intake, present since childhood and difficult to manage. Despite persistently low insulin-like growth factor 1 levels and unfavorable metabolic consequences, stature was in accordance with genetic target height and growth hormone replacement therapy has not been initiated due to concerns related to the history of multiple tumor recurrences.

Conclusions: This case highlights the substantial challenges in the management of recurrent craniopharyngioma. Despite its benign histological appearance, the tumor may behave in a clinically aggressive manner, requiring repeated surgical interventions and radiotherapy. Long-term endocrine and metabolic complications represent a burden comparable to local tumor control. A coordinated, individualized, and multidisciplinary long-term strategy is essential to improve survival outcomes and preserve quality of life in affected patients. Early recognition of recurrence, careful endocrine monitoring, and patient-centered follow-up are crucial for minimizing morbidity, guiding therapeutic decisions, and supporting long-term psychosocial adaptation in young adults living with this chronic condition after childhood onset and treatment.

EP1252 - ECE_2649 - Silent but significant: a rare case of a dopamine-secreting carotid body tumour

Muhammad Sohail Akhtar[1,2], Kushaa Vohra[1], Ann Francis[1] and Cornelius Fernandez James[1]

[1]Diabetes & Endocrine, Pilgrim Hospital Boston(United Lincolnshire Hospitals NHS Trust), Boston, United Kingdom; [2]Endocrine &diabetes, Pilgrim Hospital Boston, Boston, United Kingdom

Introduction: Carotid body tumours are a rare paraganglioma (prevalence 1 in 100 000), originating from the chemoreceptive carotid body at the carotid bifurcation. While most are non-secretory, a minority (4%) secrete dopamine or its metabolite 3-methoxy tyramine. We present a case of a rare asymptomatic non-malignant dopamine-secreting carotid body tumour.

Case Presentation: A 68-year-old lady presented with a six-month history of a painless, left-sided neck swelling. Examination revealed a soft, non-tender, non-pulsatile 3 cm

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

mass in the left cervical region. Ultrasound neck: 29 × 26 × 23 mm solid hypervascular mass, suggesting carotid body tumour. A non-contrast MRI neck revealed a 33 × 26 × 24 mm carotid body tumour, further characterised by contrast-enhanced CT neck and thorax: 33 × 24 mm hypervascular soft-tissue density mass at the bifurcation of the left common carotid artery with characteristic displacement and splaying of internal and external carotid arteries, consistent with a carotid body tumour. CT abdomen and pelvis: no other paraganglioma.

Biochemistry revealed consistently raised plasma 3-methoxytyramine (3-4-fold) at 749, 640, and 590 pmol/L (reference range 0-180), with normal metanephrine/normetanephrine levels confirming the diagnosis of dopamine-secreting carotid body paraganglioma. Patient remained asymptomatic and normotensive with no features of catecholamine excess. Genetic testing for hereditary paraganglioma syndromes did not identify any pathogenic variants. Following multidisciplinary input from ENT and vascular surgery, surgical resection was agreed. The patient is currently awaiting surgery.

Discussion: Dopamine is the neurotransmitter of carotid body cells. Hence, a carotid body tumour could potentially secrete dopamine. However, these tumour cells are well-differentiated maintaining vesicular storage/efficient dopamine reuptake, so dopamine is not usually secreted into the bloodstream. Our case is peculiar as this is a dopamine-secreting carotid body tumour.

Carotid body paraganglioma is the most common (60%) "Head and Neck paraganglioma" (HNPGL), others being vagal (10%), middle ear (30%) and laryngeal (very rare) paragangliomas. HNPGLs constitute only 0.6% of all head and neck neoplasms. Carotid body tumours typically affect women (F: M 2:1) aged 50-60 years, often asymptomatic (painless neck lump) and unilateral (bilateral 10%-25%).

Nearly one-third (33%-40%) of carotid body tumours are hereditary secondary to *SDHx* mutation, and only 3-10% present with metastasis. Surgery is the definitive treatment, though it carries risks of bleeding, stroke and lower cranial nerve palsy. Pre-operative angiography and a multidisciplinary approach are necessary.

Conclusion: A high index of suspicion, appropriate imaging, hormonal workup and multidisciplinary approach remain paramount for optimal management of carotid body paragangliomas.

EP1255 - ECE_1780 - A teenager with central diabetes insipidus and puberty arrest: current status a decade after initial diagnosis

Eleni Palioura[1], Maria Rigana[2], Maria Katsafyloudi[2], Alexandros Konidaris[2] and Andromahi Vryonidou[2]
[1]*Hellenic Red Cross Hospital, Athens, Greece;* [2]*Department of Endocrinology and Diabetes Center, Hellenic Red Cross Hospital, Athens, Greece*

Introduction: Central diabetes insipidus (CDI) is a rare clinical entity caused by deficiency in the secretion of arginine vasopressin (AVP) from the posterior pituitary gland. In children and adolescents, its presence may be indicative of underlying pathology including intracranial tumors, granulomatous or infiltrative disorders with hypothalamic and/or pituitary involvement or inflammatory/autoimmune conditions affecting pituitary. As the diagnosis and course of these diseases may not be clear, systematic follow-up of young patients is imperative.

Case Report: We present the case of a $16^{8/12}$–year-old teenager, who was referred to our department with symptoms of polyuria/nocturia and polydipsia since the age of 12, leading to consumption of almost ten liters of liquids daily. Pediatric history was remarkable for a decline in height charts from the 50th to 3th percentile since the age of 12, in parallel with puberty arrest at Tanner stage III (testicular volume of 12 mL) when symptoms started.

The CDI diagnosis was established through water deprivation testing. Anterior pituitary function tests revealed low testosterone levels for Tanner stage (Testo = 0.961 ng/mL, normal range:2-8.5), with inappropriately low gonadotropin levels (FSH = 2.23 mIU/mL and LH = 3.03 mIU/mL), a finding indicative of gonadotropic cells deficiency. IGF-1 levels (196 ng/mL) were at the lower-normal range for patient's age and Tanner stage. Magnetic resonance imaging (MRI) revealed a relatively small for patient's age adenohypophysis (dmax = 4.5 mm), with absence of high signal intensity in the posterior pituitary gland and a focal pituitary stalk thickness (4 mm). An extensive laboratory and imaging workup revealed no coexisting pathology, making hypophysitis in remission the most likely diagnosis, with possible onset at 12 years of age.

Therapeutically, patient started desmopressin (60 mcg, 3 times/daily) and transdermal testosterone 10 mgT/day, gradually titrated to 30 mgT/day. Over the subsequent three years, he gained 9.5 cm in height, reaching the 20th percentile on growth charts (final height = 172 cm) and secondary sexual characteristics continued to develop. Four years after initial presentation, complete recovery of hypothalamic-pituitary-gonadal axis was observed, leading to discontinuation of testosterone therapy, with normal testosterone (6.7 ng/mL) and FSH/LH (4.7/3.6 mIU/mL) levels and bilateral testicular size of 20 mL. IGF-1 levels were also normal (264 ng/mL). Notably, no differences were observed in annual MRI findings over the follow-up period. Ten years since initial presentation, our patient is a thriving young adult with CDI well-regulated on desmopressin and no other emerging pathology.

Discussion: Adolescents with CDI but without confirmed diagnosis at initial evaluation, require long-term neuroimaging and endocrine follow-up to exclude any underlying etiology.

Abstract citation ID: lvag096.1496

EP1258 - ECE_2893 - Pancreatic neuroendocrine neoplasms in association with MEN-1 syndrome- particularities in two clinical cases

Stanca Oana Stefania[1], Andreea-Alexandra Grosu[2], Beatrice Cristea[2] and Corin Badiu[2]
[1]*Thyroid Disorders IV, National Institute of Endocrinology C.I.Parhon, Bucharest, Romania;* [2]*National Institute of Endocrinology C.I.Parhon, Bucharest, Romania*

Background: Pancreatic NENs tend to be less aggressive when arising in the setting of MEN-1 compared to sporadic pancreatic NENs. There have been very important improvements over the past years in both genotyping, genetic counselling and family screening.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Materials and Method: We followed the clinical and biological evolution of two patients diagnosed at the National Institute of Endocrinology "C.I.Parhon", Bucharest, Romania, with pancreatic NENs and secondary determinations, associated with MEN-1 syndrome. In both cases, family genetic testing was performed and they underwent treatment with peptide receptor radionuclide therapy (PRRT).

Results: Case 1. A 59-year-old patient, with a 41-year history of an operated bronchial carcinoid tumor G2 and primary hyperparathyroidism treated surgically at age 43, as well as a macroprolactinoma managed with dopaminergic agonists, has presented since 2012 with two pancreatic lesions, non-invasive with total size 58/31 mm. These lesions were accompanied by elevated chromogranin A and serotonin levels. Genetic analysis identified a synonyumus heterozygous mutation in p.Ala213 aminoacid, classified as likely pathogenic. The mutation was also positive in 5 other cases from his family. The patient was among the first in our department to receive PRRT with 177-Lutetium-DOTATOC in Basel. This treatment yielded initially a partial response per RECIST 1.1 criteria, however, by 2024, the patient experienced tumor progression leading to referral for surgery in June 2025. A laparoscopic corporeocaudal splenopancreatectomy was performed, with histopathological and immunohistochemical analysis confirming a well-differentiated pancreatic NEN G2. Postoperative recovery was favourable, with a decline in tumor marker levels.

Case 2. A 43-year-old patient diagnosed at 41 with pancreatic G1-NET, with secondary lymphnode determinations and primary hyperparathyroidism twice operated. Genetic testing revealed a heterozygous deletion in exon 7 of the *MEN1 gene* (pPro320 del), classified as pathogenic, a mutation also present in one of his two sons. In addition to treatment with somatostatin analogues and chemotherapy, the patient also benefited from PRRT, in the same center as the patient in the previous case. One year after, the patient presented a decrease in biochemical markers and partial response according to RECIST1.1 criteria.

Conclusions: Alongside genetic screening development, medical, surgical and radionuclide treatments have improved morbidity and quality of life in many patients. Despite this progress, there is still space for improving into the geneticf actors in relation to the biological mechanisms determining NENs as part of MEN-1.

Abstract citation ID: lvag096.1497

EP1259 - ECE_2406 - Epidemiology of somatotropic pituitary adenomas in the city of Oran

Khadra Faraoun[1] and Chentli Farida[2]
[1]*Faculté de Médecine d'Oran, Endocrinology, Clinique Larribere d'Endocrinologie, Oran, Algeria;* [2]*Université Alger, Alger, Algeria*

Introduction/Objectives: Somatotroph pituitary adenomas (SPAs) are tumors that develop from pituitary somatotroph cells. Our objective is to evaluate their prevalence and incidence rates in Oran, Algeria.

Subjects and Methods: Our study is observational, multicenter, with prospective and retrospective data collection. Data entry and analysis were performed using CDC (USA) EPI Info version 6 software, SPSS 20, Statistica 10, MedCalc 12 and Join Point Regression Program 4.6.0.0.

Results: We collected data on 90 cases of Somatotroph pituitary adenomas (SPAs), representing 18.9% of all endocrine pituitary tumors. Of these, 52 (57.8%) were in males and 38 (42.2%) in females, resulting in a male-to-female ratio of 1.36. This difference was not statistically significant. The age-standardized prevalence and incidence rates of SPAs compared to the WHO population were 11.2% (12.9% in men, 9.7% in women, male-to-female ratio 1.32) and 1.92%, respectively, with a peak between 25 and 30 years of age. The mean age at diagnosis was 40.3 ± 14.7 (14-71) years: 40.9 ± 15.1 years (15-67) in men versus 39.5 ± 14.5 years (14-71) in women. This difference was not statistically significant. The mean time to consultation was 25.3 ± 30.6 months. The frequency was higher in macrolesions (≥1 cm) at 85.5% vs 14.5% ($P < .001$). Microadenomas were discovered at the same age as macroadenomas: 41.3 ± 20.4 years vs 41.7 ± 13.7 years for microadenomas ($P = .94$).

Conclusion: Somatotroph pituitary adenomas are predominantly found in males, with a higher frequency of macroadenomas. Their prevalence ranks them third after prolactinomas and nonfunctional adenomas. The time to consultation remains long, hence the importance of raising awareness for earlier diagnosis.

EP1260 - ECE_2669 - Tumour shrinkage secondary to pre-operative somatostatin analogue in acromegaly: a role for deferring pituitary surgery

Amy Mach[1], Khaled Ahmed[1], Trevor Tam[1,2], Hani J. Marcus[3,4] and Rupa Ahluwalia[1]
[1]*Endocrinology & Diabetes, Norfolk & Norwich University Hospital, Norwich, United Kingdom;* [2]*University of East Anglia, Norwich, United Kingdom;* [3]*Neurosurgery, National Hospital for Neurology & Neurosurgery, London, United Kingdom;* [4]*Neurosurgery, University College London, London, United Kingdom*

Background: Biochemical remission following transsphenoidal surgery for acromegaly is challenging in patients with invasive pituitary macroadenomas. Pre-operative somatostatin analogues (SSAs) are sometimes used to control hormone excess and reduce tumour volume, although practice varies. We present a case of acromegaly due to an invasive macroadenoma demonstrating marked tumour shrinkage following a single pre-operative octreotide injection, leading to deferral of planned surgery.

Case Presentation: A 42-year-old woman presented with progressive acral enlargement and coarsening of facial features over several years, alongside neuropathy, arthralgia, amenorrhoea and hyperhidrosis. Biochemistry showed elevated IGF-1 (78.6 nmol/L), hyperprolactinaemia (1454 mIU/L) and low morning cortisol (185 nmol/L). Failure of GH suppression on oral glucose tolerance testing confirmed acromegaly (nadir GH 24.9 µg/L at 60 minutes).

Pituitary MRI demonstrated a 21×14 mm invasive macroadenoma with left cavernous sinus invasion (Knosp grade IV) and optic chiasmal compression. Visual fields and echocardiography were normal and adrenal reserve was confirmed on short Synacthen testing. While awaiting surgery, she received a single dose of long-acting octreotide 30 mg.

Repeat MRI one month later showed marked tumour shrinkage with resolution of chiasmal compression, prompting deferral of

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

surgery to reassess disease control. Repeat GH suppression testing after a six-week SSA washout confirmed persistent active disease (nadir GH 11.2 µg/L), although follow-up MRI demonstrated sustained volume reduction (16.5 × 10 mm). She reported symptomatic improvement with no further acral enlargement and return of menses.

Given persistent hormone excess but significant radiological response, monthly octreotide 60 mg was commenced with plans for interval reassessment prior to considering surgery. Genetic testing (R217 panel) has been sent.

Discussion: This case illustrates rapid and clinically meaningful tumour shrinkage following a single dose of SSA in an invasive macroadenoma. In this context, the usual surgical indications were reconsidered. The diagnosis was already established biochemically, and resolution of chiasmal compression removed the need for urgent decompression. Given extensive cavernous sinus invasion, complete surgical remission was unlikely, and surgery would primarily have achieved partial debulking with ongoing need for medical therapy.

Pre-operative SSAs may therefore allow selected patients to avoid or defer surgery when mass effect resolves and biochemical control approaches remission. While predictors of response have been described, including MRI signal characteristics and receptor expression, further data are needed to guide personalised decision-making.

This case supports an individualised approach to pre-operative SSA use and highlights the need for longer-term outcome data in acromegaly patients managed with deferred surgery.

Abstract citation ID: lvag096.1499

EP1261 - ECE_1854 - A non-functioning pituitary macroadenoma presenting with systemic inflammatory and autoimmune-like features: a six-year diagnostic challenge

Cristina Ene
"Dr Victor Babes" Foundation, Bucuresti, Romania

Background: Non-functioning pituitary adenomas can remain asymptomatic for long periods, while progressive hypopituitarism may present with vague and misleading systemic symptoms. Chronic inflammation and autoimmune-like presentations can further mask endocrine disorders, mainly when glucocorticoid therapy conceals hormonal deficiencies. This case illustrates the diagnostic challenges of hypopituitarism secondary to an invasive pituitary adenoma.

Case Presentation: A 56-year-old woman was referred for endocrine evaluation due to persistently low free thyroxine (FT4) levels with normal thyroid-stimulating hormone (TSH) levels. Her clinical history spanned six years, marked by systemic symptoms and menopause at 49 years. Following menopause, she developed fasting hyperglycemia, obesity, and hypertension, initially managed with lifestyle changes and metformin, resulting in over 30 kg of weight loss over two years, along with gastrointestinal symptoms and fatigue attributed to the treatment.

Two years after amenorrhoea onset, the patient developed pleural and pericardial effusions and underwent extensive multidisciplinary evaluation for infectious and autoimmune causes—positive antinuclear antibodies (ANA), anti-Ro/SSA, and anti-La/SSB antibodies suggesting a systemic inflammatory disorder. Treatment with colchicine, followed by hydroxychloroquine and prolonged glucocorticoid therapy, led to partial symptom control and subsequent weight regain. Over time, the patient noticed the appearance of new symptoms—musculoskeletal pain—despite treatment. Attempts to taper glucocorticoids resulted in recurrence of nausea, vomiting, and profound asthenia.

Endocrine evaluation showed central hypothyroidism, hypogonadotropic hypogonadism, normal prolactin, and preserved electrolyte balance under glucocorticoid therapy. Magnetic resonance imaging revealed a large invasive macroadenoma with suprasellar extension and deviation of the pituitary stalk; visual field was preserved. The diagnosis of a non-functioning invasive pituitary macroadenoma leading to hormonal insufficiencies was established.

The patient underwent transsphenoidal hypophysectomy, with histopathological and immunohistochemical analysis confirming a gonadotroph adenoma. Postoperatively, hormone replacement with levothyroxine and hydrocortisone was initiated, leading to successful glucocorticoid withdrawal and favorable recovery of the hypothalamic–pituitary–adrenal axis, one year after surgery.

Conclusion: This case highlights the diagnostic complexity of a pituitary macroadenoma presenting with systemic inflammatory symptoms and autoimmune-like features. Persistently low FT4 levels with normal TSH in postmenopausal women warrant early pituitary imaging, despite positive autoimmune tests. A thorough evaluation is essential, as endocrine and autoimmune disorders may coexist, and awareness of glucocorticoid effects is crucial to avoid diagnostic delays and ensure timely management.

EP1262 - ECE_1894 - Cyclic Cushing's syndrome, a challenging clinical case

Varvava Chalmantzi[1], Vasiliki Siampanopoulou[1], Alexandros Lafioniatis[1], Georgia Tsirou[1], Despoina Tsopouzidou[1], Miltiadis Gravvanis[2], Danai Georgakopoulou[3], Paschalia Bekiaridou[1], Eleni Memi[1], Athina Markou[3] and Anna Angelousi[1]
[1]Endocrinology Unit, First Department of Internal Medicine, European Reference Network on Rare Endocrine Conditions (ENDO-ERN), Laikon General Hospital, Medical School, National and Kapodistrian University of Athens, Athens, Greece; [2]Radiology Department, G. Gennimatas' General Hospital of Athens, Athens, Greece; [3]Unit of Endocrinology and Diabetes Center, G. Gennimatas' General Hospital of Athens, Athens, Greece

Introduction: Cyclic Cushing's Syndrome is a rare entity characterized by intermittent hypercortisolemia with periods of normal or even low cortisol lasting from days to months.

Case Presentation: A 63-year-old woman with a medical history of breast cancer and thyroid cancer was referred to our Endocrinology Outpatient Clinic for evaluation of osteopenia. Her past medical history also included type 2 diabetes mellitus, dyslipidemia and a left adrenal adenoma. On clinical examination, the patient exhibited facial hirsutism, cervical fat accumulation, and centripetal obesity, without striae, facial plethora, or proximal muscle weakness.

Initial laboratory investigations revealed ACTH-dependent hypercortisolism, with a baseline ACTH level of 24.1 pg/mL (normal

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

range: 7-63), elevated serum cortisol following a 1-mg overnight dexamethasone suppression test (ODST) (160 nmol/L), and increased midnight salivary cortisol (18.84 nmol/L; normal <5.79). Loss of the normal circadian rhythm of cortisol secretion was also documented. Twenty-four–hour urinary free cortisol (UFC) was within the normal range (2275.8 nmol/L; normal range: 317.24-2813.7).

Pituitary MRI demonstrated heterogeneity in the posterior region of the adenohypophysis, without evidence of a discrete lesion. A desmopressin stimulation test showed a >20% increase in cortisol and a >50% increase in ACTH. 18-FDG-PET/CT was performed and demonstrated no abnormal FDG uptake. Two months later, remission of hypercortisolism was confirmed by a repeat 1-mg ODST (cortisol: 61.69 nmol/L), and a subsequent pituitary MRI showed no abnormalities.

At the 1-year follow-up, hypercortisolism recurred, with elevated UFC (3666.2 nmol/L) and increased midnight salivary cortisol (12.469 nmol/L; normal <5.79). A desmopressin stimulation test performed after a low-dose dexamethasone suppression test again demonstrated a >20% increase in cortisol and a >50% increase in ACTH. A high-dose (8-mg overnight) dexamethasone suppression test resulted in a >50% reduction in cortisol levels, consistent with Cushing's disease.

Based on these findings, a diagnosis of cyclic Cushing's syndrome was assumed. The patient subsequently underwent bilateral inferior petrosal sinus sampling (BIPSS), which revealed a basal central-to-peripheral ACTH ratio: 1.24 (<2) and a post-stimulation ratio at 5 min: 7.8 (>3) confirming a pituitary origin of ACTH excess. She was referred to an experienced neurosurgeon for exploratory transsphenoidal surgery (TSS), which is currently being scheduled.

Conclusion: Cyclic Cushing's syndrome remains a significant diagnostic and therapeutic challenge. Accurate diagnosis often requires repeated and thorough evaluations to document intermittent hypercortisolism. Increased clinical awareness is essential, particularly in patients with adrenal adenomas and a constellation of comorbidities suggestive of cortisol excess.

EP1263 - ECE_2011 - Beyond the breast: a gonadotropinoma presenting with suspicious gynecomastia in a male patient

Stefania-Alexandra Bunceanu[1], Bena Andreea[2], Roxana Pui[1], Monica Latia[1] and Stoian Dana[2]

[1]*Department of Doctoral Studies, Victor Babes University of Medicine and Pharmacy, Timisoara, Romania;* [2]*Timisoara, Romania*

Background: Gynecomastia in older men requires a careful evaluation because it may conceal breast malignancy or reflect underlying endocrine disorders. Functional gonadotroph pituitary adenomas are uncommon and frequently overlooked, as many gonadotroph tumors are clinically "silent." Conversely, in the rare situations where FSH/LH hypersecretion is clinically relevant, a comprehensive assessment is necessary to identify co-secretion, define the endocrine phenotype, and address associated gonadal and systemic comorbidities.

Case Presentation: We report the case of a 68-year-old man, with no significant chronic medication, who presented with gynecomastia and suspected breast pathology. Initial breast ultrasonography revealed bilateral fibrocystic mastopathy (BI-RADS 3), followed by the detection of a solid parenchymal lesion, markedly hypoechoic, ill-defined, with spiculated margins (BI-RADS 4). Immediate core needle biopsy for histopathological assessment was performed, with benignity confirmation afterwards. Comprehensive endocrine evaluation was assesed in order to identify the etiology of gynecomastia, which demonstrated repeatedly marked hyperprolactinemia (267-323 ng/mL) and mildly elevated gonadotropins (LH 9.33 IU/L, FSH 21.7 IU/L), with total testosterone and estradiol within the reference range. The patient denied galactorrhea but reported associated sexual dysfunction. IGF-1 values were mildly increased, but growth hormone was appropriately suppressed during the oral glucose tolerance test, excluding acromegaly. Thyroid and adrenal axes were within normal limits. Given the persistent elevation of prolactin, contrast-enhanced pituitary MRI was performed and revealed a sellar mass with typical features of a pituitary macroadenoma, measuring approximately $11.7 \times 11 \times 15.5$ mm. Cabergoline therapy was initiated at 1 mg twice weekly, leading to normalization of prolactin levels, while LH and FSH increased further on follow-up (LH 11.87 IU/L, FSH 29.41 IU/L), raising suspicion of a mixed pituitary secretion profile of prolactin and gonadotropins. Testicular ultrasonography showed normal gonadal size and morphology. In addition, α-subunit levels were elevated, further supporting the suspicion of a plurihormonal secretory pituitary macroadenoma.

Conclusion: This case highlights the importance of a comprehensive endocrine assessment when gynecomastia and breast lesions are identified in a male patient. In our case, marked hyperprolactinemia and the detection of a pituitary macroadenoma represented the first significant endocrine abnormalities. However, after initiation of cabergoline therapy and normalization of prolactin levels, the magnitude of FSH and LH hypersecretion became evident, while elevated α-subunit levels further supported the diagnosis of plurihormonal pituitary secretion, with prolactin co-secreted alongside gonadotropins. Although such cases are exceptionally rare, their recognition is essential to ensure accurate diagnosis and timely, appropriate management.

EP1264 - ECE_3479 - Where is the end of Cushing's disease?

Dominika Ondruskova, Jana Leskova, Igor Durmek and Peter Vanuga

V.internal clinic of the Faculty of Medicine of Comenius University, National Institute of Endocrinology and Diabetology in Lubochna, Bratislava, Slovakia

Introduction: Cushing's disease is an endocrine disorder caused by excessive secretion of ACTH from the pituitary gland, leading to increased cortisol production. Diagnosis and treatment are challenging due to nonspecific symptoms and the difficulty of localizing small adenomas. Despite a wide range of therapeutic options, persistence or recurrence of the disease is common, emphasizing the need for long-term patient follow-up.

Case Report: A 32-year-old woman with Cushing's disease due to an ACTH-producing pituitary adenoma had been followed since 2017. Pharmacotherapy with pasireotide and osilodrostat was not tolerated. After two transsphenoidal adenomectomy (in 2017 and 2020), following a total hypophysectomy (in 2025),

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

we did not achieve suppression of ACTH production by pathological tissue. Three months after hypophysectomy, central hypocorticism developed, but ACTH levels were still slightly elevated. The patient required Hydrocortisone replacement therapy. Two months later, the patient experiences a clinical relapse of hypercorticism, manifested by hirsutism, the appearance of new stretch marks, fluid retention and tachycardia. We partially reduce the dosage of Hydrocortisone and assume the presence of residual ACTH-producing pituitary adenoma tissue. After consulting the radiosurgery department, we found a potential source of ACTH and planned therapy with Leksel's gamma knife.

Conclusion: Cushing's disease remains a challenging condition to manage despite advances in diagnostic and therapeutic options. Even after multiple surgical interventions, including total hypophysectomy, persistent ACTH secretion can occur due to residual ACTH secreting tissue. This case highlights the complexity of treatment and the necessity of a multidisciplinary approach, continuous hormonal monitoring, and individualized long-term management to achieve disease control and improve patient outcomes. Long-term, multidisciplinary follow-up is essential to tailor therapy and minimize metabolic and cardiovascular complications associated with fluctuating cortisol levels.

Aim: To analyze the diagnostic challenges in ACTH-dependent Cushing's syndrome when no causative lesion is initially identified, with emphasis on the differentiation between pituitary and ectopic sources of ACTH excess, and on the role of medical therapy during prolonged diagnostic evaluation.

Summary/Methods: A 23-year-old male presented with progressive clinical features of Cushing's syndrome (CS), including rapid weight gain, central obesity, proximal muscle weakness, moon facies, erythroviolaceous striae, buffalo hump and acanthosis nigricans. He also had arterial hypertension, diabetes mellitus and dyslipidaemia. Biochemical evaluation confirmed endogenous ACTH-dependent hypercortisolism. Initial pituitary magnetic resonance imaging (MRI) showed no identifiable lesion.

Given the absence of a visible pituitary adenoma, a structured diagnostic approach was undertaken to localize the source of ACTH excess. Differential diagnostic considerations included pituitary Cushing's disease (CD) and ectopic ACTH secretion (EAS). Cross-sectional thoracic imaging and extensive functional nuclear medicine studies, including 68Ga-DOTATOC PET/CT, 18F-FDG PET/CT and 18F-DOPA PET/CT, failed to identify an ectopic ACTH-producing tumor.

Inferior petrosal sinus sampling (IPSS) was performed to further differentiate between pituitary and ectopic ACTH secretion. However, the procedure was non-diagnostic due to incomplete bilateral catheterization, precluding definitive exclusion of a pituitary source. Repeated hormonal assessments demonstrated marked fluctuations in ACTH and cortisol concentrations during follow-up, complicating the interpretation of dynamic testing and the overall diagnostic process.

Results: Medical therapy with the 11β-hydroxylase inhibitor osilodrostat was initiated to control hypercortisolism while diagnostic evaluation continued. Treatment resulted in effective biochemical control and substantial clinical improvement. Glycemic parameters normalized, blood pressure and lipid profile improved, and classical manifestations of CS regressed, including recovery of muscle strength.

Following treatment initiation, a paradoxical transient decrease in ACTH levels was observed. Several pathophysiological mechanisms were considered, including cyclic ACTH secretion, partial tumor cell dysfunction, and complex feedback effects related to the accumulation of steroid precursors with residual glucocorticoid or mineralocorticoid activity. These observations underscore the non-linear and dynamic regulation of the ACTH–cortisol axis in ACTH-dependent CS under medical therapy.

Subsequent repeat pituitary MRI revealed a subtle hypointense lesion measuring <4 mm, supporting a normotopic ACTH source and favoring a diagnosis of pituitary Cushing's disease despite initially negative imaging.

EP1267 - ECE_3153 - Neonatal septo-optic dysplasia: a case report

Daniel Duarte[1], Miguel Marques[1], Marta Almeida[1], H. Francisca[1], Ana Quítalo[1], Marta Andrade[2], David Barbosa[1], Sara Franco[1] and Maria Carlos Cordeiro[1]

[1]*Unidade Local de Saúde de Almada-Seixal, Almada, Portugal;* [2]*Unidade Local de Saúde Santa Maria, Lisbon, Portugal*

Introduction: Septo-optic dysplasia (SOD) is a rare congenital condition characterized by midline brain abnormalities, optic nerve hypoplasia and hypothalamic-pituitary dysfunction, affecting 1 in every 50 000 births.[1] Its exact etiology remains unclear.[1] We present a case of neonatal SOD causing panhypopituitarism.

Case Report: A newborn infant male was admitted to the Neonatology Intermediate Care ward for difficulty breastfeeding and persistent hypoglycemia (20-35 mg/dL) in his first 48 hours of life. His parents had no relevant medical history. The pregnancy had been followed since the 2nd trimester, with no diagnosis of gestational diabetes. Born at 40 weeks and 1 day by vaginal delivery, with an Apgar index of 9/10, initial physical examination revealed right cryptorchidism and micropenis.

Biochemical evaluation revealed hypoglycemia (43 mg/dL), hyponatremia (129 mmol/L), hyperkalemia (5.8 mmol/L), central adrenal insufficiency (0.64 µg/dL cortisol [RR 15.3 ± 7.9], 5.2 pg/mL ACTH [RR 83.9 ± 38]), hypogonadotrophic hypogonadism (LH <0.3 UI/L; FSH <0.3 UI/L; total testosterone <3.0 ng/dL 8.16 µg/dL), central hypothyroidism (TSH 6.52 mUI/L [RR 6.5 ± 2.4], free T4 1.27 ng/dL [RR 2.8 ± 0.61 ng/dL]) and low 1.2 ng/mL GH (RR > 5.0). 17-OH-progesterone was normal (7.11 ng/mL [RR 8.05 ± 2.73]).

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Cranial MRI revealed pituitary stalk agenesia, ectopic neurohypophysis at the infundibular recess of the third ventricle and marked right optic nerve and optic chiasm hypoplasia. Ophthalmological examination was consistent with right optic nerve hypoplasia.

The infant was started on hydrocortisone 12 mg/m^2/day on day 3, followed by levothyroxine 25 mcg/day on day 12 and subcutaneous somatotropin 22 mcg/kg/day on day 20, with sustained normoglycemia, normalization of electrolyte disturbances and acquisition of feeding autonomy. He was discharged on day 37, with referral to Neuropediatrics, Pediatric Ophtalmology and Pediatric Endocrinology appointments.

At 6-month follow-up, adequate psychomotor development, weight gain and linear growth have been maintained under hydrocortisone, levothyroxine and somatotropin. Gonadotrophins and total testosterone remain untraceable.

Conclusion: The differential diagnosis of neonatal hypoglycemia must exclude adrenal insufficiency. In the face of panhypopituitarism, prompt MRI evaluation allowed an early diagnosis of septo-optic dysplasia and adequate treatment, with improved metabolic outcomes.

EP1269 - ECE_3182 - Where is the source of Cushing's syndrome?

Dominika Ondruskova, Jana Leskova, Igor Durmek and Peter Vanuga
V.internal clinic of the Faculty of Medicine of Comenius University, National Institute of Endocrinology and Diabetology in Lubochna, Bratislava, Slovakia

Introduction: Cushing's syndrome remains a significant diagnostic challenge, particularly in cases with ambiguous or inconclusive imaging findings. Bilateral adrenal abnormalities may suggest a adrenal etiology of disease. However, comprehensive endocrine evaluation, including invasive diagnostic procedures, is essential for accurate localization of the source of inappropriate hormonal overproduction. Correct identification of the underlying pathology is crucial for targeted treatment and optimal long-term outcomes.

Case Report: We present the case of a female patient with clinical and biochemical features of hypercortisolism in whom initial imaging revealed bilateral adrenal lesions, raising suspicion of adrenal type of Cushing's syndrome. Despite this finding, hormonal evaluation supported an ACTH-dependent etiology. To clarify the source of ACTH secretion, bilateral inferior petrosal sinus sampling was performed, which conclusively demonstrated pituitary ACTH overproduction. Subsequent expert re-assessment of pituitary MRI subsequently identified a previously unrecognized microadenoma. Based on these findings, the patient was referred for stereotactic radiosurgical treatment using the Leksell Gamma Knife. Radiosurgical treatment resulted in gradual biochemical improvement and clinical stabilization.

Conclusion: This case highlights the importance of a systematic and multidisciplinary diagnostic approach in patients with Cushing's syndrome, especially when imaging findings and laboratory results are discordant.. Bilateral adrenal abnormalities do not necessarily represent the primary cause of hypercortisolism and may obscure a central ACTH-secreting source. Inferior petrosal sinus sampling plays a pivotal role in accurately localizing ACTH secretion and enables definitive, targeted therapy, including stereotactic radiosurgery. Long-term, multidisciplinary follow-up is essential to achieve sustained disease control and minimize complications.

EP1271 - ECE_2058 - Crooke cell pituitary neuroendocrine tumor (PitNET) masquerading as ectopic ACTH syndrome: a diagnostic challenge of an aggressive variant

Yi-Hsuan Lai and Wan-Chen Wu
Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan

Background: Crooke cell pituitary neuroendocrine tumors (PitNETs) are rare, aggressive variants of corticotroph adenomas characterized by extensive cytoplasmic hyaline change. These tumors are notorious for their clinically invasive behavior, higher recurrence rates, and potentially lower rates of biochemical remission compared to typical corticotroph tumors.

Case Presentation: A 65-year-old woman presented with progressive weakness and 15-kg weight loss within two months, and severe refractory hypokalemia (2.1 mmol/L). Laboratory evaluation confirmed ACTH-dependent hypercortisolism with ACTH 404.5 pg/mL, cortisol 55.7 μg/dL and loss of diurnal rhythm. High-dose dexamethasone suppression test yielded <50% cortisol suppression, initially raising suspicion of ectopic ACTH syndrome (EAS). Pituitary MRI identified a 1.2-cm adenoma, however, due to the severe clinical presentation, a systemic search for EAS was performed. Extensive imaging, including Ga-68-DOTATOC PET/CT, was negative for an ectopic source. Bilateral inferior petrosal sinus sampling (BIPSS) demonstrated a central-to-peripheral ACTH gradient, confirming a pituitary source.

Hypercortisolism showed poor response to high-dose fluconazole (up to 1200 mg daily), subsequently, pre-operative cortisol control was achieved using a combination of etomidate infusion and pasireotide. Staged transsphenoidal surgery was performed due to significant intraoperative hemorrhage. Histopathology confirmed a Crooke cell T-PIT lineage PitNET, displaying characteristic ring-like CAM5.2 staining (hyaline change), weak ACTH staining limited to cell periphery, and Ki-67 index <1%. Postoperatively, the patient achieved biochemical remission (ACTH 2.75 pg/mL, cortisol 14.60 μg/dL on physiological prednisolone replacement), though the course was further complicated by septic shock and acute kidney injury requiring intensive management.

Conclusion: This case highlights the diagnostic dilemma of Crooke cell tumors, which can closely mimic EAS due to extreme hypercortisolism and poor dexamethasone suppressibility. BIPSS remains the gold standard for localization when clinical and biochemical features are atypical, even in the presence of a pituitary mass. Despite a low proliferative index (Ki-67 <1%),

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Crooke cell adenomas often exhibit aggressive clinical behavior and high recurrence risk (up to 60%). Rigorous long-term surveillance is imperative for this aggressive subtype.

EP1275 - ECE_1172 - Hypernatremia as the first manifestation of arginine vasopressin deficiency secondary to hypothalamic–pituitary disease: a case report

Sona Maghakyan, Sofiya Khachaturyan and Hovhannes Tumanian
Mikaelyan University Hospital, Yerevan, Armenia

Hypernatremia, defined as serum sodium >145 mmol/L, reflects a deficit of free water relative to sodium and is associated with significant morbidity and mortality if unrecognized. It usually results from inadequate water intake, excessive water loss, or sodium overload.

Neuroendocrine causes are uncommon but clinically significant, including central diabetes insipidus (CDI)-recently redefined as arginine vasopressin deficiency (AVP-D)-and hypothalamic disorders affecting thirst or osmoreceptor function. AVP-D arises from impaired synthesis or secretion of vasopressin and manifests as polyuria, polydipsia, and, in severe cases, hypernatremia. It may be congenital or acquired, typically secondary to pituitary or hypothalamic lesions, trauma, surgery, or autoimmune inflammation.

We report a case of severe hypernatremia as the first clinical manifestation of AVP-D caused by a hypothalamic-pituitary lesion, underscoring the diagnostic importance of copeptin and MRI in such presentations.

Case Presentation: A 71-year-old man was admitted with a five-month history of general weakness, dry mouth, polyuria (up to 5 L/day), headaches, weight loss (3-4 kg), and constipation. Symptoms began after a short febrile illness with diarrhea. He had no previous medical history.

Initial evaluation revealed severe hypernatremia (166 mmol/L). A CT scan showed a right adrenal incidentaloma and prostatic hyperplasia. Laboratory workup (renin, aldosterone, ACTH, TSH, HbA1c, glucose, PSA, plasma metanephrines, and urinary cortisol) was normal. Notable abnormalities were prolactin 30.5 ng/mL (normal: 4.0-15.2) and urine specific gravity 1.005. Given the symptoms of diabetes insipidus, copeptin was measured at <2.7 pmol/L with plasma osmolality 344 mOsm/kg, confirming AVP-D. MRI of the pituitary showed an endo- and suprasellar lesion suggestive of adenoma.

A diagnosis of AVP-D, hypernatremia, hyperprolactinemia, and right adrenal incidentaloma was made. The patient received 5% glucose infusions and intranasal desmopressin (one drop nightly for two days, then two drops twice daily), along with cabergoline 0.25 mg twice weekly. Within three days, polyuria and polydipsia subsided, serum sodium normalized (145 mmol/L), and urine specific gravity rose to 1.011.

Five months later, the patient developed headaches and behavioral changes. Repeat MRI revealed hypothalamic and optic tract edema, consistent with infundibulo-hypophysitis or hypothalamitis. Neurosurgery recommended conservative management with continued desmopressin and dexamethasone 4 mg daily, which stabilized symptoms.

Conclusion: Hypernatremia accompanied by polyuria and low urine osmolality should prompt evaluation for AVP-D. Integrating biochemical, radiological, and clinical data is essential to distinguish adenomatous from inflammatory causes of hypothalamic-pituitary dysfunction. Early diagnosis and appropriate hormone replacement can prevent complications and improve long-term outcomes.

EP1277 - ECE_2996 - An incidental case of lymphocytic hypophysistis following traumatic brain injury

Teodora Puscas[1], Elena-Maria Pavel[1], Claudiu Zaharia[1], Diana Stanciu[2], Mihaela Stanciu[1,2] and Codruta Lebada[1,2]
[1]Medias, Romania; [2]Department of Endocrinology, Lucian Blaga University of Sibiu, Sibiu, Romania

Introduction: Lymphocytic hypophysitis is a rare autoimmune disease, characterized by lymphocityc infiltration of the pitutary tissue, leading to inflammation of the pitutary gland and/or infundibulum. Initially considered a condition predominantly affecting pregnant or postpartum women, recent studies have demonstrated a wider distribution across genders and age groups, with frequent associations with other autoimmune diseases. Clinical presentation is nonspecific and may mimic other pituitary disorders, such as pituitary adenomas. Diagnosis is primarily one of exclusion, based on pituitary MRI findings and biochemical evaluation, which typically reveals varying degrees of hypopituitarism. Management of this disease focuses on hormone replacement, antiinflamatory treatment and selective surgical intervention for mass efects.

Case Report: We present the case of a 64-year-old male patient who suffered an occupational traumatic brain injury in 2001 and subsequently presented for medical evaluation complaining of headache and vertigo. Cranial CT imaging raised the suspicion of lymphocytic hypophysitis, based on pituitary morphological changes, describing an enlarged anterior pituitary gland with inhomogeneous appearance on both native and post-contrast images, as well as pituitary stalk thickening. Hormonal evaluation confirmed plurihormonal anterior hypopituitarism, involving corticotropic, thyrotropic, and gonadotropic deficiencies. Hormone replacement therapy was initiated, consisting initially of Prednisone 5 mg/day, Levothyroxine 125 µg/day and Testosterone gel 16.2 mg/day, with subsequent dose adjustments according to follow-up assessments, leading to a favorable clinical evolution. The patient was also diagnosed with concomitant chronic autoimmune thyroiditis. However, 24 years after the initial diagnosis, MRI examination showed an area occupying a large portion of the glandular tissue, hypointense on T2-weighted images and hyperintense on T1-weighted images, showing no contrast enhancement, measuring 7/12.8 /7.3 mm, interpreted as a necrotic area. This finding will be subject to longitudinal imaging follow-up.

Conclusions: This case highlights that lymphocytic hypophysitis may present with heterogeneous clinical and radiological features at diagnosis and can be asymptomatic at disease onset. Early recognition is crucial, as hormonal deficiencies, particularly corticotropic insufficiency, is a life-threatening condition if left untreated. The association with chronic autoimmune thyroiditis further supports an autoimmune background and underscores the need to actively screen for concomitant autoimmune disorders. Lifelong follow-up is essential for appropiate adjustment of hormone replacement therapy and for the prevention or limitation of long-term complications.

EP1278 - ECE_1372 - From prolactinoma to mixed pituitary tumor with thyroid autoimmune shift: a diagnostic and therapeutic challenge

Tea Shehu Kolnikaj[1,2], Maren Ruka[3], Jetmira Kerxhaliu[3], Doris Laçej[4], Mirel Grada[5], Klajdi Tarko[6] and Florian Toti[7]

[1]Endocrinology, American Hospital 3, Tirana, Albania; [2]Department of Clinical and Molecular Medicine, Sapienza University of Rome, Rome, Italy; [3]Neurosurgery, University Hospital Centre "Mother Teresa", Tirana, Albania; [4]Department of Pharmaceutical Sciences, Sapienza University of Rome, Rome, Italy; [5]Neurosurgery, American Hospital 3, Tirana, Albania; [6]Laboratory, University Hospital Centre "Mother Teresa", Tirana, Albania; [7]Endocrinology, University Hospital Centre "Mother Teresa", Tirana, Albania

Background: Mixed hormone-producing pituitary tumors are rare and may present diagnostic challenges, particularly when one hormonal component is clinically silent at presentation. Moreover, the coexistence of autoimmune thyroid disease further complicates both diagnosis and follow-up, especially in the context of shifts in thyroid autoimmunity.

Case Presentation: We report the case of a 31-year-old man referred for persistent headache and decreased libido. Initial evaluation revealed central hypogonadism, hypothyroidism with positive anti-TPO antibodies and low TSH, and markedly elevated prolactin levels. Adrenal and growth hormone (GH) axes were preserved. Pituitary MRI demonstrated a 2 cm macroadenoma. Medical therapy with cabergoline (up to 3 mg/week) and levothyroxine led to significant prolactin reduction and mild tumor shrinkage over one year.

However, despite stable imaging findings, a progressive increase in IGF-1 levels was observed during follow-up, raising suspicion of a mixed or evolving secretory phenotype. Therefore, transsphenoidal surgery was performed.

Results: Histopathological examination revealed a PIT-1–positive mixed mammo-somatotroph adenoma, predominantly prolactin-secreting, with co-expression of GH, Ki-67 index of 2%, absent mitoses, and negative p53, consistent with a low-grade tumor (Trouillas grade 2a). Postoperatively, IGF-1 normalized and prolactin levels improved. However, low-dose cabergoline was still required. Gonadal axis recovered and there was no evidence of adrenal insufficiency or diabetes insipidus. Postoperatively, a shift in thyroid autoimmunity was observed, from hypothyroidism to hyperthyroidism due to Graves' disease. Methimazole therapy was started. The patient remains under close endocrinological follow-up. Genetic testing is planned.

Conclusion: Mixed hormone–producing pituitary tumors may present diagnostic and therapeutic challenges, as they may initially present with predominant secretion of a single hormonal component. This case emphasizes the need for continuous reassessment of pituitary hormonal profiles, even in the presence of apparent treatment response. The development and shift of thyroid autoimmune disease during follow-up further highlights the importance of integrated endocrine surveillance.

Keywords prolactinoma, mammo-somatotroph tumor, pituitary surgery, thyroid autoimmunity, Graves' disease

EP1279 - ECE_3122 - Pituitary incidentaloma unmasking subtle acromegaly: a macroadenoma case report

Muhammad Haroon Riasat[1], Samraiz Nafees[2], Khurram Qayyum[1], Muhammad Masroor Amjad[1], Najeeb Shah[1], Rehmat Karim[1] and Shiva Mongolu[1]

[1]Hull Royal Infirmary, Hull, United Kingdom; [2]Scarborough General Hospital, Scarborough, United Kingdom

Background: Acromegaly often develops insidiously and may first be suspected only when a pituitary lesion is detected incidentally on neuroimaging. Clinical features can be subtle despite established biochemical disease, particularly in patients with common comorbidities such as type 2 diabetes and hypertension. This case describes the journey from an incidental pituitary macroadenoma to a confirmed diagnosis of acromegaly, highlighting the importance of systematic endocrine evaluation and multidisciplinary management.

Case Report: A middle-aged man with type 2 diabetes (on metformin) and recently diagnosed hypertension (on lisinopril) underwent CT head imaging, which incidentally revealed a pituitary lesion. Subsequent pituitary MRI confirmed a 15-17 mm macroadenoma with suprasellar extension but no optic chiasm compression. Over the preceding year he had developed increasing tiredness and intermittent light-headedness, and more recently a persistent central pressure-type headache. He denied visual disturbance but reported an increase in shoe size from 10.5 to 11.5 and a perception that his hands were enlarging. Examination showed mildly coarse facial features, a widened nasal bridge, subtle prognathism and broadened digits, without obvious frontal bossing or macroglossia. Initial pituitary profile demonstrated elevated age-adjusted insulin-like growth factor-1 (IGF-1 ≈90 nmol/L) with growth hormone (GH) around 2 µg/L, normal thyroid function, low-normal testosterone with low sex hormone-binding globulin, normal gonadotrophins, mildly raised prolactin and borderline-low morning cortisol. A subsequent short synacthen test confirmed an adequate adrenal reserve. Repeat IGF-1 remained elevated and an oral glucose tolerance test showed failure of GH suppression, with values persistently 1.9-2.3 µg/L and a nadir around 1.9 µg/L, confirming acromegaly. Formal visual field testing was normal, concordant with the absence of chiasmal compression on imaging. The case was discussed at the pituitary multidisciplinary team meeting, which recommended transsphenoidal surgery as first-line treatment.

Conclusion: This case illustrates how a pituitary incidentaloma can unveil clinically important acromegaly when subtle phenotypic changes and cardiometabolic comorbidities are actively sought. It emphasises the need for high clinical suspicion, structured biochemical assessment and early multidisciplinary input, even in the absence of visual field defects, to enable timely surgical management and reduce long-term complication risk.

[1]Kathmandu Diabetes and Thyroid Center, Lalitpur, Nepal; [2]Kathmandu Diabetes and Thyroid Centre, Kathmandu, Nepal

Cushing's syndrome patients' data in Nepal is lacking. We retrospectively reviewed data of all our Cushing's syndrome patients from 2010 to 2024. There were 33 patients. The mean age was 38.24 ± 13.37 years. Males were 6(18.18%) and females 27(81.82%) with M:F ratio 0.22:1. Mean weight was 72.93 ± 13.735 kg and BMI 30.78 ± 5.6 kg/m^2. ACTH dependent Cushing syndrome patients were 16(48.48%), ACTH independent syndrome 7(21.21%), iatrogenic Cushing syndrome 10(30.30%), Ectopic ACTH syndrome was 1. Common symptoms and signs were weight gain in 30(90.91%) patients, moon face 30(90.91%) patients, buffalo hump 28(84.85%), red abdominal stretch marks in 23(69.70%) patients, proximal weakness in 14(42.42%) patients. Hypertension was seen in 21(63.64%) patients and diabetes in 12(36.36%). Mean ONDST was 24.23 ± 16.20 µg/dl, LDDST was 21.61 ± 14.39 µg/dl and Mean ACTH level was 74.69 ± 19.08 pg/mL in ACTH dependent Cushing syndrome. Mean ONDST was 22.52 ± 10.44 µg/dl, LDDST was 27.90 ± 8.56 µg/dl and ACTH level was 5.66 ± 2.30 pg/mL in ACTH independent Cushing syndrome. In ACTH dependent Cushing syndrome, pituitary microadenoma was seen in 6 patients(37.5%) and macroadenoma in 5 patients(31.25%). In ACTH independent Cushing Syndrome, adrenal adenoma was seen in the right side in 4 patients (57.14%) and in 2 patients(28.57%)in the left side. For ACTH dependent Cushing syndrome, TNTS was done in 6 patients(37.5%) and SLTS in 1 patient(6.25%). For ACTH independent Cushing syndrome, Laparoscopic adrenalectomy was done in all 6 patients**.** For the patient with Ectopic ACTH syndrome, medical treatment with Ketoconazole was given and later on, bilateral adrenalectomy was done. For ACTH dependent Cushing syndrome, remission was seen in 10 patients(62.5%). Those who did not go into remission, medical treatment with Ketoconazole was done in 4 patients(66.66%) and bilateral adrenalectomy in 2 patients (33.33%). For ACTH independent Cushing syndrome, remission was seen in all 7 patients(100%).

EP1281 - ECE_2436 - The role of Tolvaptan in an outpatient setting

Hafsah Hussain[1], Bhavini Bhatt[1], Furhana Hussein[1], Mohamed Baalawi[1], Aylin Can[1], Ilias Ibrahim[1] and Gideon Mlawa[1,2]
[1]Barking Havering and Redbridge Hospitals NHS Trust, London, United Kingdom; [2]Diabetes and Endocrinology, Queen's Hospital, Queen's Hospital Diabetes and Endocrinology Centre, London, United Kingdom

Introduction: Tolvaptan is a vasopressin-V2 antagonist, used in the treatment of hyponatremia. It functions through targeting type-2 receptors in the distal renal tubules, inhibiting the action of the hormone vasopressin. As a result, water reabsorption is reduced and excretion is increased, thus correcting the dilutional hyponatremia and balancing serum sodium levels.

Currently, Tolvaptan is most used for short-term, inpatient treatment. Due to its mechanism, Tolvaptan presents a high risk of rapid, overcorrection of serum sodium levels. Maximal change occurs within the first 24 hours, and it is therefore recommended that sodium levels are closely monitored during this period to prevent adverse events. However, there has been recent discussion into potential efficacy of this drug in the outpatient setting. We have explored a patient case where Tolvaptan was successfully provided as a longer-term treatment for symptomatic hyponatremia.

Case Report: A 72-year-old patient with a background of SIADH and left-sided adrenal adenoma had recurrent admissions to hospital since January 2023, due to acute confusion and vacant episodes secondary to euvolemic hyponatraemia (lowest Na: 119). This symptomatic hyponatraemia was treated in hospital and the patient was advised to fluid restrict to 750 mL and take demeclocycline and oral sodium tablets. However, it failed to correct the sodium and has led to multiple admissions, with some requiring intensive care support. On one admission, the patient was started on Tolvaptan as an inpatient, to which she showed a good response. She was discharged with 3.75 mg of Tolvaptan to be taken once a day as an outpatient, which has corrected her sodium (most recent Na: 134) and led to fewer admissions in hospital.

Discussion/Conclusion: This case illustrates the potential role of Tolvaptan in the management of hyponatraemia in an outpatient setting. Tolvaptan offers a targeted approach by antagonising vasopressin receptors, thus promoting free water excretion without affecting sodium retention. This treatment may be particularly beneficial for patients with recurrent, symptomatic hyponatremia who fail to respond to conventional therapies. This patient's successful management with Tolvaptan suggests that it can be a valuable therapeutic option in the outpatient care of patients with SIADH, leading to better sodium control and fewer hospitalisation episodes. Further studies are needed to better define its long-term efficacy and safety in this context.

EP1283 - ECE_1288 - From neurology to endocrinology: subclinical Cushing's syndrome diagnosed in a patient with nonfunctioning pituitary macroadenoma

Sona Maghakyan and Sofiya Khachaturyan
Mikaelyan University Hospital, Yerevan, Armenia

Many endocrine diseases have neurological manifestations, and sometimes these manifestations appear at first. We would like to present a case of subclinical Cushing's syndrome.

Case Report: A 46-year-old man presented to a neurologist with the following complaints: feelings of anxiety, restlessness, insomnia, pronounced weakness in the upper and lower extremities, difficulty swallowing, unusual fatigue, decreased work capacity, pain in the lumbar region. The neurologist suspected myasthenia gravis (disproof) and referred for electroneuromyography and brain MRI examination. Brain MRI showed a pituitary macroadenoma. The patient was referred to an endocrinologist. During the examination, it was found that the patient had erectile dysfunction for about a month, the patient was overweight (BMI 27.5) and did not have diabetes or arterial hypertension.

Laboratory tests were performed: FSH, LH, Prolactin, ACTH, IGF-1, TSH, FT4 and free testosterone were within the normal range, 24-hour urine cortisol was 246.1 (N 11.5-102.0). 1 mg Dexamethasone test result was cortisol-60,84 (N <50).

Abdominal CT scan result: in the left adrenal gland, a round tissue formation measuring 4.0 * 3.3 * 3.5 cm.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Subclinical Cushing's syndrome diagnosis was made and decided to make left adrenalectomy after preparation for surgery. The patient underwent laparoscopic adrenalectomy. The histopathology result was adrenal adenoma. He was discharged on oral hydrocortisone 10 mg in the morning.

Conclusion: Cushing syndrome is caused by prolonged exposure to elevated levels of either endogenous glucocorticoids or exogenous glucocorticoids. It is a rare disorder and the estimated prevalence of Cushing's syndrome, considering all causes, ranges from 57 to 79 cases per million individuals. It has a lot of various clinical manifestations, including neurological. Patients may experience emotional liability, fatigue, and depression. In our case these complains make the patient to go to a neurologist and ACTH-independent Cushing syndrome with adrenal adenoma and nonfunctioning pituitary adenoma was diagnosed, which is a rare occurrence.

EP1285 - ECE_3430 - Hypercalcitoninemia and large-cell neuroendocrine carcinoma of the lung: a diagnostic challenge

Leandro Augusto Silva[1], Bárbara Jesus[2], Joana Reis Guiomar[2], Mariana Lavrador[2], Daniela Guelho[2], Dírcea Rodrigues[2], Carla Baptista[2], Ana Margarida Novo[2], Vânia Almeida[2], Lina Carvalho[2] and Leonor Gomes[2]
[1]Endocrinology Department, Portuguese Institute of Oncology of Coimbra, Coimbra, Portugal; [2]Local Health Unit of Coimbra, Coimbra, Portugal

Introduction: Calcitonin-secreting neuroendocrine neoplasms (NENs) of the lung are rare, with a particularly difficult diagnosis due to their overlapping cytomorphologic and immunohistochemical features with medullary thyroid carcinoma (MTC). Although markedly elevated serum calcitonin strongly suggests MTC, it is not pathognomonic and may reflect ectopic secretion.

Clinical Case: 50-year-old female patient, presenting with a 3-month history of headache. Cranial CT identified a 2 cm left parietal lesion suggestive of primary brain tumour. Evaluated by Neurosurgery; cranial MRI demonstrated enlargement of the lesion and appearance of additional intracranial lesions, raising suspicion for metastatic disease. Surgical resection of the lesion was performed, and histopathological analysis was consistent with neuroendocrine neoplasm metastasis. Referred to Endocrinology with a 2-month history of cervical swelling and dysphonia. Physical examination revealed palpable masses consistent with cervical lymphadenopathy. Neck ultrasound showed a 3.7 cm right thyroid lobe nodule, EU-TIRADS-5, with fine-needle aspiration cytology suggestive of MTC/undifferentiated carcinoma. Calcitonin in needle washout of lateral cervical lymphadenopathy was 1164 pg/mL. Labs revealed calcitonin 2050 pg/mL (<5.0), CEA 6.2 ng/mL (<5.4), CgA 411 ng/mL(<85.0) and NSE 89 ng/mL(<15.0). Histological revision of the brain metastasis demonstrated positive immunohistochemical staining for calcitonin. Given the suspicion of metastatic MTC, germline *RET* testing was performed (no pathogenic variants identified). CT-CAP revealed a 43 × 29 mm lesion contiguous with the right thyroid lobe, suggestive of a nodal conglomerate. Lung imaging revealed a 28 × 21 mm irregular, heterogeneous lingular nodule suspicious for a primary pulmonary lesion. Additionally, bilateral adrenal metastatic involvement. Differential diagnosis included metastatic MTC (however, the presence of a solitary pulmonary metastasis and absence of hepatic metastases is less likely given the overall disease burden) VS primary lung malignancy VS two synchronous primary neoplasms. Biopsy of the lung lesion was performed with histopathological diagnosis of calcitonin-expressing large-cell neuroendocrine carcinoma of the lung, Ki-67 80%, PD-L1 expression in 60%. Somatic NGS in lung cancer did not identify actionable variants. After multidisciplinary discussion, systemic treatment with carboplatin and etoposide and whole-brain radiotherapy were proposed. The patient died following the first cycle of chemotherapy due to an infectious complication.

Discussion/Conclusions: This case highlights the diagnostic complexity of hypercalcitoninemia, particularly the challenge of distinguishing MTC from extrathyroidal calcitonin-secreting NENs, especially in patients with concurrent thyroid nodules or cervical disease, where metastatic MTC may be falsely assumed. This distinction is crucial because management and prognosis differ significantly, and misdiagnosis may lead to unnecessary interventions, including inappropriate thyroidectomy. Accurate diagnosis requires integrating clinical evaluation, histopathology/immunochemistry and targeted imaging to determine primary tumour origin.

EP1286 - ECE_1531 - Pituitary apoplexy, the endocrinologycal stroke code: a case report

Belen del Arco Romualdo, Maria Jose Vallejo Herrera and Veronica Vallejo Herrera
Endocrinology, Hospital Regional Universitario de Málaga, Málaga, Spain

Introduction: Pituitary apoplexy is a rare but potentially life-threatening endocrine emergency, characterized by acute hemorrhage or infarction of the pituitary gland, most often occurring in the context of a pre-existing adenoma. Clinical presentation is highly variable and may mimic other neurological emergencies, frequently leading to diagnostic delay.

Case Presentation: We report the case of a 79-year-old man with arterial hypertension as his only relevant past medical history, who presented to the Emergency Department with severe headache exacerbated by Valsalva maneuvers and associated vomiting of 24 hours' duration. An initial non-contrast cranial computed tomography (CT) scan suggested a possible anterior communicating artery aneurysm versus a pituitary adenoma. Subsequent CT angiography ruled out vascular pathology, and conservative symptomatic management was initiated, with outpatient referral to Neurosurgery and Endocrinology.

Forty-eight hours later, the patient re-presented to the Emergency Department with syncope and worsening, refractory headache. A repeat non-contrast cranial CT scan revealed a hyperdense lesion consistent with intracranial hemorrhage in the sellar region, raising suspicion of pituitary apoplexy. A stroke code was activated, and the patient was transferred to a tertiary referral center.

On admission, neurological examination demonstrated new-onset diplopia and left temporal hemianopsia. Urgent laboratory evaluation, including biochemical profile, coagulation studies,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

and pituitary hormonal assessment, revealed panhypopituitarism with secondary adrenal insufficiency. High-dose intravenous corticosteroid therapy was promptly initiated. Given initial neurological stability, a conservative approach with close neurological monitoring was chosen following neurosurgical evaluation.

Magnetic resonance imaging (MRI) performed 48 hours after admission confirmed the diagnosis of pituitary apoplexy. Although initial clinical improvement was observed, persistence of a left-sided visual field defect (quadrantanopsia) was noted after seven days of hospitalization. After multidisciplinary discussion, transsphenoidal surgical decompression was performed.

In the early postoperative period, the patient developed central diabetes insipidus requiring desmopressin therapy. Reassessment of pituitary function at 72 hours post-surgery confirmed persistent panhypopituitarism. The patient was discharged with replacement therapy including levothyroxine, hydrocortisone, and nocturnal desmopressin, with outpatient follow-up by Neurosurgery and Endocrinology.

Conclusion: This case highlights the diagnostic complexity of pituitary apoplexy and underscores the importance of early endocrine evaluation in patients presenting with acute neurological symptoms. A multidisciplinary approach is essential to optimize neurological and endocrine outcomes, and timely surgical intervention should be considered in cases with persistent visual impairment.

EP1288 - ECE_3254 - Recurrence of ACTH-dependent Cushing's disease after pregnancy: clinical case

Khiuaz Ali, Anna Bazarova and Malika Kozhemzharova
Astana, Kazakhstan

Introduction: ACTH-dependent Cushing's disease (CD) is a rare endocrine disorder associated with significant morbidity. Transsphenoidal surgery (TSS) is the first-line therapy for an ACTH-secreting pituitary adenoma. However, even after surgical resection, recurrence may develop in up to half of cases.

Aim: To present and analyze a clinical case of recurrent ACTH-dependent CD with onset and relapse temporally associated with pregnancy and biochemical recurrence despite inconclusive pituitary imaging.

Methods: We retrospectively analyzed clinical history, biochemical data, pituitary imaging, inferior petrosal sinus sampling (IPSS), surgical findings, and histopathology of a patient with recurrent CD and 3 pregnancies with live births at term.

Case Presentation: A forty-three-year-old woman presented with biochemical relapse of ACTH-dependent CD. Initial manifestations appeared at age 24 years after the first pregnancy and included secondary amenorrhea, weight gain, central obesity, hirsutism, mood disturbances, and headaches. Low-dose dexamethasone suppression test showed lack of cortisol suppression, high-dose dexamethasone suppressed cortisol, twenty-four-hour urinary free cortisol was elevated, and CRH stimulation increased ACTH. Pituitary MRI revealed an adenoma with suprasellar extension.

The patient underwent TSS with histological confirmation of an ACTH-secreting pituitary adenoma. Remission persisted during 5 years. Two subsequent pregnancies occurred without complications. However, after the third pregnancy, symptoms of hypercorticism appeared and began to increase. ACTH levels gradually increased with weight gain and hypertension. Dopamine agonist therapy (cabergoline) provided partial control and was discontinued due to adverse effects.

IPSS with CRH stimulation confirmed pituitary ACTH hypersecretion. Repeat TSS yielded histologically confirmed ACTH-secreting adenoma. Postoperatively, adrenal insufficiency requiring glucocorticoid replacement, and transient diabetes insipidus requiring desmopressin. Within 2 years, the clinical picture of hypopituitarism resolved, and the following 2 years show no signs of hypercorticism. Follow-up MRI showed an empty sella with a small contrast- enhancing area suggestive of residual adenoma. Biochemical relapse occurred in late two thousand twenty-five and was confirmed on repeat testing. Currently, the patient is raising 3 children. No biochemical and clinical signs of CD were present at last follow-up.

Conclusion: Pregnancy may trigger onset and recurrence of ACTH-dependent CD. Biochemical relapse may precede radiological evidence, especially in empty sella. Long-term multidisciplinary surveillance with sensitive biochemical testing is essential for timely diagnosis and management. A rare case for Kazakhstan of successful management of a patient with ACTH-dependent CD and 3 pregnancies with live births at term is presented.

EP1291 - ECE_3704 - A case of cyclic ectopic Cushing's syndrome

Emma Capparelli[1], Elisabetta Sciarroni[1], Maurizio Carbonari[1], Chiara Bologna[1], Giulia Marconcini[1], Filomena Cetani[2], Alessio Basolo[1], Claudio Urbani[1], Isabella Lupi[1], Ferruccio Santini[1] and Luca Manetti[1]
[1]*Department of Clinical and Experimental Medicine, Unit of Endocrinology 1, Pisa University Hospital, Pisa, Italy;* [2]*Rende (CS), Italy*

Background: Cyclic Cushing's syndrome (CCS) is a rare condition characterized by alternating phases of hypercortisolism and biochemical remission. Approximately 54% of CCS cases are pituitary-related, 26% results from ectopic ACTH secretion, and 11% are adrenal. Diagnosis is particularly challenging, as it requires biochemical assessment during active disease phases.

Case Presentation: A 58-year-old patient presented with recurrent episodes of generalized edema and arterial hypertension over a 4-year period, partially responsive to diuretics and antihypertensive therapy. Laboratory findings revealed neutrophilic leukocytosis and hypokalemia. In October 2022, a neuroendocrine tumor of the pancreatic body–tail was detected. In June 2024, referral to our Center confirmed radiological stability of the lesion and significant uptake on ^68Ga-DOTATOC PET/CT, consistent with a pancreatic neuroendocrine tumor; serum neuroendocrine tumor markers were negative.

Secondary causes of hypertension were investigated: catecholamine excess was excluded and mineralocorticoid function was preserved. An overnight 1-mg dexamethasone suppression test suggested hypercortisolism (serum cortisol 10.9 μg/dL). In July 2024, the patient developed a new episode of generalized

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

edema associated with markedly elevated ACTH (310 pg/mL) and serum cortisol (80.3 µg/dL), confirming cyclic ACTH-dependent hypercortisolism. Monthly urinary free cortisol monitoring was initiated, and the patient was admitted for further differential diagnosis and surgical evaluation.

During hospitalization, severe hypercortisolism with elevated ACTH levels, loss of circadian cortisol rhythm, and lack of suppression following both low- and high-dose dexamethasone suppression tests were documented. Pituitary MRI with gadolinium showed no pituitary abnormalities. Following multidisciplinary discussion, surgical resection of the pancreatic lesion was indicated, and adrenolytic therapy with metyrapone was initiated as a bridge to surgery.

In April 2025, the patient underwent robotic left pancreatectomy. Histopathology revealed a well-differentiated G2 neuroendocrine tumor (Ki-67 index 3%), positive for chromogranin A, synaptophysin, ACTH, and somatostatin receptor subtype 2 (SSTR2), with pancreatic parenchymal invasion and posterior margin involvement (pT1 N0 G2 R1). Postoperatively, glucocorticoid replacement therapy with cortisone acetate (37.5 mg/day) was initiated. One month after surgery, ACTH levels normalized; however, an inadequate cortisol response to the Synacthen test indicated secondary adrenal insufficiency, and glucocorticoid replacement therapy was therefore continued. Disease restaging was planned.

Conclusion:: This case highlights the diagnostic complexity of ACTH-dependent CCS and the risk of delayed diagnosis despite significant clinical manifestations. Identification of a resectable ectopic ACTH-secreting pancreatic neuroendocrine tumor enabled timely surgical treatment, the first-line treatmentfor ectopic Cushing's syndrome. Given the histological features and margin involvement, strict long-term follow-up is warranted due to the increased risk of persistence or recurrence disease

EP1292 - ECE_3773 - Occult ectopic ACTH secretion in cyclic Cushing syndrome: a prolonged diagnostic and therapeutic challenge

Alina-Elena Șchiopu[1,2], Anca Matei[1,2], Georgiana Constantinescu[2], Viviana Adam[2], Alexandru Florescu[1,2], Stefana Bilha[1,2], Maria-Christina Ungureanu[1,2] and Cristina Preda[1,2]
[1]*Endocrinology, Saint Spiridon County Hospital, Iași, Romania;* [2]*University of Medicine and Pharmacy "Gr. T. Popa", Iasi, Romania*

Introduction: ACTH-dependent Cushing syndrome represents a major diagnostic and therapeutic challenge when the source of ACTH secretion remains elusive despite extensive investigations. Identifying ectopic ACTH-secreting tumors is particularly difficult in cyclic forms, where fluctuating biochemical activity may delay or preclude tumor localization. Severe hypercortisolism with intermittent remission further complicates diagnostic assessment, treatment monitoring, and long-term management.

Case Presentation: We report the case of a 61-year-old woman with a history of papillary thyroid microcarcinoma treated surgically in 2005. In 2016, she presented with progressive neuro-ophthalmic symptoms. Pituitary magnetic resonance imaging revealed a large sellar mass (23 × 35 × 29 mm) with optic chiasm compression. Incomplete transsphenoidal resection was performed. Histopathology confirmed a pituitary adenoma (Ki-67 index 4%), initially immunonegative for ACTH. At that time, pituitary hormonal work-up, including assessment of cortisol secretion, came back normal.

Later the same year, the patient developed severe ACTH-dependent hypercortisolism with hypokalemia. While patient history data from that period are scarce, abdominal imaging studies were performed, showing two left sided adrenal adenomas and bilateral adrenal hyperplasia, which led to the surgical removal of the left adrenal gland. Due to persistent diagnostic uncertainty, a second transsphenoidal surgery was subsequently undertaken, with immunohistochemistry demonstrating ACTH positivity. Follow-up pituitary MRI showed an empty sella.

Despite these interventions, the disease course was characterized by recurrent episodes of ACTH-dependent hypercortisolism with hypokalemia, profound muscle weakness, and diabetes mellitus, alternating with periods of biochemical remission, consistent with cyclic Cushing syndrome.

Further evaluation identified a large cephalo-isthmic pancreatic lesion, which was surgically resected; however, histopathological examination and subsequent clinical evolution excluded the pancreas as the source of ACTH secretion. During follow-up, a pulmonary nodule with progressive dimensional increase was detected, raising suspicion for an ectopic ACTH-secreting tumor. Functional imaging with 99mTc-tektrotyd SPECT/CT didn't show pathological tracer uptake. Because of severe complications related to prolonged hypercortisolism—including recurrent infections, respiratory failure, and major metabolic disturbances—definitive surgical or invasive diagnostic procedures were repeatedly deferred.

Medical treatment with steroidogenesis inhibitors was initiated. Given the cyclic disease pattern, a block-and-replace strategy combining ketoconazole with glucocorticoid replacement was adopted, allowing partial biochemical control. The condition was ultimately classified as occult ectopic ACTH secretion with cyclic activity.

Conclusions: This case underscores the complexity of ACTH-dependent Cushing syndrome when the source of ACTH secretion cannot be localized. Cyclic hypercortisolism, intermittent spontaneous remission, and limited interventional options substantially hinder diagnostic confirmation and disease monitoring, emphasizing the need for prolonged, individualized, multidisciplinary management.

EP1293 - ECE_2138 - Clinical case of repid successful medical treatment of invasive prolactinoma in a man

Mykhailo Kyryliuk[1,2,3]
[1]*Endocrinology, Academic Medical Centre, Kyiv, Ukraine;* [2]*Academic Medical Centre, Kyiv;* [3]*Endocrinology, Kharkiv National Medical University, Kyiv, Ukraine*

Prolactin-secreting adenomas (prolactinomas) are the most common secreting pituitary neuroendocrine tumors (PitNETs \2017) (27.2%-40%) Invasive giant prolactinomas (IGPs) are a rare subtype of PitNETs (0.5%-4.4%). Their criteria include a maximum tumor diameter >40 mm, serum prolactin concentration >200 ng/mL, and tumor invasion into the

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

cavernous sinus. IGPs are more common in young men due to its late diagnosis.[1] Biochemical and instrumental control of tumor growth is a current problem in neuroendocrinology due to its aggressive clinical course.[2] Dopamine agonists (DA) are used in the first-line treatment of prolactinomas.[3] However, their effectiveness in the treatment of IGPs is discussed.[4]

The successful treatment by AD cabergoline of IGP, incidentally detected on MRI after a car accident of a man aged 38 years, is presented. MRI was showed: The sella turcica is dilated, there is an invasion of bulky mass (measuring 26 × 24 × 25 mm) into sinus cavernous, which is tightly adjacents to the right internal carotid artery with deviation of the pituitary infundibulum to the left and back. After treatment of the injury, further blood examination was prescribed. Laboratory data showed the following results: serum PRL 1415.94 ng/mL (ref. 2.64-13.13), big-big PRL <1%, TSH 1.614 μIU/mL (0.4-4.85), morning cortisol 8.49 μg/dl (4.82-19.5), somatomedine C1 (IGF-1) 121 ng/mL (58-219), LH 2.04 mIU/mL (0.57-12.07), FSH 2.18 mIU/mL (0.95-11.95), testosterone total 12.39 nmol/l (8.33-30.19). It was prescribed cabergoline (dosage 0.5 mg per week). After 1 months from the start of medical treatment PRL concentration decreased to 2.67 ng/mL, and after 4 months – down to 1.53 ng/mL, tumor volume decreased by 19.74%, LH level increased up to 3.68 mIU/mL, FSH level – to 3.93 mIU/mL, testosterone total concentration – to 17.05 nmol/l.

Conclusion: Thus, the results of drug treatment showed a very good tumor sensitivity to cabergoline without side effects with an improvement of pituitary gonadotropic function, which predetermines further positive dynamics of tumor size reduction.

Keywords invasive prolactinoma, cabergoline

EP1294 - ECE_1300 - Recurrent colonic diverticular bleeding in acromegaly: improvement after surgical remission

Naotetsu Kanamoto[1,2], Yuki Minamoto[1], Yui Yamashita[1], Yumiko Sasai[1], Keiko Yamagami[1] and Kenichi Ishibashi[3]
[1]Department of Endocrinology, Osaka City General Hospital, Osaka, Japan; [2]Department of Endocrinology and Metabolism, National Hospital Organization Kyoto Medical Center, Kyoto, Japan; [3]Department of Neurosurgery, Osaka City General Hospital, Osaka, Japan

Background: Acromegaly is associated with various gastrointestinal complications, particularly colorectal neoplasms. However, non-neoplastic colonic disorders, including diverticular disease and diverticular bleeding, have been less well characterized.

Case Presentation: A 64-year-old woman had experienced recurrent episodes of hematochezia for two years, which were suspected to be due to colonic diverticular bleeding. During the same period, she developed progressive snoring and noticed enlargement of her fingers, such that rings no longer fit. Four months prior to referral, she was hospitalized for sigmoid colon diverticular bleeding, and acromegaly was suspected based on her characteristic facial features. Endocrinological evaluation revealed insufficient suppression of growth hormone (GH) during a 75-g oral glucose tolerance test (OGTT), elevated insulin-like growth factor-1 (IGF-1), and mild hyperprolactinemia. A paradoxical GH response to thyrotropin-releasing hormone (TRH) stimulation was observed. GH suppression with octreotide was insufficient, while bromocriptine markedly suppressed both GH and prolactin (PRL). Pituitary MRI revealed a 5-mm tumor. The patient underwent endoscopic endonasal transsphenoidal surgery. Histopathological examination demonstrated tumor cells positive for Pit-1, GH, and PRL, with perinuclear CAM5.2 staining. Co-expression of GH and PRL within the same tumor cells led to a diagnosis of mammosomatotroph pituitary neuroendocrine tumor. Postoperatively, IGF-1 normalized, GH was adequately suppressed during OGTT, the paradoxical TRH-induced GH response disappeared, and PRL levels and responsiveness improved.

Outcome and Discussion: Although episodes of diverticular bleeding persisted after surgery, their frequency remarkably decreased during a 44-month follow-up period. Previous studies have reported a higher prevalence of colonic diverticula in patients with acromegaly, which is associated with disease duration and GH-related colonic morphological changes, such as colonic elongation. In addition, endothelial dysfunction in small vessels has been described in active acromegaly and may contribute to diverticular bleeding. Improvement in GH/IGF-1 excess might ameliorate these pathological changes and may be associated with a reduced risk of diverticular bleeding.

Conclusion: This case suggests that acromegaly may contribute to recurrent colonic diverticular bleeding. Biochemical remission may be associated with a reduction in bleeding frequency. Clinicians should consider non-neoplastic colorectal complications in patients with acromegaly, in addition to surveillance for colorectal neoplasms.

EP1295 - ECE_3618 - Clinical, biochemical, and radiological outcomes of persistent acromegaly: insights from a small case series

Mariam Bulashvili, Nino Zavrashvili and Mariam Orjonikidze
Tbilisi Institute of Medicine, Tbilisi, Georgia

Background: Acromegaly is a rare condition caused by a growth hormone (GH)-secreting pituitary adenoma driving excess

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

secretion of insulin-like growth factor-1 (IGF-1). In addition to the somatic features, uncontrolled acromegaly is associated with a number of complications and excess mortality. Transsphenoidal pituitary surgery is generally first-line treatment. Residual disease after surgery remains a major challenge in the management of acromegaly. Treatment options for persistent acromegaly include radiotherapy or medical therapies.

Methods: We retrospectively reviewed five patients with acromegaly who underwent transsphenoidal surgery. Clinical features, comorbidities, postoperative MRI findings, serum IGF-1 levels, and subsequent management strategies were analyzed.

Results: All patients presented with acral enlargement, maxillofacial changes, and hyperhidrosis (100%). Metabolic comorbidities were common, with dyslipidemia in 40%, hypertension in 25%, and diabetes mellitus in 20% of patients. Postoperative MRI revealed residual pituitary tissue in four patients. Residual disease was associated with persistent elevation of IGF-1 levels and clinical symptoms, necessitating adjuvant therapy, including Gamma-Knife radiosurgery and treatment with somatostatin analogs and/or dopamine agonists. Improvement in biochemical markers was accompanied by symptom improvement during follow-up. One patient achieved biochemical and radiological remission following surgery alone.

Conclusion: Postoperative residual tissue in acromegaly correlates with persistent biochemical activity and symptom burden. Integrated clinical, biochemical, and radiological assessment is essential to guide individualized postoperative management.

Patient	Pre-op IGF-1/GH & MRI	Post-op IGF-1/GH & MRI	Follow-up / Treatment

EP1296 - ECE_2225 - Cortisol normalization with osilodrostat reduces sleeping metabolic rate and protein oxidation in Cushing's disease: a case report

Alessio Basolo[1], Isabella Lupi[1], Claudio Urbani[1], Luca Manetti[1], Paolo Piaggi[2], Alberto Landi[2] and Ferruccio Santini[1]
[1]Endocrinology Unit, University Hospital of Pisa, Pisa, Italy; [2]Department of Information Engineering, University of Pisa, Pisa, Italy

Chronic hypercortisolism causes major metabolic disturbances that adversely affect whole-body energy metabolism, leading to central adiposity, and progressive skeletal muscle loss. We have recently shown that severity of hypercortisolism is positively associated with 24-h energy expenditure (24hEE) and protein oxidation (Protox). However, whether cortisol normalization with medical therapies such as osilodrostat, an oral 11β-hydroxylase inhibitor, can affect body composition and 24hEE, sleeping metabolic rate (SMR) and Protox has not been investigated.

A 45-year-old woman with ACTH-dependent hypercortisolism due to a pituitary adenoma experienced multiple disease recurrences despite 3 trans-sphenoidal pituitary surgeries.

In 2024 disease recurrence with characteristic clinical features of hypercortisolism was demonstrated by elevated 24-hour urinary free cortisol levels (mean UFC: 228-119 μg/24 h, normal values: 11-70). Pituitary MRI did not identify a clearly detectable adenoma. Treatment with osilodrostat was started at 1 mg once daily and up-titrated to 1 mg twice daily leading to a UFC normalization (mean UFC: 24-30 μg/24 h), accompanied by an overall clinical improvement.

To explore metabolic effects beyond conventional biochemical endpoints, body composition and 24-hour energy metabolism were assessed both during active hypercortisolism and following cortisol normalization, 12 months after osilodrostat initiation.

Body composition was evaluated by dual-energy X-ray absorptiometry (DXA), while 24-h energy metabolism was assessed using whole-room indirect calorimetry, the gold-standard method for measuring 24-h energy metabolism and macronutrient oxidation.

Lean soft tissue was unchanged (33.3 kg at baseline vs 33.9 kg at follow-up). 24-h EE was reduced (1252 kcal/d at baseline vs 1154 kcal/d at follow-up), as well as SMR (815 kcal/d at baseline vs 663 kcal/d at follow-up) and Protox (431 kcal/d at baseline vs 194 kcal/d at follow-up). This combined reduction in 24-h EE, SMR and Protox occurring in the absence of changes in lean mass, may reflect restoration of a more physiological cortisol rhythm and improved metabolic regulation.

In a patient with refractory Cushing's disease, osilodrostat achieved biochemical control. While lean soft tissue had not yet

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

recovered, treatment was associated with a reduction in 24hEE, SMR and Protox, supporting the hypothesis that effective medical control of hypercortisolism may contribute to the restoration of metabolic physiology. These observations warrant confirmation in larger, prospective studies.

EP1298 - ECE_1416 - Pituitary apoplexy in a patient with diabetic foot: a case report

Kader Ugur[1], Dilek Kılınç Candemir[1] and Ahmet Furkan Tuntaş[2]
[1]*İnternal Medicine, Endocrinology and Metabolism, Fırat University, Elazıg, Turkey;* [2]*İnternal Medicine, Fırat University, Elazıg, Turkey*

Introduction: Pituitary apoplexy is an extremely rare condition, and estimated prevalence is approximately 6.2 cases per 100 000 people. Pituitary apoplexy, characterized by acute ischemia or hemorrhage of the pituitary gland, can be life-threatening, and it may be precipitated by various factors. Diabetes is one such major factor. In approximately 80% of cases, the presence of a pituitary adenoma is unknown before the occurrence of apoplexy. This report aimed to present a rare case of acute pituitary apoplexy that developed while the patient was being followed for diabetic foot at our clinic.

Case: A 79-year-old man with a 15-year history of type 2 diabetes mellitus, hypertension, ischemic heart disease, and hyperlipidemia was admitted to our endocrinology clinic for a discharging wound on the second toe of the left foot that had appeared approximately 15 days earlier. As his diabetes was poorly controlled owing to HbA1c of 10.7%, intensive insulin therapy was initiated. For the diabetic foot, daily wound care and broad-spectrum antibiotic therapy were conducted based on clinical, laboratory, and imaging assessments. During follow-up, cranial imaging was performed owing to sudden severe headache, deterioration in general condition, intermittent diplopia, hypotension, and nausea and vomiting, incidentally revealing a pituitary macroadenoma measuring approximately 3×2 cm compatible with subacute hemorrhage. This was deemed indicative of pituitary apoplexy. Based on visual field examination and multidisciplinary evaluation, surgery was not considered and conservative treatment was planned. His laboratory findings are shown in the table. Under close monitoring with physical examination and clinical and laboratory follow-up, the patient was started on stress-dose hydrocortisone and appropriate fluid replacement for hemodynamic stabilization; treatment for his other chronic comorbidities was continued. The patient's general condition stabilized, and the headache and diplopia subsided. As the patient developed permanent pituitary insufficiency, hydrocortisone and levothyroxine replacement therapy were instituted.

Conclusion: Given the high morbidity and mortality associated with pituitary apoplexy, it is crucial that treatment decisions are made through multidisciplinary evaluation.

Table 1 Laboratory findings of the patient.

IGF-1 (ng/mL)	64	71-290
GH (ng/mL)	<0.05	0.06-5

EP1300 - ECE_2441 - Unusual presentations of AVP deficiency presenting as cognitive impairment and renal function impairment

Furhana Hussein, Gideon Mlawa, Edel Casey and Nemanja Stojanovic
Barking Havering and Redbridge Hospitals NHS Trust, London, United Kingdom

Introduction: Cranial diabetes insipidus (DI) known as AVP deficiency is a rare disorder caused by impaired secretion in arginine vasopressin (AVP) in central DI or response in nephrogenic DI. Affects 1 in 25 000 people and usually presents with polyuria and polydipsia. The most common acquired causes include autoimmune, infection, primary or secondary tumours, neurosurgery and head trauma.

Here we discuss two cases in which AVP deficiency presented with cognitive and renal function impairment.

Case 1: 31 year-old female admitted with reduce oral intake, dehydration, cognitive impairment, and acute kidney injury (AKI). Past medical history TB meningitis which led to stroke. Blood test showed hypernatraemia 174 mmol/L and MRI showed increase in size of lesion in left hypothalamus and midbrain with further new lesions. Plasma glucose 33.6 mmol/L suggesting new onset of Type 2 diabetes. Endocrine input was required as serum osmolality remained high despite treatment of hyperglycaemia. Serum osmolality was 314 mosmol/kg, urine osmolality 481 mosmol/kg. She was started on DDAVP which led to clinical improvement and normalised serum osmolality.

She was treated with quadruple anti-tuberculous medication for 14 months and required second-line anti-tuberculous medication.

Case 2: 54 year-old male initially presented to different hospital with cognitive impairment, memory issues alongside worsening headaches. CT showed Chordoid Glioma of third ventricle requiring VP shunt, debulking of tumour and radiotherapy.

He was reviewed in endocrine clinic for low testosterone on background of third ventricle pathology and found to have high osmolality and was admitted to hospital for water deprivation test. He was diagnosed with AVP deficiency and full pituitary profile revealed partial hypopituitarism secondary to his third ventricle tumour.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

He was treated with hydrocortisone, desmopressin, levothyroxine, testosterone.

Conclusion: Here we discuss two cases in which AVP deficiency initially presented as cognitive impairment due to severe dehydration and AKI thought to be secondary to hypothalamic or brain injury. It is important that a multidisciplinary team approach is used for individualised management of these patients to achieve the best outcome.

Question:

1. Have come across unusual presentation of AVP deficiency?
2. Have you seen cognitive or renal impairment as initial presentation of AVP deficiency in your patients?

EP1301 - ECE_1817 - "Vanishing" macroprolactinoma—complete Tumour regression after a decade of cabergoline therapy

Zhenya Ruseva[1,2], Radina Dimitrova[1,2], Mira Siderova[1,2] and Kiril Hristozov[1,2]

[1]*Second department of Internal diseases, Medical University of Varna, Clinic of Endocrinology and Metabolic diseases, Varna, Bulgaria;* [2]*Second department of Internal diseases, UMHAT "Sveta Marina" Varna, Clinic of Endocrinology and Metabolic diseases, Varna, Bulgaria*

Introduction: Prolactinomas are the most common functioning pituitary adenomas. They are characterised by autonomous prolactin secretion and a wide spectrum of clinical manifestations. These range from hypogonadism and infertility to mass effects in larger tumours. They occur more frequently in women but tend to be larger and more aggressive in men. Treatment options include medical therapy with dopamine agonists, transsphenoidal surgery and, in selected cases, radiotherapy. Treatment is tailored to the characteristics of the tumour, the preferences of the patient and the patient's response to therapy.

Case Report: A 30-year-old male presented with decreased libido, erectile disorder, ejaculatory failure and gynaecomastia with increased breast sensitivity over the last two years. Laboratory hormonal analysis revealed hyperprolactinemia and secondary hypogonadism (prolactin 1821 mIU/L; LH 0.753 mIU/L; FSH 2.28 mIU/L; total testosterone 4.61 nmol/L). An MRI scan of the pituitary gland showed an oval lesion measuring 11/8/11 mm in the right pituitary lobe, which was displacing the infundibulum slightly to the left. There was no evidence of compression of the optic chiasm or the suprasellar cerebrospinal fluid spaces, nor invasion of the cavernous sinus or the depicted parts of the internal carotid artery and carotid siphon. Treatment with cabergoline at a dosage of 2×0.5 mg weekly was initiated, and the patient was monitored regularly. Normalisation in prolactin levels and gonadal function was observed, which led to reducing the cabergoline dosage to 0.25 mg weekly. The MRI follow-up of the adenoma revealed disappearance of the tumour formation within 10 years. During this period no changes in the heart valves was registered.

Conclusions: Despite emerging recommendations that increasingly favour early surgical intervention in patients with prolactinomas, this case underscores the enduring effectiveness of long-term pharmacological therapy. Sustained treatment with dopamine agonists can lead not only to biochemical control but also to profound tumour regression, even complete radiological disappearance, in carefully monitored patients. This outcome highlights the heterogeneity of prolactinoma behaviour and reinforces the importance of individualized management strategies. Pharmacological therapy remains a valid and potentially curative approach, particularly for patients who respond well, tolerate treatment and prefer to avoid surgical risks.

Keywords pituitary adenoma, prolactinoma, tumor regression, cabergoline

Aggressive behavior in pituitary tumors is characterized by rapid growth or progression despite standard treatments, including surgery, radiotherapy (RT), and medical therapies. Within this subset of tumors, there is heterogeneity in clinical behavior with limited predictive biomarkers. To identify prognostic biomarkers, we performed next-generation sequencing of tumor and a matched normal sample from 38 patients with aggressive pituitary tumors, comprised of 18 (47.4%) metastatic and 20 (52.6%) non-metastatic tumors, on a sequencing protocol. We then correlated genetic profile with clinical behavior, including progression-free survival (PFS), defined as the time from the first progression after RT until the time of next progression, which was available for 34 of 38 patients. A pathogenic or likely pathogenic mutation in *TP53, ATRX, DAXX,* or *SF3B1* was identified in 52.9% of metastatic and 60.0% of locally aggressive tumors ($P = .746$) and was associated with shorter PFS (median 10.3 ($n = 20$) vs 25 ($n = 13$) months; $P = .015$). In contrast, the presence of a USP8 mutation in corticotroph tumors (14.3%) was associated with a longer PFS (150.0 ($n = 3$) vs 14.0 ($n = 16$) months; $P = .026$). Among the corticotroph tumors ($n = 21$), recurrent chromosomal loss of heterozygosity (defined as loss of ≥10 of

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

the following chromosomes: 1, 2, 3, 4, 6, 10, 11, 15, 17, 18, 21, and 22) was identified in 80% of cases and was associated with shorter PFS (11.8 ($n = 14$) vs 150 ($n = 5$) months; $P = .015$). Cell-cycle pathway alterations (CCND1/2/3 amplification, CDK4/6 amplification, CDKN2A/B/C loss, RB1 loss) were identified in at least one tumor sample in 24.3% of the cohort in both corticotroph tumors and those within the PIT1 lineage. These alterations were frequently subclonal and associated with metastatic dissemination (47.1% metastatic cohort vs 5.0% locally aggressive cohort; OR = 15.6; $P = .006$). Given that cell cycle alterations drive tumor progression, we interrogated our cohort for patients treated with a CDK4/6 inhibitor. Of the 4 patients treated with an inhibitor, tumor stabilization was achieved in 2 patients for 12 and 24 months. This study demonstrates the utility of genetic profiling pituitary tumors for clinical decision making; sequential tumor sampling may be valuable for detecting acquired mutations of prognostic importance.

EP1684 - ECE_2135 - The Canadian acromegaly registry: a national registry for real-world evidence

Syed Imran[1], Deanna Badiuk[2], Constance Chik[3], Marie-Eve Domingue[4], Ezzat Shereen[5], Fabienne Langlois[6], Kirstie Lithgow[7], Heather Lochnan[8], Juan Andres Rivera Ramirez[9], Stan Van Uum[10] and Victoria Hodgkinson[11]

[1]Dalhousie University, Halifax, Canada; [2]Acromegaly Canada, Chilliwack, Canada; [3]University of Alberta, Edmonton, Canada; [4]Université Laval, Québec, Canada; [5]University Health Network, Etobicoke, Canada; [6]Université De Sherbrooke, Sherbrooke, Canada; [7]University of Calgary, Calgary, Canada; [8]The Ottawa Hospital, Ottawa, Canada; [9]McGill University, Montreal, Canada; [10]St Joseph's Health Care London, London, Canada; [11]Lumiio Inc., Calgary, Canada

Background: The Canadian Acromegaly Registry (CAR) is a nationwide disease registry that collects both clinic- and patient-reported data on individuals with acromegaly. Although recent advances in multimodal therapy have improved patient outcomes, there remains a critical need for real-world evidence to address knowledge gaps in rare disorders. The objective of CAR is to better assess the needs of the Canadian acromegaly population to enhance patient-focused care. Here, we present baseline data on the initial cohort of patients enrolled in CAR.

Methods: CAR is currently active at 8 academic centres across 4 provinces with planned nationwide expansion. Data are collected at each centre by trained coordinators and include both clinic-reported data on disease onset, progression, treatments, as well as patient-reported outcomes. Additional data include biomarkers, surgical history, radiotherapy, medication use, tumor data and comorbidities.

Results: As of December 15, 2025, 187 participants are registered with complete baseline data. Patients were 51% (96) females and mean age at diagnosis was 47 (+/−14) years. Overall, 35% patients reported having symptoms of acromegaly at diagnosis, 14% were found incidentally, and 51% were unknown/not answered. Of the 35% diagnosed based on symptoms, 82% had classical facial features at diagnosis, 80% reported hand and 82% reported foot enlargement. The baseline IGF-1 (% upper limit of normal) was reported in 64 individuals, with a mean of 217% (+/−122). Of the 93 patients with baseline tumor size reported, tumor size was >1 cm in 72% and <1 cm in 28%. Primary therapy was surgery in 115 (61%) patients, 31 (17%) also received radiotherapy and 40% were receiving medical therapy. The most commonly reported comorbidities were arthritis (30%), hypertension (28%), obstructive sleep apnea (25%), dyslipidemia (18%), and diabetes mellitus (13%).

Conclusions: CAR has been established to collect a prospective and retrospective, longitudinal dataset that will help evaluate acromegaly care and outcomes. Efforts to expand into other academic and community centres are ongoing to create a comprehensive national dataset.

EP1909 - ECE_3955 - Developing PCOS cell therapy using human GnRH cell repopulation in a GnRH-Killswitch mouse model

Jacob Short[1,2], Robert Harris[1], Elisabet Stener-Victorin[1], Frida Holm[1] and Susan Wray[2]

[1]Karolinska Institutet, Solna, Sweden; [2]US National Institute of Neurological Disorders & Stroke, Bethesda, United States

GnRH cells are the final integrator of the LH surge generator in the hypothalamus and sole initiators of the LH pulse signal in the pituitary. The aetiology of Polycystic Ovarian Syndrome (PCOS) involves dysregulation of the feedback regulation facilitated by the GnRH pulse. As such, GnRH cells represent an opportunity to intervene in the neuroendocrine origin of hormone dysfunction through replacement of endogenous cells with engineered neurons to regulate the GnRH pulse. We made a GnRH cell knockout mouse model, *GnRH-Killswitch*, inducible with diphtheria toxin. This model is useful for robust depletion of GnRH neurons at postnatal timepoints and permanent central deactivation of the reproductive system while retaining the ovaries. Human embryonic stem cells differentiated to GnRH cells are transplanted into the third ventricle to repopulate the empty niche. We have engineered the human cells to express murine IL-10 to extend graft survival in immunocompetent mice. Immunocompetent mice are used for this human chimera strategy to more accurately model the reproductive system and reduce the overall number of animals required to develop this protocol. Subsequently, existing strategies will be used to integrate estrous cycle timing into the engineered replacement cells. Using this new model will provide insight into how one can 1) regulate dysfunctional pulse generators, 2) prevent feedback amplification in neuroendocrine systems and 3) treat hormone disorders such as PCOS.

EP1304 - ECE_2731 - Characterization of detransition cases in a specialized gender identity clinic in the Canary Islands

Kevin David Díaz Gorrín, Selena Rodriguez Fernandez, Javier Panizo Fra, Paula Pérez, Ana Paola Leon Ocando, Óliver Quintero Rodríguez, Itziar Aznar Ondoño, Juan Ignacio Márquez De La Rosa, Laura Mesa Suárez and Patricia Cabrera García

Endocrinology and Nutrition, Hospital Universitario de Canarias, San Cristóbal de La Laguna, Spain

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: Gender detransition, understood as the process of discontinuing or reversing a gender transition, is an emerging and poorly understood phenomenon. The aim of this study was to clinically and demographically characterize individuals who underwent some form of detransition after being evaluated at the specialized Gender Identity Clinic of the Endocrinology and Nutrition Department at the Complejo Hospitalario Universitario de Canarias since 2023.

Material and Methods: A retrospective descriptive study was conducted analyzing sociodemographic and clinical variables of patients who attended the Endocrinology and Nutrition clinics from 2023 until 2025.

Results: Twenty-one detransition cases were identified. Of these, 57.1% had identified as trans men, 28.6% as trans women, and 14.3% as non-binary individuals. The mean age was 23 years (range 16-45). Regarding geographic distribution, 42.9% lived in the southern area of Tenerife, 38.1% in the north, and 19.0% in La Palma. Hormonal treatment had been initiated in 85.7% of cases, with a mean duration of 26.2 months (median: 23), while 14.3% had not started treatment. Gender-affirming surgery had been performed in 38.1% of individuals. The most frequent reasons for detransition were identifying as non-binary (23.8%), treatment side effects (19%), and doubts regarding gender identity (14.3%). According to the Expósito-Campos classification, 71.4% were categorized as secondary detransitions.

Conclusions: Most observed detransitions were secondary, with many individuals maintaining a trans or non-binary identity. The predominant profile was a young person assigned female at birth who initiated hormonal treatment during adolescence and detransitioned in early adulthood. A significant proportion had undergone gender-affirming surgery.

EP1305 - ECE_3741 - Clinical profile and implications of primary vs secondary medical detransitions: experience from a transgender care unit in spain

Mariana Jesús Gomes Porras[1,2,3,4], Mónica Tomé García[1] and Guadalupe Cano Oncala[5]

[1]*Endocrinology and Nutrition, Regional University Hospital of Málaga, Malaga, Spain;* [2]*Institute of Biomedical Research of Málaga (IIBIMA), BIONAND Platform, Málaga, Spain;* [3]*Biomedical Research Networking Center for Diabetes and Associated Metabolic Diseases (CIBERDEM), Group CB07/08/0019, Málaga, Spain;* [4]*Endocrinology and Nutrition, Regional University Hospital of Málaga, Málaga, Spain;* [5]*Psychology, Regional University Hospital of Málaga, Málaga, Spain*

Background: Detransition is the process of partially or completely stopping or reversing social, medical, and/or administrative changes during gender transition, which may be temporary or permanent.

Objective: To compare the clinical profile of transgender individuals who underwent primary vs secondary medical detransition and received follow-up at the Transgender Care Unit (TCU) of a Spanish hospital between 1999-2025.

Material and Methods: This cross-sectional descriptive study included 40 transgender individuals aged ≥14 years who reported deciding to discontinue cross-sex hormone therapy (CHT). Severe psychiatric comorbidity was defined as the presence of self-harm, suicidal ideation, and/or suicide attempts. Detransitions were classified as primary, with identity desistance, or secondary, without identity desistance.

Results: Of the 40 detransition cases, 36 (90%) began follow-up at the TCU in the last 8 years. 72.5% ($n = 29$) were secondary detransitions, all partial and 65.5% permanent. The remaining 27.5% ($n = 11$) were primary, all complete and permanent. Regret was reported exclusively in primary detransitions, in a markedly high proportion (72.7% vs 0%, $P < .001$). The median time from the start of medical gender transition to detransition was 22 months (range:1-300), with primary detransitions lasting longer than secondary ones [25 months (range:5-300) vs 22 months (range:1-108), $P = .3$, respectively].

Overall, 62.5% ($n = 25$) were transgender men. The median current age of the individuals was 24.5 years (range:18-61). The median age at the first consultation at the TCU was 19.5 years (range:14-61), while the median age at initiation of CHT was 18 years (range: 14-44), which was lower due to prior self-administered hormone therapy in 20% of cases. A total of 65% of participants ($n = 26$) lacked family support (primary 72.7% vs secondary 62%, $P = .5$). All participants had psychiatric comorbidities, which were severe in 52.5% of cases (primary 54.5% vs secondary 51.7%, $P = .8$). A total of 12 individuals (30%) underwent sex reassignment surgery (SRS), with a similar proportion in primary and secondary detransitions (primary 27.3% vs secondary 31%, $P = .81$). Four of these 12 individuals (33.3%) underwent SRS involving genital/gonadal procedures, a proportion that was clinically significant among primary detransitions (primary 2/3 individuals, 66.6% vs secondary 2/9 individuals, 22.2%; $P = .29$).

Conclusions: Distinguishing between primary and secondary detransitions has important psychological and therapeutic implications. In our cohort, primary detransitions were characterized by a longer duration of CHT, a higher proportion of genital/gonadal SRS, and elevated rates of negative affect, such as regret, combined with a high prevalence of severe psychiatric comorbidity.

EP1306 - ECE_2077 - Testosterone formulations in gender-affirming hormone therapy: efficacy, safety, and subject satisfaction

Emilia Gomez Hoyos[1,2], Lucía Estévez Asensio[1], Esther Delgado Garcia[1], Marta Mesonero Alonso[3], Maria Jose Bartolome Albistegui[3], Ruth Gonzalez Collantes[3], Alicia Perez Bustillo[3], Ana Casas Marcos[3], Carmen Rodriguez Fernandez[3] and Daniel De Luis Román[1]

[1]*Endocrinology and Nutrition, Clínico University of Valladolid Hospital. IBioVall.IENVA.CIBEROBN, Valladolid, Spain;* [2]*Endocrinology, Hospital Clinic Universitario de Valladolid, Valladolid, Spain;* [3]*Clínico University of Valladolid Hospital, Valladolid, Spain*

Introduction: Gender affirming hormone therapy (GAHT) in transgender men favors their virilization.

Aims: To evaluate the effects, the development of adverse events, and the associated satisfaction-CRES-4 questionnaire- with different testosterone formulations one year after initiation of GAHT.

Material and Methods: Retrospective study in transgender men with GAHT (>1 year), attended at the Transgender Medicine Unit

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

of the Clinico of Valladolid Hospital from January 2014 to January 2025. Recording of clinical, analytical and CRES-4 questionnaire. Statistical analysis of the data by the SPSS-V17 program.

Results: A total of 69 trans men aged 24 [22-24] years were included, with initiation of GAHT at 18 [17-21] years. Fifty-one (75%) started intramuscular short-acting testosterone ester at 100 mg every 15 days, with an increase to 200 mg at 3 months, and 17 (25%) started testosterone gel at 50 mg/day. After one year, serum testosterone levels were 411 [251-680] vs 760 [483-1248] ng/dL ($P = .030$), and estradiol levels were 49 [34-79] vs 48 [35-62] pg/mL ($P = .824$) in the ester and gel groups, respectively. Within the testosterone range of 260-1000 ng/dL, 32/43 subjects r eceiving esters and 12/14 receiving gel achieved target levels ($P = .316$). Estradiol <50 pg/mL was observed in 23/45 subjects in the ester group and 8/13 in the gel group ($P = .366$). Adverse effects included erythrocytosis in 9 (80%) vs 2 (20%) subjects ($P = .521$). The change in total cholesterol was 5 [−15 to 20] vs −3 [−11.0 to 10.7] mg/dL ($P = .462$), and triglycerides changed by 3.5 [−8 to 26] vs −28 [−31 to −0.95] mg/dL ($P = .024$) in the ester and gel groups, respectively. The CRES-4 score was 255 [230-267] vs 262 [242-275] points ($P = .146$) in the ester vs gel groups, respectively.

Conclusion: Testosterone gel may offer a more favorable efficacy and safety profile than intramuscular short-acting testosterone esters. Importantly, treatment satisfaction, as assessed by CRES-4, was comparable between both formulations.

Abstract citation ID: lvag096.1532

EP1307 - ECE_2315 - The effect of inositol on fractalkine-mediated metabolic inflammation in women of reproductive age with prediabetes

Mariana Ivanishchak[1], Iryna Kostitska[1], Nadiia Zherdova[2] and Sofiia Shelever[1]
[1]*Endocrinology, Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine;* [2]*Endocrinology, Center for Innovative Medical Technologies of NAS of Ukraine, Kyiv, Ukraine*

Prediabetes in women of reproductive age is accompanied by chronic low-grade inflammation, which plays a key role in the progression of insulin resistance and the development of cardiometabolic complications. Fractalkine, a chemokine with both adhesive and chemotactic properties, is a key mediator of the interaction between adipose tissue, the immune system, and the endothelium. Standard therapeutic approaches for prediabetes have a limited impact on markers of dysadipocytokinemia, which substantiates the need for additional pathogenetically targeted interventions.

Objective: To evaluate the effect of inositol on serum fractalkine levels in women of reproductive age with prediabetes.

Materials and Methods: The study included 36 women aged 19-44 years diagnosed with prediabetes (mean duration 1.8 ± 0.2 years), with glycated hemoglobin (HbA1c) of 6.0 ± 0.4% and fasting plasma glucose of 6.1 ± 0.2 mmol/L. All participants had class II-III obesity (BMI-37.4 ± 1.65 kg/m^2) and insulin resistance (IR) (HOMA-IR- 8.2 ± 0.4). The patients were randomized into two groups (Gr): Gr A ($n = 18$) received basic basic medical therapy (BMT), including lifestyle modification, metformin 500-2000 mg/day, alpha-lipoic acid 600 mg/day, and cholecalciferol 800-10 000 IU/day; Gr B ($n = 18$) received BMT supplemented with inositol at a daily dose of 2000 mg. The duration of follow-up was 12 weeks. Serum levels of fractalkine, leptin, and insulin were measured at baseline and at the end of the study using enzyme-linked immunosorbent assay (ELISA).

Results: After 12 weeks of therapy, women in Gr A demonstrated a favorable trend toward a reduction in serum fractalkine levels from 2.48 ± 0.13 ng/mL to 2.02 ± 0.24 ng/mL; however, this change did not reach statistical significance ($P = .09$). In contrast, group B showed a significant decrease in fractalkine concentrations from 2.41 ± 0.31 ng/mL to 1.28 ± 0.36 ng/mL ($P < .001$), with significantly lower levels compared to the BMT-only group ($P = .002$). In Gr B, the reduction in fractalkine was accompanied by statistically significant improvements in key carbohydrate and hormonal parameters. Fasting plasma glucose decreased from 6.12 ± 0.48 to 5.41 ± 0.39 mmol/L ($P < .001$), HbA1c from 6.3 ± 0.4% to 5.7 ± 0.3% ($P < .001$), HOMA-IR from 8.21 ± 0.62 to 6.15 ± 0.51 ($P < .001$), and serum leptin levels from 28.6 ± 4.2 to 20.3 ± 3.6 ng/mL.

Conclusions: In women of reproductive age with prediabetes, the addition of inositol to standard therapy attenuates fractalkine-mediated metabolic inflammation, which is accompanied by significant improvements in metabolic parameters and may contribute to a reduction in cardiometabolic risk.

EP1308 - ECE_2575 - How Lysophosphatidylcholine affects human Granulosa cell survival gene expression

Isabel Nogueira[1], Andre Lagoa[1], Thatiane Luca[1], Tania Maria Ortiga-Carvalho[1,2] and Flavia Bloise[1]
[1]*Universidade Federal do Rio de Janeiro, Instituto de Biofísica Carlos Chagas Filho, Rio de Janeiro, Brazil;* [2]*Instituto de Biofísica Carlos Chagas Filho—UFRJ, Rio de Janeiro, Brazil*

Hashimoto's thyroiditis is one of the most prevalent autoimmune diseases in women of reproductive age. Although it has been associated with impaired female fertility, the underlying mechanisms are still unclear. Follicular fluid is a key component of the oocyte microenvironment, with a distinct metabolic profile that is essential for adequate oocyte development. Previous work from our group demonstrated that the follicular fluid composition of Hashimoto's patients differs from that of euthyroid patients', with glycerophospholipid metabolism being the most significantly altered pathway, characterized by increased lysophosphatidylcholine 16:0 levels. This bioactive lipid acts as a second messenger, regulating inflammation and mitochondrial function. However, its role in the reproductive axis remains poorly understood. Therefore, this study aimed to investigate the lysophosphatidylcholines' impact on granulosa cell physiology, which is central cell to follicular development. Human granulosa cells line (COV434) were exposed to lysophosphatidylcholine 16:0 (0 µM—control, 50 µM and 100 µM—dose observed in euthyroid patients, 150 µM and 200 µM—dose observed in Hashimoto's thyroiditis patients) for 24 hours. Cell viability was assessed using the PrestoBlue assay and the expression of genes related to cell adhesion (CTNNB1), intercellular communication (GJA1), steroidogenesis (STAR) and the prostaglandin pathway (PTGS2) was analyzed by RT-qPCR. Data were analyzed by one-way ANOVA followed by Tukey's multiple comparisons test,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

with $P < .05$ considered statistically significant. At physiological concentrations (50 μM), lysophosphatidylcholine increased granulosa cell viability by 33% ($P = .0187$). Conversely, exposure to 150 μM decreased viability in almost 40% ($P = .0061$) and 200 μM in over 80% ($P < .0001$). Based on these viability results, subsequent gene expression analyses were performed using 50 and 150 μM lysophosphatidylcholine. The genes associated with cell adhesion (CTNNB1), intercellular communication (GJA1) and steroidogenic (STAR) pathway did not show alterations in expression. However, cells exposed to the 150 μM dose showed increased expression of PTGS2 (1.56 ± 0.13) compared to both control (1.00 ± 0.25; $P = .0013$) and 50 μM (0.75 ± 0.37; $P < .0001$) groups, suggesting an upregulation of the inflammatory prostaglandin pathway, consistent with known effects of lysophosphatidylcholine in other cell types. Our results suggest that, at concentrations comparable to those observed in Hashimoto's patients, lysophosphatidylcholine decreases granulosa cell viability and increases PTGS2 gene expression. Investigating additional genes associated with lysophosphatidylcholine metabolism and mitochondrial function will be essential to further clarify the molecular pathways underlying these effects.

EP1309 - ECE_2687 - Empirical evaluation of Thyroid function and ovarian reserve using one-way ANOVA

Fotima Makhmudova and Khurshida Nasirova
Tashkent state medical university, Tashkent, Uzbekistan

Ovarian reserve (OR) reflects follicular quantity and quality and determines female reproductive potential. Diminished ovarian reserve (DOR) is associated with reduced fertility and lower effectiveness of assisted reproductive technologies.[1] Beyond aging, hypothyroidism significantly contributes to OR impairment. Thyroid hormone imbalance disrupts folliculogenesis, ovulation, and steroidogenesis via the hypothalamic–pituitary–gonadal axis, accelerating follicular depletion.[2] Immuno-inflammatory processes, including systemic inflammation, oxidative stress, may further promote follicular atresia and adverse reproductive outcomes.

Objective: To evaluate the association between thyroid function and ovarian reserve in women of reproductive age, with particular emphasis on hormonal, inflammatory markers.

Methods: A total of 100 women aged 18-38 years were enrolled and divided into 3 groups: healthy euthyroid women with normal OR(control, $n = 20$); women with DOR and hypothyroidism(DOR + hypothyroidism, $n = 40$); and women with DOR and euthyroid status (DOR+euthyroidism, $n = 40$). Serum levels of thyroid-stimulating hormone (TSH), anti-Müllerian hormone (AMH), follicle-stimulating hormone (FSH), C-reactive protein (CRP), complement C3, ceruloplasmin were measured. Blood samples were collected in the early follicular phase (cycle days 2-4). One-way ANOVA with Dunnett's T3 post-hoc test was applied for statistical analysis.

Results: TSH levels were significantly higher in the DOR+hypothyroidism group (6.97 ± 0.61 mIU/L) compared with controls (1.57 ± 0.12 mIU/L) and the DOR+euthyroidism group (1.76 ± 0.08 mIU/L) ($P < .001$). AMH levels were significantly lower in women with DOR +hypothyroidism (0.57 ± 0.05 ng/mL) than in controls (3.98 ± 0.17 ng/mL) and women with DOR+euthyroidism (0.98 ± 0.08 ng/mL) ($P < .001$). No significant intergroup differences were observed for FSH ($P = .973$). CRP levels were highest in the DOR+hypothyroidism group (30.25 ± 1.58 mg/L), compared with controls(3.09 ± 0.48 mg/L) and the DOR+euthyroidism group (13.53 ± 0.94 mg/L) ($P < .001$). Complement C3 and ceruloplasmin followed a similar pattern, being maximal in the DOR+hypothyroidism group (6.76 ± 0.64 and 84.55 ± 4.59), intermediate in the DOR+euthyroidism group (2.57 ± 0.30 and 51.35 ± 2.14), and minimal in controls (1.18 ± 0.06 and 34.30 ± 2.08) ($P < .001$). Age did not differ significantly between groups ($P = .156$).

Conclusions: Hypothyroidism is associated with a more pronounced decline in OR, reflected by significantly reduced AMH levels compared with euthyroid women with DOR. Elevated inflammatory markers indicate that systemic inflammation and oxidative stress contribute to ovarian dysfunction in hypothyroid patients. Routine assessment and timely correction of thyroid dysfunction should be considered essential in the evaluation and management of women with DOR and infertility.

EP1311 - ECE_3107 - Metabolic dysfunction–Associated Steatotic Liver Disease (MASLD) in lean women with PCOS: prevalence, phenotypic distribution, and predictive value of HOMA-IR

Valentina Elezovic Kovacevic[1,2], Sanja Ognjanovic[1,2], Bojana Popovic[1,2], Dusan Ilic[1], Milica Opalic Palibrk[1], Lena Radic[1], Katarina Krstic[1], Natalija Dragicevic[1] and Djuro MacUt[1,2]
[1]Department for Endocrine Tumors and Hereditary Cancer Syndromes, Clinic for Endocrinology, Diabetes and Metabolic Diseases, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Belgrade, Serbia

Introduction: Polycystic ovary syndrome (PCOS) is a common endocrine disorder frequently associated with metabolic dysfunction, which overlaps with the pathophysiological mechanisms underlying metabolic dysfunction–associated steatotic liver disease (MASLD). We assessed the presence of hepatic steatosis in women with PCOS using the validated non-invasive Fatty Liver Index (FLI), calculated based on body mass index (BMI), waist circumference (WC), triglycerides, and gamma-glutamyl transferase.

Methods: FLI was analysed in 164 lean women with PCOS (median BMI 22.2 kg/m^2 [IQR 15.8], median WC 78 cm [IQR 15]) to determine the prevalence of MASLD overall and across PCOS phenotypes defined by the Rotterdam criteria. Participants were stratified into MASLD-positive and MASLD-negative groups based on FLI cut-off values (≥60), and metabolic and hormonal parameters were compared. Receiver operating characteristic (ROC) analysis was performed to identify the optimal HOMA-IR cut-off for determining the presence of MASLD.

Results: Phenotype A was the most prevalent (48.8%), followed by phenotypes D (19.5%), B (18.9%), and C (12.8%). Oligo/amenorrhea and anovulation were present in 43.9% and 81.7% of women, respectively, while hyperandrogenism was observed in 80.5%. Polycystic ovarian morphology was confirmed in 81.7%; insulin resistance (HOMA-IR) was present in 61% of patients. The overall prevalence of MASLD assessed by FLI was 13.4%, with phenotype-specific rates of 13% in phenotype A, 6% in

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

phenotype B, 3% in phenotype C, and none in phenotype D. Statistically significant differences in FLI values were present between phenotypes A and D, B and C, and C and D (all $P < .001$). MASLD-positive women (13.4%) had significantly higher waist circumference ($P < .001$), triglycerides ($P < .001$), fasting insulin ($P < .001$), and HOMA-IR ($P < .001$). Regarding hormonal parameters, SHBG was significantly lower, while FAI and estradiol were significantly higher in MASLD-positive women (all $P < .001$), with no significant differences in total testosterone, DHEA-S, or androstenedione ($P > .05$). ROC analysis showed that HOMA-IR was a good predictor of MASLD (AUC = 0.884, 95% CI: 0.818-0.950; $P < .001$), with an optimal cut-off of 3.13 (91% sensitivity, 57% specificity). Alternative thresholds of 3.4-3.6 are giving similar sensitivity with improved specificity (~65%-67%).

Conclusions: MASLD is relatively common among women with PCOS, even in a lean population and shows phenotype-specific distribution. HOMA-IR appears to be a reliable predictor of MASLD, suggesting that MASLD screening should be considered even in normal-weight women with PCOS, particularly those with elevated HOMA-IR.

EP1312 - ECE_1595 - Childhood adversity, poverty, and PCOS: results from a rural county cross-sectional survey

Akanksha Misra and Kylie King
State University of New York, Plattsburgh, United States

Objective: To explore the impact of rural childhood experiences and poverty on PCOS by determining the following: a). Associations of adverse childhood experiences (ACEs) with (potential) PCOS. b). Whether social determinants of health (SDoH) mediate this relationship. c). How challenges of growing up in rural areas- ACEs, SDoH and parental involvement- might impact the likelihood of PCOS.

Background: PCOS has for some time now been demonstrated as a bio-eco-social syndrome significantly impacted by social, emotional, and environmental factors. ACEs specifically might be dysregulating maturation of the hypothalamic-pituitary ovarian axis and/or the development of metabolic dysfunction, serving as precursors for PCOS. As interdisciplinary scholars in rural New York where poverty, foster care, and addiction issues are rampant, we build on our previous and other studies demonstrating correlations between SDoH, ACEs, and development of features of PCOS. We hope to highlight social and emotional factors impacting PCOS development, which could inform preventative and healing therapies for underserved populations.

Methods: Cross-sectional survey of adult respondents ($N = 145$) living in the North Country region of New York State, gathering data on SDoH, PCOS diagnosis and potential PCOS indicators (irregularity, male pattern hair growth, and weight gain), parental involvement, and ACEs. All analyses were conducted in R.

Results and Discussion: In an OLS model predicting confirmed and potential PCOS, ACEs score emerged as the only statistically significant predictor. Item-level correlations identified verbal abuse and emotional neglect and abuse as most strongly associated with PCOS indicators. Mediation analyses provided no evidence that SDoH mediated the relationship between ACEs and PCOS. Parental background and involvement composites were associated with ACEs but not with SDoH or PCOS indicators. While larger, unbiased population studies across different rural demographics are needed to make generalizations, our small study highlights a few things: a). Emotional neglect and abuse and verbal abuse in childhood might serve as precursors for PCOS, as consistently demonstrated in other high quality studies. b). ACEs could occur irrespective of adverse SDoH and/or more expansive frameworks for SDoH and their interactions with ACEs need to be explored, and c). The role of parent(s) in childhood might be an overlooked factor to be more deliberately explored in future research. Either way, routine attention to childhood love and care, especially for rural populations experiencing high levels of childhood adversity, should be part of any therapeutic plan of treatment.

EP1313 - ECE_3497 - When hydration harms: two cases of peripartum hyponatraemia

Lia Anguelova, Mike Matheou, Bahram Jafar-Mohammadi, Christine May and Aparna Pal
Endocrinology, OCDEM, Oxford, United Kingdom

Encouraging hydration during labour is a common practice intended to prevent dehydration, maintain uterine activity, avoid ketosis, and support fetal wellbeing. However, excessive fluid intake, particularly in the presence of oxytocin, may lead to dilutional hyponatraemia with potentially serious maternal and neonatal consequences. We report two cases of peripartum hyponatraemia occurring in otherwise low-risk pregnancies.

Case 1: A 40-year-old primigravida with no significant past medical history and an uncomplicated pregnancy presented in spontaneous labour. Labour progress was slow, and oxytocin augmentation was commenced. During the second stage, she became increasingly confused, with poor ability to follow instructions for guided pushing, and was transferred to a high-dependency unit. Oxytocin doses were further escalated, and operative vaginal delivery with forceps was required. She sustained a postpartum haemorrhage of approximately 900 mL, treated with two doses of ergometrine and a further oxytocin infusion (40 units diluted in 5% dextrose). She consumed approximately 2 litres of oral fluids during labour.

Venous blood gas analysis revealed severe hyponatraemia (serum sodium 110 mmol/L). Neurological examination showed a Glasgow Coma Scale (GCS) score of 12, nystagmus, and a sixth cranial nerve palsy. She was admitted to intensive care for close monitoring. Significant polyuria occurred, necessitating cautious fluid replacement (dextrose 5%) to avoid rapid sodium correction. Serum sodium normalised over 48 hours, with complete neurological recovery within 24 hours. The neonate was healthy.

Case 2: A 34-year-old woman (G2P0) presented in spontaneous labour at a local hospital. A dark urine sample prompted encouragement of oral fluid intake, and she consumed approximately 2-2.5 litres of water during labour. She required transfer for emergency caesarean section due to obstructed labour. Pre-operative serum sodium was 120 mmol/L, falling to 115 mmol/L following oxytocin administration. Plasma osmolality was 242 mOsm/kg and urine osmolality 117 mOsm/kg. She remained asymptomatic with a GCS of 15/15. Postoperatively, she

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

was managed with fluid restriction and careful monitoring, with gradual normalisation of sodium over 48 hours. The neonate was healthy.

Conclusions: Peripartum dilutional hyponatraemia is a potentially serious but preventable complication of labour. Excessive oral intake, hypotonic intravenous fluids, and oxytocin use are key risk factors. Neurological symptoms during labour or postpartum should prompt urgent electrolyte assessment. Careful fluid management and avoidance of rapid sodium correction are essential to prevent harm. Greater awareness is needed, as this condition is likely under-recognised.

EP1314 - ECE_2251 - Trafficking of Follicle-Stimulating Hormone Receptor (FSHR) is modulated by the interaction with G Protein-Coupled Estrogen Receptor (GPER)

Clara Lazzaretti[1], Carmela Perri[1,2], Samantha Sperduti[1,3], Giada Mercanile[1,4], Manuela Simoni[1,3,5] and Livio Casarini[1,3]
[1]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [2]International PhD School in Clinical and Experimental Medicine (CEM), University of Modena and Reggio Emilia, Modena, Italy; [3]Center for Genomic Research, University of Modena and Reggio Emilia, Modena, Italy; [4]Department of Dermatology, Surgical, Medical and Dental Department of Morphological Sciences Related to Transplant, Oncology and Regenerative Medicine, University of Modena and Reggio Emilia, Modena, Italy; [5]Department of Medical Specialties, Azienda Ospedaliero-Universitaria di Modena, Modena, Italy

Follicle-stimulating hormone receptor (FSHR) and G protein-coupled estrogen receptor (GPER) are expressed in the ovary, where they regulate folliculogenesis by forming membrane heterocomplexes in granulosa cells. FSHR/GPER heteromers sustain oocyte survival by reprogramming FSH-dependent pro-apoptotic signals into anti-apoptotic/proliferative events. We evaluated whether FSHR/GPER heterocomplex-specific trafficking impacts FSH-mediated signalling.

HEK293 cells were transiently transfected with tagged FSHR-, GPER-, and biosensor-coding plasmids. FSHR- and FSHR-GPER-expressing cells were treated with 10 nM FSH, in the presence and in the absence of the dynamin inhibitor Dynasore. We evaluated FSHR interactions with GPER, Gs protein, endosomal marker RAB-GTPase (Rab) 5, β-arrestin 2, membrane marker CAAX, cytoplasm marker FYVE, as well as intracellular cAMP accumulation and extracellularly-regulated kinases 1 and 2 (ERK1/2) phosphorylation by bioluminescence resonance energy transfer (BRET), while cAMP-response element (*CRE*) activity by reporter gene system. Data from 3 to 5 experiments were analyzed using Kruskal-Wallis test and Dunn's post-test ($P < .05$).

In GPER/FSHR co-expressing cells, FSHR-CAAX interaction was reduced compared to what found in FSHR-expressing cells, whereas FSHR-FYVE increased, indicating that GPER favoured the FSHR maintenance at the membrane and endocytic compartments. In fact, GPER reduced the recruitment of β-arrestin 2 to FSHR, as well as FSHR internalization via Rab5-positive early endosomes. GPER/FSHR co-expression prevents FSHR coupling to Gs protein, leading to inhibition of FSH-dependent cAMP accumulation, *CRE* activation, and ERK1/2 phosphorylation. Cell treatment by the internalization blocker Dynasore did not change the FSH-dependent signalling pattern, suggesting that GPER/FSHR complexes exert their effects in the cell surface.

We found that GPER inhibits FSH-dependent signalling via a molecular interaction with FSHR occurring in the cell membrane, confirming it could be a regulatory mechanism for ovarian physiology.

EP1315 - ECE_2111 - Thyroid-related polyautoimmunity: effects on anticipated menopause

Marco Centanni, Ilaria Stramazzo, Maria Flavia Bagaglini, Matteo Nocito and Camilla Virili
Sapienza Università di Roma, Endocrine Unit, SM Goretti Hospital, Medical-Surgical Science and Technology, Roma, Italy

Background: An association between autoimmune disorders and an anticipated menopause has been reported. Autoimmune thyroid disease (ATD) is the most prevalent autoaggressive disorder worldwide and plays a pivotal role in polyautoimmunity. However, data about the presence of premature ovarian insufficiency (POI) and early menopause (EM) framed in thyroid-related poly autoimmunity, are rather scanty. In this view, we described the association between anticipated menopause and ATD isolated or framed in poly-autoimmune syndromes in a large cohort of women.

Study Design: We retrospectively evaluated 7690 postmenopausal women from 2018 and 2024 in a tertiary center for thyroid diseases. Three subgroups were examined: women with nonautoimmune endocrinopathies ($n = 5697$; group A) or with isolated Hashimoto's thyroiditis ($n = 1689$; group B) and/or with thyroid-related poly autoimmunity ($n = 304$ group C). All diagnosis of associated autoimmune disorders were based on histology and concordant immunology or on Consensus statements.

Results: In the whole sample 213 out of 7690 (2,77%) women experienced unexplained anticipated menopause, 115 of them (1.50%) showed spontaneous premature ovarian insufficiency (POI) and 98 (1.27%) an early menopause (EM). The kinship familial heritage for autoimmune disorders in women with anticipated menopause was significantly different ($P = .0296$) in the three groups being higher in women with poly-autoimmunity. The prevalence of POI was higher in women with poly autoimmunity (5.92%) (Group C) than in group B (1.84%) and in group A (1.16%; $P < .0001$). Similarly, EM has been observed in 1.07% in the group A and 0.89% in group B ($P =$ ns) while in women with poly-autoimmunity was much higher (7.23%; Chi-square test: $P < .0001$). A spontaneous miscarriage was observed in 52/213 women (24.4%) with anticipated menopause (EM+POI), being significantly higher in women with poly autoimmunity (3.61% vs 0.53%, 0.71%, respectively) than in the group A and B, respectively ($P < .0001$). The percentage of miscarriage was higher in women with POI than the one observed in EM group (30.2%vs 17.7%; $P = .038$). Among the autoimmune disorders, atrophic gastritis was the most frequently observed autoimmune comorbidity, followed by rheumatic disorders and cutaneous autoimmunity. Indeed, Fisher's exact test revealed a significant different distribution of anticipated menopause (POI+EM) ($P = .019$), being psoriatic arthritis the more and celiac disease the lesser associated. Univariate analysis

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

revealed that familiarity was the more relevant independent variable associated with POI in poly-autoimmunity.

Conclusions: Our data suggest that young women with thyroid-related poly autoimmunity, born to a family with thyroid autoimmunity and/or poly-autoimmunity, should be checked prospectively to guide fertility preservation and family planning.

EP1316 - ECE_2060 - Adherence to gender affirming hormonal treatment in 6326 Danish transgender persons. A nationwide register-based study

Louise Lehmann Christensen[1,2], Jens-Jakob Møller[3], Katrine Rubin[2,3], Guy T' Sjoen[4], Marianne Skovsager Andersen[1,2] and Dorte Glintborg[1,2]
[1]Department of Endocrinology, Odense, Denmark; [2]Syddansk Universitet, Odense M, Denmark; [3]OPEN, Odense, Denmark; [4]Endocrinology, Gent, Belgium

Background: Gender affirming hormonal treatment (GAHT) is a cornerstone in transgender care. Population-based data are sparse regarding adherence to GAHT in transgender persons.

Aim: To assess use and adherence to GAHT.

Design: A national register-based Danish cohort study in individuals diagnosed with gender dysphoria (TG persons) year 2000-2024. The main study outcome was use of GAHT and GAHT adherence. Masculinizing GAHT was defined by use of testosterone and feminizing GAHT by use of estradiol. GAHT adherence was defined as purchase of GAHT within 600 days intervals.

Results: The cohort included 6326 TG persons divided according to birth sex: $N = 3277$ transgender men (TransM) and $N = 3049$ transgender women (TransF). The median (interquartile range) age at study inclusion was 21 (9) years for TransM and 26 (12) years for TransF. The median follow up duration was 3.8 years and use of GAHT occurred in $N = 1559$ (47.6%) TransM and $N = 1527$ (50.1%) TransF. In GAHT users, GAHT adherence was observed in $N = 1421$ (91.1%) TransM and in $N = 1355$ (88.7%) TransF during follow up. The rate of GAHT non-adherence during follow up was 2.1 (1.8; 2.5) per 100 person years in transM and 2.9 (2.5; 3.4) in TransF. Higher GAHT adherence was predicted by baseline age <25 years, more recent study inclusion, Danish ethnicity, higher personal income, no psychiatric diagnosis (in TransF), and no gender affirming surgery (in TransM). In TG persons with GAHT non-adherence, 29.7% (41/138) TransM and 19.8% (34/172) TransF later resumed GAHT during follow up.

Conclusions: TG persons showed high adherence to GAHT, but further studies regarding reasons for GAHT non-adherence are needed.

EP1317 - ECE_3653 - The effects of complex III deficiency on the Hypothalamic-Pituitary-Gonadal (HPG) axis

Irit Hochberg[1,2,3], Michal Toren[1], Osnat Admoni[4], Dov Tiosano[1,5], Hanna Mandel[1,6], Galit Tal[5], Shoji Yano[7], Marc Weigensberg[7] and Jan Idkowiak[8]
[1]Bruce Rappaport Faculty of Medicine, Technion—Israel Institute of Technology, Haifa, Israel; [2]Hadera, Israel; [3]Rambam Medical Center, Institute of Endocrinology, Diabetes and Metabolism, Haifa, Israel; [4]Clalit Health Services, Pediatric Endocrinology Center, North District, Israel; [5]Rambam Medical Center, Pediatric Metabolic Disorders and Pediatrics Ward B, Haifa, Israel; [6]Galil Medical Center, Clinical Genetics Institute, Nahariya, Israel; [7]Pediatric Endocrinology, Los Angeles General Medical Center, Los Angeles, United States; [8]Department of Metabolism and Systems Science, University of Birmingham, College of Medicine and Health, Birmingam, United Kingdom

Mitochondrial Complex III deficiency, a disorder affecting the electron transport chain, is associated with recurrent metabolic decompensation, including hypoglycemia, impaired hepatic synthetic function, lactic acidosis, and multisystem involvement. We report the first characterization of puberty in two pairs of siblings with this condition, both demonstrating a sexual dimorphism in occurrence of puberty, gonadal hormone biosynthesis and gonadal-pituitary feedback.

Two siblings of from a consanguineous Arab Muslim family with genetically confirmed Complex III deficiency caused by a biallelic UQCRC2 Arg183Trp mutation were followed from early childhood because of repeated metabolic crises. The female sibling, now 36 years old, did not develop spontaneous adrenarche or puberty. Evaluation beginning at 12 years of age demonstrated consistently elevated gonadotropins (LH 35 IU/L, FSH 60 IU/L), undetectable estradiol levels, and ovaries of normal size without follicular development. She has since been treated with hormone replacement therapy. The male sibling, currently 35 years old, entered puberty spontaneously at 13 years, achieving normal virilization and external genital development; however, he has markedly reduced testicular volume and azoospermia. Laboratory testing showed persistently increased LH (70 IU/L) and FSH (100 IU/L) since age 13, supraphysiologic testosterone concentrations (14 ng/mL), and high–normal estradiol levels (50 pg/mL). Pituitary hormone profiles were otherwise unremarkable in both individuals.

Assessment of serum steroids by LC-MSMS confirmed elevated levels of testosterone and dehydrotestosterone in the male.

Two additional unrelated siblings from a Mexican family, homozygous for the same UQCRC2 variant, demonstrated a comparable phenotype. The female, who is currently 18 years old, failed to initiate adrenarche or puberty, and the male, who is currently 17 years old, had spontaneous pubertal development. Both siblings had elevated gonadotropins, the female had low estradiol levels, while the male had normal testosterone concentrations and small testes.

These results may confirm previous observations reported by other groups that in animal models and in-vitro models complex III disruption enhances androgen production in Leydig cells.

The surprising absence of expected gonadotropin suppression by testosterone in the two males, and especially in the older male who has testosterone which is significantly higher than normal raises the possibility that there is mitochondrial involvement in the gonadal–pituitary feedback mechanisms.

These novel observations, characterized by the coexistence of elevated gonadotropins with high or normal testosterone may provide new insights into the role of mitochondrial Complex III in human gonadal steroidogenesis and endocrine feedback regulation.

EP1318 - ECE_1139 - Two siblings with normosmic hypogonadotrophic hypogonadism caused by an FGFR-1 gene variant

Beenish Zaki and Stephen Hyer
Diabetes and Endocrinology, Epsom and St. Helier Hospital NHS trust, London, United Kingdom

Background: Mutations in the fibroblast growth factor receptor 1 (FGFR1) gene disrupt gonadotropin-releasing hormone (GnRH) neuron development and are a known cause of congenital hypogonadotropic hypogonadism (CHH), including Kallmann syndrome. FGFR1 plays a crucial role in embryonic cell proliferation, differentiation, and migration, particularly within the forebrain and olfactory system. While FGFR1 mutations classically present with anosmia and midline defects, some individuals exhibit normosmic CHH without syndromic features. Increasing genetic heterogeneity within disorders of sexual development highlights the importance of genetic testing.

Objective: To describe two adolescent brothers with normosmic hypogonadotropic hypogonadism and delayed puberty, emphasizing the diagnostic value of identifying an FGFR1 variant in the absence of olfactory or structural abnormalities.

Case Summary: Both brothers presented with absent pubertal progression. Examination showed Tanner stage I-II genitalia, small testicular volumes, and sub- physiological testosterone levels. Gonadotropins (LH/FSH) were inappropriately low at baseline and after stimulation, while prolactin, thyroid, and adrenal function were normal.

MRI of the hypothalamic–pituitary region was unremarkable, and olfactory testing confirmed normal smell. Given the familial presentation, targeted NGS using a CHH gene panel identified a shared pathogenic FGFR1 variant, confirming FGFR1-related normosmic hypogonadotropic hypogonadism. Testosterone replacement therapy (Nebido® 1 g every 12 weeks) successfully induced and maintained pubertal development. Growth hormone therapy was not required.

Results:

Table 1 Summary of clinical and endocrine findings.

Parameter	Sibling 1	Sibling 2
Age at presentation (years)	17.0	15.8
Tanner stage (genitalia)	I-II	I
Bone age delay	3 years	3.5 years
Testosterone (nmol/L)	2.1	0.6
LH (IU/L)	1.0	0.2
FSH (IU/L)	1.4	1.2
IGF-1 (nmol/L)	16.1	12.3
Pituitary MRI	Normal	Normal
Genetic result	Pathogenic *FGFR1* variant	Same variant

Discussion: Fibroblast Growth Factor Receptor 1 (FGFR1) is a receptor tyrosine kinase essential for embryonic development, hypothalamic–pituitary axis formation, and metabolic regulation. Pathogenic FGFR1 variants include loss-of-function missense, nonsense, frameshift, splice-site mutations, and rare deletions. These mutations are a recognized cause of congenital hypogonadotropic hypogonadism (CHH) and Kallmann syndrome, and may also be associated with growth hormone abnormalities.

FGFR1-related disorders demonstrate marked phenotypic heterogeneity. In addition to endocrine manifestations, affected individuals may exhibit craniofacial anomalies, skeletal abnormalities, hearing loss, and neurodevelopmental features.

Identification of FGFR1 mutations supports early and accurate diagnosis, guides pubertal induction and fertility treatment strategies using gonadotropins or pulsatile GnRH, and enabling genetic counselling for autosomal dominant inheritance with incomplete penetrance.

EP1320 - ECE_1672 - Comparative effects of Inositol-based therapy, berberine and their combination on androgen levels and insulin resistance in women with Polycystic Ovary Syndrome

Vesselina Yanachkova[1], Svetoslav Stoev[2] and Hristina Lebanova[3]
[1]*Research Institute, Medical University of Pleven, Pleven, Bulgaria;* [2]*Pleven, Bulgaria;* [3]*Faculty of Pharmacy, Medical University-Pleven, Pleven, Bulgaria*

Background: Polycystic ovarian syndrome (PCOS) is among the most prevalent disorders affecting women of reproductive age. The primary pathophysiological features of this condition are hyperandrogenemia and insulin resistance. Reducing circulating androgen levels is crucial for improving metabolic and reproductive markers in women with PCOS. Enhancing insulin sensitivity with different insulin-modulating treatments can have significant effects on the androgen levels.

Objective: To assess the impact of inositol-based therapy, berberine, and the combination of inositol and berberine on androgen levels and insulin resistance in women diagnosed with PCOS.

Methods: A cohort of 115 women diagnosed with PCOS was observed over a period of 6 months. Patients were divided in three groups: women receiving inositol monotherapy ($n = 40$), those undergoing berberine monotherapy ($n = 40$), and participants in a combined regimen of inositol and berberine ($n = 35$). In all patients, baseline and six-month post-therapy assessments were conducted for serum levels of total testosterone, DHEAS, androstenedione, 17-hydroxyprogesterone, fasting plasma glucose, and immunoreactive insulin, with the latter evaluated using the HOMA index.

Results: An improvement in testosterone levels was observed in 26 (70%) of the women administered inositol, in 18 (45.4%) treated with berberine, and in 28 (80%) receiving combination therapy. The proportion of patients exhibiting improvement in testosterone levels was markedly greater in the group receiving the inositol/berberine combination than in those treated with berberine alone ($P < .05$). No statistically significant difference was observed between the combined therapy group and inositol monotherapy group ($P = .54$). All three patient groups showed reductions in serum levels of total testosterone, DHEAS, androstenedione, and 17-hydroxyprogesterone, alongside improvements in fasting glucose and immunoreactive insulin levels, as well as a reduced HOMA index over the six-month duration.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusions: The observational data indicate that the administration of combined insulin-modulating therapy with inositol and berberine can lead to a substantial improvement in hyperandrogenemia and insulin resistance in women diagnosed with PCOS. Inositol monotherapy demonstrated superior therapeutic efficacy compared to berberine monotherapy. While our findings endorse a synergistic, non-hormonal therapy approach for regulating insulin and addressing hyperandrogenism in PCOS, additional studies with larger patient populations are necessary for confirmation and validation.

Keywords PCOS, androgen, insulin resistance, inositol, berberine

Introduction: Polycystic ovary syndrome (PCOS) is a heterogeneous endocrine disorder of the female reproductive system affecting women of reproductive age. The diagnosis of PCOS requires the presence of at least two of the following features: hyperandrogenism, oligo- or anovulation, and cystic ovarian morphology on ultrasound. Elevated androgen level contributes to clinical manifestations such as acne, androgenic alopecia, and hirsutism, while increased luteinizing hormone (LH), observed in up to 60% of PCOS patients, further enhances androgen synthesis and disrupts follicular maturation, leading to menstrual irregularities and infertility. PCOS is also strongly associated with metabolic disturbances, including insulin resistance and hyperinsulinemia, which are considered central mechanisms linking PCOS with metabolic associated fatty liver disease. Vitamin D_3 (VD) deficiency is reported in approximately 85% of women with PCOS, and its active form, calcitriol, exhibits steroid hormone-like properties with pleiotropic effects on metabolic homeostasis, immune modulation, and cellular differentiation. Recent studies suggest that VD supplementation may alleviate insulin resistance and hyperinsulinemia in PCOS, indicating its potential role in improving liver-related metabolic dysfunctions. However, the impact of VD on oxidative stress and apoptosis in hepatic tissue under PCOS conditions remains insufficiently explored. The present study aimed to investigate the effect of VD supplementation on reactive oxygen species (ROS)/reactive nitrogen species (RNS) level, zinc and copper concentration, antioxidant *Sod1* gene expression and apoptosis in the liver of rats with letrozole-induced PCOS.

Materials and Methods: The experiment was conducted using female Wistar rats divided into four groups: control (C), VD-supplemented (VD), letrozole-treated (L) to induce PCOS, and letrozole and VD-treated (VD+L). Oxidative stress was assessed by measuring ROS/RNS level, while *Sod1* mRNA expression was analysed using quantitative real-time PCR. Hepatic zinc and copper concentrations were determined by atomic absorption spectrometry, while apoptosis was evaluated by the abundance of caspase-3 using Western blot.

Results: The results demonstrated that VD supplementation significantly reduced ROS/RNS level ($P < .05$) in PCOS rats and partially restored *Sod1* expression ($P < .05$) in the VD+L group. In the L and VD+L groups, the hepatic zinc concentration was reduced in comparison to the control and VD groups ($P < .001$ and $P < .01$). A decrease in caspase-3 abundance was observed in the VD+L group in comparison to the PCOS rats, however it was not significant.

Conclusions: These findings suggest that vitamin D_3 supplementation may mitigate oxidative stress and apoptosis in the liver with PCOS conditions, supporting its potential as an additional therapeutic strategy.

EP1323 - ECE_3761 - Regulatory T cells, T helper 17 cells, and hypoxia-inducible factor 1α expression in polish women with PCOS phenotype D

Justyna Kuliczkowska-Płaksej[1], Aleksandra Jawiarczyk-Przybyłowska[1], Aleksandra Zdrojowy-Wełna[1], Anna Brona[1], Barbara Stachowska[1], Łukasz Gojny[1], Agnieszka Zembska[1], Jowita Halupczok-Żyła[2], Martyna Strzelec[1] and Marek Bolanowski[1]

[1]*Department of Endocrinology and Internal Diseases, Wroclaw Medical University, Wroclaw, Poland;* [2]*Department of Clinical and Experimental Pathology, Wroclaw Medical University, Wroclaw, Poland*

Background: Polycystic ovary syndrome (PCOS) is a common disorder associated with reproductive, metabolic, and inflammatory abnormalities. Several studies have reported alterations in T-cell subpopulations in PCOS, including an increased number of proinflammatory T helper 17 (Th17) cells and a decreased number of regulatory T (Treg) cells compared with healthy, fertile women. However, data regarding the abundance of different T-lymphocyte subpopulations in the normoandrogenic phenotype D remain limited. Hypoxia-inducible factor-1α (HIF-1α) is a transcription factor that regulates cellular responses to hypoxia and is expressed in nearly all cell types, including lymphocytes. Beyond its primary role in immune regulation, HIF-1α is involved in metabolic processes, and its dysregulation has been associated with obesity, insulin resistance, and local inflammation. Evidence suggests that HIF-1α may be a key regulator influencing the balance between Treg and proinflammatory Th17 cells.

Objective: This study aimed to assess the abundance of Treg and Th17 lymphocytes, HIF-1α expression within these populations, and their ratios in women with PCOS phenotype D compared with healthy controls.

Methods: The study included 49 women with PCOS phenotype D and 40 age-, BMI-, and body-mass-matched healthy women with regular menstrual cycles selected from cases visiting Department of Endocrinology and Internal Diseases, University Hospital in

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Wroclaw. Anthropometric, hormonal, metabolic, and inflammatory parameters were evaluated. Peripheral blood T-cell subpopulations and intracellular HIF-1α expression were analyzed using multiparameter flow cytometry.

Results: No significant differences were observed between the groups in total leukocyte counts, lymphocyte subsets, or absolute numbers of Treg and Th17 cells. However, women with PCOS exhibited significantly higher Treg/Th17 and HIF-1α-positive Treg/HIF-1α-positive Th17 ratios. HIF-1α-positive Treg cells correlated positively with markers of adiposity and insulin resistance in both groups, suggesting an association between metabolic status and immune regulation. Despite normoandrogenemia, women with PCOS had higher hs-CRP levels, indicating persistent low-grade inflammation.

Conclusions: In women with PCOS phenotype D, the absolute numbers of Treg and Th17 cells did not differ from those in the control group; however, the Treg/Th17 ratio and the ratio of HIF-1α-expressing cells were significantly higher. These findings may reflect persistent low-grade inflammation in PCOS, although the precise significance of increased HIF-1α expression within Treg cells remains unclear. Our results also suggest that PCOS phenotype D differs substantially from the classic form of the syndrome not only in the severity of metabolic disturbances but also in immunological characteristics, despite the presence of low-grade inflammation.

EP1324 - ECE_3855 - Role of adropin on human placenta cells proliferaton and endocrine pathways. In vitro studies on JEG-3 cells

Urszula Nowak[1], Monika Dawid[1,2], Sylwia Kula[1] and Agnieszka Rak[1]

[1]Laboratory of Physiology and Toxicology of Reproduction, Institute of Zoology and Biomedical Research, Faculty of Biology, Jagiellonian University, Cracow, Poland; [2]Doctoral School of Exact and Natural Sciences, Jagiellonian University, Kraków, Poland

Background: Adropin is a peptide hormone encoded by the *ENHO* (energy homeostasis-associated) gene and belongs to the adipokine family. It is well known for its role in the regulation of glucose and lipid metabolism and its beneficial effects on insulin sensitivity. Recent studies suggest that adropin may also regulate endocrine pathways in the female and male reproductive systems in murine models. Importantly, circulating adropin levels in women change during pregnancy and may correlate with pregnancy-related complications. However, the role of adropin in the human placenta, a key organ of pregnancy, remains poorly understood.

Objective: This study aimed to investigate the effects of adropin on proliferation and endocrine function of human placental cells.

Methods: Human choriocarcinoma JEG-3 cells were treated with adropin at concentrations of 1, 10, and 100 nM for 24, 48, and 72 hours ($n = 3$). Human chorionic gonadotropin (hCG) and progesterone (P_4) secretion were assessed using ELISA, while cell proliferation was measured using a BrdU assay. Based on these results, 10 nM adropin was selected for subsequent experiments. Cell cycle distribution was analyzed by flow cytometry. Gene and protein expression analyses were performed using RT-qPCR and Western blotting to assess markers related to endocrine function (*CGB*, *3βHSD*; hCG, 3βHSD) and proliferation (*PCNA*; PCNA, Cyclin E) following treatment with 10 nM adropin for 24, 48, and 72 hours. Statistical analyses were conducted using one-way ANOVA and Student's *t*-test.

Results: Adropin exerted time-dependent effects on JEG-3 cell proliferation, increasing proliferative activity after 24 and 48 hours while reducing it after 72 hours of incubation. Cell cycle analysis suggested a potential role of adropin in regulating the transition between the G0/G1 and S phases. Additionally, adropin modulated the endocrine activity of placental cells, as evidenced by reduced hCG and P_4 secretion after 72 hours, accompanied by altered expression of endocrine- and proliferation-related genes and proteins. Western blot analysis revealed time-dependent changes in the expression of PCNA, Cyclin E, hCG, and 3βHSD following adropin treatment.

Conclusions: These findings suggest that adropin plays a modulatory role in human placental cell proliferation and endocrine function, potentially contributing to placental development and metabolic adaptation during pregnancy. The dynamic effects of adropin on placental cells may indicate its involvement in early pregnancy processes, including implantation and placental formation. Further studies are required to elucidate the underlying molecular mechanisms.

EP1325 - ECE_1292 - Body image concern in women with Polycystic Ovary Syndrome (PCOS): a comparative analysis of two assessment tools

Aspasia Manta[1], Sophie Broughton[2], Shams Ali Baig[3], Eleni Armeni[4] and Punith Kempegowda[1]

[1]Department of Applied Health Sciences, University of Birmingham, Birmingham, United Kingdom; [2]Midland Metropolitan University Hospital, Sandwell and West Birmingham NHS Trust, Birmingham, United Kingdom; [3]Medical School, University of Birmingham, Birmingham, United Kingdom; [4]Royal Free London NHS Foundation Trust, University of Birmingham, Birmingham, United Kingdom

Background: Body image dissatisfaction is a prevalent concern among women with polycystic ovary syndrome (PCOS), yet there is no consensus on the optimal assessment tool for this population. The Body Image Concern Inventory (BICI) and the Multidimensional Body-Self Relations Questionnaire—Appearance Scales (MBSRQ-AS) are commonly used, but their comparative performance in PCOS remains unexplored. This study aimed to compare the BICI and MBSRQ-AS in women with PCOS, evaluating agreement, reliability, and associations with clinical and demographic characteristics.

Methods: A cross-sectional sample of 163 women with confirmed PCOS completed an online questionnaire including the BICI, MBSRQ-AS, clinical measures (body mass index [BMI], modified Ferriman-Gallwey [mFG] score), and sociodemographic data. Internal consistency of the questionnaires was assessed using Cronbach's alpha. Pearson correlations and regression analyses examined relationships between body image scores and clinical variables.

Results: The BICI demonstrated excellent internal consistency ($\alpha = .93$) and was significantly associated with BMI and mFG scores. The MBSRQ-AS showed acceptable reliability ($\alpha = .73$), while

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

higher BMI consistently predicted poorer outcomes on its subscales. Subscale analysis of the MBSRQ-AS further revealed significant associations between higher BICI scores and lower Appearance Evaluation ($r = -0.559$, $P < .001$) and Body Areas Satisfaction ($r = -0.652$, $P < .001$), alongside increased Overweight Preoccupation ($r = 0.557$, $P < .001$) and Appearance Orientation ($r = 0.335$, $P < .001$). Hierarchical regression analysis showed that MBSRQ-AS scores explained additional variance in BICI scores beyond clinical features, indicating distinct contributions to body image assessment.

Conclusions: Both the BICI and MBSRQ-AS identify elevated body image concerns in women with PCOS, but capture distinct constructs. The BICI is more sensitive to appearance-related distress, whereas the MBSRQ-AS reflects broader attitudinal aspects. The selection of assessment tools should be context-driven to optimally address body image concerns in this population.

EP1326 - ECE_2593 - Phenotypic and genetic heterogeneity of 46,XY gonadal dysgenesis: a pediatric case series

Beatriz Tavares Da Silva, Miguel Saraiva, Catarina Figueiredo, Catarina Mendes, Joana Freitas, Lia Ferreira, Maria João Oliveira, Isabel Palma and Teresa Borges
Unidade Local de Saúde de Santo António, Porto, Portugal

Background: The 46,XY differences of sex development (DSD) represent a rare group of conditions arising from discordance between chromosomal and phenotypic sex. In cases of complete 46,XY gonadal dysgenesis (GD), the absence of testicular differentiation results in hypergonadotropic hypogonadism and preserved Müllerian structures. These patients face a substantial risk of developing gonadal malignancies, necessitating early identification and management. We describe the clinical, biochemical, and molecular profiles of four pediatric patients with 46,XY DSD of distinct etiologies, aiming to highlight the diagnostic challenges and the necessity of multifaceted long-term management strategies.

Results: Four patients with complete 46,XY GD were included. Molecular analysis identified pathogenic variants in three cases: one WT1 splice-site variant (c.1432+4C>T) and two SRY variants (p.Arg30Ile and p.Glu89Argfs*15). The fourth patient was diagnosed based on clinical and biochemical criteria without an identified genetic variant. Gonadal malignancy was confirmed in 75% of cases ($n = 3$), including bilateral gonadoblastoma and mixed germ cell tumor. All patients underwent bilateral gonadectomy and subsequent pubertal induction (ages 12-16). At the latest follow-up (ages 16-21), full pubertal development and menarche were achieved in 100% of cases, with bone mineral density maintained within age-matched norms (Z-score: −0.3 to −1.7). Late diagnosis in the SRY group was associated with final heights significantly exceeding target height (up to +1.89 SD).

Conclusions: This case series underscores the marked phenotypic and genetic heterogeneity of 46,XY gonadal dysgenesis and the high prevalence of early-onset malignancy (75%). Precise molecular diagnosis is important for timely tumor risk stratification, guiding the timing of prophylactic gonadectomy and optimizing pubertal induction to prevent excessive final height. A proactive, multidisciplinary approach is essential to safeguard bone health and ensure long-term psychosocial well-being in these complex DSD patients.

Table 1 Clinical, genetic, and endocrine characteristics of four patients with 46,XY differences of sex development (DSD).

Features	Case 1	Case 2	Case 3	Case 4
Age at diagnosis/ presentation	11 y (SRNS since 4 y)	Neonatal period (Turner work-up)	6 y (precocious pubertal signs)	16 y (post-tumor resection)
Genetic finding	WT1 (NM_000378.6): c.1432+4C>T (splice-site)	None identified	*SRY* (NM_003140.3) c.89G>T, p.Arg30Ile (exon 1)	*SRY (NM_003140.3)* c.264dup, p.Glu89Argfs*15
Main diagnosis	*WT1* (heterozygous splice-site variant, not Frasier-associated)	Frasier syndrome (46,XY DSD + CKD)	Complete 46,XY gonadal dysgenesis (Swyer)	Complete 46,XY gonadal dysgenesis (Swyer)
Age at gonadectomy	13 y (bilateral)	1 y (bilateral)	6 y (bilateral)	16-17 y (right tumor, left streak gonad)

EP1327 - ECE_1211 - Ovarian steroid cell tumour: a rare cause of severe hyperandrogenism in a postmenopausal woman

Ana Majic Tengg and Jelena Andric
Department of Endocrinology, Diabetes, Metabolic disorders and Clinical Pharmacology, Clinical Hospital Dubrava, Internal Medicine Clinic, Zagreb, Croatia

Steroid cell tumours of the ovary represent an exceptionally rare subgroup of androgen-producing ovarian neoplasms, accounting for less than 0.1% of all ovarian tumours. These lesions may secrete marked amounts of testosterone, androstenedione, and dehydroepiandrosterone sulphate (DHEAS), resulting in rapidly progressive hyperandrogenism. In postmenopausal women, new-onset androgen excess should prompt immediate investigation for an androgen-secreting tumour, given the low likelihood of benign or

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

functional causes. We present a rare case of severe hyperandrogenism in a postmenopausal woman secondary to an ovarian steroid cell tumour.

A postmenopausal woman presented with progressively worsening androgenic symptoms, including marked alopecia and hirsutism, without overt signs of virilization. Her medical history included multinodular goiter with subclinical hyperthyroidism, osteopenia, hypertension, and hyperlipidaemia. Initial laboratory evaluation revealed markedly elevated total and free testosterone, DHEAS, and androstenedione. A goserelin (GnRH agonist) suppression test was conducted, resulting in a significant reduction of serum testosterone levels, supporting an ovarian source of androgen excess. Pelvic ultrasonography demonstrated solid-appearing ovaries of normal size, along with a 12-mm ill-defined echogenic lesion within the endometrial cavity.

Given the severity of hyperandrogenism and imaging findings, the patient underwent laparoscopic bilateral adnexectomy. Histopathological analysis identified a steroid cell tumour, not otherwise specified (SCT-NOS) of the right ovary, composed of uniform cells with eosinophilic cytoplasm. Immunohistochemical staining was positive for SF1, inhibin, and calretinin, and negative for EMA and synaptophysin, confirming the diagnosis. No malignant features were noted. The left ovary showed no histopathological abnormalities.

Postoperatively, the patient exhibited rapid biochemical improvement, with normalization of testosterone and androstenedione. DHEAS levels decreased substantially, although occasional mild elevations persisted and were monitored. Clinically, hyperandrogenic symptoms gradually regressed. Although SCT-NOS is generally considered benign, rare recurrences have been reported; therefore, a structured follow-up plan was implemented, including annual pelvic MRI for five years with periodic androgen profiling.

This case highlights that ovarian steroid cell tumours, although rare, should be considered in postmenopausal women presenting with abrupt or severe hyperandrogenism. While timely surgical intervention is typically curative, long-term endocrine and radiologic follow-up remains essential given the unpredictable clinical course of these uncommon tumours.

EP1328 - ECE_1737 - Persistent elevation of gonadotropin levels following gonadectomy despite continued gender-affirming hormone therapy in transgender individuals

Ye Liu[1,2], Jia Yang[3], Xinzhu Wang[3], Bailin Pan[3] and Tianpei Hong[1]

[1]Beijing, China; [2]Department of Endocrinology and Metabolism, Peking University Third Hospital, Beijing, China; [3]Peking University Third Hospital, Beijing, China

Background: Following gonadectomy, the dynamic changes of gonadotropins and the reconstitution of hypothalamic-pituitary-gonadal (HPG) axis feedback under gender-affirming hormone therapy (GAHT) remain unclear.

Methods: This retrospective study analyzed 88 transgender individuals (63 transgender women [TW] and 25 transgender men [TM]) after gonadectomy on stable GAHT with 212 clinical observations. Hormone levels were measured across postoperative intervals and stratified by serum estradiol (E2) or total testosterone (T) levels. Linear mixed-effects models and generalized linear models (GLM) were used to analyze trends and associations.

Results: Both TW and TM exhibited persistently elevated FSH and LH levels across all postoperative time points, remaining significantly above cisgender reference ranges (all $P < .05$) (Tables 1 and 2). Gonadotropin levels showed an inverse dose-response relationship with sex hormones (E2 for TW, T for TM) (Table 3), but GLM indicated that suppressing LH to cisgender reference ranges would require significantly supraphysiological concentrations (E2≥1525.9 pmol/L for TW, T≥47.9 nmol/L for TM).

Conclusions: Gonadotropin levels remain sustained elevated post-gonadectomy despite GAHT. This indicates an incomplete re-establishment of HPG axis feedback, highlighting unique endocrine profiles in post-operative transgender individuals and the need to investigate the potential long-term implications of sustained high gonadotropins.

Data are presented with median (IQR).

Table 1 Characteristics of participants.

	Transgender women ($n = 63$, observations = 142)	Transgender men ($n = 25$, observations = 70)
Age at gonadectomy (years)	25.0 (22.2–28.3)	28.4 (25.6–33.0)
FSH (mIU/mL)	41.0 (20.0–66.7)	68.1 (26.1–104.5)
LH (mIU/mL)	25.7 (14.2–43.1)	31.7 (14.8–48.4)

Table 2 Gonadotropin levels over time after gonadectomy in transgender individuals.

Postoperative time (months)	[1.5, 6)	[6, 12)	[12, 18)	[18, 24)	≥24
Transgender women					
FSH (mIU/mL)	40.8 (11.9-83.5)	41.7 (19.9-70.0)	51.4 (27.1-71.4)	29.9 (18.8-46.1)	42.4 (25.2-63.6)

EP1329 - ECE_3108 - Longitudinal changes in bone mineral density (BMD) in patients with Klinefelter Syndrome (KS): a prospective observational study in a real-world setting

Francesco Costantino[1,2], Daniele Renda Livraghi[1], Veronica Maria Denichelis[1], Sara De Vincentis[1] and Vincenzo Rochira[1,2]

[1]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [2]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero- Universitaria of Modena, Modena, Italy

Introduction: Patients with Klinefelter syndrome (KS) are at risk of low bone mineral density (BMD) and fragility fractures. Therefore, guidelines recommend regular DXA assessments at the lumbar spine and femur, along with fracture risk evaluations. While BMD loss is largely attributed to hypogonadism, additional mechanisms independent of serum testosterone may also play a role. This study aimed to evaluate the longitudinal changes in BMD in KS.

Methods: This prospective, observational, longitudinal, real-world study included KS who underwent at least two evaluations of bone status and pituitary–gonadal axis. Osteoporosis, osteopenia, and age-adjusted low BMD were defined by DXA (Hologic) according to WHO and ISCD criteria.

Results: 56 patients with KS were included. At baseline, the mean age was 36.25 ± 14.86 years with mean total testosterone levels of 4.09 ± 2.90 ng/mL. The initial DXA revealed an average BMD of 0.98 ± 0.14 g/cm^2 at the total femur (TF), 0.88 ± 0.14 g/cm^2 at the femoral neck (FN) and 0.98 ± 0.12 g/cm^2 at the lumbar spine (L1-L4). The prevalence of osteoporosis, osteopenia, and low BMD for age were 3.6%, 10.7%, and 14.3%, respectively. Only two fragility fractures were observed and no patient had ever received osteoactive therapies.

Follow-up DXA scans were available after a remarkable interval of 7.68 ± 6.24 years. No significant differences in BMD were detected at FN, TF, or L1-L4 when comparing baseline and follow-up measurements. Regarding testosterone replacement therapy (TRT), 23 KS initiated TRT during follow-up, 16 were already on TRT at baseline and 14 never received TRT. Longitudinal BMD changes were not significantly different among TRT initiators, those already treated at baseline and TRT-naïve. Respectively, the average BMD percentage changes were −3.69%, −2.24% and +3.07% at TF; +1.82%, +5.42% and +3.07% at FN and −5.42%, −3.73% and −1.30% at L1-L4.

Conclusions: Despite the widespread belief that bone involvement is highly prevalent in Klinefelter syndrome, our longitudinal data indicate a low prevalence of reduced BMD and osteoporosis, along with preserved skeletal stability over time. Importantly, BMD trajectories appear largely independent of testosterone replacement therapy, with neither significant bone loss nor relevant gains at sites typically associated with fragility fractures. These findings challenge the current perception of skeletal fragility in KS and suggest that bone risk may be overestimated. Prospective studies incorporating fracture outcomes are needed to refine bone health assessment and management strategies in this population.

EP1331 - ECE_3501 - Early cardiovascular risk and metabolic dysfunction in women with Polycystic Ovary Syndrome

Shakhzoda Uchkunkhonova[1] and Zulaykho Shamansurova[2]

[1]Medical school, Central Asian University in Tashkent—CAU, Tashkent; [2]Medical school, Central Asian University in Tashkent—CAU, Akfa Medline University Hospital, Tashkent, Uzbekistan

Introduction: Polycystic ovary syndrome (PCOS) is one of the most common endocrine disorders affecting women of reproductive age. Although traditionally considered a gynecological condition, growing evidence indicates that PCOS is a systemic endocrine–metabolic disorder characterized by insulin resistance, hyperinsulinemia, and an increased risk of cardiometabolic complications. Early identification of metabolic abnormalities in women with PCOS is

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

therefore essential for preventing long-term outcomes such as type 2 diabetes mellitus and cardiovascular disease.

Objective: To assess cardiometabolic risk in women with PCOS based on published metabolic and endocrine data.

Methods: Data from recent open-access, peer-reviewed clinical studies published between 2018 and 2025 were systematically reviewed and analyzed. Extracted variables included age, body mass index (BMI), fasting glucose, lipid profile parameters, insulin resistance indices (HOMA-IR), and surrogate markers of cardiometabolic risk such as the triglyceride–glucose (TyG) index. Cardiometabolic risk was interpreted in accordance with established cardiovascular risk assessment frameworks.

Results: Data from a total of 842 women with PCOS aged 18-36 years were analyzed. Mean BMI ranged from 24.1 to 28.1 kg/m^2. HOMA-IR values ranged from 2.05 to 5.08, indicating a high prevalence of insulin resistance. Insulin resistance was observed in 57.5% of women, including those with both normal and elevated BMI. While total cholesterol and triglyceride levels were generally within reference ranges, elevated TyG index values were identified in 61% of participants, suggesting early metabolic syndrome–related alterations. Hyperinsulinemia was associated with enhanced ovarian androgen production and disruption of the hypothalamic–pituitary–ovarian axis, contributing to reproductive dysfunction. Despite young age, women with PCOS demonstrated an increased estimated cardiovascular risk compared with the general population.

Conclusions: Women with PCOS exhibit early metabolic disturbances and an increased cardiovascular risk, even at a young age. These findings highlight the importance of regular cardiometabolic risk assessment and early preventive strategies in women diagnosed with PCOS.

Keywords polycystic ovary syndrome, insulin resistance, cardiometabolic risk, cardiovascular disease, metabolic syndrome

EP1334 - ECE_3839 - Erectile dysfunction years after cessation in men with previous anabolic androgenic steroid use

Yeliz Bulut, Jon Rasmussen and Caroline Kistorp
Department of Nephrology and Endocrinology, Rigshospitalet, København Ø, Denmark

Background and Aims: Impaired erectile function have been associated with previous anabolic androgenic steroid (AAS) use. However, overall sexual function and the prevalence of erective dysfunction remain still to be elucidated among men with previous AAS use. The primary aim of the current study was to assess sexual function in current and previous AAS users compared with controls who had never used AAS.

Methods: In this cross-sectional study, men involved in recreational training were grouped according to their history of AAS use, as current AAS, former AAS (discontinued AAS use >3 months), and never users. We assessed self-evaluated sexual function using the 15-item International Index of Erectile Function (IIEF-15), which consists of five domains: erectile function (ranging from 1 to 30, accordingly, erective dysfunction is present with a score ≤24 and severe dysfunction < 6), orgasmic function (ranging from 0 to 10), sexual desire (ranging from 2 to 10), intercourse satisfaction (ranging from 0 to 15), and overall sexual satisfaction (ranging from 2 to 10). A higher score indicates better sexual function.

Results: We included 118 previous and 278 current AAS users, and 54 never users. The mean (SD) age of all participants was 35.2 (8.8) years. The accumulated duration of AAS use, geometric mean (95% CI), among current users was 188 (166;213), and among former users, 100 (82;122) weeks, $P < .001$. Among former users, the elapsed duration since AAS cessation, geometric mean (95% CI), was 2.1 (1.6;2.7) years. The prevalence of erectile dysfunction was increased in former AAS users ($n = 37$ (34%)) compared with current users (50 (19%)) and never users (5 (10%)), $P < .01$. Furthermore, severe erectile dysfunction was only present in former AAS users (12%) and current users (3%) with none reporting in the group of never AAS users, $P < .01$. Analyzed as a continuous variable, erectile function, sexual desire, intercourse satisfaction, orgasmic function and overall satisfaction were reduced among former users compared with never AAS users, $P < .001$. In a multivariable linear regression model among men with previous AAS use, using erectile function as the dependent variable, adjusted for age, every doubling of accumulated duration of AAS use (log2) was independently associated with impaired erectile function, ($P < .05$), whereas time since cessation was not.

Conclusions: Men with previous AAS use displayed a higher prevalence of erectile dysfunction alongside impairments across all five sexual function domains 2.1 years following cessation, suggesting that sexual function does not fully recover after AAS cessation.

Abstract citation ID: lvag096.1554

EP1335 - ECE_1956 - Meningioma in a patient with Turner syndrome

Eleni Palioura[1], Nikolaos Kalogeris[1], Konstantinos Barkas[2] and Andromahi Vryonidou[1]
[1]*Department of Endocrinology and Diabetes Center, Hellenic Red Cross Hospital, Athens, Greece;* [2]*Department of Neurosurgery, General Hospital of Nikaia, Athens, Greece*

Introduction: Turner syndrome is the most common sex chromosome abnormality in females, characterized by complete or partial loss of one X chromosome. There is limited evidence in the literature pointing to increased incidence of neoplasms, including meningiomas, in patients with Turner syndrome; however, no causal interference has yet been established.

Case Report: We present the case of a 40–year-old woman with Turner syndrome (45,X karyotype) who was regularly followed at our department since the age of 23, after transition from pediatric to adult care. Patient presented some typical physical features of Turner syndrome including short stature, low posterior hairline, short neck, large and low set ears, down-slanting eyes and small chin. She had no congenital cardiac anomalies, but was found to have a horseshoe kidney with normal renal function. During childhood, she received growth hormone therapy starting from age $7^{9/12}$ and continuing for seven consecutive years (until age $14^{3/12}$) with final height 147 cm. Hormone replacement therapy (HRT) was initiated with conjugated estrogen, and cyclic medroxyprogesterone acetate was introduced after menarche at age 12 years and 8 months; this therapeutic

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

approach was continued until age 22. Subsequently, patient received combined oral contraceptive pills containing ethinyl estradiol and gestodene for one year that was afterwards switched to oral regimen of estradiol valerate and dienogest until the age of 38. Since then, she is under hormone substitutive therapy consisted of transdermal 17β-estradiol and cyclic micronized progesterone. At age 39, the patient complained for dizziness and bilateral tinnitus. Magnetic resonance imaging (MRI) of the brain revealed a large extraparenchymal lesion (47 × 28 × 25 mm) located in the right parietal region, adjacent to the midline. The lesion had lobulated margins and was heterogeneously enhanced. It was in contact with the interhemispheric fissure and the superior sagittal sinus and caused displacement of the cortical gyri of the parietal cortex. Based on neuroimaging findings, the mass was presumed to represent a meningioma. Repeated brain MRIs at 6 and 12 months showed no differentiation and a follow-up examination by neurosurgeon was scheduled for the next year.

Discussion: To the best of our knowledge, this represents the 16th reported case in the literature of meningioma occurrence in a patient with Turner syndrome. It remains to be elucidating whether this coexistence is incidental or is related to genetic (loss of X chromosome) and/or hormonal (GH and HRT) factors implicated in Turner syndrome's pathogenesis and management.

EP1336 - ECE_1771 - Unmasking XXYY syndrome: a case report highlighting endocrine and neurological manifestations

Ana Gheorghe Milea[1,2] and Carmen Emanuela Georgescu[1,2]
[1]*Department of Endocrinology, Clinical County Emergency Hospital Cluj-Napoca, Cluj-Napoca, Romania;* [2]*Department of Endocrinology, Iuliu Hatieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania*

Background: XXYY syndrome is a rare sex chromosome aneuploidy, most commonly resulting from meiotic nondisjunction during spermatogenesis and, less frequently, from post-zygotic mitotic errors occurring in early embryogenesis.[1] The condition is classically associated with increased height, gonadal dysfunction, and a wide spectrum of neurodevelopmental and behavioral abnormalities.[2]

Case: Presentation: We report the case of a male patient, the first child of a non-consanguineous couple, born at term with documented perinatal distress. Initial developmental assessment revealed delayed gross motor milestone acquisition; however, significant improvement in motor function was observed following early intervention and structured rehabilitation.

At 8 years of age, the patient underwent a comprehensive neurological evaluation after three epileptic seizure episodes. Brain magnetic resonance imaging identified a pineal region tumor, radiologically consistent with a pinealocytoma, measuring 11 × 11 × 12.7 mm. Serum α-fetoprotein and β-human chorionic gonadotropin were negative. Serial imaging demonstrated stability in lesion size over time. Therapy with valproate was initiated and maintained for two years, after which treatment was discontinued at the family's request, with no subsequent seizure recurrence. The patient was also diagnosed with mild intellectual disability, mixed-type attention-deficit/hyperactivity disorder and socio-pragmatic communication disorder.

At the age of 16, he was referred for endocrine evaluation due to incomplete pubertal development, six years after pubertal onset. Presenting complaints included progressive weight gain, psychomotor agitation, and aggressive behavior. Physical examination revealed extreme tall stature (+3.91 SD), obesity, eunuchoid body proportions, and Tanner stage III pubertal development. Laboratory investigations demonstrated hypergonadotropic hypogonadism, primary hypothyroidism and dyslipidemia. Based on the clinical and hormonal findings, Klinefelter syndrome was initially suspected, prompting cytogenetic analysis, which ultimately revealed a diagnosis of 48,XXYY syndrome. Hormone replacement therapy with levothyroxine and transdermal testosterone was initiated, leading to a favorable clinical evolution.

Conclusions: This case illustrates the marked phenotypic diversity of XXYY syndrome. The coexistence of hypergonadotropic hypogonadism with tall stature, primary hypothyroidism, obesity, epilepsy, cognitive impairment, and a pineal region tumor highlights the diagnostic complexity of this condition. Early recognition and cytogenetic confirmation are essential to enable tailored hormonal therapy and coordinated multidisciplinary follow-up.

EP1337 - ECE_3006 - Finding zebras: identifying a novel mutation causing testotoxicosis

Viviana Adam[1], Alexandru Florescu[1,2], Andra Berigoi[2], Irina Puscasu[2], Teodora Vintilă[2], Stefana Bilha[1,2], Anca Matei[1,2] and Cristina Preda[1,2]
[1]*Universitatea de Medicină şi Farmacie 'Grigore T. Popa' Iaşi, Iaşi, Romania;* [2]*Endocrinology, Spitalul Sf. Spiridon Iaşi, Iaşi, Romania*

Introduction: Testotoxicosis, also known as familial male limited precocious puberty, is a rare cause of peripheral precious puberty (PPP) caused by an activating mutation of the gene encoding for the LH receptor on Leydig cells (LHCGR gene, cr2p21). Left untreated, this can cause psychosocial complications; advanced bone age and low adult height; as well as central precocious puberty.

Case Report: We examined a 5 year, 8 month old boy that was directed to the Endocrinology Clinic because of increased testicular volume, penile enlargement, and scrotal, pubic and upper lip hair. Family history was negative for precocious puberty. On clinical examination, height was 119 cm (−0.42 SD), weight was 20kg, BMI 14.2 kg/m^2 (normal), Tanner stage 2. Wrist X-ray showed a bone age of 5 years and 6 months. Hormonal evaluation demonstrated a markedly increased testosterone level, more than 10 times the upper limit of normal (7.22 nmol/L), with low FSH and LH levels (0.411 mIU/mL and 0.146 mIU/mL, respectively). Low 17OH-progesterone ruled out congenital

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

adrenal hyperplasia; imaging studies and tumor markers excluded testicular/adrenal tumors; while McCune Albright syndrome and iatrogenic PPP were excluded based on history and physical examination. Testotoxicosis was diagnosed by exclusion, and treatment with aromatase inhibitors (anastrozole, 1 mg/day) and bicalutamide (25 mg/day) was initiated. Genetic testing was later performed, identifying a previously unreported mutation in the LHCGR gene: (c.1193T>C, p.(Met398Thr). At 6 and 12 month reevaluation, no side effects were reported except for mild headache occasionally, pubertal signs regressed; gonadotropin levels remained low, while elevated testosterone persisted; and bone X-ray didn't demonstrate advancement of bone age. After 18 months, Diphereline stimulation test confirmed central precocious puberty (FSH = 3.55 mIU/mL, LH = 3.71 mIU/mL), and GnRH analogue treatment was added to the treatment plan.

Conclusions: The limited studies available suggest optimal treatment of testotoxicosis is with a combination of aromatase inhibitors and antiandrogen medications. Testosterone levels shouldn't be used as a marker for treatment efficacy; but rather focus should be on gonadotropin levels and decreasing the bone age to chronological age ratio, if advanced at diagnosis. In our case, despite early diagnosis and appropriate treatment, PPP progressed to central precocious puberty, underlying the importance of close monitoring during treatment, even if pubertal signs regress. Finally, genetic studies of the child and both parents should be carried out whenever possible; in our case, a previously unreported mutation in the LHCGR gene was identified, and the correlation between genotype and phenotype will be further explored during follow-up.

EP1338 - ECE_1482 - Anti-Müllerian hormone as a marker of ovarian reserve to preserve female fertility in radioiodine treatment of Thyroid Carcinoma

Barbora Havlinova[1,2], Katerina Koprivova[1,3] and Jiri Dolezal[1,4]

[1]Charles University Faculty of Medicine in Hradec Králové, Hradec Králové, Czech Republic; [2]3rd Department of Internal Medicine—Metabolic Care and Gerontology, University Hospital Hradec Králové, Hradec Králové, Czech Republic; [3]Department of Clinical Immunology and Allergology, University Hospital Hradec Králové, Hradec Králové, Czech Republic; [4]Department of Nuclear Medicine, University Hospital Hradec Králové, Hradec Králové, Czech Republic

Context: Differentiated thyroid carcinoma is the most common endocrinological malignancy with women being more frequently affected. There are discussions about adverse effects of radioiodine (^{131}I) on ovarian function and female fertility. Anti-Müllerian hormone (AMH) is regarded as the best endocrine marker for evaluating the physiological loss of oocytes in healthy women with regard to age.

Objective: The aims of the project are to determine ovarian reserve assessed by AMH, to determine the absorbed dose of ^{131}I in the ovary of women undergoing radioiodine treatment based on the magnitude of ^{131}I activity administered, and to evaluate the relationship between absorbed dose of ^{131}I and change in AMH level.

Materials and Methods: Over a three-year period, 74 serum samples were collected from women with thyroid carcinoma and 4 serum samples from healthy premenopausal women. AMH levels were measured using the ELISA method. In total, 5 measurements were obtained, with the first performed before radioiodine therapy and subsequent measurements at regular intervals 4-6 months. AMH levels before and after treatment were compared. At the same instant, hypothalamic-pituitary axis function was examined.

Results: We found a significant effect on reducing AMH levels and thus ovarian reserve after ^{131}I (median 3.56 vs median 1.25, $P <$ .0001). There was a strong correlation with age ($r = -0.616$ and -0.752, respectively)—AMH decreases with increasing age. The relationship between changes in AMH and menstrual cycle disturbance has not been demonstrated.

Conclusions: The question of possible long-term side effects of radioiodine remains open and therefore the need to inform patients. Consequently, predicting the end of ovarian function by assessing a simple serum biomarker could help to select an appropriate treatment strategy for young women planning pregnancy.

EP1340 - ECE_2650 - Impact of dyslipidemia on the probability of pregnancy in women undergoing IVF: a systematic review and meta-analysis

Panagiotis Anagnostis[1,2], Julia Bosdou[3], Christos Venetis[3], Evangelia Katsika[3], Kokkoni Kiose[3], Marisia Stavrinidou[3], Leonidas Zepiridis[3], Grigorios Grimbizis[3] and Efstratios Kolibianakis[3]

[1]3rd Department of Internal Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Aristotle University of Thessaloniki, Thessaloniki, Greece; [3]Unit for Human Reproduction, 1st Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece

Background/Aims: Dyslipidemia, including high concentrations of total cholesterol (TC) or low-density lipoprotein cholesterol (LDL-C) or triglycerides (TG), as well as low levels of high-density lipoprotein cholesterol (HDL-C), adversely affect cardiovascular health. However, its specific impact on in vitro fertilization (IVF) is unknown. The purpose of this study was to systematically review and meta-analyze the best available evidence regarding the impact of dyslipidaemia on IVF outcomes. The primary outcome was live birth rates, while secondary outcomes included clinical pregnancy rates, cumulative live birth and miscarriage rates.

Methods: A comprehensive literature search in PubMed, Scopus and Google Scholar was conducted until 10 January 2026. Data from eligible studies were independently extracted by two reviewers, including demographic, methodological and clinical information. Study quality was assessed using the Newcastle-Ottawa Scale. Statistical heterogeneity was evaluated using the I^2 statistic, and meta-analyses were conducted using random- or fixed-effects models, depending on the presence of significant heterogeneity. Results were expressed as relative risks (RR) or weighted mean differences (WMD) with 95% confidence intervals (CIs) and were analysed using an intention-to-treat principle.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Results: Six retrospective studies ($n = 11\,685$) published between 2018 and 2024 with moderate-to-low risk of bias were analysed. Sample size ranged from 127 to 3372 patients. Clinical pregnancy rates were lower in patients with dyslipidemia compared to those without (RR 0.85, 95% CI 0.74-0.99; random effects model; I^2 73.4%; five studies, 5477 patients). Dyslipidemia was associated with higher miscarriage rate (RR 1.24, 95% CI 1.01-1.53; I^2: 0%; four studies, 5019 patients) compared with normal lipid profile. Furthermore, patients with dyslipidemia had lower live birth rates compared to those without (RR 0.82, 95% CI 0.68-0.99; I^2 89.4%; three studies, 4972 patients).

Conclusions: This systematic review and meta-analysis is the first performed so far on this topic, showing decreased pregnancy outcomes in women with dyslipidaemia compared to those without. This underscores the importance of lipid profile screening before infertility treatment and necessitates prompt lifestyle intervention to reduce this effect.

EP1342 - ECE_2956 - Endocrine, metabolic, and skeletal characteristics of Klinefelter syndrome in a long-term real-world cohort

Ema Cindro Kostelec[1], Primož Kotnik[1,2], Tadej Battelino[1,2], Mojca Jensterle[1,3], Tomaz Kocjan[1,3], Andrej Janez[1,3] and Kristina Groti Antonic[1,3]
[1]*Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia;* [2]*Department of Endocrinology, Diabetes and Metabolism, University Children's Hospital, University Medical Center Ljubljana, Ljubljana, Slovenia;* [3]*Department of Endocrinology, Diabetes and Metabolism, University Medical Center Ljubljana, University Children's Hospital, Ljubljana, Slovenia*

Background: Klinefelter syndrome is frequently underdiagnosed and characterized by progressive hypogonadism and a high burden of multisystem comorbidities. Although testosterone replacement therapy is central to management, real-world data on timing of initiation, transition from pediatric to adult care and long-term follow-up remain limited.

Aim: To characterize age at diagnosis, describe the endocrine phenotype, and assess long-term clinical characteristics and management of patients with KS in a real-world clinical cohort.

Materials and Methods: We conducted a retrospective analysis of medical records for 62 patients treated at University Medical Centre Ljubljana by pediatric and adult endocrinology teams from 1976 to 2025. Analyzed parameters included demographics, hormonal profiles, anthropometrics, metabolic markers, bone mineral density, and comorbidities.

Results: Mean age at initial evaluation was 31.7 ± 12.1 years; only 9 of 62 patients (14.5%) were diagnosed in childhood. At testosterone initiation, mean testosterone levels were low (4.38 ± 2.70 nmol/L), with elevated luteinizing hormone (17.1 ± 11.6 IU/L) and follicle-stimulating hormone (33.5 ± 16.6 IU/L). Metabolic syndrome affected 32.7% of patients, insulin resistance 58.3%, and altered body composition was common (mean BMI 28.3 ± 6.4 kg/m^2 at diagnosis, rising to 34.6 ± 5.8 kg/m^2 with metabolic syndrome). Reduced bone mineral density occurred in 20.8% of patients under 50 years and 66.7% of those 50 years or older; testosterone therapy yielded positive effects. Additional comorbidities encompassed autoimmune (3%), oncologic (1%), neuropsyhiciatric (19%), cardiovascular and thromboembolic disorders (40%). All nine childhood-diagnosed patients transitioned successfully to adult care via a dedicated transition clinic, though 30.7% of the cohort overall discontinued regular follow-up.

Conclusions: Klinefelter syndrome in this real-world cohort was most often diagnosed in adulthood. Patients had high burden of metabolic and skeletal abnormalities. These findings highlight the importance of earlier diagnosis, timely testosterone therapy, and structured long-term endocrine management to reduce cumulative morbidity.

EP1343 - ECE_3558 - Rare 5′-UTR variants creating new upstream open reading frames provide a potential novel genetic mechanism in congenital hypogonadotropic hypogonadism

Georgios Markantes[1,2], Jack Fu[3], Harrison Brand[3], Michael Talkowski[3], Lacey Plummer[1], Stephanie Seminara[1], Ravikumar Balasubramanian[1] and Maria Stamou[1]
[1]*Reproductive Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States;* [2]*Division of Endocrinology, Department of Internal Medicine, University of Patras School of Health Sciences, Patras, Greece;* [3]*Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA, United States*

Background: Congenital hypogonadotropic hypogonadism (CHH) is a genetically heterogeneous disorder with numerous genes implicated in its pathogenesis. To date, most studies have focused on the coding regions of the genome, leaving ~50% of the CHH genetically unsolved. While the impact of non-coding regions in disease pathogenesis has recently emerged, the role of non-coding variants affecting upstream open reading frames (uORFs) within the 5′ untranslated regions (5′-UTRs), which are known to suppress downstream translation, has not been thoroughly studied.

Objective: In this study, we aimed: (i) to assess whether patients with CHH are enriched for rare 5′-UTR variants creating new uORFs, and thus having the potential to suppress downstream translation of known CHH genes compared to reproductively normal controls, (ii) to phenotypically characterize CHH individuals harboring such 5′-UTR variants.

Methods: Whole exome sequencing data of 1403 CHH subjects and 7999 reproductively normal controls from the Mass General Brigham Biobank (MGBB) was analyzed using the GATK pipeline to identify rare 5′UTR variants [minor allele frequency (MAF) <0.1% in autosomal dominant genes and <1% in autosomal and X-linked recessive genes] in 82 known CHH genes. The variants' functional effect was assessed using the UTRannotator, a VEP plugin that identifies variants disrupting existing or creating new uORFs.

Results: We detected 50 5′-UTR variants (MAF<1%) with a predicted effect in 30 genes. Such variants were more common in CHH vs controls (1.3% vs 0.7%, $P = .034$). Variants creating new uORFs were also more common in CHH probands (CHH 0.8%—Controls 0.3%, $P = .0159$), and this pertained to autosomal dominant genes ($P = .06$) but not to autosomal and X-linked recessive ($P = .114$). Variants disrupting existing uORFs were equally prevalent in CHH and Controls (0.5% vs 0.4%, $P =$ ns). Of the 11 CHH

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

probands harboring variants creating new uORFs 6 were males and 5 females; 7 had anosmia (Kallmann syndrome) and 4 normosmic CHH; and 4 had additional non-reproductive characteristics (eg, clinodactyly, short metacarpal, learning disability/speech impairment, amblyopia, ptosis, strabismus).

Conclusions: CHH cases are enriched for rare 5′UTR variants that create new uORFs in autosomal dominant genes compared to controls, underscoring the emerging role of non-coding variants in the genetic background of CHH.

Keywords congenital hypogonadotropic hypogonadism (CHH), Kallmann syndrome, 5′ untranslated regions (5′-UTR), upstream open reading frames (uORFs)

EP1344 - ECE_1600 - Cytokine dynamics following initiation of gender-affirming hormone therapy in transgender subjects

Yaël Sertons[1], Sarah Collet[1], Jeroen Vervalcke[1], Justine Defreyne[1], Sven C. Mueller[2], Mattias Hofmans[3], Carolien Bonroy[3], Valentino D'onofrio[4], Guy Snaterse[1], Guy T'sjoen[1] and Lapauw Bruno[1]

[1]Endocrinology, Ghent University Hospital, Ghent University Hospital, Gent, Belgium; [2]Psychology, Ghent University, Gent, Belgium; [3]Laboratory Medicine, Ghent University Hospital, Ghent University Hospital, Gent, Belgium; [4]Diagnostic Sciences, Ghent University, Gent, Belgium

Background: Sex is a major source of biological variation in humans, including immune responses. Evidence suggests that sex steroids have immunomodulatory properties, as they can potentially influence cytokine profiles and subsequently (auto)inflammatory responses. As a result, differences in sex steroid exposure could contribute to the known sex-related disparities in infectious and autoimmune diseases.

Objective: To study the effects of gender-affirming hormone therapy (GAHT) on the levels of multiple inflammatory cytokines and other related serum analytes in transgender individuals.

Material and Methods: Serum samples were collected from hormone-naïve trans women (TW) ($n = 30$) and trans men (TM) ($n = 30$) who initiated GAHT at the Ghent University Hospital, Belgium. Cisgender men (CM) ($n = 10$) and cisgender women (CW) ($n = 10$) were included as controls. Serum samples were collected at baseline and after ±6 months of treatment. High-sensitivity C-reactive protein (hs-CRP) was measured using immunoassay. Serum immune-related biomarkers (irBMs), including cytokines and chemokines, were determined using a commercial multiplex assay (Olink®), consisting of 45 markers. Serum estradiol and testosterone were determined using liquid-chromatography tandem mass spectrometry (LC-MS/MS).

Results: In total, 37 biomarkers could be detected, whereas 8 parameters were partially or completely below limits of quantification. After ±6 months of GAHT in TW, serum levels of ten cytokines (CCL2, CCL7, CCL11, CCL13, CCL19, CXCL9, CXCL10, CXCL11, IL15 and TNFSF10) significantly decreased, whereas IL7 increased. In TM, eight factors significantly increased (CCL2, CCL7, CCL11, CCL13, CCL19, IL17C, MMP1 and TNFSF10). In marked contrast, six of the cytokines that decreased in TW, increased in TM, showing an inverse relationship. Other immune-related biomarkers were not significantly affected, and levels of hs-CRP did not show a clinically relevant change over time. Within the cisgender reference cohort, three irBMs (CXCL10, CSF1 and OSM) were significantly higher in CW as compared to CM.

Conclusions: Six months of estrogen with antiandrogen treatment decreased serum levels of several cytokines and chemokines in TW. In contrast, cytokine and chemokine levels increased in TM upon treatment with testosterone. These distinct and generally opposite changes suggest a sex steroid-dependent impact, which could contribute to the sex-related disparities in (auto)inflammatory diseases. However additional research should explore potential clinical consequences, as well as the mechanisms involved.

EP1346 - ECE_2904 - Hyperprolactinemia in Polycystic Ovary Syndrome: clinical and biochemical differences from normoprolactinemic PCOS

Ersen Karakilic[1], Ceren Tufan[1], Emre Sedar Saygılı[1], Büşra Tunç Topuz[1] and Hayri Bostan[2]

[1]Endocrinology and Metabolism, Canakkale Onsekiz Mart University Faculty of Medicine, Canakkale, Türkiye; [2]Canakkale, Türkiye

Background: Polycystic ovary syndrome(PCOS) is a prevalent endocrine disorder characterized by hyperandrogenism and ovulatory dysfunction. Although mild hyperprolactinemia is frequently reported in PCOS, its clinical relevance and contribution to hyperandrogenism remain uncertain.

Objective: To compare the clinical, hormonal, and metabolic characteristics of hyperprolactinemic and normoprolactinemic women with PCOS and to evaluate the independent association between prolactin levels and hyperandrogenemia.

Methods: This retrospective observational study included 372 women aged 18-40 years diagnosed with PCOS according to the Rotterdam criteria between 2018 and 2025. Patients were classified as hyperprolactinemic ($n = 133$) or normoprolactinemic ($n = 239$) based on baseline serum prolactin levels, after exclusion of secondary causes of hyperprolactinemia. Clinical features, hormonal profiles, and metabolic parameters were compared between groups. Correlations between prolactin and hormonal variables were assessed using Spearman's analysis. Multivariable linear regression was performed to identify independent predictors of total testosterone levels.

Results: Hyperprolactinemic PCOS patients exhibited significantly higher LH/FSH ratios, total testosterone, DHEAS, and TSH levels compared with normoprolactinemic patients (all $P <$ .05), while age, estradiol, metabolic parameters, lipid profiles, and the prevalence of hirsutism, acne, and menstrual irregularities were similar between groups. Prolactin levels showed positive correlations with total testosterone ($r = 0.246$), DHEAS ($r = 0.182$), and TSH ($r = 0.196$) (all $P \leq .001$). In multivariable regression analysis, prolactin ($B = 0.003$, $P = .001$), LH/FSH ratio ($B = 0.045$, $P < .001$), and HOMA-IR ($B = 0.008$, $P = .029$) were independently associated with higher total testosterone levels, whereas TSH and age were not(Table 1).

Conclusions: Mild hyperprolactinemia in PCOS is associated with a more pronounced hyperandrogenic hormonal profile, independent of insulin resistance and age. These findings support a potential contributory role of prolactin in PCOS-related hyperandrogenism and suggest that hyperprolactinemic PCOS may

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

represent a distinct endocrine phenotype warranting further prospective investigation.

Table 1 Multivariable linear regression analysis for total testosterone.

Variable	B	Standardized β	95% CI (Lower)	95% CI (Upper)	*P* value
Prolactin (ng/mL)	0.003	0.183	0.001	0.005	.001
LH/FSH ratio	0.045	0.254	0.027	0.064	<.001
HOMA-IR	0.008	0.117	0.001	0.015	.029
TSH (mIU/L)	0.013	0.047	−0.016	0.043	.378
Age (years)	−0.004	−0.086	−0.009	0.001	.108

B indicates unstandardized regression coefficients; β indicates standardized coefficients; CI, confidence interval. The coefficient of determination was $R^2 = 0.144$ and adjusted $R^2 = 0.131$. No multicollinearity was detected.

EP1347 - ECE_3043 - Phenotype of Polycystic Ovary Syndrome in women with and without obesity: comparison of clinical, hormonal, metabolic and sexual features

Chiara Manzini[1], Elisa Delle Donne[1], Emma Dorato[1], Luca Persani[1,2], Linda Vignozzi[3], Marco Bonomi[1,2], Silvia Federici[1,2], Elisa Maseroli[4] and Biagio Cangiano[1,5]
[1]*Department of Medical Biotechnology and Translational Medicine, University of Milan, Milan, Italy;* [2]*Endocrinology Department & Lab of Endocrine and Metabolic Research, IRCCS Istituto Auxologico Italiano, Milan, Italy;* [3]*Department of Experimental Clinical and Biomedical Sciences "Mario Serio", University of Florence, Florence, Italy;* [4]*Andrology, Women's Endocrinology and Gender Incongruence Unit, Careggi Hospital University, Florence, Italy;* [5]*Milan, Italy*

Background: Obesity and Polycystic Ovary Syndrome (PCOS) share key pathophysiological mechanisms, including insulin resistance, hyperandrogenism and hypothalamic-pituitary-ovarian axis dysfunction. In literature, it is debated whether gonadal alterations in PCOS with and without obesity arise from distinct pathophysiological mechanisms. Some manifestations of PCOS are influenced by body mass index (BMI), but the specific ways in which obesity affects the gonadal axis remain unclear.

Aim: To compare clinical, hormonal, and sexual parameters between women with PCOS and severe obesity and women with PCOS without obesity, focusing on extreme BMI categories to minimize phenotypic overlap.

Materials and Methods: In this retrospective cross-sectional study we collected clinical data (age, BMI, Ferriman–Gallwey [F&G] score), hormonal parameters (LH, FSH, total testosterone, sex hormone binding globulin [SHBG], Δ4-androstenedione [D4A], dehydroepiandrosterone sulfate [DHEAS], anti-Müllerian hormone [AMH]), metabolic parameters (fasting glucose, lipid profile), and sexual function data (Female Sexual Function Index [FSFI]) from ninety-six women with PCOS and BMI ≥35 kg/m^2 (G1) or ≤29.9 kg/m^2 (G2). Patients were recruited from three centers (Auxologico San Luca, Careggi Hospital and Auxologico Piancavallo Hospital).

Results: Twenty-seven patients belonged to G1 and sixty-nine to G2. We found no significant difference between the two groups in terms of age, FSFI scores, LH and FSH levels, and the LH/FSH ratio. G1 showed higher F&G scores ($P = .0410$). Total testosterone and DHEAS levels were similar between groups, whereas SHBG was significantly lower and the free androgen index was higher in G1. D4A levels were lower in G2 ($P = .0444$). AMH levels were lower in G1 ($P = .0106$) and positively correlated with LH, D4A and the ovarian theca cell stimulation index (D4A × LH), independently of age, BMI, and HOMA index.

Discussion: We found that PCOS in patients with severe obesity is characterized by an increased clinical hyperandrogenism, exacerbated by reduced SHBG levels and increased free androgen fractions as compared with patients without obesity. In patients with severe obesity, we observed lower AMH levels correlating with reduced thecal stimulation, as suggested by the D4A × LH index. These findings support the hypothesis of blunted central stimulation in women with PCOS and severe obesity, consistent with the effects of obesity observed in male functional hypogonadotropic hypogonadism.

Conclusions: These findings seem to delineate a distinct endocrine, metabolic and reproductive clinical profile of PCOS due to severe obesity, characterized by reduced hypothalamic–pituitary stimulation, likely mediated by multiple interrelated factors.

Background: Women with PCOS are at increased risk of insulin resistance and associated metabolic complications, with androgen excess identified as a major driver. Sex hormone binding globulin (SHBG) is a major determinant of androgen bioavailability; both increased levels of insulin and androgens suppress hepatic SHBG biosynthesis. Testosterone and the adrenal-derived active 11-oxygenated androgen 11-ketotestosterone are major contributors to PCOS-related androgen excess and activate the androgen receptor equipotently. However, it is not known

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

whether they differ in their impact on SHBG. Here, we examined the relationship between serum SHBG, insulin resistance and circulating classic and 11-oxygenated androgens in a large cohort of women with PCOS.

Methods: We prospectively recruited treatment-naïve women with PCOS diagnosed according to Rotterdam Criteria. We collected baseline fasting blood samples and measured classic and 11-oxygenated androgens using a validated liquid chromatography-mass spectrometry multi-steroid profiling assay. Serum SHBG, plasma insulin and glucose were measured using electrochemiluminescence immunoassays. Fasting plasma glucose and insulin were used to calculate the Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) as a surrogate marker of systemic insulin resistance. Multivariate linear regression models adjusted for body mass index (BMI) were used to assess the association of SHBG with circulating concentrations of classic androgens, 11-oxygenated androgens, and the HOMA-IR.

Results: A total of 488 women with PCOS were included in the analysis [Median BMI 27.5 IQR (22.4-34.6) kg/m^2; median age 28 IQR (25-32) years]. After adjustment for BMI, SHBG was negatively associated with serum androstenedione, the central precursor of both classic and 11-oxygenated androgens ($\beta = -1.6$, $P = .02$). Similarly, SHBG was negatively associated with the potent 11-oxygenated androgen 11-ketotestosterone ($\beta = -3.8$, $P = .05$) and the slightly weaker 11-oxygenated androgen 11β-hydroxytestosterone ($\beta = -7.3$, $P = .001$). SHBG was also inversely associated with HOMA-IR ($\beta = -.03$, $P = .001$) and this relationship persisted even after adjustment for BMI ($\beta = -.02$, $P = .01$). By contrast, testosterone positively correlated with SHBG ($\beta = 3.5$, $P = .03$).

Conclusions: Serum SHBG is negatively associated with androgen excess and insulin resistance in women with PCOS. Active 11-oxygenated androgens, but not testosterone, exhibited a strong negative correlation with serum SHBG. Underlying mechanisms remain to be explored but may include that 11-oxygenated androgens exert a stronger direct suppression of hepatic biosynthesis or indirectly impact more on SHBG by driving hyperinsulinaemia.

EP1349 - ECE_2763 - Beyond infertility: themes in quality of life and lived experiences in adults with Klinefelter syndrome

Brien Mehmet[1,2], Sofia Llahana[1], Channa Jayasena[3], Steve Gillard[1] and Andrew Dwyer[4,5]

[1]School of Health & Medical Sciences, City St George's, University of London, London, United Kingdom; [2]Department of Endocrinology and Diabetes, Royal Free Hospital NHS Foundation Trust, London, United Kingdom; [3]Department of Investigative Medicine, Imperial College London, Hammersmith, London W12 ONN, United Kingdom; [4]Endocrinology, Diabetes, and Metabolism Service, Massachusetts General Hospital, Boston, Massachusetts 02114, United Kingdom; [5]Harvard Reproductive Endocrine Sciences Centre and Reproductive Endocrine Unit, Boston, United States

Background: Klinefelter syndrome (KS) is a sex chromosome aneuploidy (47, XXY) and the most common genetic cause of hypogonadism in men, affecting 1 in 450-600 male births. Alongside hypogonadism, KS is associated with a variety of complex comorbidities influencing patients' cardiometabolic health, fertility, and mental health. This contributes to increased care needs, whilst population-based studies report a 40% increased mortality risk. An earlier systematic review conducted by the authors, suggested significantly lower Quality of Life in adults with KS across all domains "physical health," "psychological health," "level of independence," and "environment." However, qualitative research providing in-depth understanding of how KS influences QoL domains in this population remains limited. This research explored the lived experiences of adults with KS and generated themes describing factors that influence QoL.

Methods: A qualitative study utilising one-hour semi-structured interviews was conducted with fourteen adults with KS. Participants were recruited via the memberships lists of a national patient support group (The Klinefelter's Association) and a closed Facebook group affiliated with a local KS clinic. Interviews were thematically analysed using a hybrid inductive and deductive coding framework based on pre-existing literature, and the World Health Organisation's quality of life guidelines.

Results: Thematic analysis identified several themes describing how adults with KS experience and interpret quality of life. Suggesting multidimensional influences where physical challenges, psychological health and future expectations are often described. Physical health was influenced by fatigue, sleep disturbances, body composition, and body image concerns, as well as the different responses to testosterone replacement therapy. Hospital and medical management experiences were integral to quality of life. Participants described a variety of challenges and benefits to accessing specialist care, treatment optimisation, clinician knowledge and effective communication, and continuity of care. Psychological health was more complex theme, with anxiety/depression, concentration issues, and difficulties regulating emotions being clearly described. However, infertility often had strong emotional significance, further influencing psychological health, shaping self-perceived identity, relationships, and future life plans. Social connections were challenging and often difficult due to communication issues and misunderstandings, leading to loneliness. Participants described making attempts to gain independence but were limited by health and social barriers.

Conclusions: Quality of life in adults with KS is influenced by an interconnected framework encompassing physical, psychological, and social factors. Optimal patient care requires a holistic, multidisciplinary approach that promotes improvement in mental health, social functioning, and self-efficacy to reduce adverse outcomes associated with this condition.

EP1350 - ECE_2081 - Assessment of metabolic aging in females with Polycystic Ovary Syndrome: a cross-sectional Biobank study

Kawthar Sultan, Khawla Ali, Nitya Kumar, Sawsan Saeed, Meshal Abdulla, Stephen Atkin, Pearl Wasif and John Flood

Royal College of Surgeons in Ireland-Bahrain, Busaiteen, Bahrain

Background: Polycystic ovary syndrome (PCOS) is the most common endocrine disorder amongst females of reproductive age. PCOS is characterized by several metabolic abnormalities including obesity and increased risk of insulin resistance (IR), both of which may contribute to accelerated metabolic aging. Metabolic age is major indicator of health and physical fitness.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

It is estimated by comparing the individual's Basal metabolic rate (BMR) to populations of the same chronological age. However, Current assessment of metabolic aging remains insufficient in females with PCOS.

Objective: To assess metabolic aging in females with PCOS.

Methods: This was a retrospective cross-sectional study utilizing data from the Polycystic Ovary Syndrome Biobank in Bahrain. Subjects' metabolic age was calculated via bioelectrical impedance. The difference between metabolic age and chronological age (age gap) was obtained for each subject. Positive values indicate a higher metabolic age than chronological age, while negative values indicate a metabolic age lower than the chronological age. HOMA-IR was utilized to estimate insulin resistance.

Results: Forty-seven PCOS subjects vs 63 control subjects were enrolled in the study. Within the PCOS cohort, metabolic age was positively correlated with age gap ($r = 0.883$, $P < .001$), HOMA-IR ($r = 0.498$, $P = .008$), c-peptide ($r = 0.371$, $P = .019$), overall body fat percentage ($r = 0$ .808, $P < .001$), body mass index (BMI) ($r = 0.649$, $P < .001$), prevalence of infertility ($r = 0$ .306, $P = .036$), and prevalence of weight gain ($r = 0$ .448, $P = .002$). Conversely, negative correlations were observed between metabolic age and free testosterone ($r = -0.484$, $P = .003$), clinical/biochemical hyperandrogenism ($r = -0.347$, $P = .018$), the total Ferriman-Gallway score ($r = -0.349$, $P = .018$), and prevalence of acne ($r = -0.356$, $P = .014$). No significant correlation was found between SHBG and metabolic age ($r = -0.0770$, $P = .687$). Higher HOMA IR values significantly predict higher metabolic age independent of chronological age ($\beta = .349$, $P = .029$). Compared to subjects without PCOS, the PCOS group showed a trend towards higher metabolic age ($r = 2.53$), though this didn't reach statistical significance ($P = .103$).

Conclusions: In PCOS, a higher metabolic age was associated with features of cardiovascular risk such as IR and obesity, and with enhanced infertility. Conversely, in PCOS the negative metabolic age suggested that free testosterone and hirsutism may relate more to actual chronological age.

Abstract citation ID: lvag096.1567

EP1351 - ECE_3492 - Menstrual distress, premenstrual symptoms, personality vulnerability traits and mental health

Mina Hagen[1], Ljiljana Marina[2,3], Natalija Antic[2], Kristina Saravinovska[2], Ana Andjelkovic[1], Anja Bosnjak[1] and Dunja Vujosevic[1]

[1]Psychology Department, Faculty of Media and Communications, Singidunum University, Belgrade, Serbia; [2]National Center for Infertility and Endocrinology of Gender, Clinic of Endocrinology Diabetes and Metabolic Diseases, University Clinical Center of Serbia, Belgrade, Serbia; [3]Faculty of Medicine, University of Belgrade, Belgrade

Menstrual distress (MD) and premenstrual symptoms (PMS) are an important indicator of how a woman's neuroendocrine system reacts to cyclical ovarian hormonal changes and are recognized as chronic stressors. Personality vulnerability (PV) traits such as Negative Affectivity, Detachment, Antagonism, Disinhibition and Psychoticism refer to stable patterns of emotional reactivity, stress coping, and interpersonal functioning that influence symptom burden and healthcare behavior. The aim was to examine whether menstrual stressors are selectively associated with specific PV traits. A total of 180 female students aged 20-35 years ($M = 22.56$; $SD = 2.88$) participated in the study. Exclusion criteria were known uterine disorders, known mental disorders, pregnancy or lactation. Forward stepwise regression analyses were performed using PV dimensions (Negative Affectivity, Detachment, Antagonism, Disinhibition, Psychoticism; assessed via PID-5-BF) as outcomes. Predictors included MD (MEDI-Q: Total Score, Menstrual Symptoms [MS], Menstrual Symptoms Distress [MSD]), PMS (SPAF), age, and hormonal contraceptive use (dummy variable). Reliability was high for SPAF and MEDI-Q ($\alpha = .85$), PID-5 trait alphas ranged from .63 (Detachment) to .71 (Antagonism). Menarche and cycle characteristics were also collected. Analysis of the PV traits revealed that scores exceeding 2—indicating moderate or higher symptom levels were found in 55 students for Negative Affectivity, 6 for Detachment, 4 for Antagonism, 4 for Disinhibition and 10 for Psychoticism. Results from SPAF indicated that 156 students met the cutoff for Moderate/Severe PMS (score >26), while 106 students reported clinically relevant menstrual distress (MEDI-Q Total Score >19). For Negative Affectivity, the final model ($F(2177) = 12.890$; $P < .001$) included SPAF ($\beta = .28$; $P < .001$) and MSD ($\beta = .18$; $P < .05$), explaining 12.7% of variance. For Antagonism, hormonal contraceptive use was the only significant predictor ($F(1178) = 4.544$; $P < .05$; $\beta = .16$; $P < .05$), explaining 2.5% of variance. No significant predictors emerged for Disinhibition, Detachment or Psychoticism ($P > .05$). Although MD and PMS were associated with higher Negative Affectivity, the cross-sectional design does not allow conclusions about causality or directionality. It is possible that stable emotional vulnerability amplifies cyclical symptom perception and distress, while recurrent severe symptoms may also reinforce anxiety-like responses over time through sleep disruption, anticipatory stress, and reduced coping capacity, which may contribute to a vicious cycle of symptom amplification and distress. These findings support the need for a multidisciplinary approach combining endocrine evaluation with targeted symptom management and stress-focused psychological interventions.

EP1352 - ECE_3353 - Performance of an automated LC-MS/MS platform for steroid hormones and vitamin D determination in routine clinical practice

Federico Ponzetto[1], Veronica Pirana[1], Alessia Cosentino[2], Alessia Melis[1], Fabio Settanni[3], Manuela Lucchiari[3], Antonello Nonnato[3], Simona Montefiori[2] and Giulio Mengozzi[1]

[1]Clinical Biochemistry Laboratory, Department of Medical Sciences, University of Turin, Turin, Italy; [2]Roche Diagnostics S.p.A. Italy, Monza, Italy; [3]Clinical Biochemistry Laboratory, City of Health and Science University Hospital, Turin, Italy

Background-Aim: Liquid chromatography-tandem mass spectrometry (LC-MS/MS) is considered the reference method for the measurement of steroid hormones and vitamin D; however, its routine implementation in clinical laboratories is often limited by complex workflows, long turnaround times, and high operator dependency. A fully automated LC-MS/MS solution has recently become available, with the aim of simplifying analytical processes and facilitating broader clinical adoption. The aim of this

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

study was to evaluate the real-world analytical performance and workflow impact of a fully automated LC-MS/MS system for routine steroid hormone and vitamin D testing in a clinical laboratory setting.

Methods: A fully automated LC-MS/MS platform (cobas® i 601, Roche Diagnostics), integrating sample preparation, chromatographic separation, mass spectrometric detection, calibration, and quality control into a single continuous workflow, was implemented at the Clinical Biochemistry Laboratory of the City of Health and Science University Hospital of Turin in May 2025, representing the first installation of this system in Italy. Method comparison studies were performed on routine patient samples for multiple endocrine analytes, including testosterone, androstenedione, aldosterone, estradiol, 17-hydroxyprogesterone, DHEA, cortisol, and 25-hydroxyvitamin D. Results obtained with the automated LC-MS/MS system were compared with existing routine methods (automated chemiluminescent immunoassays or conventional LC-MS/MS using commercial kits) by Passing-Bablok regression and Bland-Altman analysis. Workflow efficiency and turnaround times were also evaluated.

Results: A total of 977 patient samples were included in the comparison studies. Strong correlations were observed between the automated LC-MS/MS platform and routine methods for all analytes, with coefficients of determination (R^2) ranging from 0.92 to 0.99. As expected, method-dependent biases were more evident in comparisons with immunoassays, whereas agreement with routine LC-MS/MS methods was generally excellent, with slopes close to unity and limited bias. Full automation resulted in a substantial reduction in hands-on time and overall turnaround time. For example, the analysis of an 84-sample batch of aldosterone and estradiol was completed in approximately 2 hours and 40 minutes, compared with approximately 23 hours using a conventional LC-MS/MS workflow.

Conclusions: In a real-world clinical setting, the fully automated LC-MS/MS platform demonstrated robust analytical performance for a broad panel of steroid hormones and vitamin D. The integration of all analytical steps into a continuous automated workflow significantly improved laboratory efficiency, supporting the routine use of LC-MS/MS for endocrine testing in high-throughput clinical laboratories.

EP1354 - ECE_1640 - Exposure to PFAS impedes the meiotic maturation of mouse oocytes, affecting antioxidant responses and mitochondrial activity while causing DNA damage

Aleksandra Tatarczuch[1], Katarzyna Kotarska[2], Zbigniew Polański[3] and Anna Ptak[1]
[1]*Laboratory of Physiology and Toxicology of Reproduction, Jagiellonian University, Institute of Zoology and Biomedical Research, Cracow, Poland;* [2]*Laboratory of Genetics and Evolution, Jagiellonian University, Institute of Zoology and Biomedical Research, Cracow, Poland;* [3]*Cracow, Poland*

Background: Per- and polyfluoroalkyl substances (PFAS) are synthetic chemical compounds that remain in the environment for a long time due to their exceptional durability. Their widespread presence—including in drinking water, personal care products, furniture and packaging materials—makes human exposure to PFAS almost inevitable. A growing number of epidemiological studies indicate that women exposed to these compounds have elevated levels of PFAS in body fluids, including follicular fluid (FF). The data collected suggest that exposure to PFAS may adversely affect oocyte maturation and meiosis, leading to a deterioration in oocyte quality. As a result, this may reduce reproductive potential and decrease the chances of successful fertilization and embryo development.

Aim of study: The aim of study was to investigate the effect of a mixture of PFAS on the resting pool mice oocytes at germinal vesicle stage with particular emphasis on the induction of DNA damage and the assessment of their ability to continue meiotic maturation.

Methods: Oocytes were isolated from mature ovaries of female outbred OF1 mice and treated for 24 hours and then additionally 18 hours with PFAS mixture called Mix (PFOS, 224 ng/mL; PFOA, 145 ng/mL; PFHxS, 213 ng/mL; PFDA, 9 ng/mL; PFHpA, 6 ng/mL; PFUnDA, 4 ng/mL; PFNA, 2 ng/mL). The efficiency of meiotic maturation of oocytes was assessed based on morphological criteria, DNA damage were measured by RT-qPCR, mitochondrial activity, reactive oxygen species (ROS) levels and reduced glutathione (GSH) content were assessed using fluorescent dyes: MitoTracker Deep Red, H_2DCFDA and monochlorobimane (mBCl), respectively.

Results: Exposure of oocytes in the GV stage to a PFAS mixture led to a significant increase in GSH levels with a simultaneous decrease in ROS levels. In addition, increased mitochondrial activity was also observed compared to the control group, as well as significantly increased nuclear DNA damage. Furthermore in vitro oocyte maturation in the PFAS treatment group was significantly delayed, manifested by the accumulation of oocytes at the GVBD stage and a reduced percentage of oocytes reaching the MII stage.

Conclusions: PFAS mixture disrupts the normal functioning of oocytes in the GV stage, causing simultaneous changes in redox homeostasis and mitochondrial activity and exacerbating nuclear DNA damage. Despite seemingly beneficial metabolic effects, exposure to PFAS leads to delayed meiotic maturation and reduced ability of oocytes to reach the MII stage, which may indicate a potentially adverse effect of these compounds on oocyte quality and developmental competence.

EP1357 - ECE_2671 - Global trends in testosterone prescribing, 2012-2024

Joshua Gialouris[1,2], Wanxin Hou[1,2] and David Handelsman[1,2]
[1]*Andrology, ANZAC Research Institute, Sydney, Australia;* [2]*Andrology, Concord Repatriation General Hospital, Concord West, Australia*

Despite no new approved indications, global testosterone sales over the last four decades have increased by 100-fold, representing a pervasive form of prescription drug misuse. More recent reports suggest a reduction in testosterone prescribing in some countries following cardiovascular safety warnings and regulatory actions. The present study aimed to appraise contemporary multinational temporal trends in testosterone prescribing. In this observational, multinational survey, wholesale sales data to pharmacies for all testosterone products were obtained for 76 countries for each quarter from April 2012 to June 2024 inclusive.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

For each testosterone product type (short or long-acting injectable, transdermal, oral, implantable, miscellaneous [intranasal or sublingual] and low-dose transdermal for female menopausal symptoms), units sold were converted to defined monthly doses per quarter, reflecting total testosterone prescribing for each product. Total testosterone usage for each product was adjusted to annual male or female population estimates for each country. National testosterone prescribing was analysed per quarter overall and per product type on a per capita basis (defined monthly dose per 1000 men or women). Over 12 years, global per capita testosterone sales increased by 1.3-fold, with progressive increases observed in 52 out of 76 countries. The increase was driven predominantly by injectable products (increases of 2-fold and 1.5-fold for long and short-acting injectables, respectively). Per capita testosterone sales increased by 1.4-fold in USA. There was a 6-fold reduction in testosterone sales in Canada, driven by a precipitate, 13-fold reduction in transdermal product sales in Canada in 2015. Prescribing of low-dose transdermal testosterone for female use increased by 8-fold globally. Without any new indications, and amidst safety warnings, a progressive increase in testosterone use continued in most countries from 2012-2024. The pattern of increase may reflect growing testosterone misuse in younger men.

EP1358 - ECE_2008 - Primary ovarian insufficiency with bilateral hypoacusis and craniofacial dysmorphism: a case requiring advanced genetic testing

Irina Bojoga[1,2,3] and Bogdan Pascu[2,3,4]
[1]*Elias University Emergency Hospital, Bucharest, Bucharest, Romania;* [2]*University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania;* [3]*National Institute for Mother and Child Health "Alessandrescu-Rusescu", Bucharest, Romania;* [4]*EASO COM Obesity Center, Yuno Clinic, Bucharest, Romania*

Introduction: Primary ovarian insufficiency (POI) can have an autoimmune etiology and may occur as part of a genetic syndrome. Early diagnosis is essential for timely initiation of hormone replacement therapy and normal pubertal development.

Case Presentation: We present the case of a 17-year-old female with a history of secondary amenorrhea, bilateral hypoacusis, and autoimmune thyroiditis with euthyroidism who was evaluated in our department for suspected POI. Menarche occurred at 13.5 years of age, followed by irregular menstrual cycles (2-3 cycles/year). Family history was significant for autoimmune thyroiditis in the mother and maternal grandmother, irregular menses in the mother, and hypoacusis in a 19-year-old brother.

Physical examination revealed normal height and weight, with characteristic facial dysmorphism including epicanthus, micrognathia (also present in both parents), long neck, small ears, and downslanting palpebral fissures. Dental anomalies were noted, including the absence of lateral incisors, one canine, and premolars. Dermatological findings included two café-au-lait spots on the lower limbs and one hyperchromic patch on the neck. Sexual development showed Tanner stage IV for breast development, but absent axillary and pubic hair, with normal external genitalia.

Laboratory investigations confirmed POI with markedly elevated FSH (99 mUI/mL) and LH (42.5 mUI/mL), suppressed estradiol (<9 pg/mL), undetectable AMH (<0.01 ng/mL), and low progesterone and testosterone levels. Anti-ovarian antibodies were slightly elevated, suggesting autoimmune oophoritis, while anti-adrenal antibodies were negative. Thyroid function tests showed euthyroidism (TSH = 4.07 mIU/mL, FT4 = 1.06 ng/dl) with positive anti-thyroid antibodies. Pelvic ultrasound demonstrated a small tubular uterus, thin endometrium and poorly visualized ovaries. Abdomino-pelvic MRI confirmed ovaries difficult to evaluate without focal lesions. Standard karyotype analysis revealed a normal 46,XX pattern, excluding chromosomal aneuploidies.

Given the complex phenotype, comprehensive genetic testing was recommended, including whole exome/genome sequencing (WES/WGS), focusing on genes associated with POI, craniofacial dysmorphism, and hypoacusis (CLPP, ERAL1, HARS2, HSD17B4, LARS2, TWNK, SLC26A4). Hormone replacement therapy (estrogen and progesterone) was initiated to prevent long-term complications of hypoestrogenism and support normal adolescent development. Cardiac evaluation was also recommended.

Conclusions: Although less common than other autoimmune endocrine pathologies such as thyroiditis or type 1 diabetes, autoimmune oophoritis should be considered in adolescent girls presenting with amenorrhea. Early diagnosis of POI is crucial for enabling treatment initiation and normal development. The association with bilateral hypoacusis and distinctive facial features suggests an underlying genetic syndrome requiring advanced genetic testing for etiological diagnosis and optimal management.

EP1359 - ECE_1615 - Serum multi-steroid profiling analysis in Polycystic Ovary Syndrome (PCOS) and healthy individuals

Vera Dosedelova[1], James M. Hawley[1,2], Karl Storbeck[1,3] and Wiebke Arlt[1,4]
[1]*Medical Research Council Laboratory of Medical Sciences, London, United Kingdom;* [2]*Clinical Biochemistry, Manchester University NHS Foundation Trust, Manchester, United Kingdom;* [3]*Stellenbosch University, Stellenbosch, South Africa;* [4]*Imperial College London, London, United Kingdom*

Background: Polycystic Ovary Syndrome (PCOS) is the most common endocrine disorder in women. The defining feature of PCOS is androgen excess, which contributes to several symptoms such as hirsutism, acne and irregular periods. The adrenal-derived 11-oxygenated androgens were shown to significantly contribute to androgen excess in PCOS, however the clinical relevance and biological variation of 11-oxygenated androgens in PCOS and healthy population remain insufficiently understood. Here we developed a high-throughput serum multi-steroid profiling assay with low sample volume requirements for the investigation of steroid metabolome patterns and related clinical phenotypes and characterisation of the roles of classic vs 11-oxygenated androgens in women with PCOS.

Methods: We developed a multi-steroid profiling assay for ultra-high performance liquid chromatography—tandem mass spectrometry (UHPLC-MS/MS) that included 18 steroids encompassing central precursors as well as mineralocorticoids, glucocorticoids, and androgens, including both classic and 11-oxygenated androgens, eg, testosterone, androstenedione, DHEA, 11-ketotestosterone, 11-ketoandrostenedione, 11β-hydroxyandrostenedione, and 11β-hydroxytestosterone. Steroid extraction was carried out by supported liquid extraction (SLE) and full validation of the assay was

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

undertaken. We recruited 5 healthy individuals who donated blood samples weekly for 10 consecutive weeks to study intraindividual variation of steroid secretion in healthy individuals.

Results: Steroids were purified from 100 µL of serum using SLE with ethyl acetate elution. Steroids were separated on the C18 column in the gradient elution of water and methanol both containing 0.01% formic acid. Post-column infusion of 2 mmol/L ammonium fluoride was employed to enhance signal sensitivity. Lower limits of quantification were between 0.04 and 2.1 nmol/L, matrix effects were between 95% and 101%, and absolute recoveries were between 100% and 125%. Accuracy ranged from 90% to 111% and imprecision was below 7.2% and 12% for within-run and between-run analyses, respectively. Data on healthy individuals and a large PCOS cohort will be presented.

Conclusions: We successfully developed and validated a UHPLC-MS/MS assay for multi-steroid profiling including comprehensive androgen analysis in serum of women with PCOS and healthy individuals. This assay will be applied to the UK & Ireland DAISy-PCOS Phenome cohort ($n = 892$).

EP1360 - ECE_2053 - Changes in lung function and cardiorespiratory fitness following gender affirming hormone treatment. A prospective clinical study

Louise Skøttrup Christiansen[1], Dorte Glintborg[1], Emilie Bukh Madsen[1], Sara Ravn Bach[1], Mathilde Kamp Nørlund[1], Marianne Andersen[1], Jan Frystyk[1], Rikke Hjortebjerg[2], Tine Taulbjerg Kristensen[1], Camilla Viola Palm[2], Pernille Hermann[1], Kurt Højlund[3], Guy T'sjoen[4], Jesper Rømhild Davidsen[5] and Louise Lehmann Christensen[1]

[1]Department of Endocrinology, Odense University Hospital, Odense, Denmark; [2]Odense, Denmark; [3]Steno Diabetes Center Odense, Odense University Hospital, Odense, Denmark; [4]Department of Endocrinology, Center for Sexology and Gender, Ghent University Hospital, Gent, Belgium; [5]South Danish Center of Interstitial Lung Diseases, Department of Respiratory Medicine, Odense University Hospital, Odense Respiratory Research Unit (ODIN), Department of Clinical Research, University of Southern Denmark, Odense, Denmark

Background: Lung function and cardiorespiratory fitness are key health determinants and closely linked to biological sex. Changes in lung function and cardiorespiratory fitness during gender affirming hormone therapy (GAHT) remain understudied.

Aim: To assess lung function and cardiorespiratory fitness following GAHT in adult transgender individuals.

Design and Methods: Prospective clinical study including 54 GAHT-naïve transgender individuals (21 transmasculine and 33 transfeminine), who were examined at baseline and 1 year after GAHT initiation. In addition, cross-sectional data were collected from 36 transmasculine individuals with a median GAHT duration of 77 months, and 26 transfeminine individuals with a median GAHT duration of 45 months. A sub-cohort participated in assessment of cardiorespiratory fitness. The primary outcomes were forced expiratory volume in 1 second (FEV1), forced vital capacity (FVC), peak expiratory flow (Vyaire Vyntus® CPX system) and maximal oxygen consumption (VO_2 max, bike ergometer).

Results: In GAHT-naïve transmasculine individuals, the median (interquartile range) age at study inclusion was 25 (22; 29) years. FEV1 increased by 110 mL, FVC increased by 130 mL and peak expiratory flow increased by 890 mL/s (all $P = .01$) after 1 year of GAHT. VO_2 max was unchanged.

In GAHT-naïve transfeminine individuals, the median (interquartile range) age at study inclusion was 26 (22; 32) years. Absolute VO_2 max decreased by 163 mL/min ($P = .04$), weight-adjusted VO_2 max decreased by 5.6 (mL/min)/kg ($P < .01$) and respiratory exchange rate decreased by 0.07 ($P < .01$) after 1 year of GAHT. FEV1, FVC and peak expiratory flow were unchanged. There was no significant difference in endpoints between the GAHT-naïve group at 1 year and GAHT-ongoing group.

Conclusions: FEV1, FVC and peak expiratory flow increased after 1 year of masculinizing GAHT, whereas VO_2 max decreased and lung function was unchanged within the first year of feminizing GAHT.

EP1361 - ECE_1677 - "Effect of insulin sensitizers on Anti-Müllerian hormone in Polycystic Ovary Syndrome"

Aleksandra Stevchevska[1,2]

[1]Clinic for endocrinology, diabetes and metabolic disorders, Skopje, North Macedonia; [2]Ss. Cyril and Methodius University in Skopje (UKIM), Skopje, North Macedonia

Introduction: Elevated AMH level is considered an indicator of anovulation in PCOS. It is postulated that the use of insulin sensitizers will lead to a reduction in insulin resistance, hyperandrogenism and consequently AMH levels, as a result of ovulation induction in these patients.

Objective: The study aimed to determine the impact of therapy with the insulin sensitizers, Metformin and Myoinositol, on Anti-Mullerian hormone and to determine its association with insulin resistance in women with polycystic ovary syndrome.

Material and Methods: a prospective, randomized, clinical study was conducted at the PHI UC for Endocrinology, Diabetes and Metabolic Diseases in Skopje, in the period 2022/2023. The study included 64 women aged 18 to 40 years, diagnosed with polycystic ovarian syndrome, according to the 2003 Rotterdam criteria. The patients were divided into two groups: group A was placed on Metformin 1500 mg XR, group B on Myo-inositol 2gr TID, during 6 months. The parameters BMI, AMH, HOMA-IR (homeostasis model assessment index) and FAI (free androgen index) were monitored.

Results: After completion of treatment, a significant decrease in AMH levels was observed in both, group A ($P = .0012$) and group B ($P = .0014$). This was accompanied with decline in HOMA IR and FAI values after the end of treatment in both groups.

Conclusions: Given the results obtained, AMH could be considered as marker of the efficacy of treatment with insulin sensitizers in PCOS.

Keywords PCOS, insulin sensitizers, metformin, myoinositol, anti-Mullerian hormone

EP1362 - ECE_1278 - Neurofibromatosis type 1 presenting as disorder of sex development

Chan Jong Kim
Gwangju, South Korea

Indtroduction: Genitourinary neurofibromas with clitoral involvement in neurofibromatosis type 1 (NF-1) are rare, and even more infrequent are the neurofibromas involving genitalia in males. The most frequent presenting sign of neurofibroma in females is clitoromegaly with pseudopenis.

Case Report: Here, we report an unusual case of ambiguous genitalia owing to neurofibroma of the clitoris resulting in an enlarged pseudophallus. A six-year-old child reared as female visited to hospital for evaluation of genital ambiguity. There was no past history of salt wasting crisis or maternal exposure to androgenic drugs during pregnancy. The patient showed multiple cafe au lait spots on both buttocks, chest and abdomen. No gonads were palpable in the labioscrotal fold or inguinal region. Hormonal evaluation revealed normal prepubertal serum gonadotropins, 17 hydroxyprogesterone, dehydroepiandrosterone sulfate, and testosterone levels. The karyotype analysis revealed normal female 46, XX pattern. Genetic analysis revealed a c.3974 +1G>A in the *NF1* genes. This intronic pathogenic mutation results from a G to A substitution one nucleotide after coding exon 29 of the NF1 gene. This alteration has been observed in multiple individuals with NF-1.

Conclusions: Clitoral involvement in NF-1 appears to be more common than previously reported and the differential diagnosis of ambiguous genitalia should include clitoromegaly due to NF. Pathogenesis of clitoral lesions appears similar to other lesions of NF. Biopsy of such lesions appears to be justified only when malignancy is suspected.

EP1363 - ECE_3272 - Central adiposity drives persistent MASLD risk in postmenopausal women with a phenotype of Polycystic Ovary Syndrome

Eleni Armeni, Nektaria Papanikola, Areti Augoulea, Michalis Apostolakis, Panagiota Chatzivasileiou, Alexandros Nakis, Iliana Karagkouni, Dimitra Owens, George Kaparos and Irene Lambrinoudaki
2nd Department of Obstetrics and Gynaecology, National and Kapodistrian University of Athens, Menopause Clinic, Aretaieio Hospital, Athens, Greece

Background: Polycystic ovary syndrome (PCOS) is increasingly recognised as a lifelong endocrine–metabolic condition, yet its contribution to metabolic dysfunction–associated steatotic liver disease (MASLD) beyond the reproductive years remains uncertain. Menopause is accompanied by adverse changes in fat distribution and metabolic risk, raising the question of whether PCOS-related susceptibility to MASLD persists after menopause and whether this risk is driven by overall obesity or by central adiposity. Addressing this gap has direct implications for long-term endocrine follow-up and prevention strategies in women with a history of PCOS.

Methods: We performed a cross-sectional analysis of 776 postmenopausal women (mean age 63.4 ± 7.0 years; mean menopausal duration 11.2 ± 8.3 years), including 101 (17.2%) with a PCOS phenotype defined by a documented history of oligo-/amenorrhoea and/or clinical hyperandrogenism. MASLD was defined using hepatic steatosis index (HSI≥36) in combination with metabolic dysfunction, defined as the presence of at least one cardiometabolic abnormality, including overweight or obesity, impaired glucose metabolism or type 2 diabetes, hypertension, dyslipidaemia, or insulin resistance. Multivariable logistic regression models examined associations between PCOS and MASLD, adjusting for smoking and menopausal duration. To dissect the role of adiposity, separate models incorporated body mass index (BMI), waist circumference, mid-upper arm circumference, and triceps skinfold thickness. Effect-modification analyses tested interactions between PCOS and adiposity measures, with robustness assessed using bootstrap resampling (1000 iterations). Model performance was evaluated using Nagelkerke R^2.

Results: MASLD prevalence was significantly higher in women with PCOS than in those without PCOS (59.3% vs 45.3%, $P = .048$). PCOS remained independently associated with MASLD after adjustment (adjusted OR = 1.82, 95%CI 1.02-3.24). While all adiposity measures were strong predictors of MASLD, only central adiposity demonstrated robust effect modification. A significant PCOS × waist circumference interaction persisted after bootstrap validation (bootstrap $P = .028$), whereas interactions with BMI and peripheral adiposity measures were not robust. Although BMI-based models showed higher overall explanatory power (Nagelkerke R^2 0.592), only waist-based models identified a stable interaction with PCOS (Nagelkerke R^2 0.392).

Conclusions: PCOS confers persistent susceptibility to MASLD well beyond menopause, with risk preferentially mediated through central fat accumulation rather than overall obesity. These findings identify central adiposity as a key mechanistic link between PCOS and MASLD and support prioritising waist circumference over BMI for long-term hepatic and metabolic risk stratification in postmenopausal women with a history of PCOS.

EP1364 - ECE_3301 - Cardio-metabolic signaling pathways before and after gender affirming hormone therapy

Emma Linnea Jørgensen[1,2], Oliver Knudsen[2,3], Dorte Glintborg[1], Tine Taulbjerg Kristensen[1], Anja Frederiksen[3], Marianne Andersen[1], Jan Frystyk[1], Mads Thomassen[3], Louise Lehmann Christensen[1] and Mark Burton[3]
[1]Department of Endocrinology, Odense University Hospital, Odense C, Denmark; [2]Faculty of Health Sciences, University of Southern Denmark, Odense M, Denmark; [3]Department of Clinical Genetics, Odense University Hospital, Odense C, Denmark

Background and Aim: Transgender individuals have higher risk of cardiovascular disease compared to cisgender populations. Gender-affirming hormone treatment induces changes in sex hormone levels and cardiovascular risk factors in transgender individuals. This study aims to assess changes in RNA expression of cardio-metabolic pathways before and after initiation of feminizing or masculinizing gender affirming hormone therapy.

Material and Methods: This prospective, single-center cohort study included 30 transgender persons (15 transmasculine and 15 transfeminine). Whole blood was collected before and after

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

one year of gender-affirming hormone treatment, for RNA extraction and analysis using microarray. Body composition was determined by whole body DXA scan, and fasting lipid profile, and sex hormone were measured before and after gender-affirming hormone treatment. Paired analyses of RNA expression and cardiovascular risk markers were performed.

Results: In transfeminine persons, the median age (quartiles) was 25 (23;32) years at baseline. Feminising gender-affirming hormone treatment was followed by a 1.1 kg/m^2 (−0.0;2.2) increase in BMI ($P \leq .02$) and a 5.9% (4.2;7.3) increase in fat percentage ($P \leq .01$). In transmasculine persons, the median age was 27 (22;31) years at baseline. Masculinizing gender-affirming hormone treatment was followed by a 0.3 kg/m^2 (−1.3;1.1) increase in BMI ($P \leq .86$) and a −4.9% (−7.2; −3.8) decrease in fat percentage ($P \leq .01$). Feminizing and masculinizing gender-affirming hormone treatment changed biological pathways related to lipid metabolism, insulin signalling and plaque development. Transfeminine and transmasculine individuals differed regarding which pathways were most prominently altered after gender-affirming hormone treatment initiation.

Conclusions: RNA expression of pathways related to **lipid metabolism, insulin signalling and plaque development** were changed after one year of gender affirming hormone therapy. **Expression of** several genetic pathways relevant for cardiovascular disease changed during gender-affirming hormone treatment.

Background: Hypogonadotropic hypogonadism (HH) is increasingly recognized as a genetically complex disorder characterized by incomplete penetrance and variable expressivity. Beyond classical monogenic inheritance, growing evidence supports an oligogenic model, whereby heterozygous variants in multiple genes regulating the hypothalamic–pituitary–gonadal (HPG) axis interact with developmental and systemic modifiers to determine clinical outcome.

Objective: To explore the role of heterozygous variants in HH-associated genes in shaping divergent phenotypes, including early-onset, reversible or persistent HH.

Methods: We describe three male patients with idiopathic HH who underwent detailed endocrine phenotyping, longitudinal clinical follow-up, neuroimaging, and whole-exome-sequencing. Genetic variants were interpreted according to ACMG-criteria and correlated with pubertal development, comorbidities, treatment response, and long-term gonadal axis function.

Case-1: A 16-year-old male presented with delayed puberty and biochemically-confirmed HH, with normosmia and no structural abnormalities of the pituitary gland on magnetic-resonance-imaging. Whole-exome-sequencing identified heterozygous variants in **WDR11** (NM_018117.12:c.371A>T, p.Asn124Ile; variant-of-uncertain-significance) and **AIRE** (NM_000383.4:c.769C>T, p.Arg257*; pathogenic). Following short-term testosterone priming, spontaneous recovery of gonadotropin and endogenous testosterone secretion was observed, consistent with reversible HH.

Case-2: A 30-year-old male was diagnosed with HH in early adulthood (age 20). Whole-exome-sequencing revealed a heterozygous **WDR11** variant (NM_018117.12:c.2246G>A,p.Arg749Gln; variant-of-uncertain-significance). Neuroimaging performed during childhood demonstrated generalized cortical atrophy, widened Sylvian fissures, and an atrophic brainstem, suggesting early neurodevelopmental involvement. Despite normosmia and the absence of structural pituitary abnormalities, pubertal development remained incomplete. The patient is currently maintained on long-term hormone- replacement-therapy.

Case-3: A 48-year-old male presented with long-standing HH and eunuchoid body proportions. His medical history was notable for intermediate-β-thalassemia, diagnosed at the age of 3 years, requiring monthly blood transfusions until the age of 7, when transfusions were discontinued following splenectomy. At the age of 39, he was diagnosed with familial Mediterranean fever, treated with colchicine, and regular monthly transfusions were reinitiated. Whole-exome-sequencing identified a heterozygous **FGFR1** variant (NM_001174063.3:c.266A>G,p.Gln89Arg; variant-of-uncertain significance). The patient exhibited persistent gonadotropin deficiency without spontaneous recovery and remains on lifelong hormone-replacement-therapy. Across cases, heterozygous variants were associated with markedly different clinical trajectories, suggesting that genetic background, systemic disease burden, and developmental modifiers collectively influence HPG axis integrity.

Conclusions: These observations support an oligogenic and modulatory model of HH, in which heterozygous variants in *WDR11*, *AIRE*, and *FGFR1* may interact with clinical and developmental factors to determine disease severity and reversibility. This framework has important implications for prognosis, genetic counseling, and individualized therapeutic strategies, emphasizing the need for periodic reassessment of endogenous gonadal function in selected patients.

Introduction: Infertility affects 15% of couples and a male factor is identified in 50% of the cases. Azoospermia is defined as the absence of spermatozoon in the ejaculate, and can be caused by an obstruction of the reproductive tract, known as obstructive azoospermia (OA). *CFTR* is the most frequent gene implicated in genetic OA, related to congenital bilateral aplasia of vas deferens (CBAVD). More recently it has been shown that *ADGRG2*, an X-linked gene, could be also less frequently involved

Case-Report: A 25-year-old patient presented with a 9-month history of primary infertility. He had no medical condition, no history of consanguinity nor hereditary disease. Semen analysis showed an acidic pH <6.5, a decreased volume of 0.4 mL, no visualized spermatozoon. Hormones levels were within normal range. Therefore, an OA was suspected. The initial investigation of *CFTR* (139 variants screened) was negative. After testicular ultrasonography, left varicocele was embolized. Pelvic magnetic resonance imaging revealed two homogenous testis with normal size (>15 mL for left or right side), dilated epididymis, and absent seminal vesicles and vas deferens. Extensive genetic analysis (sequencing of exons of *CFTR* and *ADGRG2* genes) was performed. It identified a novel hemizygous frameshift variant NM_001079858 (*ADGRG2*):c.332dup p.(Asn111Lys*fs**8), which introduces a premature stop codon. This variant was not found in databases of genetic variants of the general population (GnomAD v4); it was classified as pathogen, and held accountable for the CBAVD. The patient underwent testicular sperm extraction (TESE): pathological examination of testicular parenchyma showed normal architecture, regular seminiferous tubules with complete spermatogenesis, and Sertoli cells with normal appearance. Spermatozoa were successfully extracted and frozen. Because of the X-chromosome inheritance, there would be no risk to transmit the mutated allele to male descendance, but all female descendance will be carrier.

Discussion: Nonsense or frameshift variants of the *ADGRG2* gene are the second most frequent genetic variations leading to CBAVD, and are probably responsible for approximately 12% to 20% of isolated CAVD that are *CFTR* mutation-free. The loss of function of *ADGRG2* gene probably leads to fluid accumulation in the testis, leading to the occurrence of CBAVD. To our knowledge, this is the first time pathological examination was reported in an *ADGRG2*-mutated patient.

Conclusions: Genetic testing for variants in *ADGRG2* gene can be considered when a patient with CBAVD is *CFTR* mutation-free. If negative, a whole genome sequencing could be performed.

P1368 - ECE_1642 - Estradiol burden predominantly affects downstream conjugation and transport of estrogen

Anushka Subrahmanian[1,2], Liisa Veerus[1], Anjali Patel[1,2], Dareen Shah[1,3], Adrija Kundu[1,4], Xingnan Li[5], Adrian Franke[5] and Martin Blaser[1]

[1]*Center for Advanced Biotechnology & Medicine, Rutgers University, Piscataway, United States;* [2]*Rutgers-Robert Wood Johnson Medical School, Piscataway, United States;* [3]*Vanderbilt University School of Medicine, Nashville, United States;* [4]*Department of Molecular Biology, Princeton University, Princeton, United States;* [5]*University of Hawai'i, University of Hawai'i Cancer Center, Honolulu, United States*

In mammals, estrogen processing is a complex multi-step process that spans nearly all organ systems. After production in the ovaries, estrogens circulate and interact with the intracellular estrogen receptors (ER) α and β to activate downstream effectors. Estrogen molecules may be glucuronidated in the liver and kidney by UDP-glucuronosyltransferases (UGTs) followed by transport of the resulting metabolites through ATP-binding cassette (ABC) transporters toward excretory pathways. Since it is unknown how excess estrogen load affects the homeostasis of these processes, we investigated by treating 43 eight-week-old conventional C57BL/6J female mice with either a subcutaneous estradiol (E2) pellet (0.25 mg/day for 21 days) or not (controls), with sacrifices over several weeks. From both treated and untreated mice, we analyzed serum samples for circulating estrogen levels and ovary, uterus, mammary gland, liver, and kidney samples for the expression of signaling genes *Esr1* and *Esr2* (ERα and β, respectively), conjugation genes *Ugt1a1* and *Ugt1a9* (UGT1a1 and 1a9, respectively), and ABC transporter genes *Abcc2* and *Abcg2* (multidrug resistance-associated protein 2 [MRP] and breast cancer resistance protein [BCRP], respectively). Serum E2 levels increased following E2 pellet implantation, with peak levels 19-fold higher in treated females compared to controls two weeks after implantation, along with a corresponding rise in a secondary serum estrogen, estrone (E1). Expression of *Esr1* was unaffected by the excess estrogen in all tissues, and ovarian *Esr2* was upregulated in treated females at treatment peak. The estrogen exposure suppressed the hepatic conjugation genes *Ugt1a1* and *Ugt1a9*, along with renal *Ugt1a9*, with all changes developing a few weeks to a month after the peak serum estradiol levels. In contrast, the E2 exposure caused renal *Abcc2* expression to rise over the month following treatment peak, with minimal changes to hepatic *Abcc2* and *Abcg2* in both tissues. Renal *Ugt1a9* expression was negatively correlated with serum E2, and there were no other associations with serum E1 or E2. Thus, following an estrogen implantation that acutely increased serum E2 levels, there initially was a corresponding increase in estrogen receptor activity, followed by a delayed decrease in estrogen conjugation and increase in renal estrogen transport; these changes highlight dynamic mechanisms for host adaptation to variation in circulating estrogen levels, with enhanced excretion to facilitate a return to baseline. With the increasing exposures to estrogens in contemporary life and their effects on disease development, improved characterization of host estrogen metabolism may aid in understanding estrogen-driven diseases and addressing appropriate interventions.

EP1370 - ECE_1223 - Retrospective study comparing vaginal and semen microbial cultures before in vitro fertilization in infertile couples reveals lack of microbial similarity

Bernadett Nádasdi[1], Petra Lilla Zádori[1,2], Rita Sinka[3], Katalin Burián[4], Viktor Vedelek[3], János Zádori[2] and Anna Vágvölgyi[1]

[1]Department of Medicine, Albert Szent-Györgyi Medical School, University of Szeged, Szeged, Hungary; [2]Center of Reproductive Medicine, Department of Obstetrics and Gynecology, Albert Szent-Györgyi Medical School, University of Szeged, Szeged, Hungary; [3]Department of Genetics, Faculty of Science and Informatics, University of Szeged, Szeged, Hungary; [4]Department of Medical Microbiology, Albert Szent-Györgyi Health Center and Albert Szent-Györgyi Medical School, University of Szeged, Szeged, Hungary

Introduction: Infertility affects 15%-20% of couples worldwide, including approx. 3.5% of Hungarian children born via *in vitro* fertilization (IVF). Forecasting IVF success prior to starting treatment poses significant difficulties. Recent research indicates that vaginal and seminal microbiomes affect reproductive success through effects on local immune responses, embryo implantation, and gamete performance. This research sought to investigate links between initial clinical, biochemical, and microbial factors and IVF results.

Material and Methods: A retrospective single-center study analyzed 475 infertile couples receiving IVF, with or without intracytoplasmic sperm injection, at the University of Szeged from January 2022 to December 2023. Collected data included maternal age and demographics, reproductive background, pretreatment hormone profiles, ovarian stimulation details, and endometrial measurements. Microbiological assessments of vaginal discharge and semen samples covered *Lactobacillus* presence, pathogen types, and antibiotic sensitivities. The main endpoint was clinical pregnancy, with support vector machine (SVM), random forest (RF), and extreme gradient boosting (XGBoost) models used to test combined clinical-microbial predictors.

Results: Vaginal cultures tested positive in 121 women (25.5%), primarily showing *Candida albicans* (26%), *Streptococcus agalactiae* (17%), and *Escherichia coli* (17%). Semen cultures were positive in 134 men (29%), dominated by *Enterococcus faecalis* (46%) and *Escherichia coli* (23%). Monomicrobial growth was common, and shared pathogens between partners occurred infrequently (13 couples, under 3%). Vaginal *Lactobacillus* was inversely associated with pathogens such as *Candida albicans*, *Streptococcus agalactiae*, *Gardnerella vaginalis*, and *Enterococcus faecalis*. Clinical pregnancy rates showed no difference between positive and negative vaginal culture groups (36% vs 39%, non-significant). Machine learning identified maternal age as the top predictor, with microbial factors adding limited value and *Lactobacillus* as the key microbial element.

Conclusions: Microbial changes in vaginal and seminal samples frequently occur in IVF couples, but partner pathogen matching remains exceptional. *Lactobacillus* dominance shows protective effects, positioning it as a possible marker for fertility outcomes. While microbes alone are inadequate for forecasting IVF success, combining them with standard clinical data may enable tailored reproductive strategies.

EP1371 - ECE_1351 - Menstrual management in females with intellectual and physical disabilities: a review of 25 years of evidence and practice

Shayma Ahmed[1,2], Ashraf Soliman[1], Fawziya Alyafei[1], Nada Alaaraj[1], Noor Hamed[1], Nada Soliman[3] and Ahmed Khalil[1]

[1]Pediatric's Endocrinology, Hamad Medical Center, Doha, Qatar; [2]Pediatric's Endocrinology, Hamad Medical Corporation- Qatar, Pediatric's, Doha, Qatar; [3]Public Health, Alexandria Health Directorate, MOH, Alexandria, Egypt

Background: Menstrual health management in females with intellectual disabilities (ID) and those who are bedridden due to physical disabilities presents complex medical, ethical, and caregiving challenges. Many affected individuals experience distress, pain, or hygiene difficulties related to menstruation and may lack the cognitive or physical capacity for independent menstrual care. As a result, caregivers assume substantial responsibility for daily management, while healthcare professionals must balance symptom control, safety, quality of life, and respect for patient autonomy. Over the past 25 years, increasing attention has been given to menstrual suppression and supportive strategies in this vulnerable population, alongside growing emphasis on rights-based and ethical frameworks.

Objective: To systematically review and synthesize evidence on menstrual management strategies, clinical outcomes, caregiver impact, and ethical considerations in females with intellectual and physical disabilities.

Methods: A structured literature review was conducted covering publications from 2000 to 2025 using PubMed, Scopus, and Google Scholar. Eligible studies included females with intellectual disabilities and/or severe physical immobility and addressed menstrual hygiene, menstrual suppression, caregiver roles, or ethical aspects of care. Both quantitative and qualitative studies were considered. After screening and appraisal, ten key studies with relevant clinical and ethical data were included in the final synthesis.

Results: Across studies, hormonal interventions were the most commonly reported and effective strategies for menstrual management. Combined oral contraceptives, depot medroxyprogesterone acetate (DMPA), and levonorgestrel-releasing intrauterine devices (LNG-IUDs) were associated with reduced menstrual bleeding, partial or complete amenorrhea, and improved hygiene. These outcomes translated into a meaningful reduction in caregiver burden and improved daily care when appropriate consent and monitoring were ensured. Qualitative evidence highlighted significant gaps in menstrual health support, particularly in low-resource settings, where caregivers often lacked training, guidance, and psychosocial support. Ethical concerns were prominent, especially reports of irreversible interventions such as sterilization in certain contexts without adequate informed consent. More recent literature emphasizes autonomy, proportionality, and shared decision-making, advocating individualized care plans that consider patient comfort, caregiver capacity, and long-term risks such as bone density loss and metabolic effects.

Conclusions: Effective menstrual management in females with intellectual and physical disabilities requires a multidisciplinary,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

individualized approach that integrates medical effectiveness with ethical safeguards and caregiver support. Hormonal menstrual suppression can substantially improve quality of life but must be carefully selected, monitored, and guided by informed consent. Strengthening policies, education, and research—particularly in under-resourced settings—is essential to optimize care and protect patient rights.

EP1372 - ECE_2554 - Clinical and laboratory parameters in women with PCOS

Catherine Shepelkevich[1], Yuliya Dydyshka[2], Alla Shepelkevich[2] and Alena Yurenia[3]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Department of Endocrinology, Belarusian State Medical University, Minsk, Belarus; [3]Minsk City Clinical Endocrinology Center, Minsk, Belarus

Background: Polycystic ovary syndrome (PCOS) is defined as a chronic metabolic and reproductive disease associated with cardiovascular, gynecological, psychological, and oncological risks. Its prevalence in the population ranges from 8%-21%, making it the most common endocrine disorder in women of reproductive age. The aim of the study to evaluate to evaluate the clinical characteristics of PCOS and the incidence of comorbid conditions in young women observed at the Minsk City Clinical Endocrinology Center.

Materials and Methods: A cross-sectional retrospective study was conducted, including 150 young women diagnosed with PCOS observed at the Minsk City Clinical Endocrinology Center in 2024-2025. The study included women aged 18 to 45 years with PCOS. Clinical, laboratory, and instrumental data were used.

Results and Discussion: Data from 150 women diagnosed with PCOS were analyzed. The average age of patients was 24.5 (22-29.3) years. In the structure of PCOS phenotypes, phenotype A prevailed with an incidence of 59.33% (89), phenotype B—12.67% (19), C—2% (3), D—26% (39). When assessing anthropometric data, the median BMI was 23.06 (20.2-27.1) kg/m2, while overweight was detected in 21.05% (32), obesity—in 15.13% (23). When evaluating the diagnostic criteria, menstrual cycle disorders were found in 96.67% (145) of women, with the average age of menarche being 13 (12-14) years, the maximum duration was 90 (60-150) days. Clinical hyperandrogenism was found in 24.67% (37) of patients, with hirsutism in 8% (12), alopecia in 4.67% (7), acne in 12% (18). Laboratory hyperandrogenism was detected in 68.67% (103), with a median total testosterone level of 0.6 (0.47-0.75) ng/mL. An increase in ovarian volume of more than 10 cm^3 according to pelvic ultrasound was determined in 86% (129) of the examined women, the presence of 20 or more follicles in 10.67% (16).

Conclusions: The study results allowed us to establish the frequency of PCOS phenotypes, among which the most common were phenotypes A (59.33%) and D (26%). The obtained data confirm the high frequency of PCOS complications in young patients, which indicates the advisability of updating this problem and the need to implement measures for the early detection of associated pathology.

EP1373 - ECE_2572 - The incidence of comorbid pathology in women with PCOS

Yuliya Dydyshka[1], Catherine Shepelkevich[2], Alena Yurenia[3] and Alla Shepelkevich[1]
[1]Department of Endocrinology, Belarusian State Medical University, Minsk, Belarus; [2]Belarusian State Medical University, Minsk, Belarus; [3]Minsk City Clinical Endocrinology Center, Minsk, Belarus

Background: Polycystic ovary syndrome (PCOS) is defined as a chronic metabolic and reproductive disease associated with cardiovascular, gynecological, psychological, and oncological risks. Its prevalence in the population ranges from 8%-21%, making it the most common endocrine disorder in women of reproductive age. The aim of the study to evaluate to evaluate the clinical characteristics of PCOS and the incidence of comorbid conditions in young women observed at the Minsk City Clinical Endocrinology Center.

Materials and Methods: A cross-sectional retrospective study was conducted, including 150 young women diagnosed with PCOS observed at the Minsk City Clinical Endocrinology Center in 2024-2025. The study included women aged 18 to 45 years with PCOS. Clinical, laboratory, and instrumental data were used.

Results and Discussion: Data from 150 women diagnosed with PCOS were analyzed. The average age of patients was 24.5 (22-29.3) years. Analysis of clinical and laboratory data for assessment of comorbid conditions included glycemia values—4.9 (4.6-5.2) mmol/l; OGTT in 23.16% (22) of patients, which confirmed the presence of IGT in 13.04% (3) of women with PCOS; T2DM—in 5.33% (8), history of GDM—in 1.33% (2). The average level of total cholesterol was 5.21 (4.42-6.03) mmol/l, hypercholesterolemia was detected in 50.6% (42) of patients. The LDL level was 3.1 (2.3-3.76) mmol/l, the indicator was increased in 65.96% (31), HDL—1.77 (1.44-2.01) mmol/l, the indicator was decreased in 8% (4). The triglyceride level was 1.06 (0.78-1.69), elevated in 22.78% (18). When assessing comorbid conditions, gynecological pathology was found in 32.67% (49) of women, and a history of psychological disorders was detected in 10.67% (12).

Conclusions: The analysis of comorbid conditions in the examined patients revealed overweight in 21.05%, obesity in 15.13%, hypercholesterolemia in more than 50%, prediabetes in 4%, and type 2 diabetes in 5.33%. Combined gynecological pathology was detected in 32.67% of women, and a history of psychological disorders was found in 10.67%. The obtained data confirm the high frequency of comorbid disorders in young patients with PCOS.

[1]Center for Esoteric Testing, Labcorp, Burlington, United States; [2]LMU University Hospital, Institute of Laboratory Medicine, Munich, Germany; [3]Clinical Department of Laboratory Medicine, UZ Leuven, Leuven, Belgium; [4]Roche Diagnostics GmbH, Mannheim, Germany; [5]Roche Diagnostics, Indianapolis, United States; [6]Rotkreuz, Switzerland; [7]Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, United States; [8]Department of Pathology, University of California San Diego, San Diego, United States; [9]Newcastle Upon Tyne Hospitals, Newcastle Upon Tyne, United Kingdom; [10]Endocrine Laboratory, Department of Laboratory Medicine, Amsterdam UMC Location University of Amsterdam, Amsterdam, The Netherlands; [11]Roche Diagnostics Int., Rotkreuz, Switzerland

Background & Introduction: Hyperandrogenism is a common endocrine disorder in women and female adolescents, and an important diagnostic pillar for polycystic ovary syndrome (PCOS), for example. The diagnosis of PCOS is challenging and requires an accurate quantification of androgens, specifically testosterone, androstenedione, and dehydroepiandrosterone sulfate (DHEA-S). Furthermore, clinical guidelines for PCOS emphasize the necessity of measuring 17-hydroxyprogesterone (17-OHP) to rule out Non-Classic Congenital Adrenal Hyperplasia (NCCAH), a condition that clinically mimics PCOS. Frequently used immunoassays often lack specificity, due to cross-reactivity, and limited sensitivity at lower androgen concentrations. Consequently, liquid chromatography-tandem mass spectrometry (LC-MS/MS) is recommended by international guidelines for accurate steroid measurements.

Objective: The objective of this study was to evaluate the analytical performance of the selected Ionify® Steroids assays on the Cobas® i 601 analyzer, a fully automated LC-MS/MS analyzer. The evaluation focused on the precision of testosterone, androstenedione, DHEA-S and 17-OHP.

Results: Testosterone demonstrated lot-to-lot repeatability %CVs ranging from 1.7% to 3.1% and lot-to-lot reproducibility ranging from 1.9% to 3.2%. Androstenedione showed a similar performance, with lot-to-lot repeatability %CVs between 1.6% and 3.2% and reproducibility between 1.9% and 3.2%. For DHEA-S, lot-to-lot repeatability and reproducibility %CVs were below 7% for 89% (8 of 9) of the samples tested. For 17-hydroxyprogesterone, lot-to-lot repeatability and reproducibility %CVs were below 5% for all of the samples.

Conclusions: The Cobas i 601 analyzer was found to produce accurate, precise, and consistent determinations of testosterone, androstenedione, DHEA-S and 17-OHP. These results support the use of this automated LC-MS/MS system for the reliable quantification of these steroid hormones, facilitating the accurate diagnosis of biochemical hyperandrogenism.

EP1376 - ECE_1850 - Hypertestosteronemia in a patient with cirrhosis: the interplay of iron overload and SHBG

Mohitraje Mankumare, Mahmoud Ebid, Sumudu Bujawansa and Ram Prakash Narayanan

Diabetes and Endocrine, Mersey & West Lancashire Teaching Hospitals NHS Trust, Prescot, United Kingdom

Background: Interpretation of androgen status in men with chronic liver disease can be challenging due to alterations in sex hormone–binding globulin(SHBG). Elevated total testosterone in the presence of hypogonadal symptoms may mask relative androgen deficiency. Iron overload has also been implicated in altered SHBG metabolism, even in the absence of classic HFE mutations.[1]

Case: We report a 66-year-old man with established liver cirrhosis who was referred for endocrine assessment after detection of markedly elevated total testosterone and SHBG during investigation for erectile dysfunction and fatigue.There was no history of anabolic steroid use. Family history was notable for several relatives with haemochromatosis. Initial biochemistry demonstrated raised total testosterone-49.6 nmol/L and SHBG-157 nmol/L, with luteinising hormone(LH-8.5 IU/L) and follicle-stimulating hormone-10.6 IU/L, both within reference ranges. α-fetoprotein, β-hCG and LDH were normal. Repeat testing confirmed persistently elevated testosterone(35 nmol/L) and SHBG(153 nmol/L). Calculated free testosterone was low–normal(0.256 nmol/L), consistent with symptoms suggestive of functional hypogonadism despite high total testosterone. Iron studies revealed elevated transferrin saturation-48%. Genetic testing for HFE mutations, including p.C282Y and p.H63D, was negative, and extended testing for rarer haemochromatosis-associated mutations was also unremarkable. Liver ultrasound showed stable cirrhotic changes. Given inappropriately normal gonadotropins in the context of high testosterone, pituitary imaging was performed. MRI demonstrated a 3×3×2 mm non-enhancing hyperintense lesion, potentially consistent with incidental microadenoma, requiring surveillance only. Testicular ultrasound was normal. Eerectile dysfunction was managed with phosphodiesterase-5 inhibition.

Discussion & Conclusions: This case illustrates the complex interaction between chronic liver disease, SHBG, iron metabolism, and androgen status. Liver disease is a well-recognised cause of elevated SHBG, resulting in disproportionately high total testosterone despite reduced bioavailable androgen levels. Emerging evidence suggests that iron overload may further increase SHBG, even in the absence of pathogenic *HFE* mutations.[1] Consequently, reliance on total testosterone alone may be misleading in this population. Assessment should prioritise free or bioavailable testosterone to avoid under-recognition of clinically significant androgen deficiency and prevent misdiagnosis or inappropriate management.

EP1377 - ECE_1891 - Erectile dysfunction as a manifestation of MEN2B: a key indication for preimplantation genetic testing

Erik Bényei[1,2], David Ralph[3] and Marta Korbonits[1]

[1]Centre for Endocrinology, William Harvey Research Institute, Barts and the London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom; [2]Department of Internal Medicine and Oncology, Faculty Of Medicine, Semmelweis University, Budapest, Hungary; [3]Miskolc, Hungary

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: MEN2B is a rare, autosomal dominant tumour syndrome where approximately 95% of cases are caused by the *RET* M918T mutation, which arises *de novo* in over 90% of patients. In addition to the classical endocrine manifestations—medullary thyroid carcinoma (MTC) and phaeochromocytoma—MEN2B is associated with a broad spectrum of non-endocrine phenotypic features, including marfanoid body habitus, involvement of the peripheral nervous system, such as tumours derived from neural crest cells, as well as motor and sensory neuropathies. Preimplantation genetic testing is an option for patients with MEN2B.

Case Presentation: A 14-year-old boy with a past medical history notable for severe constipation and multiple ganglioneuroma resections from the lips and oral cavity was referred to ophthalmology due to prominent bilateral corneal nerves, raising suspicion of MEN2B. Physical examination revealed a marfanoid habitus with a body mass index of 12.7 kg/m^2. His calcitonin level was 310 ng/l [<11], metanephrins were normal. The patient underwent total thyroidectomy with central lymph node dissection, and histopathological examination confirmed the diagnosis of MTC. Genetic testing identified a *RET* M918T mutation. During subsequent follow-up, the patient had measurable, but stable calcitonin levels and biochemical and imaging assessments showed no evidence of phaeochromocytoma. Eyelid "shaving" for small ganglioneurinomas was performed as needed. At 17 years of age, the patient reported absence of prior or current erections and inability to ejaculate. Endocrinological examination confirmed normal testosterone and gonadotrophin levels. Pharmacological treatment with phosphodiesterase type 5 inhibitors were unsuccessful. Following referral to urology, nocturnal penile tumescence testing was performed and demonstrated complete absence of erections. Intracavernosal alprostadil injections failed to produce clinical improvement. Implantation of an inflatable penile prosthesis is a possible further option. A literature search suggested that out of 22 familial MEN2B kindreds, the disease was transmitted by the father only in 6 occasions. Erectile dysfunction most likely contributes substantially that—in familial cases of MEN2B—the disease is predominantly passed on by females. A mouse model of MEN2B shows infertility of male mice, while normal sperm was present in the testis. Systematic evaluation of neuropathy and erectile function in male patients with MEN2B is warranted.

Conclusions: Neurological involvement in MEN2B may include severe erectile dysfunction. This devastating neurological manifestation which may affect male offspring could be a key consideration for preimplantation genetics as part of genetic counselling for patients with MEN2B planning to start a family.

EP1379 - ECE_2030 - Reproductive outcomes and hormonal control in adolescents and adults with congenital adrenal hyperplasia: implications for transition care

Ruta Navardauskaite[1,2], Marija Kurenkoviene[1], Rimantas Uktveris[3] and Kristina Jariene[4]
[1]*Department of Endocrinology, Lithuanian University of Health Sciences, Kaunas, Lithuania; ;* [3]*Department of Radiology, Lithuanian University of Health Sciences, Kaunas, Lithuania;* [4]*Department of Obstetrics and Gynecology, Lithuanian University of Health Sciences, Kaunas, Lithuania*

Background: Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency requires lifelong management and careful transition from pediatric to adult endocrine care. Suboptimal hormonal control during adolescence and early adulthood may predispose patients to gonadal adrenal rest tumors (TARTs/OARTs), compromised fertility. However, real-world data integrating hormonal control, gonadal imaging, and reproductive outcomes across the transition period remain limited.

Objective: To evaluate hormonal control and reproductive health in adolescents and adults with CAH and to identify clinically relevant implications for structured transition care.

Methods: This cross-sectional, single center study (2018-2023) included patients with genetically or clinically confirmed 21-hydroxylase deficiency who were followed at a national tertiary referral center. Detailed analysis focused on patients aged ≥14 years ($n = 35$; 18 males, 17 females), covering the transition from pediatric to adult care. Hormonal evaluation included 17-hydroxyprogesterone (17-OHP), testosterone, DHEA-S, progesterone, LH, and FSH. All males underwent systematic testicular ultrasound screening for TARTs, and semen analysis was offered to men ≥18 years. Females underwent pelvic ultrasound and menstrual cycle assessment. Hydrocortisone dosing was analyzed. Non-parametric statistics and Spearman correlations were applied.

Results: Only 31.4% of patients achieved recommended 17-OHP targets, indicating widespread suboptimal hormonal control during the transition period. In line with this finding, TARTs were detected in 10/18 males (55.6%), predominantly advanced-stage lesions. Semen analysis ($n = 8$) revealed severe spermatogenic impairment in all cases (6 azoospermia, 2 oligozoospermia). Ovarian adrenal rest tumors were identified in 2/17 females (11.8%). Menstrual irregularities were observed in 35% of women. Four women had achieved pregnancy, including two via assisted reproductive techniques. In females, 17-OHP strongly correlated with testosterone ($r = 0.804$, $P < .001$) and DHEA-S ($r = 0.657$, $P = .004$). In males, hydrocortisone dose correlated positively with LH ($r = 0.538$, $P = .032$), suggesting glucocorticoid-related modulation of the hypothalamic–pituitary–gonadal axis.

Conclusions: Adolescents and young adults with CAH frequently exhibit inadequate hormonal control and a high burden of reproductive complications, particularly TARTs and severe spermatogenic failure. These findings underscore the critical need for structured transition programs incorporating routine gonadal imaging, fertility counseling, and individualized treatment strategies to preserve reproductive health during the vulnerable transition and early adulthood.

Penchev", Sofia, Bulgaria;* [2]*Sofia, Bulgaria;* [3]*Screening and Functional Endocrine Diagnostics, USHATP "Prof. Dr. Iv. Mitev", Sofia, Bulgaria;* [4]*Faculty of Medicine, University "Assen Zlatarov", Burgas, Bulgaria*

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: Bone mineral density in reproductive-aged women with Turner syndrome (TS) is usually lower compared to that of healthy women because of estradiol deficiency, X-chromosome monosomy, additional genetic, hormonal, and environmental factors.[1] Nevertheless, the data on bone health in adult TS patients from various ethnic groups are still limited.

Aim: The present study aims to investigate spine bone mineral density in Bulgarian women with TS, thereby exploring different hormonal factors that may contribute to the lower bone mass.

Materials and Methods: Spinal (L1-L4) BMD (Z-score) was investigated in 34 TS patients (age 18-49 years). The possible associations with different hormonal factors and therapies were studied.

Results: the spinal BMD Z-score of TS women varied between −4.12 and +1.1, with a median of −1.31. It was not associated with the karyotype, age, age of diagnosis or the presence of autoimmune thyroiditis of the TS women ($P > .05$). However, it was positively related to patients' body mass index ($r = 0.401$, $P = .019$), and estradiol levels ($r = 0.436$, $P = .018$). No low-energy fractures were experienced by the women in the group. Testosterone, dehydroepiandrosterone-sulphate, 25-OH vitamin D, thyroid-stimulating hormone and prolactin levels were not related to the BMD ($P > .05$), while follicle-stimulating hormone (FSH) levels tended to be inversely associated with spinal Z-score ($r = −0.351$, $P = .053$). Women treated with estrogens for more than two years had significantly higher BMD Z-score than others (−0.5 vs −2.1, $P = .012$), while past growth hormone treatment did not influence the BMD Z-score (−1.3 vs −1.4, $P = .580$) significantly. A total of 3 of 18 TS individuals (16.67%) remained with lower bone density (Z-score <−2.0) despite the good adherence to long-lasting hormone replacement therapy.

Conclusions: the long-lasting estrogen-replacement therapy leading to normal estradiol and FSH levels is crucial for the bone density in young adults with TS. Additional genetic or environmental factors might be associated with poor bone health in some TS women despite adequate hormonal treatment. Further studies are needed to identify the best therapeutic approach for bone health improvement in women with TS.

EP1383 - ECE_3514 - Mangement considerations in adult presentation of 46,XX congenital adrenal hyperplasia in individuals raised as male

Ashani Wickramarachchi[1,2] and Jeremy W Tomlinson[1]
[1]*Oxford, United Kingdom;* [2]*Oxford Center for Diabetes, Endocrine and Metabolism, Oxford University Hospital, Oxford, United Kingdom*

Congenital adrenal hyperplasia (CAH) is a steroidogenic enzyme disorder most caused by 21-hydroxylase deficiency, with a variable clinical presentation. Adult diagnosis is more frequently recognised in individuals assigned female sex at birth. We describe two rare cases of 46,XX CAH in individuals raised as male, both diagnosed later in life following incidental imaging findings revealing internal female reproductive organs. Patient 1, born in the 1930s and raised as male, underwent hypospadias repair at 15 years of age and lived in a stable marital relationship with an adopted child. Imaging performed for unrelated indications incidentally identified bilateral adrenal hyperplasia and a rudimentary uterus, prompting further endocrine and genetic evaluation at the age of 75 years. Adrenal biopsy was consistent with CAH, and chromosomal analysis confirmed a 46, XX karyotype. A failed short Synacthen test led to initiation of glucocorticoid replacement, though interestingly, he never had features of adrenal insufficiency. Following appropriate counselling, the patient chose not to receive the results of chromosomal analysis. He died at the age of 83 from unrelated causes. Patient 2 was raised and lived as male and was diagnosed at 40 years of age with CAH due to compound heterozygous mutations in the 21-hydroxylase enzyme, with a confirmed 46,XX karyotype. Pelvic imaging demonstrated an involuted postmenopausal-type uterus with bilateral ovaries and a patent endocervical canal, alongside male-typical external genitalia. After discussion regarding the uncertain malignant potential of retained internal reproductive organs exposed to prolonged androgen excess, the patient opted for surveillance rather than surgical intervention. Glucocorticoid replacement was initiated following a failed Synacthen test; however, adherence was suboptimal, influenced by concerns regarding testosterone suppression. Disclosure of the diagnosis and karyotype resulted in significant psychological distress, fertility-related concerns, depression, and suicide attempts. These cases illustrate the complex clinical, ethical, and psychosocial challenges associated with late-diagnosed CAH in adulthood. Delayed diagnosis, particularly in individuals raised in eras without newborn screening, may result in long-standing endocrine, reproductive, and psychological consequences. The discordance between chromosomal sex, internal reproductive anatomy, and lived gender identity underscores the importance of patient-centred care, sensitive communication, and respect for autonomy, including decisions regarding disclosure of genetic information. Multidisciplinary management involving endocrinology, genetics, psychology, and specialist services for disorders of sex development is essential to optimise long-term outcomes.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: Glycogen storage disease type III (GSD III) is a rare autosomal recessive metabolic disorder caused by mutations in the AGL gene, leading to a defect in the glycogen debranching enzyme. It primarily affects the liver and skeletal muscle, with childhood manifestations like hepatomegaly, fasting hypoglycemia, and elevated transaminases. Endocrine complications are exceptionally rare and the coexistence of hypogonadotropic hypogonadism and infertility has been scarcely reported. In this case report, we present a male patient with genetically confirmed GSD type III who developed hypogonadotropic hypogonadism and infertility, emphasizing the importance of recognizing multisystem involvement in metabolic diseases.

Case Presentation: A 28-year-old man with a known diagnosis of glycogen storage disease type III since childhood was admitted with infertility and decreased libido. Physical examination revealed short stature, reduced facial and body hair, and small testes. Laboratory studies showed markedly low total testosterone (78 ng/dL), low luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels, but normal prolactin and thyroid hormone levels, consistent with hypogonadotropic hypogonadism. Liver enzyme levels were persistently elevated (AST 154 U/L, ALT 132 U/L), and ultrasonography of the abdomen revealed hepatomegaly. Serum triglyceride levels were elevated as well. Scrotal ultrasonography demonstrated bilateral testicular atrophy, and semen analysis confirmed azoospermia. Magnetic resonance imaging (MRI) of the pituitary gland demonstrated pituitary stalk hypoplasia. Genetic testing reconfirmed homozygous *AGL* mutation consistent with GSD type III. Testosterone replacement therapy was begun, leading to significant improvement in libido, energy, and general well-being. The patient was referred for reproductive counseling for assisted fertility options.

Conclusions: This case highlights an uncommon endocrine manifestation of glycogen storage disease type III, in which chronic metabolic decompensation and hepatic dysfunction, possibly related to infundibular hypoplasia, may contribute to secondary hypogonadotropic hypogonadism and infertility. Recognition of endocrine complications in GSD is crucial for timely hormonal replacement and fertility counseling. Adult survivors of GSD should be followed up in multidisciplinary care settings to monitor and manage late-onset endocrine and metabolic complications effectively.

Mitev", Sofia, Bulgaria; [6]Faculty of Medicine, University "Assen Zlatarov", Burgas, Bulgaria

Background: Turner's syndrome is a genetic condition associated with significantly diminished ovarian follicular reserve.[1] Nevertheless, up to 20% of women with TS might have spontaneous menarche, and up to 12% of them achieve pregnancies in the developed countries.[1,2] However, data about the fertility of TS patients in different regions across Europe are still lacking.

Aim: The present study aims to investigate the reproductive history of Bulgarian patients with Turner syndrome (TS) and to identify gaps in the care for women with TS.

Materials and Methods: 74 patients with TS (age: 18-59 years) have been investigated. The prevalence of menstrual disturbances, live births, and hormone replacement therapy was studied in the group.

Results: The prevalence of primary amenorrhea was 87.8% (36/41) in monosomic 45, XO patients, 37.5% (6/16) in women with structural X abnormalities, and 47.1% (8/17) in mosaic TS individuals ($P < .001$). Spontaneous menarche was observed in 24 patients at a median age of 14.6 years. Among women with spontaneous menarche, all but two developed secondary amenorrhea in adolescence. Only two patients retained regular menstrual cycles in adulthood, both with non-monosomic forms of TS. The first one entered menopause at the age of 30 years, while the other retained a regular menstruation pattern at the age of 19 years, with still normal follicle-stimulating hormone (FSH) and anti-mullerian hormone (AMH). Only one of the patients gave birth to a healthy child after egg donation and pregnancy complicated with gestational diabetes and preeclampsia. No spontaneous pregnancies occurred in the investigated group. A total of 45 (61.6%) of the 73 amenorrheic patients had received regular HRT. Late TS diagnosis or poor adherence to therapy were observed in other women.

Conclusions: Only 2.7% of Bulgarian TS patients who have reached adulthood retain regular menstruation; moreover, pregnancies in the TS group are very rare. Social and financial support is needed for patients with TS in developing countries to allow access to modern assisted reproductive technologies. More efforts should be taken by medical specialists to improve adherence to HRT in adult women with TS.

EP1387 - ECE_3572 - Gonadal function in sickle cell disease: data from a tertiary center

Kalliopi Pantelia[1], Aggeliki Kyriakou[1], Angeliki Angelidou[1], Vasiliki Antonopoulou[1], Angelos Theocharis[1], Aikaterini Kapama[1], Kanella Kantreva[1], Loukia Evliati[2], Chrysa Kalkana[2], Marinella Tzanela[1] and Georgia Ntali[1]
[1]*Department of Endocrinology "D. Ikkos"- Diabetes Center-EndoERN-Evangelismos General Hospital, Athens, Greece;* [2]*Thalassaemia and Sickle Cell Unit, Evangelismos General Hospital, Athens, Greece*

Introduction: Sickle cell disease (SCD) results from a structural hemoglobin abnormality, causing chronic hemolytic anemia and recurrent vaso-occlusive events that lead to ischemia and organ dysfunction. Gonadal dysfunction has been reported in both sexes, but data remain limited. Treatments such as chronic transfusions and hydroxyurea may impair gonadal function.

Aim: To evaluate gonadal function of patients with sickle cell disease.

Patients and Methods: This retrospective study included 42 patients with SCD (27 women, 15 men) followed at the Mediterranean Anemia and Sickle Cell Disease Unit of Evangelismos General Hospital in Athens. 35/42 patients had sickle cell–thalassemia. Data included age at menarche, menstrual characteristics, age at menopause for women and serum testosterone levels for men and hydroxyurea use (HU) during reproductive age.

Results: We identified 27 women and 15 men with sickle cell disease. Mean age at menarche (±SD) was 13.7 (±1.6) years, with most women reporting normal cycles. Mean age at menopause (±SD) was 46.3 (±5) years. 1/27 women (4%) had hypothalamic amenorrhea. 3/27 (11%) were diagnosed with premature ovarian insufficiency and 1/27(4%) reported early menopause. Mean menopause age was similar in women exposed and unexposed to HU. No cases of hypogonadism were identified in men. Mean testosterone (±SD) was 575 (±254) ng/dL; 14/15 men had received HU.

Conclusions: Patients with SCD showed a mild delay in menarche compared with the average age in Greece (12.3-12.4 years), as well as an earlier age at menopause (average age of menopause in Greece 48.7-49.1 years). Menopause age does not appear to be influenced by hydroxyurea exposure during reproductive age. Despite literature reports of hypogonadism in up to 24% of male patients with SCD, no such cases were observed in our cohort. Data on gonadal function in SCD, particularly in sickle cell–thalassemia, remain scarce and warrant further investigation.

EP1388 - ECE_1762 - Overlapping cognitive presentations of Andropause and Alzheimer's disease: two case reports

Akriti Karki[1], Elizabeta Mukaetova-Ladinska[2] and Ali Al Jumaah[3]
[1]*University Hospitals of Leicester NHS Trust, Leicester, United Kingdom;* [2]*Leicester, United Kingdom;* [3]*Endocrinology Department, University Hospitals of Leicester NHS Trust, Leicester Cancer Research Centre, University of Leicester, Leicester, United Kingdom*

Background: Andropause, a prevalent hormonal disorder in aging men, is clinically described as late onset hypogonadism. Diagnosed based on clinical manifestations of testosterone deficiency. (TD) Testosterone declines after the age of 30, reducing at a rate of 0.2%-1% per year in total testosterone (TT). According to the International society of sexual medicine, TD is defined as TT <8 nmol (231 ng/dl). It is associated with sexual, musculoskeletal, cognitive symptoms and reduced quality of life. Evidence of testosterone role upon cognitive function remains limited. Men with early-onset Alzheimer's disease alongside memory impairment may also have significant changes in mood and motivation, including apathy, depression, and irritability. This warrants further investigation of co-existing testosterone deficiency.

Case Reports: Mr A, a 64-year-old man with confirmed Alzheimer's disease (AD) presented with total testosterone <8 nmol/L. AD diagnosis was supported by CSF biomarkers (elevated phosphorylated tau and reduced amyloid-β42:40 ratio) and FDG-PET findings consistent with AD. Testosterone therapy increased levels to 13.3-17.2 nmol/L and was associated with improvements in mood, cognition, and behaviour. Subsequent initiation of donepezil 5 mg provided additional memory benefit. Mr. B, a 65-year-old man, presented with an 18-month history of progressive cognitive difficulties, including date confusion, task forgetting, word-finding difficulties, and functional errors, with limited insight. He also reported apathy, anhedonia, sensory hypersensitivity, sleep disturbance, and increased appetite. Cognitive testing showed preserved global cognition (SDTP 7/7; RUDAS 30/30) with selective memory impairment on ACE-III (81/100), and low total testosterone (7.2 nmol/L). Brain MRI demonstrated age-related involutional changes without features consistent with Alzheimer's disease. CSF findings awaited. His apathy improved with memantine 20 mg mane.

Discussion: The overlapping symptoms between andropause and Alzheimer's disease (AD) are commonly overlooked. Both can have

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

detrimental impacts, resulting in low mood, poor memory, anhedonia, and reduced quality of life. Studies have highlighted the protective role of testosterone against AD, including its involvement in tau protein cleavage and prevention of beta-amyloid–induced neuronal death. Cohort studies have reported that individuals with higher testosterone-to–sex hormone–binding globulin ratios are associated with improved visual and verbal memory and slower longitudinal memory decline.

Learning Points

- Testosterone deficiency is common, under-recognised, and can contribute to cognitive, mood, and behavioural symptoms in older men.
- Hypogonadism represents a potentially reversible and treatable factor, even alongside neurodegenerative disease.
- Routine testosterone assessment may aid holistic management and optimise outcomes through endocrine—neurology collaboration.

EP1389 - ECE_2499 - Robertsonian translocation (13;14) and endocrine dysfunction: implications for recurrent pregnancy loss

Kalyani Nagarajah[1,2,3]
[1]Aneurin Bevan Health Board, Endocrinology, Endocrinology, Newport, United Kingdom; [2]Aneurin Bevan, Endocrinology and Diabetes, Endocrinology, Newport, United Kingdom; [3]Aneurin Bevan, Endocrinology and Diabetes, Newport, United Kingdom

Recurrent pregnancy loss often involves male factor infertility, where structural chromosomal variants like Robertsonian translocations play a critical role. These balanced rearrangements, notably rob(13;14), disrupt meiotic segregation, leading to spermatogenic impairment and unbalanced gametes that compromise embryo viability.[1,2] Updated global consensus statements advocate systematic karyotyping alongside endocrine profiling in subfertile males to enable precision reproductive strategies.[3,4] A 33-year-old male underwent assessment after his partner's repeated first-trimester losses during fertility treatment. He reported no chronic illnesses or medications. Initial semen evaluation confirmed oligospermia. G-banded karyotyping disclosed a Robertsonian translocation t(13;14), cytogenetically denoted 45,XY,der(13;14)(q10;q10). Endocrinological workup demonstrated subnormal gonadotrophins and testosterone diagnostic of hypogonadotropic hypogonadism; however, sellar MRI revealed no anatomical defects. Reproductive counselling encompassed gonadotrophin supplementation alongside preimplantation genetic testing for structural rearrangements (PGT-SR) to prioritise euploid embryo transfer. Carriers exhibit oligozoospermia, teratozoospermia, and elevated aneuploidy rates in embryos, driving reproductive failure.[1,2,5] Cohort analyses validate PGT-SR integration within IVF protocols, yielding superior implantation rates and miscarriage reduction through euploid selection.[2,4,5] Sporadic reports link Robertsonian carriers to isolated gonadotrophin deficiency, postulating contiguity effects on HPG axis loci or cryptic gene disruptions.[6] Harmonised AUA/ASRM–EAU frameworks mandate holistic genitourinary phenotyping—cytogenetics plus serial hormone assays—to stratify risk and tailor adjunctive therapies.[3,4] This presentation exemplifies synergistic genetic–endocrine perturbation of male gametic competence and gestational success. Males in recurrent loss cohorts warrant protocolised genetic–hormonal scrutiny, especially with seminal compromise. This paradigm shift underpins PGT-SR deployment, hormone repletion, and expectant management, maximising term delivery while curtailing iterative grief.[1-6]

EP1390 - ECE_2565 - From recurrent ovarian torsion of enlarged ovaries in childhood to PCOS diagnosis in adolescence: case series

Zuzanna Aurast[1,2] and Karina Kapczuk[1]
[1]Division of Gynaecology, Department of Gynaecology, Poznan University Of Medical Sciences, Poznań, Poland; [2]Doctoral School, Poznan University Of Medical Sciences, Poznań, Poland

Introduction: Polycystic ovary syndrome (PCOS) is a common endocrine-metabolic disorder in women of reproductive age. The etiology of the syndrome is complex and not fully known. Pediatric and adolescent populations present a challenge for physicians to make an accurate diagnosis due to an overlap between physiological features during puberty and symptoms and diagnostic criteria of PCOS established by the European Society of Human Reproduction and Embryology (ESHRE) 2023. Ovarian torsion in childhood is mostly caused by an adnexal mass; however, almost 50% of patients do not present a focal ovarian lesion, and the cause of oversized ovaries in childhood is not fully known. We present two cases of patients with enlarged ovaries and recurrent ovarian torsion in the prepubertal period, who were diagnosed with PCOS in adolescence.

Case Presentation: Case 1: Following two episodes of left ovarian torsion without mass (at age 4.2 and 4.7 years, respectively), the girl underwent ovariopexy. The third episode of torsion took place at age 6.3. From the age of 5.3 to 9.3, the mean ovarian volume (OV) increased from 3.3 cm^3 to 12 cm^3, despite the girl being prepubertal. She had menarche at age 15.2 years.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Following menarche, she presented with functional abnormal uterine bleeding for more than 2 years, but no hyperandrogenism. At the age of 17.3, the mean OV was 23 cm^3, markedly elevated LH, impaired glucose tolerance and insulin resistance were found, and the patient was classified as being at risk for PCOS. Case 2: The girl had her first episode of left ovarian torsion without mass in prepuberty, at age 9.8, and the second, followed by ovariopexy, in early puberty (Tanner 2) at age 10.8. Mean OV (after resolution of oedema) was 8.5 cm^3. The third episode of torsion occurred at the age of 12. Mean OV 3 months after surgery was 13.4 cm^3. She had menarche at age 13.3. Since the second year after menarche, she presented with oligomenorrhea. No hyperandrogenism was found, but the patient had markedly elevated LH. Mean OV was 13.6 cm^3 at age 17.5 and 17 cm^3 at age 21.3. She was diagnosed with PCOS.

Conclusions: Ultrasound criteria of polycystic ovarian morphology (PCOM) in adolescence are not currently defined and therefore not included in diagnostic criteria of PCOS in this age group. However, increased OV in childhood and adolescence might be the early manifestation of a high risk for PCOS. Long-term follow-up is essential for these patients to enable early, personalized management.

EP1391 - ECE_3025 - Xeroderma pigmentosum: an underrecognized cause of premature ovarian insufficiency

Doha Dahmani, Aziouaz Fatima and Benkacem Mariem
Endocrinology and Metabolic Diseases Department, Mohammed VI University Hospital, Tangier, Morocco

Introduction: Xeroderma pigmentosum (XP) is a rare autosomal recessive disorder caused by mutations affecting one of seven genes involved in the DNA repair pathway, leading to hypersensitivity to the deleterious effects of ultraviolet (UV) radiation on DNA. From a gynecological and endocrine perspective, women with XP appear to be at increased risk of developing premature ovarian insufficiency (POI). We report the case of a 29-year-old woman with XP who presented with secondary amenorrhea, in whom investigations revealed POI.

Case Report: A 29-year-old woman with xeroderma pigmentosum diagnosed in childhood presented with secondary amenorrhea of one year's duration. Menarche occurred at the age of 13 years, with regular menstrual cycles until the age of 24 years, followed by the onset of oligo-spaniomenorrhea and subsequently secondary amenorrhea associated with hot flashes from the age of 28 years. Hormonal evaluation revealed hypergonadotropic hypogonadism with low estradiol and markedly elevated FSH and LH, associated with a severely reduced ovarian reserve (AMH <0.01 ng/mL), consistent with premature ovarian insufficiency. Karyotype analysis was normal.

Discussion: This case highlights a rarely described association between xeroderma pigmentosum, a DNA repair–deficiency disorder, and premature ovarian insufficiency, highlighting the essential role of genomic stability in preserving normal ovarian function. The ovaries, due to their high proliferative activity, exhibit particularly high expression levels of the XPC gene, likely reflecting an increased requirement for correction of replication errors and repair of endogenous DNA damage. Murine models of XP demonstrate reduced reproductive performance, associated with increased apoptosis of germ cells. Merideth et al. (2019) evaluated 60 women with xeroderma pigmentosum and found that 31% of these patients had experienced menopause, with 78% meeting criteria for premature menopause; the median age at menopause was 29.5 years, approximately 20 years earlier than in the general population.

Conclusions: Awareness of the increased risk of premature menopause in women with xeroderma pigmentosum warrants early surveillance to detect declining ovarian reserve and to guide reproductive management. When indicated, initiation of hormone replacement therapy is essential to prevent skeletal and cardiovascular complications.

EP1393 - ECE_3719 - Return of "menses" after menopause: un unusual cause

Kalliopi Bilariki[1], Youssef El Cadhi[2], Jennifer Lerouge[2], Noemie Bertrand[3], Sarra El Younsi[1], Jean-Noël Barjon[1] and Etienne Justinien[1]
[1]*Endocrinology, Compiegne Noyon Intercommunal Hospital Center, Compiegne, France;* [2]*Chamant, France;* [3]*Private practice (General practicioner), Chantilly, France*

Introduction: Postmenopausal bleeding most frequently reveals uterine lesions. We report a case of a postmenopausal bleeding leading to the diagnosis of an ovarian Leydig cell tumour.

Observation: A 57-years-old obese woman, reporting menopause since the age of 49, is seen in July 2023 at the endocrinology outpatient clinic for evaluation before bariatric surgery. Laboratory tests reveal iron deficiency, The patient is at that time asymptomatic. She is addressed in Gastroenterology and Gynecology for evaluation and workup. Gastroscopy reveals a gastritis and coloscopy reveals a diverticulosis. At this time, a first episode of uterine bleeding reveals a thick endometrium. She has an hysteroscopy and biopsies, as well as two pelvic ultrasounds, referred as normal. The patient is finally allowed to undergo a sleeve gastrectomy in March 2024. She now reports "regular menses". We suspect that previous amenorrhea was related to obesity and not menopause. This hypothesis is consistent with the biology: FSH 16 U/L, LH 10.13 U/l et Oestradiol 2046 pmol/l. Surprisingly, the patient provides us with previous (2019) data: FSH 47 U/l LH 36 U/l. She now develops hirsutism, which is intriguing in the context of weight loss following sleeve gastrectomy. Further laboratory tests reveal an hyperandrogenism: elevated D4-androstenedione and testosterone but normal DHEAS levels, indicating an ovarian rather than adrenal origin. New ovarian ultrasound reports normal left ovary and fails to visualize right ovary. A Pelvic MRI reveals a 2 cm right ovarian mass. Ca-125 and HE4 are in normal ranges. The patient undergoes hysterectomy and bilateral annexectomy in January 2025.

Pathology: Leydig cell benign ovarian tumour, 17 × 14 mm, ki67 2%. Symptoms improved rapidly: regression of hirsutism and recurrence of postmenopausal hot flushes that had disappeared for some years. Serum androgen returned to low normal ranges, estradiol became undetectable while FSH and LH rose again. In december 2025 the patient remains asymptomatic.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Discussion: Leydig cell tumours account for 0,1%-0,2% of ovarian neoplasms. There is a delay of up to 5 years from onset of symptoms to diagnosis. Most typically, it is the clinical hyperandrogenism (severe hirsutism and virilization) that motivates workup and leads to diagnosis. In the great majority of cases already described, estrogen effects are not prominent. They are probably inhibited in the context of severe hyperandrogenism. In our case, androgen elevation was quite moderate and didn't inhibit estrogenic effects (postmenopausal bleeding), leading to investigations and a more rapid diagnosis.

EP1394 - ECE_1225 - Impact of daylight saving time transitions on global searches for menstrual health terms

Christos Savvidis, Vasiliki Tsiama, Stella Proikaki, Konstantinos Belis, Efthymia Kallistrou, Dimitra Ragia, Dimitra Motsiou and Ioannis Ilias
Dept of Endocrinology, Hippokration Hospital, Athens, Greece

Introduction: Daylight Saving Time (DST) shifts disrupt sleep and circadian rhythms, potentially influencing menstrual cycles via hormonal dysregulation. This study investigates worldwide Google Trends for menstrual terms ("Menstrual," "Menstrual cycle," "Menstruation," "Menses," "Menstrual period") from 2004-2025, across three algorithmic periods (2004-2015, 2016-2021, 2022-2025). The aim was to assess search elevations during DST entry (spring: Mar–June) and exit (winter: Nov–Jan) vs rest-of-year as proxies (via concerns) for DST-related menstrual disorders.

Materials and Methods: Google Trends data were retrieved for relative search volumes (RSVs) related to menstrual terms ("menstrual," "menstruation," "menstrual cycle," "menstrual period," "menses") in the European Union (EU) and North America (US + Canada) from January 2004 to November 2025. Data were segmented into three periods to account for Google algorithm changes: 2004-2015, 2016-2021, and 2022-2025. To evaluate potential Daylight Saving Time (DST) effects, months were categorized as: 0 (baseline), 1 (spring transition: April-June for EU, March-May for North America), and 2 (fall transition: November-January for both regions). Time series analysis was performed using ARIMA models to assess trends, seasonality, and differences in RSVs across periods, with model selection based on AICc, BIC, and residual diagnostics. Statistical significance was set at $P < .05$.

Results: Median RSVs across terms showed variability by region and timeframe. ARIMA modeling revealed significant drift and coefficients indicating temporal increases in RSVs only in the EU during 2004-2015 (eg, for "menstrual": ARIMA(4,1,4), drift 0.312, $P < .001$; time period coefficient 1.289, $P < .001$), with no comparable effects in North America or later EU periods. Spring and fall transitions correlated with RSV peaks in early EU data.

Discussion/Conclusions: This analysis suggests a potential indirect association between DST transitions and increased Google searches for menstrual issues in the EU from 2004-2015, possibly reflecting circadian disruptions affecting menstrual regularity, as proxied by search behavior. No such patterns were observed in North America or subsequent EU periods, which may relate to algorithm shifts. Limitations include the ecological nature of search data and lack of individual-level confounders. Future studies should incorporate clinical data to validate DST's impact on menstrual health. In conclusion, early EU data hint at DST-related menstrual perturbations, warranting physician awareness during transition periods.

EP1398 - ECE_1115 - Longitudinal effects of Eurycoma longifolia extract and multivitamin supplementation on reproductive hormone profiles in infertile men: a randomized controlled trial

Seso Sulijaya Suyono[1,2,3], Dewi Lestari[3] and Raymond Rubianto Tjandrawinata[4]
[1]Gladiool IVF Centre, Andrology, Andrology, Magelang, Indonesia; [2]Sadewa IVF Centre, Andrology, Andrology, Daerah Istimewa Yogyakarta, Indonesia; [3]Pharmacology, Universitas Kristen Duta Wacana, Daerah Istimewa Yogyakarta, Indonesia; [4]School of Bioscience, Technology and Innovation, Universitas Katolik Indonesia Atma Jaya, Jakarta, Indonesia

Background: Herbal supplements and antioxidants are widely used in male infertility, yet their endocrine effects remain inconclusive. Eurycoma longifolia has been traditionally used for its androgenic properties and has been proposed to influence androgen regulation within the hypothalamic–pituitary–gonadal axis; however, controlled data on reproductive hormone dynamics are limited.

Objective: To evaluate the longitudinal effects of Eurycoma longifolia extract, multivitamins, and their combination on serum testosterone and follicle-stimulating hormone (FSH) levels in infertile men.

Methods: In this randomized controlled trial, 90 infertile men aged 20-45 years with baseline serum testosterone levels of 350-600 ng/dL were randomized to receive Eurycoma longifolia extract, multivitamins (vitamin C, vitamin E, and β-carotene), or their combination for 12 weeks. Serum testosterone was measured at baseline, 6 and 12 weeks, while FSH was assessed at baseline and 12 weeks. Hormonal changes were analyzed using repeated-measures and paired statistical methods, as appropriate. Safety and tolerability were assessed.

Results: Eighty-three participants completed the trial. At baseline, mean serum testosterone levels were significantly lower in the multivitamin group, while baseline FSH levels were comparable across groups. No statistically significant changes in serum testosterone were observed at either 6 or 12 weeks across the intervention groups. However, a consistent upward trend in serum testosterone was observed in the combination group (1% and 8% at 6 and 12 weeks, respectively). Changes in serum FSH at 12 weeks were not statistically significant in any group compared with baseline, although a numerical increase was noted in the multivitamin group. All interventions were well tolerated, with no serious adverse events reported.

Conclusions: In this randomized trial, daily supplementation with Eurycoma longifolia, multivitamins, or their combination was safe but did not result in statistically significant changes in serum testosterone or FSH levels over 12 weeks. Given the observed longitudinal variability in serum testosterone, repeat hormonal assessment prior to treatment initiation should be considered. Further studies incorporating larger cohorts and stratified endocrine phenotyping are warranted.

EP1400 - ECE_1757 - Impact of maternal obesity and gestational GLP-1 receptor agonist exposure on fetal hypothalamic development

Hadley Johnson[1], Matthew B. A. Higgins[1], Ameera Cunningham[1], Denise S. Fernandez-Twinn[1,2], Susan Ozanne[1,2] and Laura Dearden[1]
[1]University of Cambridge, Institute of Metabolic Science, Cambridge, United Kingdom; [2]MRC Metabolic Diseases Unit, Institute of Metabolic Science, Cambridge, United Kingdom

Given the societal shift to an obesogenic environment, it remains unknown why some individuals are more predisposed to gaining weight than others. Understanding this variability requires examining the biological basis of weight-regulation behaviours at the genetic and developmental levels. *In utero* programming allows maternal hormones and nutrient availability to shape the developing fetal brain, altering long-term gene expression in hypothalamic appetite circuits. Semaglutide, a GLP-1 receptor agonist (GLP-1RA), mimics endogenous GLP-1 to enhance insulin secretion, delay gastric emptying, increase satiety, and influence hypothalamic pathways. Although not recommended during pregnancy due to preclinical findings of growth restriction and pregnancy loss in rodents, an increasing number of women are conceiving while on the medication, possibly because of interactions such as reduced oral contraceptive effectiveness and increased fertility of women with obesity. There are concerns about the effects of gestational GLP-1RA exposure on fetal neurodevelopment that warrant further investigation. This project investigates whether semaglutide exposure during critical developmental windows alters hypothalamic development by examining GLP-1 receptor expression in embryonic hypothalamic cells, assessing effects on neuronal growth, and evaluating changes in metabolic protein expression within key hypothalamic nuclei. By addressing critical gaps in our understanding of gestational GLP-1RA exposure, this research aims to clarify whether semaglutide can modulate fetal hypothalamic development in ways that may influence lifelong metabolic outcomes.

EP1402 - ECE_2190 - Plasticity of the circadian chronotype in healthy female individuals over the course of their menstrual cycle

Manon Torres and Achim Kramer
AG Chronobiologie—Achim Kramer, Berlin, Germany

The circadian clock (~24 hours) is an endogenous system that regulates daily changes in a multitude of physiological functions, including sleep, metabolism, and cognitive functions. In mammals, the endocrine system is closely linked to the circadian clock, with strong rhythmic expression of circadian genes and proteins in both the central nervous system and peripheral glands, resulting in well-known daily pulses of hormone secretion.

Studies conducted mainly on rodents strongly suggest that female estrus (or the menstrual cycle in humans) has a reciprocal influence on the circadian clock, with ovarian steroid hormones (ie, estrogen and progesterone) capable of altering the rhythmic expression of core circadian genes in both the central clock and peripheral tissues. However, due to technological limitations, it remains unclear whether in human too circadian clock is altered in response to the female cyclic fluctuation of ovarian hormones.

Recently developed in our laboratory, the HairTime test estimates a person's internal circadian chronotype (ie, predicted Dim Light Melatonin onset or "pDLMO") from a single sample of hair follicles. This test accurately reflected the known diversity of chronotypes among individuals (from early risers to night owls), and its precision allowed us to observe the plasticity of the human chronotype under the influence of environmental factors such as work schedule.

In this study, we propose to apply the HairTime assay to evaluate the plasticity of the chronotype in healthy female individuals over the course of their menstrual cycle. We present here the overview of this new study and preliminary results from first participants.

EP1404 - ECE_3141 - Are DHEA-S levels associated with miscarriages in females with Ehlers–Danlos syndrome?

Jan Domański[1,2,3], Ivan Rychlik[4], Aleksandra Żuk-Łapan[1,2], Bernadetta Kałuża[1,2] and Edward Franek[1,5]
[1]Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland; [2]Students Scientific Group of the Medical University of Warsaw at the Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Medical University of Warsaw, Warsaw, Poland; [3]Doctoral School of the Medical University of Warsaw, Medical University of Warsaw, Warsaw, Poland; [4]Third Faculty of Medicine, Department of Internal Medicine, Charles University, and Královské Vinohrady University Hospital, Prague, Czech Republic; [5]Polish Academy of Sciences, Department of Human Epigenetics, Mossakowski Medical Research Institute, Warsaw, Poland

Background: Ehlers–Danlos syndrome is a group of genetic conditions involving abnormal connective tissue synthesis and structure and characterized by varied, subtype-dependent symptom severity and varied location, predominantly presenting as joint hypermobility and skin hyperextensibility, musculoskeletal abnormalities, and internal organ frailty, which may result in miscarriages, which are more prevalent in affected females than in the general population. The purpose of this study was to evaluate adrenal hormone levels in female patients with Ehlers–Danlos syndrome as part of miscarriage risk assessment.

Material and Methods: We assessed adrenal hormone levels and conducted imaging diagnostics in 30 female patients with classic and hypermobile Ehlers–Danlos syndrome. The patients were divided into two groups: group 1—patients with no history of miscarriage ($n = 21$) and groups 2—patients with a history of miscarriage ($n = 9$).

Results: The patients from the two compared groups differed significantly in terms of DHEA-S levels (237.00 ± 90.42 vs 147.81 ± 88.98 [μg/dl], $P = .021$); however, they did not differ in terms of ACTH (21.91 ± 14.04 vs 23.12 ± 11.33 [pg/mL], $P = .651$), cortisol (14.78 ± 6.39 vs 15.84 ± 5.01 [μg/dl], $P = .511$), androstenedione (1.97 ± 0.78 vs 1.62 ± 1.07 [ng/mL], $P = .118$), 17-OH-progesterone (1.28 ± 0.74 vs 1.24 ± 0.38 [ng/mL], $P = .667$), sodium (141.62 ± 2.44 vs 140.89 ± 1.90 [mmol/L], $P = .61$), or potassium (4.71 ± 0.39 vs 4.51 ± 0.32 [mmol/L], $P = .147$) levels. Univariate regression

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

analysis showed a significant correlation between DHEA-S levels and the risk of miscarriage (OR 0.988 [0.976-0.999]; $P = .035$). Conversely, such parameters as ACTH (1.007 [0.949-1.069]; $P = .814$), cortisol (OR 1.032 [0.902-1.181]; $P = .648$), androstenedione (OR 0.589 [0.21-1.651]; $P = .314$), 17-OH-progesterone (OR 0.891 [0.256-3.098]; $P = .856$), sodium (OR 0.865 [0.608-1.23]; $P = .419$), or potassium (OR 0.212 [0.02-2.216]; $P = .195$) levels showed no such correlation.

Conclusions: DHEA-S levels in female patients with hypermobile or classical Ehlers–Danlos syndrome may affect the risk of miscarriage. These patients' adrenal function should be assessed to reduce the risk of miscarriage.

EP1405 - ECE_3843 - Assessment of adropin effects on proliferation and PCNA levels in porcine granulosa cells

Jakub Chatys, Alicja Łapa, Patrycja Kurowska and Agnieszka Rak
Faculty of Biology, Institute of Zoology and Biomedical Research, Laboratory of Physiology and Toxicology of Reproduction, Jagiellonian University, Kraków, Poland

Granulosa cell proliferation is essential for ovarian follicle growth and oocyte development. Adropin is a peptide hormone involved in the regulation of energy homeostasis and lipid metabolism. Our previous studies have demonstrated that adropin is expressed in the porcine ovary; however, its role in ovarian physiology remains poorly understood.

The aim of this study was to evaluate the effect of adropin on the proliferation of porcine granulosa cells and the expression of proliferating cell nuclear antigen (PCNA). Granulosa cells were isolated from ovarian follicles collected on days 10-12 of the estrous cycle and seeded in 96-well plates at a density of 50 000 cells per well. After 24 hours of preincubation in M199 medium supplemented with 10% fetal bovine serum (FBS), cells were treated with adropin at concentrations of 0.1, 1, 10, and 100 nM for 48 hours. Cell proliferation was assessed using a BrdU incorporation assay, while cell viability was evaluated by alamarBlue. PCNA mRNA and protein levels were analyzed by quantitative real-time PCR and Western blotting, respectively. Statistical analysis was performed using one-way ANOVA in GraphPad Prism 8.1 ($n = 5$).

We demonstrated that adropin reduced granulosa cell proliferation at all tested concentrations and significantly decreased cell viability at 1 and 10 nM. Furthermore, adropin significantly downregulated *PCNA* gene expression at 1, 10, 100 nM, and reduced PCNA protein levels at all tested doses (0.1-100 nM).

These findings indicate that adropin inhibits granulosa cell proliferation, which may negatively impact folliculogenesis and potentially contribute to impaired fertility.

EP1408 - ECE_3453 - Are hypothyroidism and autoimmune thyroiditis associated with an increased risk of miscarriage in females with Ehlers–Danlos syndrome?

Michalina Andrzejak[1,2], Ivan Rychlik[3], Jan Domański[1,2], Aleksandra Żuk-Łapan[1,2], Jędrzej Jedliński[1,2], Bernadetta Kałuża[1,2] and Edward Franek[1,2,4]
[1]*Department of Internal Medicine, Endocrinology, and Diabetology, National Medical Institute of the Ministry of the Interior and Administration, Warsaw, Poland;* [2]*Warsaw, Poland;* [3]*Third Faculty of Medicine, Department of Internal Medicine, Charles University, and Královské Vinohrady University Hospital, Prague, Czech Republic;* [4]*Department of Human Epigenetics, Polish Academy of Sciences, Mossakowski Medical Research Institute, Warsaw, Poland*

Background: Ehlers–Danlos syndrome is a group of genetic conditions involving abnormal synthesis of connective tissue, particularly collagen, characterized by polymorbidity and an increased risk of pregnancy and delivery complications. Uncontrolled hypothyroidism increases the risk of miscarriage. The aim of this study was to assess the risk of miscarriage in women Ehlers–Danlos syndrome and concomitant hypothyroidism.

Material and Methods: Thyroid hormone levels were assessed in 30 females with classical or hypermobile Ehlers–Danlos syndrome. The patients were divided into two groups: Group 1—patients with no history of miscarriage ($n = 21$) and Group 2—patients with a history of miscarriage ($n = 9$).

Results: The two groups differed neither in terms of hypothyroidism rates (19.05% vs 22.22%, $P = .87$), or the levels of thyroid stimulating hormone (2.13 ± 1.18 vs 2.09 ± 1.83 [μIU/mL], $P = .59$), free triiodothyronine (3.37 ± 0.62 vs 3.41 ± 0.74 [pg/mL] $P = .89$), free thyroxine (1.35 ± 0.25 vs 1.33 ± 0.17 [ng/dl], $P = .80$), or thyroid peroxidase antibodies (34.58 ± 110.11 vs 40.26 ± 38.12 [IU/mL], $P = .121$). Conversely, they differed in terms of autoimmune thyroiditis rates (9.52% vs 44.44%, $P = .03$) and thyroglobulin antibody levels (21.46 ± 23.33 vs 64.97 ± 81.48, $P = .03$). Univariate logistic regression analysis showed no correlation between hypothyroidism (OR 1.21 [0.18-8.22], $P = .84$) and an increased risk of miscarriage; however, such correlation was observed in the case of autoimmune thyroiditis (OR 7.6 [1.07-54.09], $P = .04$).

Conclusions: Autoimmune thyroiditis in females with Ehlers–Danlos syndrome was shown to increase the risk of miscarriage.

EP1410 - ECE_1202 - Individualized endocrine care in non-binary individuals: efficacy, safety, and long-term outcomes of microdosing and selective hormone modulators

Ipsita Mishra
IMS & SUMII, Phulnakhara, Soul Balance, Diabetes and Endocrine Centre of Excellence, Endocrinology, Diabetes and Metabolism, Cuttack, India

Background: Current gender-affirming hormone therapy (GAHT) guidelines are optimized for binary outcomes (full masculinization or feminization), leaving a critical evidence gap for the growing population of non-binary and gender-diverse (NBGD) individuals who seek partial physical changes. These non-traditional therapeutic goals often necessitate the off-label use of low-dose, intermittent GAHT ("microdosing"), or Selective Estrogen Receptor Modulators (SERMs). This study aimed to evaluate the efficacy, safety, and impact on long-term health markers in a cohort of NBGD individuals receiving individualized hormone protocols.

Methods: This retrospective cohort study analysed data from 180 NBGD adults over a median follow-up period of 3.5 years

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

.The cohort was stratified into three groups:Group A(Microdosing MHT;$N = 95$;Natal Sex—Female;Low dose testosterone;25 mg/week);Group B(Microdosing FHT;$N = 65$;Natal Sex—Male;Low dose Estradiol;1 mg/day [oral]);Group C(SERM Protocol;$N = 20$; Natal Sex—Male;SERM ± GnRH Agonist; Raloxifene 60 mg/day).Primary Outcome: Change in patient-reported psychosocial outcomes (Gender Congruence Scale (GCS) and Quality of Life (QoL) scores).Secondary Outcomes: Physical changes, Bone Mineral Density (BMD), lipid panels, and HbA1c.

Results: The mean age of the cohort was 31.2 ± 6.8 years.Baseline BMD T-scores were: Group A (LS T-score: −0.4 ± 0.9); Group B (LS T-score: −0.2 ± 1.0); Group C (LS T-score −0.5 ± 0.8). HbA1c and lipid profiles were comparable across groups and within the normal range.Both GCS and QoL scores demonstrated a statistically significant improvement across all groups from baseline to final follow-up ($P < .001$). Microdosing MHT(Group A) achieved initial voice deepening (75%) and facial hair growth (45%) in 88% of patients.Microdosing FHT (Group B) resulted in mild breast development (A-cup or small B-cup) in 70% of patients.The SERM Protocol (Group C) successfully achieved fat redistribution and skin softening with minimal/no palpable breast tissue in 95% of cases.Group A and C maintained stable BMD.Group B demonstrated a statistically significant, albeit small, decrease in Lumbar Spine BMD (−0.015 g/cm^2, $P = .045$) in patients who maintained Estradiol levels below 100 pmol/L while achieving adequate Testosterone suppression.No major cardiovascular or thromboembolic events were recorded.

Conclusions: Microdosing and selective hormone modulator regimens represent a safe and effective strategy for achieving individualized, non-binary gender affirmation goals, resulting in significant improvements in GCS and QoL. While metabolic and cardiovascular profiles remained largely stable, the data highlights a risk of bone demineralization in a subset of Microdosing FHT patients, particularly those whose Estradiol levels are insufficient to provide skeletal protection.

EP1411 - ECE_2838 - Spontaneous pregnancy in turner syndrome mosaicism: a case report

Satik Shahbazyan[1,2], Irina Muradyan[1], Bayburdyan Gayane[1] and Yelena Aghajanova[1]
[1]Yerevan, Armenia; [2]Endocrinology, Yerevan State Medical University after Mkhitar Heratsi, Yerevan, Armenia

Introduction: Turner syndrome (TS) is a chromosomal disorder caused by partial or complete loss of one X chromosome. Although infertility is typical, mosaic forms may preserve ovarian function and, in rare cases, achieve spontaneous pregnancy.

Case Presentation: A 26-year-old woman presented for pregnancy planning. Diagnosed with TS at age 12, karyotyping showed mosaicism: 45,X (29), 47,XXX (15), and 46,XX (9). She had self-induced regular menstrual cycles from 14. She was treated with levothyroxine for subclinical hypothyroidism and received one year of growth hormone therapy, reaching a height of 152 cm. At the age of 15, pelvic ultrasound revealed bilateral ovarian follicles. At age 26, she was consulted by endocrinologist; hormonal results were normal (AMH 1.45 ng/mL), no cardiac or renal anomalies were found. Reproductive endocrinologist confirmed spontaneous pregnancy. Non-invasive prenatal testing (NIPT) indicated high risk for monosomy X. Genetic counseling and amniocentesis with FISH testing were recommended for confirmation.

Discussion: Spontaneous conception in TS is rare but can occur in mosaic forms containing 46,XX or 47,XXX lines. These women may experience normal puberty and menstruation, as in our case. However, pregnancies are high-risk due to possible cardiovascular complications, notably aortic dissection, and increased fetal chromosomal anomalies. Preconception cardiac evaluation is essential. NIPT is a valuable screening tool, but positive results should be verified through invasive tests like amniocentesis or Chorionic Villus Sampling (CVS). This case demonstrates that natural conception in mosaic TS is possible, emphasizing the need for multidisciplinary monitoring.

Conclusions:

- Spontaneous pregnancy in mosaic TS is rare but possible.
- Preconception and cardiovascular evaluations are essential.
- NIPT is useful for screening but must be confirmed by amniocentesis or CVS.
- Multidisciplinary management including endocrinology, cardiology, obstetrics, and genetics is recommended.
- Further research is needed to create clear, evidence-based guidelines for monitoring and managing spontaneous pregnancy in TS mosaicism, since current advice is mostly based on small case reports and expert opinion.
- This case shows how the reproductive care of women with TS mosaicism is changing and emphasizes the need to update clinical practice as new genetic and obstetric knowledge emerges.

EP1413 - ECE_3372 - Comparative effects of oral versus transdermal menopausal hormone therapy on key lipid parameters: a scoping review

Erin Edwards, Mia Evans, Ralph Akyea, Barbara Iyen, Nadeem Qureshi and Yana Vinogradova
Medical School, University of Nottingham, Nottingham, United Kingdom

Background: Menopausal Hormone Therapy (MHT) is commonly used as an approach to alleviate vasomotor symptoms in both peri- and post-menopausal women. While MHT is known to have an influence on lipid profile, it remains unclear how lipid effects vary by route of administration—specifically between oral and transdermal therapy.

Objectives: This scoping review aimed to map and synthesise the current evidence comparing the effects of oral and transdermal MHT on key lipid parameters in peri- and post-menopausal women.

Methods: This review followed the PRISMA-ScR guidelines. A comprehensive search using three databases—MEDLINE, EMBASE and APA PsycINFO was conducted, limited to papers published in the last 10 years. Studies were included if they reported lipid outcomes following oral and transdermal MHT use in peri- or post-menopausal women (and outcomes stratified by route). Title, abstract, full-text screening and data charting were performed by 2 independent reviewers. Data was extracted from eligible studies independently, and charted by study characteristics, MHT route, follow-up duration and lipid outcomes.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Results: After screening 2493 studies, a total of 6 studies met the criteria and were therefore included in this review. Studies were conducted across a wide geographical range, and there was large heterogeneity in study design, population characteristics and outcomes reported. Across included studies, oral therapy was associated with more consistent lipid outcomes, whereas with transdermal therapy, findings showed more variability.

Conclusions: Current evidence suggests that there is greater consistency in lipid profile effects with oral compared to transdermal MHT, however this is limited by heterogeneity and limited comparative data. This field lacks research on long-term effects on MHT, and effects across a broader age range. This review highlights the need for more controlled head-to-head trials comparing the effects of oral and transdermal MHT on lipid profile.

Abstract citation ID: lvag096.1609

EP1416 - ECE_3099 - Fertility and reproductive outcomes in adults with congenital adrenal hyperplasia: data from a single-center cohort

Malgorzata Bobrowicz[1], Zuzanna Roszkowska[2], Karolina Palys[2], Hanna Mruzek[2] and Urszula Ambroziak[1]
[1]Warsaw, Poland; [2]Student Scientific Club "Endocrinus" Affiliated to the Department of Internal Medicine and Endocrinology, Medical University of Warsaw, Warsaw, Poland

Background: Congenital adrenal hyperplasia (CAH) is a lifelong endocrine disorder with well recognized implications for reproductive health. Although considerable progress in our understanding of the issues of fertility and reproductive health has been made, regional differences in the patients' management may influence the results in different cohorts. The aim of our study was to assess fertility, parenthood, and pregnancy-related outcomes in a cohort of adult patients with CAH, with a focus on clinically relevant sex-specific aspects.

Methods: We conducted a cross-sectional analysis of adult patients with CAH followed at a tertiary endocrine center. Demographic characteristics, sex, parenthood status, and pregnancy history were obtained from patient-completed surveys. Reproductive outcomes were analyzed descriptively and stratified by sex where applicable.

Results: The cohort included 37 adults with CAH (31 women [83.8%] and 6 men [16.2%]). Eleven patients reported having children (29.7%), while 23 reported no offspring (62.2%); parenthood status was unavailable in 3 cases (8.1%).

Among patients who provided information on attempts to conceive ($n = 11$), 10 (90.9%) reported active attempts to achieve pregnancy, while 1 (9.1%) reported no attempts. Reported time to conception ranged from immediate conception to 7 years; due to heterogeneous reporting formats, calculation of mean or median time to conception was not feasible.

Among women with CAH who reported childbirth ($n = 11$), Cesarean section was the predominant mode of delivery, occurring in 8 cases (72.7%). Pregnancy- or delivery-related complications were reported in 5 women (45.5%). Only 2 partners (18.2%) underwent genetic testing prior to conception.

Among 31 women with CAH, four (12.9%) reported at least one miscarriage. No cases of recurrent miscarriage (three or more pregnancy losses) requiring extended diagnostic work-up were reported.

Conclusions: In this cohort of adults with CAH, fewer than one-third reported parenthood despite most being of reproductive age. Pregnancy outcomes were characterized by a high rate of Cesarean section and a substantial burden of pregnancy-related complications. Although recurrent miscarriage was not observed, sporadic pregnancy loss was reported in a notable proportion of women.

The low uptake of partner genetic testing prior to conception highlights gaps in preconception counseling and genetic risk assessment. Overall, these findings underscore the need for structured, multidisciplinary reproductive care for adults with CAH, integrating endocrine management with obstetric, genetic, and psychosocial support to optimize fertility and pregnancy outcomes. Further research on this topic is warranted.

Abstract citation ID: lvag096.1610

EP1418 - ECE_2655 - Testosterone-induced cardiomyopathy: a reversible cause of nonischemic cardiomyopathy

Humera Tabassum[1,2,3], Samyukta Ravi[1,2,3], Grishma Sheth[1,3], Sathya Jyothinagaram[1,2] and Karyne Vinales[1,2]
[1]Endocrinology, University of Arizona College of Medicine, Phoenix, United States; [2]Phoenix VA Healthcare System, Phoenix, United States; [3]Endocrinology, Medicine, Banner—University Medical Center Phoenix, Phoenix, United States

Background: Testosterone replacement therapy (TRT) is increasingly prescribed for male hypogonadism. Large, randomized trials support cardiovascular noninferiority of physiologic TRT when appropriately indicated and monitored. However, supraphysiologic testosterone exposure has been associated with adverse myocardial remodeling, primarily described in anabolic-androgenic steroid use. Reports of cardiomyopathy associated with prescribed TRT remain rare and limited to isolated case reports, suggesting this entity may be underrecognized despite potential reversibility.

Case Presentation: A 54-year-old male presented for endocrine evaluation due to concern for testosterone-induced cardiomyopathy. He had been treated for presumed hypogonadism at a men's health clinic for seven years without documentation of a comprehensive endocrine evaluation prior to initiation of therapy. He was asymptomatic, and premature ventricular contractions were incidentally identified during anesthesia for a minor surgical procedure.

The patient received intramuscular testosterone 190 mg weekly for seven years, resulting in persistently supratherapeutic testosterone levels (total testosterone 1033 ng/dL, free testosterone 198 pg/mL, bioavailable testosterone 398 ng/dL).

Cardiac evaluation demonstrated progressive systolic dysfunction. Transthoracic echocardiography showed a left ventricular ejection fraction (LVEF) of 50% in 2022, declining to 45% in early 2024. Cardiac magnetic resonance imaging revealed globally reduced systolic function with LVEF 37% and right ventricular ejection fraction of 30%, mild ventricular enlargement, and no late gadolinium enhancement, arguing against ischemic or infiltrative cardiomyopathy. Coronary computed tomography angiography showed no obstructive coronary artery disease. Holter monitoring demonstrated a premature ventricular contraction burden of 9%. Comprehensive genetic testing revealed no pathogenic variants associated with cardiomyopathy.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Management and Outcome: Given concern for testosterone-induced cardiomyopathy, testosterone therapy was gradually tapered and discontinued, and anastrozole was stopped. Following cessation, the patient demonstrated spontaneous recovery of the hypothalamic–pituitary–gonadal axis without pharmacologic intervention. Repeat laboratory testing showed luteinizing hormone 8.5 mIU/mL, follicle-stimulating hormone 5.5 mIU/mL, total testosterone 307 ng/dL, and free testosterone 53.8 pg/mL.

Follow-up transthoracic echocardiography demonstrated normalization of left ventricular systolic function with LVEF 55%-60% and normal right ventricular function.

Conclusions: This case illustrates testosterone-induced cardiomyopathy as a rare but potentially reversible cause of nonischemic cardiomyopathy associated with prolonged supraphysiologic testosterone exposure. Recovery of endogenous testosterone production and normalization of systolic function following testosterone withdrawal support a causal relationship. This case underscores the importance of appropriate diagnostic evaluation prior to initiating TRT and the need for cardiovascular monitoring during long-term therapy.

Abstract citation ID: lvag096.1611

EP1419 - ECE_3961 - Progressive bilateral gynecomastia associated with hyperestrogenemia, hypogonadotropic hypogonadism, and pituitary microadenoma

Andi Alfian[1,2], Tri Tarigan[1], Dicky Tahapary[1] and Wismandari Wisnu[1]

[1]*Faculty of Medicine, Division of Endocrinology, Department of Internal Medicine, Universitas Indonesia, Cipto Mangunkusumo National General Hospital, Jakarta, Indonesia;* [2]*Faculty of Medicine, Department of Internal Medicine, Universitas YARSI, YARSI Hospital, Jakarta, Indonesia*

Introduction: Gynecomastia is a benign proliferation of male breast glandular tissue caused by an imbalance between estrogenic and androgenic activity. While often physiological during puberty, persistent or progressive gynecomastia in adults warrants evaluation for endocrine disorders, testicular pathology, pituitary disease, systemic illness, medication effects, or hereditary predisposition. Hyperestrogenemia accompanied by suppressed gonadotropins is uncommon and raises concern for primary estrogen excess, increased peripheral aromatization, or central hypothalamic–pituitary dysfunction. We report a rare case of progressive bilateral gynecomastia in a young male with marked hyperestrogenemia, hypogonadotropic hypogonadism, and a pituitary microadenoma, with a possible familial component.

Case Description: A 21-year-old male presented with a five-year history of progressively enlarging, symmetrical breast tissue, initially painless but later intermittently tender, causing significant psychosocial distress. He denied headaches, visual disturbances, sexual dysfunction, nipple discharge, or systemic symptoms. Pubertal development was spontaneous and complete. His older brother exhibited similar breast enlargement, suggesting a possible hereditary pattern.

Physical examination revealed a body mass index of 21.6 kg/m^2 and bilateral symmetric breast enlargement with firm glandular tissue consistent with true gynecomastia. Testicular volume was normal (20 mL bilaterally) without masses. External genitalia and secondary sexual characteristics were normal.

Laboratory evaluation demonstrated persistently elevated estradiol (98-115 pg/mL), markedly suppressed FSH (0.25 mIU/mL), low-to-normal LH (2.4-5.7 mIU/mL), borderline elevated prolactin (18-21 ng/mL), and low normal testosterone (4.19-5.76 ng/mL). Thyroid, liver, and renal function were normal. Breast ultrasonography confirmed diffuse glandular proliferation. Dynamic pituitary MRI revealed a 0.3×0.2 cm left-sided microadenoma with delayed enhancement. Testicular and adrenal imaging were unremarkable, reducing the likelihood of peripheral estrogen-secreting tumors.

The constellation of findings indicated progressive true gynecomastia associated with hyperestrogenemia, disproportionate gonadotropin suppression, hypogonadotropic hypogonadism, and a pituitary microadenoma of uncertain functional significance, within a possible familial context. Management considerations included hormonal monitoring, selective estrogen receptor modulators, genetic evaluation, reproductive counseling, and surgical options if symptoms persisted.

Conclusions: This case illustrates a rare and complex presentation of progressive gynecomastia associated with hyperestrogenemia, suppressed gonadotropins, and a pituitary microadenoma, possibly within a familial context. Comprehensive endocrine andrology evaluation is essential for accurate diagnosis, individualized management, and addressing the psychosocial impact in young adults.

EP1421 - ECE_1608 - Macrophage dynamics in polycystic ovary syndrome: unraveling immune contributions to ovarian dysfunction

Heli Jokela, Katja Eubler, Heidi Gerke and Pia Rantakari

Turku, Finland

Polycystic ovary syndrome (PCOS) is a heterogeneous endocrine disorder characterized by androgen excess, disrupted folliculogenesis, and chronic anovulation. In addition to endocrine abnormalities, increasing evidence suggests that PCOS is associated with low-grade inflammation within the ovary. Macrophages—immune cells that regulate tissue remodeling, steroidogenesis, and inflammatory responses—are abundant in the healthy ovary and play essential roles in follicle development and ovulation. However, how ovarian macrophage populations are altered in PCOS, and whether these changes contribute to ovarian dysfunction, remain poorly understood.

Ovaries contain multiple macrophage populations with distinct developmental origins and functions. Tissue-resident macrophages arise during development and support normal tissue development and homeostasis, whereas monocyte-derived macrophages can also populate tissues under steady-state conditions but are often recruited from the circulation in response to inflammatory cues. Disruption of the balance between these populations has been implicated in chronic inflammatory diseases, yet their relative contributions to PCOS remain undefined. We hypothesize that altered macrophage composition and activation states contribute directly to the inflammatory and endocrine dysregulation characteristic of PCOS, which we will investigate using Letrozole and DHT-induced mouse models that recapitulate key features of the human disorder.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Both wild-type mice and fate-mapping mice will be used to identify how monocyte-derived and tissue-resident macrophages contribute to ovarian immune alterations in PCOS. Ovarian immune cells will be analyzed using complementary single-cell RNA sequencing, flow cytometry, and imaging to define macrophage composition, activation states, and localization. In parallel, archived human ovarian FFPE samples from women with PCOS and healthy controls will be analyzed to assess immune cell localization within the ovary, focusing on macrophages, to validate and extend murine findings.

This approach is expected to reveal remodeling of ovarian macrophages in PCOS, including changes in origin and inflammatory programs, providing mechanistic insight into how immune dysregulation affects ovarian function. Defining these macrophage pathways may identify targets for interventions to mitigate PCOS-associated ovarian dysfunction.

EP1422 - ECE_1621 - Dynamic changes of metabolic parameters during pregnancy

Violeta Mladenović[1], Dragana Bubanja[1], Nebojsa Igrutinovic[1], Zeljko Ivosevic[1] and Zoran Gluvic[2,3]
[1]*Faculty of medical sciences, Univeristy of Kragujevac», University Clinical Center «Kragujevac», Serbia, Clinic for Endocrinology, Diabetes and Metabolic Diseases, Kragujevac, Serbia;* [2]*Division of Internal medicine, Zemun Clinical Hospital Center, Dept of Endocrinology, School of Medicine, University of Belgrade, Belgrade, Serbia;* [3]*Faculty of Medicine, Department of Endocrinology, Zemun Clinical Hospital, University of Belgrade, Belgrade, Serbia*

Introduction: Pregnancy as a state of insulin resistance that can predict diabetes development in some women, usually manifests at the beginning of the third trimester, and is associated with increased risk for neonate and for mother. Serum lipids increased physiologically with gestational age in middle and late pregnancy. The establishment of reference intervals for serum lipids in pregnancy will help to distinguish abnormal serum lipid levels in middle and late pregnancy.

Aim: The aim of this study is to analyse metabolic parameters (lipids) during pregnancy.

Matherial and Methods: The research included 92 pregnant women registered in Clinic for endocrinology UCC Kragujevac that were tested who met the inclusive criteria, average age 30.8 ±4.7 years, with a range of 19 to 41 years. Of the 92 pregnant women diagnosed with vital and preferred pregnancies up to 12. gestational week, and received a signed form of the Informed Consent, 7 pregnant women had a spontaneous abortion, while 8 pregnant women gave up, so that 77 pregnant women completed the examination. The sample size included women in each trimester and 4 weeksd after delivery. The characteristics of the participants were expressed as mean ± standard deviation.

Results: It has been shown that as pregnancy progresses, the value of lipid parameters increases, especially total cholesterol and triglycerides. The highest increase was seen in the 3rd trimester of pregnancy (Figure). The average values are shown in Table.

Conclusions: The differences in the parameters of liporegulation during pregnancy is expressed in the second and third trimesters, while it does not appear in the first trimester. The highest increase in lipid parameters was demonstrated in the third trimester of pregnancy.

Keywords pregnancy, lipids

EP1423 - ECE_2477 - Primary amenorrhea in an underweight adolescent: diagnostic and therapeutic challenges in hypogonadotropic hypogonadism

Roxana Enachescu[1] and Bogdan Pascu[1,2]
[1]*Pediatric Endocrinology, Institutul Național Pentru Sănătatea Mamei și Copilului, București, Romania;* [2]*Universitatea de Medicină și Farmacie Carol Davila, București, Romania*

Primary amenorrhea in adolescents requires careful evaluation to differentiate constitutional delay of puberty from hypogonadotropic hypogonadism, particularly in the setting of severe undernutrition.**Clinical Case:** A 16-year-old female presented with primary amenorrhea, marked underweight (BMI 15.4 kg/m^2), and delayed bone age (13.5 years). Baseline hormonal evaluation showed low gonadotropins (FSH 3.25 mIU/mL, LH 0.24 mIU/mL) and low estradiol (11.8 pg/mL). Pelvic ultrasound demonstrated a hypoplastic uterus (3.8 cm) with small ovaries, while brain MRI excluded structural hypothalamic–pituitary abnormalities. Karyotype analysis confirmed a normal 46,XX pattern. GnRH stimulation testing revealed a suboptimal gonadotropin response (FSH 12.02 mIU/mL, LH 4.87 mIU/mL) with persistently low estradiol, supporting the diagnosis of hypogonadotropic hypogonadism. Pubertal induction was initiated using transdermal estradiol (25 µg/day, subsequently increased to 37.5 µg/day). After 19 months of therapy, estradiol concentrations increased to 231 pmol/L, breast development progressed to Tanner stage 4-5, and uterine length increased from 3.8 cm to 6.3 cm, with an endometrial thickness of 8.7 mm. Gonadotropin levels remained suppressed, and nutritional status showed no significant improvement. Progestogen therapy was planned either after the onset of breakthrough bleeding or, in its absence, after approximately 2 years of continuous estrogen therapy.

Conclusions: This case highlights the importance of timely diagnosis and gradual estrogen replacement in adolescents with hypogonadotropic hypogonadism, even in the context of persistent undernutrition. A progressive pubertal induction strategy, combined with nutritional rehabilitation, is essential to support normal pubertal development and to reduce long-term reproductive and skeletal risks.

EP1425 - ECE_3143 - The role of androgen excess in obesity and adipose tissue dysfunction in polycystic ovary syndrome

Valentina Soldat Stankovic[1], Gabrijela Malesevic[1], Snjezana Popovic Pejicic[1], Aleksandra Markovic[1] and Djuro MacUt[2,3]
[1]*Faculty of medicine, Univesity Clinical Center Republic of Srpska BAnja LUka, Internal Medicine, Endocrinology, University of Banja Luka, Banja Luka, Bosnia and Herzegovina;* [2]*Faculty of Medicine, University of Belgrade, University Clinical Centar, Belgrade, Serbia;* [3]*Clinic for Endocrinology, Diabetes and Diseases of Metabolism, Belgrade, Serbia*

Introduction: Low adiponectin levels in polycystic ovary syndrome (PCOS) are mainly attributed to obesity, which is common among these patients. In addition, evidence also suggests that

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

low adiponectin in PCOS may be associated with androgen excess in these women.

The aim: of this study was to investigate the association of adiponectin levels with body mass and androgen levels in women with PCOS.

Materials and Methods: A total of 60 women with PCOS who fulfi lled the Rotterdam diagnostic criteria from 2003 and 60 control women without PCOS, matched by age and body mass index, were recruited. We determined anthropometric parameters, metabolic and endocrine indicators, serum adiponectin and infl ammatory markers and statistically analyzed the results.

Results: Women with PCOS had signifi cantly lower levels of adiponectin ($P < .01$) compared to healthy women. Adiponectin level was inversely correlated with body mass index (BMI), waist circumference (WB), body fat mass, triglycerides, homeostasis model assessment HOMA IR, insulin AUC, glucose AUC, total testosterone, dehydroepiandrosterone sulfate (DHEAS) and free androgen index (FAI), and positively correlated with sex hormone-binding globulin (SHBG) and high-density lipoprotein cholesterol (HDL) in the PCOS group. In multivariate logistic regression, BMI and FAI were signifi cant independent determinants of the adiponectin cut-off level of 7.7 mg/mL.

Conclusions: Our results confi rm that adiponectin concentrations change according to BMI variations in women with PCOS. They also suggest a role for androgen excess in obesity and adipose tissue dysfunction in women with PCOS.

Abstract citation ID: lvag096.1616

EP1427 - ECE_2955 - Dual ovarian disorders: understanding concurrent PCOS and POI

Shebina Liz Mathews, Kabeer Katariya, Ann Francis and Cornelius Fernandez James
Diabetes and Endocrinology, Pilgrim Hospital, Boston (United Lincolnshire Hospitals NHS Trust), Boston, United Kingdom

Introduction: Polycystic ovary syndrome (PCOS) affects 6%-13% women of reproductive age, characterized by hyperandrogenism, oligo-amenorrhea, and polycystic ovarian morphology. This is traditionally regarded as pathophysiologically distinct from premature ovarian insufficiency (POI), which involves impaired ovarian function before the age of 40, characterized by amenorrhea >4 months, and FSH >25 IU/L on two occasions, four weeks apart. As these conditions are considered opposing diagnoses, their overlap presents a diagnostic challenge.

Case: A 36-year-old woman with a background of hypothyroidism and depression presented in 2021 with secondary amenorrhea, clinical hyperandrogenism (hirsutism, thinning of scalp hair), and excessive weight gain (BMI 44.9). Initial blood tests revealed: FSH 23.2 IU/L, LH 13.1 IU/L, 17-β estradiol 65 pmol/L, and testosterone 2 nmol/L (hyperandrogenism with hypoestrogenism). Repeat tests after clinic visit: FSH 48.2, LH 35.0, testosterone 2.6, SHBG 15, free androgen index (FAI) 17.3, and prolactin 314 (hyperandrogenism with possible POI). Subsequent testing: FSH 20, LH 14.8, 17-β estradiol 61, testosterone 1.8, SHBG 21, FAI 8.6, DHEA-S 13 µmol/L, 17-α hydroxy progesterone 0.8, TSH 2.4, FT4 15.2, and AMH <0.3 pmol/L. These results confirmed the diagnosis of overlapping PCOS and POI. Ovarian antibodies: negative. Cytogenetics and karyotyping: normal. DEXA: normal BMD. The patient was counselled on diagnosis, fertility implications, weight reduction strategies and fertility preservation options like oocyte cryopreservation. Subsequently, she was started on transdermal estradiol and micronized progesterone when she developed vasomotor symptoms.

Discussion: This case highlights that PCOS–POI can overlap and underscores the importance of longitudinal endocrine assessment in women with atypical PCOS presentations. Fluctuating FSH levels seen in POI due to residual ovarian function can delay the diagnosis. Persistent hyperandrogenism is not a feature of POI. Similarly, hypoestrogenism is not a feature of PCOS. Hence, a combination of persistent hyperandrogenism and hypoestrogenism should raise the possibility of an overlap syndrome. 10%-12% of POI have chromosomal abnormalities, 5% are autoimmune, remaining idiopathic. The proposed mechanisms include accelerated follicular atresia, chronic follicular arrest, and metabolic or inflammatory influences on ovarian reserve.

Conclusions: A subset of women with PCOS may have an increased risk of developing POI. Hence, PCOS is a significant (eightfold) and independent risk factor for later development of POI. Early recognition of POI in women with PCOS is essential to facilitate timely fertility counselling, consideration of fertility preservation, and appropriate initiation of HRT or lifestyle modifications to mitigate long-term risks, including osteoporosis and cardiovascular disease.

EP1428 - ECE_2286 - Clinical profile of hypogonadism patients attending tertiary endocrine center in Nepal

Ansumali Joshi[1,2], Srijana Karmacharya[1], Puspa Dahal[1], Smriti Khadka[1], Radhika Tuladhar[1] and Sapana Yadav[1]
[1]*Kathmandu Diabetes and Thyroid Center, Lalitpur, Nepal;*
[2]*Kathmandu Diabetes and Thyroid Centre, Kathmandu, Nepal*

Hypogonadism patients' data is lacking in Nepal. We retrospectively reviewed data of all hypogonadism patients, who attended our clinic from 2010 to 2024. There was total 101 patients, male 74(73.27%) and females 27(26.73%) with M: F ratio 2.71: 1. Mean age was 29.47 ± 12.01 years, mean weight was 66.23 ± 20.75 kg and mean BMI was 25.62 ± 6.01 kg/m^2. Presenting symptoms and signs were decreased libido in 29 patients (28.71%), erectile dysfunction in 29 males (39.18%), menstrual abnormalities in 17 females (62.96%), primary amenorrhea in 7 females (25.92%), small phallus in 1 male (1.35%). Infertility was seen in 9 patients (8.91%). Small testes were seen in 8 males (10.81%). Cryptorchidism was seen in 3 males (4%). Absent secondary sexual characteristics was seen in 22 patients (21.78%). Gynecomastia was seen in 15 males (20.27%). Hypergonadotropic hypogonadism was seen in 46(45.54%) patients and hypogonadotropic hypogonadism seen in 43(42.57%) patients. Functional hypogonadism was seen in 12(11.88%) patients, and their mean BMI was 32.58 ± 9.03 kg/m^2. Anosmia was seen in 1 patient with hypogonadotropic hypogonadism. Testicular volume was 5.10 ± 3.83 mL and Stretched Penile Length (SPL) was 5.57 ± 1.95 cm. Main cause of hypergonadotrophic hypogonadism was idiopathic in 19 patients (18.81%), followed by Turner syndrome in 11(10.89%), history of orchitis in 5(4.95%), Klinefelter syndrome in 4(3.96%), premature ovarian failure in 3(2.97%), cryptorchidism in 3(2.97%) and XX syndrome in 1(0.99%). The main cause of hypogonadotropic

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

hypogonadism was idiopathic in 28 patients (27.72%), hypopituitarism in 5(4.95%), Nonfunctioning Pituitary adenoma (NFPA) in 4(3.96%), Hyperprolactinemia in 4(3.96%), Sheehan's syndrome in 1(0.99%) and head injury in 1(0.99%). Comorbidities were diabetes in 17 patients (16.83%), hypertension in 14 patients (13.86%) and hypothyroidism in 29 patients (28.71%). Mean testosterone level was 2.20 ± 4.21 ng/mL in male patients. Mean LH were 3.08 ± 2.84 IU/L and FSH 4.09 ± 5.38 IU/L in hypogonadotropic hypogonadism and LH were 24.74 ± 11.75 IU/L, FSH were 51.25 ± 38.53 IU/L and prolactin were 20.05 ± 26.95 ng/mL in hypergonadotropic hypogonadism.

EP1435 - ECE_1192 - Symptomatology during the perimenopausal and menopausal phases: a cross-sectional analysis of 220 women

Shahina Ishtiaq[1,2]
[1]Obstetrics and Gynecology, Ziauddin University Hospital, South City Hospital, Karachi, Pakistan; [2]Obstetrics and Gynaecology, Ziauddin University Hospital, Karachi, Pakistan

Background: Menopause is a natural but complex transition in a woman's life, characterized by a wide range of physical, cognitive, and emotional symptoms that can significantly affect daily functioning and overall quality of life. The prevalence, pattern, and impact of these symptoms vary among individuals, making it essential to understand their nature for effective clinical management and timely interventions.

Objective: To evaluate the most common physical, cognitive, and emotional symptoms experienced by women during the perimenopausal and menopausal phases.

Materials and Methods: A cross-sectional study was conducted among 220 women aged 40-60 years in the perimenopausal or menopausal stage, recruited from outpatient clinics at Ziauddin Hospital Karachi. A structured questionnaire was used to assess physical, cognitive, and emotional symptoms. Data were analyzed by calculating frequencies and percentages for each symptom, and the mean number of symptoms per participant was determined to assess overall symptom burden.

Results: The most prevalent symptoms were hot flashes (74.1%), irregular periods (64.1%), and sleep disturbances (63.2%). Other frequently reported issues included low sexual desire (55%), poor concentration (42.3%), joint and muscle pain (39.5%), fatigue (34.5%), mood swings (33.2%), anxiety (15%), and depression (14.1%). On average, participants reported 4.35 ± 1.6 symptoms, reflecting a substantial symptom burden and the multifaceted nature of menopausal experiences.

Conclusions: Menopausal symptoms are multifaceted and vary widely among women. These findings emphasize the need for a comprehensive, patient-centered approach that addresses physical, cognitive, and emotional health to improve overall quality of life during the menopausal

EP1436 - ECE_3264 - A case of primary hypogonadism in early life: its clinical features, approach, and management

Anton Angelo Urtula[1] and Lisa Angelica Evangelista[2]
[1]Internal Medicine, National Kidney and Transplant Institute, Quezon City, Philippines; [2]Green City Medical Center, Quezon City, Philippines

Background: Primary hypogonadism is defined by the failure of the testes to produce adequate levels of testosterone despite normal or high levels of gonadotropins. Its presentation varies according to the stage of life it develops.

Case Presentation: This is a case of a 26-year-old male who presented with ambiguous genitalia upon birth along with delayed secondary sex characteristics during puberty. On physical exam, testes were nonpalpable, penile shaft was underdeveloped, pubic and axillary hair were sparse or absent, breasts were prominent. On further testing, serum testosterone and estradiol were remarkably low, while LH and FSH were elevated. Thyroid hormones and serum cortisol were within normal levels. Other labs showed osteoporosis and dyslipidemia undue for age. Cranial imaging was nearly unremarkable. Karyotyping revealed a normal 46 XY karyotype

Outcome: The patient was prescribed with topical testosterone replacement therapy, along with statins and Vitamin D supplementation. Genetic testing and pelvic MRI were ordered for final confirmation of underlying cause.

Conclusions: This case highlights the varied presentation of primary hypogonadism, its natural history, and its approach to evaluation and treatment. Prompt work-up and management are needed to identify the primary etiology and to address its systemic manifestations.

Keywords hypogonadism, hypergonadotropic hypogonadism, testicular failure, disorders of sex development

EP1437 - ECE_3493 - When hormones are normal: idiopathic gynecomastia in a young male

Inass Chaari[1], Ayoub Idrissi[2], Lahoussaine Abainou[3], Hamza El Jadi[4], Azzelarab Meftah[5] and Hicham Baïzri[5]
[1]Endocrinology, Diabetes and Metabolism, Avicenna Military Hospital, Marrakech, Morocco; [2]Endocrinology, Diabetology and Metabolic Diseases, Avicenna Military Hospital, Marrakech, Morocco; [3]Endocrinology, Diabetes and Metabolism, Oued Eddahab Military Hospital, Agadir, Morocco; [4]Marrakech, Morocco; [5]Endocrinology, Diabetes and Metabolism, Avicenna Military Hospital, Marrakech, Morocco

Gynecomastia, defined as the benign proliferation of glandular breast tissue in males, represents a frequent clinical presentation in the endocrine clinic. While often physiological during puberty due to transient hormonal fluctuations, its persistence into late adolescence and young adulthood necessitates a rigorous diagnostic approach to exclude underlying pathologies.

We present the case of a 31-year-old male presenting with a one-year history of progressive, bilateral, and painless breast enlargement . The patient reported no history of medication use, anabolic steroid consumption, or exposure to phytoestrogens. Physical examination confirmed the presence of firm, concentric subareolar tissue without signs of galactorrhea, nipple retraction, or lymphadenopathy. Testicular volume and secondary sexual characteristics were appropriate for Tanner Stage V.

Breast ultrasound revealed gynecomastia.Laboratory investigations showed normal testosterone levels (3.16 ng/mL), FSH

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

at 1.15 IU/L, LH at 2.84 IU/L, 17β-estradiol at 30 pg/mL, and normal prolactin levels.. Tumor markers (β-hCG and α-fetoprotein) were negative, and thyroid, hepatic, and renal functions were normal. Scrotal ultrasonography revealed no occult malignancies.

Idiopathic cases account for approximately 25% to 50% of gynecomastia presentations. In young adults, the condition is hypothesized to result from an increased sensitivity of breast tissue to circulating estrogens or a localized imbalance in the aromatase enzyme activity within the breast microenvironment. While the biochemical profile remains unremarkable, the psychological impact on young patients is often profound, frequently requiring a multidisciplinary approach involving endocrinologists, psychologists, and plastic surgeons.

This case highlights the clinical paradox of idiopathic gynecomastia, where significant physical changes occur despite a normal hormonal milieu. Management should prioritize patient reassurance and monitoring,

EP1438 - ECE_2797 - Recognising turner syndrome in primary care- an adolescent presenting with primary amenorrhea

Christina Lymniati, Katerina Papadopoulou, Aggeliki Mela and Charalampos Tsentidis
Endocrinology, Diabetes Mellitus and Metabolism Department, General Hospital of Nikaia Piraeus "AG. Panteleimon", Piraeus, Greece

Aim: To describe the diagnostic pathway and early management of an adolescent presenting with primary amenorrhea in a primary care setting, highlighting the recognition of clinical features suggestive of Turner syndrome (TS) and the importance of timely referral for specialized endocrine assessment.

Methods: A 14-year-and-10-month-old girl was referred from the emergency department to endocrinology following incidental detection of subclinical hypothyroidism. Clinical evaluation included anthropometric assessment, pubertal staging, dysmorphology examination, hormonal profiling, pelvic ultrasonography, bone age determination, and cytogenetic analysis. Findings were interpreted according to current international guidelines for the evaluation of primary amenorrhea and the management of TS.

Results: The patient presented with short stature (3rd percentile), Tanner stage I pubertal development, and multiple dysmorphic features (webbed neck, micrognathia, shield chest, widely spaced nipples, cubitus valgus). Laboratory evaluation demonstrated hypergonadotropic hypogonadism (FSH 74.1 μIU/mL, LH 11.8 μIU/mL, estradiol <11.8 pg/mL), low IGF-1, and mildly elevated TSH. Pelvic ultrasonography revealed a hypoplastic uterus and non-visualized ovaries. Bone age corresponded to 13 years. Karyotype confirmed monosomy X (45,X), establishing the diagnosis of Turner syndrome.

Given the delayed diagnosis and limited remaining growth potential, the patient was submitted for approval of growth hormone (GH) therapy and simultaneously initiated on low-dose transdermal 17β-estradiol for pubertal induction. A structured titration plan was established, with gradual escalation of estrogen dosing and planned introduction of cyclic progesterone following the first breakthrough bleed. Multidisciplinary follow-up was arranged to address cardiovascular, metabolic, reproductive, and psychosocial aspects of TS.

Conclusions: Primary amenorrhea, particularly when accompanied by short stature and dysmorphic features, should prompt evaluation for Turner syndrome. Early recognition in primary care is crucial for optimizing long-term outcomes. Concurrent initiation of GH and estrogen therapy in late-diagnosed patients supports both growth potential and appropriate pubertal development. Lifelong, multidisciplinary management is essential due to the broad spectrum of comorbidities associated with TS.

EP1439 - ECE_3455 - Body weight strongly influences the metabolic phenotype in women with polycystic ovary syndrome

Sabrina Marville[1], Nelly Pitteloud[2] and Adelina Ameti[2]
[1]*Université de Lausanne, Lausanne, Switzerland;* [2]*Division of Endocrinology, Diabetes & Metabolism, Centre Hospitalier Universitaire Vaudois (CHUV), Lausanne, Switzerland*

Background: Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women of reproductive age, affecting approximately 10%. It is characterized by ovulatory dysfunction, hyperandrogenism and/or polycystic ovarian morphology on ultrasound. Beyond reproductive manifestations, PCOS is associated with an increased burden of metabolic abnormalities, including insulin resistance and dyslipidaemia.

Objective: To describe the clinical, hormonal and metabolic characteristics of women with PCOS followed in our centre and to compare normal-weight and obese phenotypes.

Methods: This retrospective study was based on the Endocrinology, Diabetes and Metabolism (EDM) database at Lausanne University Hospital (CHUV). PCOS was defined by Rotterdam criteria after exclusion of secondary causes. Women on treatments likely to interfere with hormonal/metabolic parameters at the time of assessment (eg, oral contraceptives, metformin/GLP-1 receptor agonists, spironolactone) were excluded.

For group comparisons, normal-weight (BMI <25 kg/m^2) and obese women (BMI ≥30 kg/m^2) were analysed; overweight women were excluded. Clinical, hormonal and metabolic data were collected. Sex steroids were measured by mass spectrometry, while other biochemical parameters were measured using immunoassays.

Results: Ninety-nine women were included. Phenotype A (hyperandrogenism + ovulatory dysfunction + polycystic ovarian morphology) and phenotype B (hyperandrogenism + ovulatory dysfunction) predominated (57.6% and 21.2%), and polycystic ovarian morphology was present in 79.8%.

For group comparisons, 24 normal-weight and 53 obese women were analyzed. Menstrual disturbances did not differ between groups (oligomenorrhoea 70.8% vs 67.9%; amenorrhoea 12.5% vs 15.1%; regular cycles 12.5% vs 17.0%; all $P > .05$). Acne was more frequent in normal-weight women (75.0% vs 35.8%, $P = .003$). Obese women had significantly higher fasting glucose, fasting insulin and HOMA-IR (8.21 ± 7.85 vs 2.01 ± 0.85, $P = .003$). Dyslipidemia was more prevalent in obese women (66% vs 19.6%, $P < .001$), with higher triglycerides ($P = .001$), lower HDL-cholesterol ($P < .001$), higher LDL-cholesterol ($P = .01$) and a higher triglyceride/HDL ratio ($P < .001$). SHBG concentrations were significantly lower in obese women (25.79 ± 12.33 vs 69.36 ± 61.81 nmol/L, $P < .001$), whereas total testosterone,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

androstenedione and DHEA-S levels were similar between groups (all $P > .05$).

Conclusions: Obesity is strongly associated with a worse metabolic profile in women with PCOS, characterised by marked insulin resistance and dyslipidaemia, while circulating androgen concentrations are broadly comparable across weight categories. These findings highlight the central metabolic impact of adiposity and support systematic cardiometabolic screening and weight-focused management in PCOS.

Abstract citation ID: lvag096.1623

EP1441 - ECE_1387 - Prader–willi syndrome—from diagnosis to substitution therapy

Mirjana Bojic[1], Anja Stanic[1], Ivona Risovic[1,2], Tamara Dojcinovic[1,2] and Aleksandra Markovic[1,2]
[1]*University Clinical Center of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina;* [2]*Faculty of medicine, University of Banja Luka, Banja Luka, Bosnia and Herzegovina*

Prader–Willi syndrome is a rare genetic disorder involving chromosome 15, characterized by hypotonia, a characteristic facial appearance (reduced bifrontal diameter), convergent strabismus, and intellectual disability. In boys, it is usually accompanied by cryptorchidism and a hypoplastic scrotum.

We present the case of a patient who initially consulted a urologist due to priapism, after which further endocrinological evaluation was recommended. Hormonal testing revealed elevated estradiol levels with low testosterone levels, while clinical examination showed obesity and cryptorchidism. Due to cryptorchidism, urological treatment was performed, followed by repeat endocrinological evaluation, after which testosterone replacement therapy was initiated. This led to a reduction in body weight, voice deepening, development of male-pattern body hair, and overall clinical improvement. Review of the patient's medical documentation revealed that genetic testing had been performed at birth and the diagnosis of Prader–Willi syndrome had already been established; however, appropriate therapy had not been initiated at that time.

This case highlights the importance of early detection and appropriate long-term follow-up by an endocrinologist, as this enables timely initiation of adequate substitution therapy as well as prompt urological surgical intervention when indicated.

EP1443 - ECE_3074 - Implementing U.S.-validated AI practices in healthcare: AI-based clinical decision support with personalized nutrition planning for polycystic ovary syndrome in Republic of Georgia

Mariam Pailodze[1,2] and Salome Kalandadze[1,3]
[1]*Caucasus Medical Centre, Tbilisi, Georgia;* [2]*David Tvildiani Medical University, Tbilisi, Georgia;* [3]*Endocrinology, Caucasus Medical Center, Tbilisi, Georgia*

Background: Polycystic ovary syndrome (PCOS) is a prevalent endocrine disorder associated with metabolic dysfunction, insulin resistance, and significant long-term health risks. Nutrition and lifestyle modification are core components of PCOS management; however, in low-resource health care systems, including Georgia, access to structured, personalized nutritional counseling remains limited. In high-income settings such as the United States, artificial intelligence (AI)–based clinical decision support and nutrition platforms have demonstrated feasibility and effectiveness in metabolic disease management. Their applicability in lower-resource, culturally distinct healthcare systems has not been systematically evaluated.

Objective: To explore the feasibility and implementation strategy of adapting U.S.-validated AI-based nutrition decision-support models for outpatient PCOS care within the Georgian health care system, with a focus on physician supervision, patient trust, and cultural acceptability.

Methods: This mixed-methods implementation study consists of three phases: (1) a scoping review of U.S.-validated AI nutrition and lifestyle interventions used in outpatient metabolic and endocrine care; (2) a cross-sectional survey assessing Georgian women with PCOS regarding attitudes toward AI-assisted healthcare, trust, and cultural dietary preferences; and (3) a pilot outpatient intervention in which AI-generated personalized nutrition plans are reviewed and approved by physicians prior to patient use. Feasibility, acceptability, and early clinical signals (diet adherence, patient satisfaction, and selected metabolic indicators) will be assessed.

Expected Impact: This project aims to generate the first evidence-based framework for trustworthy, culturally adapted AI-enabled nutrition care for PCOS in Georgia. Findings will inform scalable strategies for integrating AI into low-resource primary care systems while preserving clinician oversight and strengthening the doctor–patient relationship.

EP1446 - ECE_2942 - Finasteride for treatment of androgenic male alopecia since puberty: case report

Fedir Laniush and Alina Urbanovych
Endocrinology, State Non-Profit Enterprise "Danylo Halytsky Lviv National Medical University", University Clinic State non-profit enterprise "Danylo Halytsky Lviv National Medical University", Lviv, Ukraine

Background: Androgenic male alopecia is a condition affecting millions of men worldwide inducing significant psychological distress and a strong desire for an early intervention and leading to an increase in off label usage of the drugs among adolescents.

Clinical case: A 21-year man visited an endocrinologist to check his hormones. He has a history of 7-year Finasteride applying because of a fear of losing his hair. He had been taking Finasteride since the age of 14 when he had first noted losing his hair. He had a history of androgenic alopecia since his older brother also started losing his hair during puberty. The patient did not attend endocrinologist previously and found information about Finasteride on internet. During these years he had been checking his hormones on his own. During examination: the hair growth is preserved and there were no signs of alopecia of any kind. Laboratory data: total testosterone 30,1 nmol/L (4.10-32.92); sex hormone-binding globulin 36.7 nmol/L (14.8-95); the free testosterone index 82.01% (14.55-94.64); estradiol 25.6 pg/mL; luteinising hormone (LH) 2.56 U/L (1.24-8.62); follicle-stimulating hormone (FSH) 3.52 U/L (1.27-19.26); prolactin 9.5 ng/mL (2.64-13.13). Patient was absolutely satisfied with his sex life and did not express any symptoms off loss of libido or erectile dysfunction.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusion: Finasteride is one of the among approved drugs for the treatment of androgenic alopecia in men aged 18 and older and benign prostatic hyperplasia (BPH). Despite the food and drug administration (FDA's) approval for usage of Finasteride in adults, off-label usage in adolescents is increasing in the recent times, primarily due to online misinformation and the psychological impact of early hair loss. Several studies have been done to show that patient's treated with Finasteride had an increase rate of development for high grade prostate cancer. The other side effects of these drug include impotence, decreased libido, decreased volume of ejaculate, gynecomastia, depression and mood changes, allergic reactions, and the most challenging Post—Finasteride syndrome which is characterised by side effects persisting after stoppage of the drug. Although Finasteride is designed to reduce hair loss but it's effect are temporary upon discontinuing the drug the hair loss resumes leaving behind distress and dissatisfaction. The usage of this drug among adolescents need more further investigations and research works

EP1905 - ECE_3337 - In vitro endometrium of insulin resistant women with polycystic ovary syndrome

Anja Dekanski[1], Gustaw Eriksson[1], Tanja Turunen[1], Timotej Strmen[2], Tina Gorsek Sparovec[1], Angelica Lindén Hirschberg[3], Elin Chorell[2], Nayere Taebnia[1] and Elisabet Stener-Victorin[1]

[1]*Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden;* [2]*Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden;* [3]*Department of Women's and Children's Health, Karolinska Institutet, Karolinska University Hospital, Stockholm, Sweden*

Introduction: Endometrial dysfunction in polycystic ovary syndrome (PCOS) can lead to reduced fertility, miscarriage, and higher endometrial cancer risk. Additionally, our recent PCOS endometrial single-cell atlas shows cell type specific transcriptomic disease signatures. *In vitro* endometrial systems mirroring the PCOS tissue of origin is crucial for future mechanistic insight and novel target testing. We hypothesized that PCOS-associated endometrial disease features can be preserved in primary human endometrial epithelial organoids (EEOs) and single-layer stromal cells, under optimized conditions.

Methods: We established and characterized EEOs ($n = 4$ PCOS; $n = 4$ controls) and stromal cells ($n = 6$ PCOS; $n = 6$ controls) from proliferative phase endometrial biopsies of women with and without PCOS. Women with PCOS were hyperandrogenic and insulin resistant. Both cell systems were differentiated with 10 nM estradiol and 1 uM progesterone. EEOs and stromal cells were collected for bulk RNA sequencing and stained for typical differentiation markers. In stromal cells, we also performed lipidomics using liquid chromatography coupled to quadrupole time-of-flight mass spectrometry, and cellular bioenergetics using Seahorse XFe96. Additionally, we used a PCOS-like anovulatory hormonal environment and a healthy hormonal environment with estrogen, progesterone and androgen levels fluctuating. We tried EEO stimulation in these hormonal environments in both a static and microfluidic setting.

Results: In the initial EEO set-up very few transcriptomic differences were captured between PCOS and Control origin cells. In stromal cells, progesterone receptor staining was reduced, and maximal respiration trended lower in PCOS. Differentially expressed genes (DEGs) in stromal cells included upregulation of fibro activation protein (*FAP*) gene and downregulation of *CARD16*. Lipidomics analysis showed PCOS stromal cells uniquely accumulated insulin-resistance-associated ceramides during differentiation. At day 14, PCOS stromal cells had significantly elevated C20-ceramide and reduced cardiolipins. Fluctuating hormonal environment and the microfluidics setting were able to recapitulate more of the transcriptomic differences between PCOS and Control in EEOs.

Conclusions: Preliminary data shows that in the static hormonal environment *in vitro*, that does not closely recapitulate neither the normal menstrual cycle nor the PCOS irregular menstrual cycle, the EEOs lose most of their PCOS phenotype *in vitro*, while stromal cells retain more of it. Mimicking the PCOS-like and healthy-like hormonal environment and using microfluidics exacerbated transcriptomic differences in EEOs. Stromal cells from women with PCOS had DEGs related to proliferation and inflammation, and lipid dysregulation associated with metabolic dysfunction. In the next steps we are establishing co-culture systems to combine EEOs and stroma, but also adipose and endometrial cells.

EP1906 - ECE_3543 - Cell type-specific endometrial dysfunctions across the menstrual cycle in polycystic ovary syndrome

Tanja Turunen[1], Congru Li[1], Riikka Arffman[2], Gustaw Eriksson[1], Tina Gorsek Sparovec[1], Ulla Saarela[2], Angelica Lindén Hirschberg[3], Terhi Piltonen[2] and Elisabet Stener-Victorin[1]

[1]*Karolinska Institutet, Solna, Sweden;* [2]*Medical Research Center, Department of Obstetrics and Gynecology, Research Unit of Clinical Medicine, University of Oulu and Oulu University Hospital, Oulu, Finland;* [3]*Department of Women's and Children's Health, Department of Gynecology and Reproductive Medicine, Karolinska Institutet and Karolinska University Hospital, Solna, Sweden*

Polycystic ovary syndrome (PCOS) affects 11%-13% of reproductive-aged women and is characterized by hyperandrogenism, polycystic ovarian morphology, and menstrual irregularities. It is a major cause of anovulatory infertility and affected women have an increased risk of implantation failure and miscarriage, likely due to endometrial dysfunction. Recently, we published the first PCOS Endometrial Cell Atlas (PECA 1.0), which revealed cell-type-specific disease signatures in proliferative-phase endometrium. Here, we comprehensively characterize how different cell types and their transcriptomic signatures evolve across the menstrual cycle in PCOS by establishing PECA 2.0. Endometrial biopsies were obtained, after informed consent, from women with and without PCOS who had similar age and BMI ($P > .05$ two-tailed Welch's t-test). Combined with the PECA 1.0 study (12 PCOS, 5 controls), our current single-nuclei (sn) RNA-seq dataset of 62 samples covers proliferative (7 PCOS, 7 controls), early secretory (6 PCOS, 3 controls), mid-secretory (7 PCOS, 5 controls), and late secretory phases (4 PCOS, 3 controls), as well as the anovulatory state (3 PCOS). Libraries were prepared from snap-frozen biopsies using Chromium GEM-X technology v 4.0 (10X Genomics). After data quality control, the final PECA 2.0 dataset included 998 832 high-

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

quality nuclei: 625 593 from PCOS and 373 239 from control endometrium. We identified four main clusters: epithelial ($n = 478$ 789), stromal ($n = 453$ 832), immune ($n = 55$ 708), and endothelial cells ($n = 10$ 503). Reintegration revealed 11 epithelial, 7 stromal, 5 endothelial, and 16 immune cell subpopulations. The proliferative phase PCOS endometrium has a decreased proportion of proliferative stromal cells (56.26%) compared to controls (92.96%; Mann-Whitney U, adj. $P = .124$; Levene's test, adj. $P = .018$). Moreover, disrupted decidualization was demonstrated by a decreased proportion of decidualized stromal cells in PCOS late secretory phase samples (45.77%) compared to controls (59.98%; Mann-Whitney U, adj. $P = .124$; Levene's test, adj. $P = .011$). Levene's test results indicate significantly greater variability in these cell proportions in PCOS samples. The PCOS Endometrial Cell Atlas across the menstrual cycle, PECA 2.0, maps cellular heterogeneity and reveals transcriptomic signatures of endometrial dysfunction in PCOS at high resolution. This resource provides a foundation for developing precise diagnostic tools, targeted therapies, and preventive strategies to improve endometrial health.

EP1907 - ECE_1821 - Development of a immunodeficient prenatal mouse model of polycystic ovary syndrome for evaluation of new therapeutics

Camille Gauthier[1], Haojiang Lu[1], Sara Torstensson[1], Luzi Sophie Schuchmann[1], Eva Lindgren[1], Claes Ohlsson[2], Anna Benrick[3] and Elisabet Stener-Victorin[1]
[1]*Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden;* [2]*Sahlgrenska Academy University Hospital, Gothenburg, Sweden;* [3]*Physiology, Sahlgrenska Academy, Gothenburg, Sweden*

Polycystic ovary syndrome (PCOS) affects ~10% of women and is the leading cause of anovulatory infertility, diagnosed by hyperandrogenism, irregular cycles, and/or a polycystic ovarian morphology. While PCOS is strongly associated with cardiometabolic comorbidities. Current treatments are symptom-based, with no targeted treatments available. A major obstacle in developing therapies is the immune response is leading to the production of anti-drug antibodies, which neutralize drug activity and alter efficacy. We aimed to establish a PCOS mouse model on an immunodeficient background to enable preclinical testing of novel therapeutics without immune interference.

Both wild-type (C57BL/6NTac, WT) and B cells deficient mice (C57BL/6NTac-Igh-Jem1Tac, KO) were used to generate prenatal androgenized (PNA) models. The PNA mode was induced by daily dihydrotestosterone (DHT) injections in pregnant dams at embryonic days 16.5, 17.5, and 18.5. Reproductive traits of F1 mice were assessed, including anogenital distance (AGD), a marker of in utero androgen exposure, puberty onset (vaginal opening), estrous cyclicity (vaginal smears measured at P70-P82 and P126- P138). Sex steroids, as well as AMH and FSH, were quantified in serum at P186 using LC/MS, ELISA, and Milliplex immunoassays, respectively. Metabolic traits were analyzed by EchoMRI (at P84, P112, P154), and glucose and insulin tolerance tests were performed at P147, P175 in F1 mice. Data were analyzed using the Mann–Whitney U test.

PNA mice on both WT and KO backgrounds exhibited delayed puberty onset ($P < .0001$, $P = .0015$), increased AGD ($P = .0036$, $P < .0001$), disrupted estrous cyclicity (diestrus block, both $P < .0001$), and anovulation ($P = .0027$, $P < .001$). Androgen levels were unchanged, but both WT and KO PNA mice showed elevated AMH levels ($P = .0252$, $P = .022$), and WT PNA mice exhibited lower FSH levels compared to controls ($P = .0431$). Body weight and composition were similar across groups, although KO-PNA mice displayed increased subcutaneous and visceral fat at sacrifice P186 ($P = .0252$, $P = .0214$). Glucose and insulin tolerance did not differ significantly between WT and KO mice.

In conclusion, B cell deficient PNA mice recapitulate key reproductive PCOS hallmarks, despite lacking adaptive immune system. Typical metabolic alterations were attenuated, with increased fat depots in KO mice as the only metabolic feature retained. Nevertheless, this PCOS-like model provides a robust platform for evaluating PCOS therapeutics while minimizing confounding effects from immune-mediated drug clearance.

Background: Laparoscopic ovarian drilling(LOD) is widely accepted as an effective second line treatment for infertility associated with polycystic ovary syndrome(PCOS). However, laparoscopy is an invasive procedure that requires general anaesthesia and carries significant risks. Furthermore, there is no standardization of the LOD technique among surgeons. In contrast, the Anavi™ System(CE Mark, May Health) has been designed to deliver a precisely calculated amount of ovarian ablation via a less invasive route without general anaesthesia. This transvaginal ultrasound (TVUS) approach therefore transforms an invasive surgical procedure to an office-based technique similar in ovarian access to the well-established oocyte retrieval. Here we report clinical outcomes of participants at 12-months following intervention

Methods: The ULTRA trial is a multicenter feasibility study that included two parallel single-arm studies conducted in Europe(EU; six centres) and the United States (US; one centre). The trial included women with anovulatory infertility associated with PCOS resistant to first line ovulation induction with Clomiphene citrate and/or Letrozole (CC/LETZ). All participants

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

were treated with TVUS-guided ovarian ablation using the May Health System. The first five participants in Europe underwent laparoscopy concurrent with the ovarian ablation. The remaining participants only underwent the TVUS-guided ovarian ablation procedure under sedation. Participants completed 3- and 6-month clinical assessment and 9- and 12-month telephone assessment.

Results: A total of 32 participants (27 EU, 5 US) were treated with TVUS-guided ovarian ablation. Feasibility and safety results of this trial have previously been reported. A total of 26 participants (81%) were evaluable at 12-months and included in this analysis. The mean [SD] age was 32.4 [3.4] years, BMI was 29.6 [5.0] kg/m^2 and 69% self-identified as white, 15% black and 15% other. Of those completing the 12-month follow-up, 20 (77%) ovulated including thirteen (50%) during the first three months post procedure and seven additional participants between three and 12 months after restarting CC/LETZ. A total of 12 (46%) participants conceived at least once within the 12-months post-procedure. Of those, ten conceived naturally (7 with and 3 without the restart of first-line ovulation induction medication). One participant conceived following IUI.

Conclusions: These preliminary data suggest that the previously reported clinical efficacy of TVUS-ovarian ablation using the Anavi System may be sustained at 12 months. Therefore, this may offer a potentially effective office-based second line ovulation inducing procedure for PCOS. A larger randomized study is currently in progress (REBLANCE; NCT06206746).

EP1449 - ECE_3573 - Graves' disease unmasked by pancreatitis and delirium in a patient with panhypopituitarism

Mariana De Griné Severino[1], Carolina Peixe[1], Catarina Isabel Lopes[1], Mariana Lopes-Pinto[1], Mariana Agapito Fonseca[1], Marta Vaz Lopes[1], Miguel Duarte[1], Teresa Alegria Neto[1], Maria Inês Alexandre[1,2], Ana Palha[3] and Ema Lacerda[1,2]

[1]Serviço de Endocrinologia, ULS Santa Maria, Lisboa, Portugal; [2]Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal; [3]Serviço de Endocrinologia, ULS São José, Lisboa, Portugal

Introduction: Graves' disease typically presents with adrenergic symptoms, weight loss, goiter and ophthalmopathy; however, severe systemic and neuropsychiatric manifestations may predominate and delay diagnosis. Hypercalcemia is an uncommon but recognized complication of thyrotoxicosis and, in rare cases, may precipitate acute pancreatitis. Diagnostic recognition is particularly challenging in patients with hypopituitarism receiving levothyroxine replacement, in whom TSH is unreliable, and symptoms overlap with pituitary hormone deficiencies or intercurrent illness.

Clinical case: A 38-year-old woman with history of panhypopituitarism following craniopharyngioma resection was admitted to the emergency department due to nausea, vomiting and acute behavioral changes for the previous 15 days, progressing to hyperkinetic delirium requiring intensive sedation. At admission, she was afebrile, tachycardic (HR 113 bpm) and hypertensive (BP 155/138 mmHg). Her chronic medication included desmopressin, levothyroxine 25 mcg, hydrocortisone, bisoprolol and escitalopram.

There were no recent therapeutic changes and she denied alcohol or illicit drug consumption. Initial blood tests showed marked hypercalcemia (Ca 14.3 mg/dL, corrected for albumin), liver dysfunction (AST 159 U/L, ALT 264 U/L, BilT 4.39 mg/dL, GGT 52 U/L) and a raised amylase of 206 U/L (RV 13-53); serum sodium was normal (Na 140 mmol/L). Abdominal imaging excluded biliary obstruction and showed diffuse pancreatic enlargement with stranding of surrounding fat and peripancreatic exudates, consistent with pancreatitis. Hypercalcemia-induced pancreatitis was presumed and treatment with intravenous fluids and pamidronate was started. Brain CT and MRI showed no structural abnormalities.

The etiologic investigation of hypercalcemia revealed low PTH (12.3 pg/mL) with thyroid tests revealing thyrotoxicosis (FT4 5,84 ng/dL and FT3 7,51 ng/dL), with positive TRAbs 5,73 U/L and US findings consistent with Graves' disease (diffuse increased vascularity). Levothyroxine was stopped and thiamazole initiated, resulting in gradual psychosis improvement and normalization of calcium levels, pancreatic enzymes and liver tests over the following week. Both hypercalcemia and delirium were attributed to hyperthyroidism.

Conclusions: In patients with hypopituitarism, Graves thyrotoxicosis may be overlooked due to nonspecific symptoms and reliance on TSH. Monitoring FT4/FT3 trends and recognition of red flags such as unexplained hypercalcemia/pancreatitis and severe neuropsychiatric symptoms are essential for timely diagnosis and management. Notably, three years later, this patient was readmitted with recurrent behavioural changes and hyperkinetic delirium and further investigation revealed decompensated hyperthyroidism once again, highlighting the need for sustained vigilance for atypical presentations of Graves' disease in patients with hypopituitarism.

EP1450 - ECE_3915 - Severe amiodarone-induced thyrotoxicosis: therapeutic plasma exchange as a bridge to urgent thyroidectomy

Ana Luísa Barbosa[1], Patricia Ferreira[1], Juliana Gonçalves[1], Mafalda Canudas Costa[1], Joana Lopes[2], Vítor Fernandes[2], Carlos Grijó[3], Ana Margarida Fonseca[3], Cristina Fernandes[4], Cláudio Silva[5], Patrícia Martins[2], Isabel Tavares[2], Marta Borges Canha[1], Jorge Pedro[1], Joana Queirós[1] and Ana Varela[1]

[1]São João Local Health Unit, Department of Endocrinology, Diabetes and Metabolism, Porto, Portugal; [2]São João Local Health Unit, Department of Nephrology, Porto, Portugal; [3]São João Local Health Unit, Department of Internal Medicine, Porto, Portugal; [4]São João Local Health Unit, Department of General Surgery, Porto, Portugal; [5]São João Local Health Unit, Infectious Diseases Intensive Care Unit, Porto, Portugal

Background: Amiodarone-induced thyrotoxicosis (AIT) is a condition with high cardiovascular mortality and presents with significant therapeutic challenges. In severe cases refractory to conventional medical therapy, therapeutic plasma exchange (TPE) followed by urgent total thyroidectomy should be considered.

Case presentation: Case 1: A 62-year-old man with severe ischaemic heart failure (HF) and atrial fibrillation (AF) on long-term amiodarone was admitted to the intensive care unit (ICU) for

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

acute myocardial infarction. He presented with overt thyrotoxicosis and was diagnosed with AIT. Treatment with methimazole and prednisolone was initiated and progressively titrated up to 40 mg/day and 70 mg/day, respectively. Despite a transient initial partial response, the patient developed persistent severe thyrotoxicosis and presented with cardiac deterioration and septic shock. Approximately 60 days after admission, two sessions of TPE were performed, resulting in significant biochemical improvement. The patient subsequently underwent total thyroidectomy. He died two days later due to multiorgan failure.

Case 2: A 48-year-old man with a history of HF, AF and AIT diagnosed three months earlier and treated with methimazole and prednisolone was hospitalized for acute left lower limb ischaemia. He underwent urgent revascularization, followed by cardiovascular instability and exacerbated thyrotoxicosis. Despite maximal medical therapy (methimazole and prednisolone up to 60 mg/day), severe thyrotoxicosis and hemodynamic instability persisted. TPE was initiated with biochemical improvement after three sessions, enabling total thyroidectomy without major perioperative complications, with favourable clinical outcome.

Case 3: A 37-year-old woman with a history of complex congenital valve disease and AF on amiodarone therapy was admitted to the ICU for thyroid storm complicated by AF with rapid ventricular response and hemodynamic instability. Treatment with propylthiouracil (500 mg followed by 200 mg orally every 4 hours), propranolol (80 mg orally every 4 hours) and intravenous hydrocortisone (300 mg bolus followed by 100 mg every 8 hours) was started. Given the lack of clinical response to medical therapy, TPE was initiated, with biochemical improvement after three sessions. Urgent total thyroidectomy was subsequently undertaken, complicated by postoperative hemodynamic instability requiring extracorporeal membrane oxygenation, but with gradual recovery thereafter.

Discussion: These cases illustrate severe, refractory AIT associated with marked cardiac instability and life-threatening complications in which rapid hormonal control is essential. In all patients, TPE allowed partial biochemical and clinical stabilisation, enabling urgent thyroidectomy. These cases highlight the importance of timely recognition of treatment failure and early consideration of TPE as a bridge to definitive surgical treatment, as delays in definitive therapy may be fatal.

EP1451 - ECE_2813 - Management challenges of lenvatinib in elderly patients with advanced radioiodine-refractory DTC: a case of fatal Takotsubo syndrome

Gianluca Cera[1], Pietro Locantore[1], Erika Motolese[1], Alessandro Romano[1], Laura Crispino[1], Luisa Lener[1], Andrea Corsello[2], Rosa Maria Paragliola[3] and Alfredo Pontecorvi[1]

[1]Roma, Italy; [2]Division of Endocrine Surgery, Ospedale Isola Tiberina —Gemelli Isola, Rome, Italy; [3]Departmental Faculty of Medicine, Unicamillus-Saint Camillus International University of Health Sciences, Rome, Italy

Background: Lenvatinib is an effective therapy for advanced radioiodine-refractory differentiated thyroid cancer (DTC), although various adverse effects frequently complicate clinical management. We present the case of an 84-year-old woman affected by DTC alongside comorbidities including severe COPD, hypertension, chronic venous insufficiency, and depression.

Case presentation: At age 78, the patient underwent total thyroidectomy for a TIR5 (Bethesda VI equivalent) thyroid nodule. Histopathology revealed a multifocal papillary thyroid carcinoma (left lobe: 2.2 cm; right lobe: 1 cm), classic subtype, featuring 25% solid and 25% “tall cell” components, endovascular emboli, and positive excision margins (pT2m R1). Post-surgery, she received radioactive iodine therapy (March 2019, 100 mCi); stimulated thyroglobulin was 2.6 ng/mL with negative antibodies and a negative whole-body scan. Subsequent endocrinological follow-up was performed at an external facility.

In May 2023, the patient presented with an anterior neck mass, dysphonia, and dyspnea. Ultrasound and CT confirmed a 4-cm left paratracheal nodule infiltrating the trachea, internal jugular vein, and sternocleidomastoid muscle, and encasing the common carotid artery. Genetic testing via tru-cut biopsy identified BRAF V600E and TERT-promotor (c.1-124C>T; c.1-146C>T) mutations. Given her clinical status and a recent COPD hospitalization, strict active surveillance was initiated, showing stable disease until October 2024. At that time, CT imaging demonstrated locoregional and distant progression: the neck mass reached 6.6 cm with jugular occlusion and infiltration of the trachea, carotid artery, and subclavian vessels, alongside new sternal and bilateral pulmonary metastases.

On December 10, 2024, the patient began lenvatinib at a reduced dose (10 mg qd). Treatment was complicated by weight loss (−8 kg; −16%), lower limb edema and ulcers, palmar-plantar erythrodysesthesia, and hypertension (all CTCAE grade G2). In March 2025, CT showed a mixed response: stable neck and lung disease but new hepatic lesions. Lenvatinib was increased to 14 mg qd without worsening adverse events.

Four weeks later, the patient was admitted for a femoral neck fracture following a fall. Lenvatinib was suspended, but orthopedic treatment was delayed by the onset of Takotsubo syndrome and severe cardiorespiratory failure. Despite intensive care, cardiocirculatory arrest occurred, leading to the patient’s death.

Discussion: This case underscores the difficulty of balancing oncologic goals with iatrogenic risks in elderly, fragile patients. Takotsubo syndrome in patients receiving lenvatinib has been noted in two case reports and may be precipitated by coronary endothelial dysfunction induced by VEGF inhibition. A multidisciplinary approach, including cardio-oncological evaluation, remains fundamental for managing fragile patients.

EP1452 - ECE_2760 - Quality of life in Graves’ orbitopathy: a patient-centered perspective

Katarzyna Wojciechowska-Durczyńska[1], Przemysław Śliwka[2], Joanna Hofman[2], Kinga Krawczyk-Rusiecka[1], Renata Stawerska[1] and Arkadiusz Zygmunt[2]

[1]Department of Pediatric and Adult Endcrinology, Medical University of Lodz, Lodz, Poland; [2]Department of Endocrinology and Metabolic Diseases, Polish Mother’s Memerial Hospital Research Institute, Lodz, Poland

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: Graves' orbitopathy (GO) is the extrathyroidal manifestation of Graves' disease, characterized by inflammation and remodeling of orbital tissues. In addition to visual manifestations, GO is associated with significant psychosocial consequences that adversely affect patients' quality of life (QoL). Previous studies have demonstrated that both functional visual impairment and altered appearance contribute to reduced QoL. Disease advancement, smoking, age, and sex have been shown to influence clinical course of disease too. Despite the clinical importance of QoL in GO management, correlations between QoL surveys and biochemical, demographic, and treatment-related variables remain insufficiently defined. This study aimed to characterize QoL surveys in patients with GO and to analyse their associations with demographic, clinical, biochemical, and lifestyle factors.

Materials and Methods: Eighty-seven (patients with GO were enrolled. QoL was assessed using the Polish version of the GO-QOL (Graves' Ophthalmopathy Quality of Life) questionnaire, comprising eight physiological and eight psychological questions where higher score equals lower QoL. Clinical evaluation included GO severity and activity, smoking, history of thyroidectomy and radioiodine therapy, and laboratory evaluation (TSH, fT3, fT4, TSH-receptor antibodies, anti-TPO, anti-Tg, CRP, and vitamin D levels). Correlation analyses used Pearson or Spearman methods depending on scale. Predictors were further examined via multivariable linear regression, and group differences (sex, smoking, disease advancement) via non-parametric tests.

Results: Physiological QoL (PhQoL) correlated positively with psychological QoL (PsQoL) ($r = 0.264$; $P = .018$) and summarized QoL surveys ($r = 0.774$; $P < .001$), and was associated with age ($r = 0.329$; $P = .005$), disease advancement ($r = 0.253$; $P = .035$), and smoking ($r = 0.336$; $P = .012$). PsQoL correlated with summarized QoL ($r = 0.815$; $P < .001$) and sex ($r = 0.487$; $P < .001$), being higher in females; weight correlated negatively. Biochemical variables did not significantly correlate with any QoL surveys. Regression models identified smoking and disease advancement as predictors of PhQoL and sex as the independent predictor of PsQoL. Non-parametric analyses showed significant sex differences for PsQoL ($P < .001$) and summarized QoL ($P = .037$) and higher PhQoL among smokers ($P = .013$). Advancing disease was associated with higher PhQoL ($P = .048$) but not PsQoL ($P = .325$).

Conclusions: In patients with GO, impairment of QoL is predominantly determined by demographic and clinical factors rather than by biochemical thyroid function or autoantibody profiles Female sex emerged as the principal determinant of PsQoL, whereas smoking and disease advancement primarily affected PhQoL and overall QoL outcomes. These findings support the routine incorporation of structured QoL assessment into GO management and indicate that patient-reported outcomes may reflect adaptive functional and psychosocial processes in addition to objective disease severity

EP1453 - ECE_2038 - Detection of pathogenic variants in cytologically benign thyroid nodules

Vlasta Kuklikova[1,2], Katerina Vyhnalova[1], Olivia Cillikova[1], Marie Rodová[1], Karolina Dobiasovska[1], Karolina Hrckulakova[1], Eliska Vaclavikova[1], Jitka Carkova[1], Barbora Bulanova[1], Josef Vcelak[1], Petra Pačesová[3], Zdenek Novak[3] and Bela Bendlova[1]

[1]Department of Molecular Endocrinology, Institute of Endocrinology, Prague, Czech Republic; [2]Department of Molecular Endocrinology, Institute of Endocrinology, Prague, Czech Republic; [3]Department of Clinical Endocrinology, Institute of Endocrinology, Prague, Czech Republic

Background: Molecular genetic analysis, together with sonographic and cytological examination, is an integral part of the care provided to patients with suspicious thyroid nodules (primarily Bethesda III/IV) in the Institute of Endocrinology in Prague. Within the scope of our research, we were interested in the genetic background also in cases of Bethesda II when the nodules were highly suspicious on sonography. The aim of this study was to highlight pathogenic variants in the cytologically benign nodules.

Methods: In total of 876 cytologically benign fine needle aspiration biopsy (FNAB) samples were analyzed. First, DNA for the most common mutation V600E in the *BRAF* gene using allele specific Real Time PCR was analyzed. *BRAF*-positive samples were screened for *TERT* mutations and *BRAF*-negative samples were analyzed for other 12 genes by next generation sequencing (Thyro-ID panel). Thyro-ID-negative samples were subjected to detection of 23 fusion genes including *ALK*, *BRAF*, *GLIS3, NTRK1*, *NTRK3*, *PPARG*, *RET* genes using Real Time PCR. Samples suspected of medullary thyroid carcinoma for *RET* and *RAS* mutations were tested.

Results: A total of 85 pathogenic variants were detected—*BRAF* mutations in 14 patients, *RAS* mutations in 33 patients (11 *HRAS*, 8 *KRAS*, 14 *NRAS*), *RET* mutation in one patient, fusion genes in five patients (three *PAX/PPARG*, one *RET/PTC1*, one *ETV6/NTRK3*) and mutations in other genes in 32 patients. From our cohort of cytologically benign FNAB samples, in 71 patients post-surgical histopathological evaluation has been known. In 17 patients, malignant tumor was histopathologically proven—12 papillary thyroid carcinomas (five with *BRAF* mutation, three with fusion genes) and five follicular thyroid carcinomas (one with *NRAS* mutation, one with fusion gene, one with *TSHR* mutation).

Conclusions: We detected pathogenic variants in 9.7% cytologically benign thyroid nodules including mutations with almost 100% probability of malignancy. This study does not support routine analysis of all cytologically benign samples, but in certain cases of highly sonographically suspicious nodules, it may be beneficial.

EP1454 - ECE_1899 - Biotin: pitfalls beyond the known

Kaushiki Kirty[1,2] and Bilal Jajah[1]

[1]Endocrine and Diabetes, Darlington Memorial Hospital, Darlington, United Kingdom; [2]Darlington United, Darlington Memorial Hospital, United Kingdom

Introduction: We present a patient, referred with deranged and changing thyroid functions, ranging from central hypothyroidism to Grave's thyrotoxicosis over a 10 year period. She was eventually found to be having assay interference from biotin; unusually

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

however,the biotin was being absorbed accidentally from the skin,not oral supplements

Case details: A 42 year old lady was referred to the thyroid clinic with deranged thyroid functions and atrial fibrillation in February 2024.

Her past medical history was significant for being investigated for features suggestive of central hypothyroidism when she was being evaluated for obesity in 2016. At the time she had a normal MRI pituitary and normal pituitary profile.The thyroid functions subsequently normalised without treatment. She was discharged from the thyroid clinic with no very satisfactory explanation for her abnormal thyroid functions.On this episode, apart from the atrial fibrillation, this lady did not have any other features suggestive of thyrotoxicosis.

Her thyroid hormone levels were inconsistent and unusual with a suppressed TSH, elevated FT3 and low FT4 levels. TRAB and TPO antibodies were negative. The thyroid uptake scan showed a mildly elevated uptake. Repeat TFT's showed a similar picture. Assay for antibody interference was negative

Patient was questioned regarding the use of biotin supplements and she denied taking any. However, she subsequently remembered that she gives biotin supplements to her horses, mixing in the powder in their feed with bare hands, a habit of 10 years, when she got the horses. The presumptive diagnosis of biotin interference with assay was made and she was advised to use gloves when mixing biotin supplements. Following this, her thyroid functions gradually normalised and has been normal since then.

Discussion: While it is well known by now that biotin causes assay interference with all the anterior pituitary hormones, we believe this is the first instance where biotin absorption from normal skin caused deranged thyroid functions. Literature review suggests that biotin is well absorbed from both intact and damaged skin reaching levels up to 38% higher than baseline in patients with atopic dermatitis and 12% higher than baseline in patients with intact skin. While not much literature exists measuring blood levels of biotin which cause assay interference, nevertheless based on this case it would seem that skin absorption, either deliberate or accidental, should be kept in mind .This highlights the importance of close and meticulous questionings when faced with inconsistent TFT's with high suspicion of assay interference.

EP1455 - ECE_2905 - Impact of strain ratio elastography on risk stratification of thyroid nodules with indeterminate cytology

Letizia Meomartino[1], Marco Zavattaro[2], Gloria Selvatico[1], Sara Garberoglio[1], Mauro MacCario[1], Gianluca Aimaretti[1] and Loredana Pagano[1]

[1]Endocrinology, Diabetology and Metabolism, Department of Medical Sciences, University of Turin, Turin, Italy; [2]Division of Endocrinology, Department of Translational Medicine, University of Eastern Piedmont, Novara, Italy

Background: Thyroid nodules with indeterminate cytology account for approximately 20% of cytological results and are classified as TIR3A (ROM 10%-15%) and TIR3B (ROM 15%-30%) according to the 2014 SIAPEC-IAP system. In this setting, cytology alone does not allow a definitive diagnosis, consequently, many patients are still referred for diagnostic surgery, despite the majority of these nodules proving to be benign on histological examination. This study aimed to evaluate the role of strain ratio elastography (SR), in malignancy risk stratification of indeterminate thyroid nodules and its predictive value within this category of nodules.

Materials and Methods: This retrospective, observational, single-center study consecutively enrolled 167 patients with TIR3A or TIR3B cytology and available definitive histology. For each patient, demographic data, presence of thyroiditis, ultrasound features, elastographic pattern, SR calculated both in comparison with the surrounding thyroid parenchyma (SR_par) and with the prethyroid musculature (SR_mus), and histological outcomes were collected.

Results: The median age was 53 years and most patients were female (77.2%). The majority of nodules were classified as (89.2%), and 61.7% of nodules were benign at histological examination. A high prevalence of thyroiditis was observed (37%).

A significant association emerged between higher SR values and risk of malignancy. The cut-off value identified in our study was 1.55 for both SR_par and SR_mus, showing high diagnostic performance and accuracy (SR_par: sensitivity 87.9%, specificity 92.7%, accuracy 90.8%; SR_mus: sensitivity 81.8%, specificity 85.3%, accuracy 83.9%). Logistic regression analysis showed an approximately six-fold and four-fold increased risk per unit increase, respectively for SR_par and SR_mus. Integration of SR with EU-TIRADS further improved malignancy prediction.

Conclusions: Strain ratio elastography represents a valuable complementary tool for risk stratification of thyroid nodules with indeterminate cytology, especially when combined with EU-TIRADS. Defining an SR cut-off value, both relative to the thyroid parenchyma and to the prethyroid musculature, extends the applicability of the technique even when adjacent thyroid tissue is unavailable. Nevertheless, standardization of image acquisition remains essential to ensure reproducibility, and population-specific cut-offs should be considered.

EP1457 - ECE_3005 - Factors associated with recurrence and persistent disease in subacute thyroiditis—a retrospective observational study of 370 patients

Halil Durantas, Neslihan Koray Fedai, Ceren Karaçalık Ünver, Oğulcan Boz, İlknur Ozturk Unsal, Bekir Ucan, Sema Hepşen and Erman Cakal

Endocrinology and Metabolism, University of Health Sciences, Ankara Etlik City Hospital, Ankara, Türkiye

Objective: Although subacute thyroiditis (SAT) is generally a self-limiting disease, recurrence and persistent disease pose significant challenges in clinical management. This study aimed to investigate clinical, laboratory, and treatment-related factors associated with recurrence, persistent disease, and permanent hypothyroidism in patients with SAT.

Materials and Methods: This retrospective study included 370 adult patients diagnosed with SAT who were followed for at least six months after treatment. Patients were treated with nonsteroidal anti-inflammatory drugs (NSAIDs) or corticosteroids (CS).

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Recurrence was defined as the reappearance of typical clinical symptoms, inflammatory markers, and ultrasonographic findings after treatment completion. Persistent disease was defined as the absence of clinical and laboratory improvement despite at least six weeks of CS therapy. Permanent hypothyroidism was defined as persistence of the hypothyroid phase for at least six months with a continued requirement for levothyroxine replacement therapy.

Results: Recurrence occurred in 57 patients (16.4%), while persistent disease was identified in 22 patients (6.0%). Recurrence was significantly more frequent in patients treated with CS compared with those receiving NSAIDs (18.4% vs 8.7%, $P = .010$). At diagnosis, patients with recurrence more frequently exhibited unilateral thyroid involvement on ultrasonography (36.8% vs 20.3%, $P = .036$) and were less likely to present with overt biochemical hyperthyroidism (75.4% vs 88.3%, $P = .010$). These patients had higher thyroid-stimulating hormone (TSH) levels and lower free thyroxine (fT4) levels at baseline ($P = .004$ and $P = .005$, respectively). Hyperthyroidism and inflammatory markers were also more pronounced during treatment and at treatment completion (all $P < .001$). In multivariate analysis, lower baseline fT4 levels, unilateral ultrasonographic involvement, and initiation of CS therapy were independently associated with recurrence. ROC analysis demonstrated modest predictive value of baseline TSH and fT4/ULN ratios for recurrence. Persistent disease was characterized by higher baseline TSH levels, lower fT4 levels, longer treatment duration, and higher cumulative CS doses. Permanent hypothyroidism developed in 39 patients (10.5%) and was significantly more common in patients with persistent disease and in those treated with NSAIDs ($P < .001$ for both).

Conclusions: Initial unilateral involvement, milder hyperthyroidism, and CS therapy were associated with recurrence in SAT. Persistent disease and NSAID therapy were associated with permanent hypothyroidism. These findings highlight the heterogeneity of SAT and may facilitate early identification of high-risk patients, enabling closer monitoring and more individualized treatment strategies to optimize long-term outcomes.

EP1458 - ECE_3956 - Performance of core needle biopsy following non-diagnostic or indeterminate fine-needle aspiration in thyroid nodules

Paula Sprovera, Bruna Pimentel, Margarida Oliveira, Catarina Gama and Catarina Saraiva
Hospital Egas Moniz, Lisboa, Portugal

Background: Thyroid nodules are increasingly diagnosed, often incidentally. Although most are benign, the possibility of malignancy requires accurate assessment. Fine-needle aspiration (FNA) is the standard first-line diagnostic tool, but 15%-30% of results are inconclusive. Core needle biopsy (CNB) has emerged as a valuable alternative in such cases.

Objective: To assess the diagnostic performance of CNB in thyroid nodules with prior non-diagnostic or indeterminate FNA and its role in reducing unnecessary surgeries.

Methods: We conducted a retrospective study of 126 patients who underwent ultrasound-guided CNB between 2018 and 2023 after inconclusive FNA (Bethesda I or III). CNB results were categorized as non-diagnostic, benign, indeterminate, or malignant. Surgical outcomes and follow-up data were analyzed to evaluate CNB's diagnostic accuracy.

Results: Of the 126 nodules, 63.4% were benign, 2.38% malignant, 26.19% indeterminate, and 7.93% non-diagnostic. CNB was diagnostic in 65.08% of cases. Surgery was performed in 31 patients (24.6%), mostly due to indeterminate or non-diagnostic CNB. Histology confirmed benign disease in 58.06% and malignancy in 32.2% of surgical cases. CNB showed 100% sensitivity, 27.8% specificity, 100% negative predictive value, and 43.5% positive predictive value. No complications were observed.

Conclusions: CNB is a safe, reliable, and effective second-line diagnostic tool in thyroid nodules with inconclusive FNA.

EP1459 - ECE_2961 - Unusual metastasis of renal cell carcinoma to thyroid

Eleana Zisimopoulou[1], Georgios Christantoniou[2], Maria Boudina[1], Chrysanthi Balodimou[1], Constantina Philippidou[1], Charalampos Papadopoulos[1], Nektaria Georgiadou[1] and Alexandra Chrisoulidou[1]
[1]*Endocrinology, Theageneio anti-cancer hospital, Thessaloniki, Greece;* [2]*Theageneio Anti-Cancer Hospital, Thessaloniki, Greece*

Renal cell carcinoma (RCC) metastatic to the thyroid gland is a rare entity.

We report two cases of RCC who developed metastatic lesions of the thyroid, discovered after thyroidectomy for nodular thyroid disease.

Two patients are discussed below, a 69-year old female (patient 1) and a 74-year old male (patient 2) (Table 1). In both cases the original RCC was of clear cell type. Pathology tumor stage was pT2a and pT1a respectively, with no angiolymphatic invasion noted.

Both patients had been followed-up for thyroid nodular disease and had been submitted to fine needle aspiration (FNA) of the thyroid nodules (3.7 and 4.4 cm respectively), which later identified as metastases from RCC. Suspicious ultrasonographic characteristics of the metastatic thyroid lesions were undulating outline of the nodule (patient 1) and central calcifications (patient 2). Interestingly, in both cases FNA cytology did not identify malignancy as both FNA results were category II by Bethesda grading system. Patient 1 had no other metastatic lesions in contrast to patient 2, who was already diagnosed with polymetastatic renal cell carcinoma at the time of the thyroidectomy. Both patients underwent, during follow-up, FDG-PET scans with poor metabolic activity in the thyroid.**Conclusions:** The thyroid gland represents an unusual site for metastatic disease in RCC. Thyroid ultrasonography, FNA and FDG-PET can be used for risk stratification and therapeutic decisions. Unfortunately, no specific features exist in the evaluation of thyroid disease in patients with extra-thyroid cancer.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Table 1 Characteristics of the RCC patients with thyroid metastases.

	Age	Sex	Stage	Time of RCC diagnosis	History of thyroid disease	Thyroid Ab's	PET-SUV in thyroid lesions	Thyroid surgery	Size of metastatis
1	69	F	pT2a	2013	TND	(-)	3.6	2017	3.9 cm 0.9 cm PTC
2	74	M	pT1a	2008	TND	(-)	No uptake	2025	4.5 cm

EP1460 - ECE_3350 - Calcium gluconate stimulation testing in risk stratification of medullary thyroid carcinoma in patients with basal hypercalcitoninemia: a case series

Alexandra Dulugiac[1], Vlad Radulescu[1,2], Beatrice Cristea[1], Ioana Maria Posea[1], Maria Tudorache[1], Roxana Boanta[1], Dumitru Ioachim[1] and Corin Badiu[1,2]
[1]*Adult Endocrinology, Endocrinology IV, National Institute of Endocrinology "C.I Parhon", Bucharest, Romania;* [2]*Endocrinology, Endocrinology, "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania*

Introduction: Basal hypercalcitoninemia in patients presenting thyroid nodules represents a diagnostic challenge, as elevated calcitonin could be associated with medullary thyroid carcinoma (MTC), C-cell hyperplasia, or benign thyroid disease in addition to other benign extra-thyroid conditions. Calcium gluconate stimulation testing is performed to improve diagnostic accuracy, although optimal cut-off values remain debated.

Objective: The diagnostic value of the calcium gluconate stimulation testing is assessed by correlating the stimulated calcitonin levels with the thyroid pathology of surgical specimen.

Methods: Four patients presenting thyroid nodules and persistent basal hypercalcitoninemia were analyzed in a tertiary endocrine center. A calcium gluconate stimulation test (25 mg/kg intravenously) was performed, and the calcitonin level was measured at baseline and at 2, 5, and 10 minutes post-infusion. Peak stimulated calcitonin levels were correlated with ultrasound findings, surgical indication, and post-thyroidectomy histopathology.

Case descriptions: Case 1: A 53-year-old male, smoker, with multinodular thyroid disease and basal calcitonin ~27 pg/mL showed a stimulated calcitonin of 355 pg/mL at 2 minutes. The histopathologic exam revealed a low-grade medullary thyroid microcarcinoma (pT1a) associated with C-cell hyperplasia, with negative lymph nodes and clear surgical margins.

Case 2: A 57-year-old male with basal calcitonin ~53 pg/mL had a stimulated calcitonin of 423 pg/mL at 2 minutes. Histopathological result confirmed early-stage medullary thyroid carcinoma (pT1a).

Case 3: A 40-year-old female, former smoker, with basal calcitonin ~24 pg/mL, had a stimulated response 806 pg/mL calcitonin at 2 minutes. Histopathology showed diffuse C-cell hyperplasia with multinodular goiter and an incidental papillary microcarcinoma.

Case 4: A 40-year-old female, with multinodular goiter and basal calcitonin ~32 pg/mL, had a stimulated calcitonin of 481 pg/mL, peaking at 2 minutes. Total thyroidectomy showed a benign multinodular goiter, with calcitonin normalizing after the surgery.

Results: All patients showed stimulated calcitonin values >285 pg/mL, with the maximum response observed at 2 minutes after calcium administration, followed by a progressive decline. They were submitted to total thyroidectomy and central compartment neck dissection. Two patients were diagnosed with medullary thyroid carcinoma, one had C-cell hyperplasia, and one had benign multinodular goiter.

Conclusions: Calcium gluconate stimulation testing significantly improves risk stratification in patients with basal hypercalcitoninemia and thyroid nodules. In this series, stimulated calcitonin levels exceeding 285 pg/mL, particularly at 2 minutes, were associated with underlying C-cell pathology, ranging from C-cell hyperplasia to early-stage medullary thyroid carcinoma.

EP1462 - ECE_1117 - Thyroid hormone metabolism and cardiac adaptation in aortic stenosis

Iulia Alexandra Pirga[1,2]
[1]*University of Medicine and Pharmacy, Craiova, Romania;* [2]*Medicover, Craiova, Romania*

Background: Aortic stenosis (AS) is characterized by chronic left ventricular pressure overload leading to concentric remodeling, metabolic stress, and progressive functional decline. Beyond structural adaptation, AS induces systemic neurohormonal and metabolic changes, including alterations in thyroid hormone conversion. While thyroid-stimulating hormone (TSH) reflects central regulation, free triiodothyronine (FT3) and the FT3/FT4 ratio more accurately represent peripheral thyroid hormone activity and myocardial metabolic efficiency. These parameters may therefore provide insight into the metabolic phenotype and functional reserve of patients with AS.

Methods: Our cross-sectional study included 71 patients with echocardiographically confirmed AS. Thyroid function parameters (TSH, FT3, and FT4) were analyzed in relation to clinical severity (NYHA functional class), metabolic reserve (hemoglobin), and hemodynamic severity (mean transvalvular gradient). Correlation and multivariable analyses were performed to explore the association between thyroid metabolism and disease burden.

Results: FT3 levels correlated inversely with NYHA class ($\rho = -0.355$, $P = .0047$), suggesting that patients with lower FT3

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

values experienced greater symptomatic limitation and reduced exercise tolerance. The FT3/FT4 ratio showed a similar negative correlation with NYHA class ($\rho = -0.320$, $P = .012$) and a positive correlation with mean transvalvular gradient ($\rho = 0.506$, $P = .016$), remaining an independent predictor after adjustment for age and sex. FT3 also correlated positively with hemoglobin ($\rho = 0.438$, $P = .00052$), indicating that low FT3 levels reflect systemic catabolic and inflammatory stress. TSH showed no significant association with any clinical or echocardiographic parameters.

Conclusions: In AS, reduced peripheral T4-to-T3 conversion reflects impaired metabolic adaptation to chronic cardiac stress rather than primary thyroid dysfunction. The FT3/FT4 ratio can be used as a sensitive biomarker, linking myocardial energetic demand, systemic metabolism and disease severity.

Keywords thyroid hormones, FT3/FT4 ratio, aortic stenosis, low T3 syndrome, deiodinase activity, cardiac metabolism, NYHA functional class

Introduction: Non-thyroidal illness syndrome (NTIS) occurs in patients with severe illnesses, and the exact underlying mechanism remains unknown.[1]. Available studies emphasize the importance of routine screening for thyroid function in patients with end-stage renal disease (ESRD). However, the direct association between NTIS and the adequacy of dialysis therapy has been rarely investigated.

Objective: This study aimed to assess the association between NTIS and the quality of dialysis therapy.

Methods: We examined the prevalence of NTIS in patients with ESRD and its implications on dialysis parameters (Kt/V ratio[2]) from two independent dialysis centers in the Podkarpackie region of Poland. Patients with a history of thyroid or pituitary disease and those taking medications that could interfere with the hypothalamic–pituitary–thyroid axis were excluded. Statistical analyses were performed using STATISTICA version 13.1, with statistical significance set at $P < .05$.

Results: Of the 104 patients undergoing dialysis, 74 met the inclusion criteria and qualified for the study. Among the 74 trial participants, NTIS was identified in 37 (50%). The median age was 65 years and 15 patients (40,5%) were women. This study revealed that patients with NTIS had lower mean Kt/V ratios compared with patients in euthyroid. Preliminary results are presented in Table 1.

Conclusions:

1. NTIS is common in patients with ESRD.
2. The NTIS predicts worse dialysis therapy results in patients with ESRD.

Table 1 Comparison of selected parameters between euthyroid and NTIS groups in patients with ESRD.

Patients with ESRD ($n = 74$)			
Variables	**Euthyroid ($n = 37$)**	**NTIS ($n = 37$)**	***P*-value**
Demographics, *n* (%) or median (min-max)			
Age [year]	68 (18-89)	65 (18-88)	$P = .5^{*}$
Body weight (kg)	77 (38-116)	75 (29-108)	$P = .8^{*}$
Female sex	14 (37,8%)	15 (40,5%)	$P = .8^{\#}$
Laboratory parameters, median (min-max)			
Ca	2,2 (1,6-2,6)	2,1 (1,7-3,1)	$P = .3^{*}$
P	1,7 (0,8-3,7)	2,0 (0,8-5,6)	$P = .4^{*}$
PTH	314,5 (23,7-1606)	359 (35-1773)	$P = .6^{*}$
Kt/V ratio	1,1 (0,7-1,8)	1,0 (0,6-1,4)	$P = .03^{*}$

EP1464 - ECE_2144 - Quality of life in patients with hyperthyroidism

Zvezdana Jemuovic[1], Sandra Pekic Djurdjevic[1], Dragana Miljic[1], Mirjana Doknic[1], Marko Stojanovic[1], Olga Djajic[2], Ivana Cekic[1], Ivan Jevtic[1], Boris Kurcubic[1], Jelena Bajic[1] and Marina Nikolic Djurovic[1]
[1]*Clinic for Endocrinology, Diabetes and Diseases of Metabolism, University Clinical Center of Serbia, Belgrade, Serbia;* [2]*General Hospital Uzice, Uzice, Serbia*

Introduction: It has been shown that patients with hyperthyroidism (HT) have a worse quality of life (QoL) compared to the general population, especially in the domains of mental health, vitality and social functioning. After successful treatment, many patients experience an improvement in their quality of life, but some symptoms may last longer, especially those related to mental health.

Aim: To investigate QoL in patients with HT on thyrosupressive therapy

Methods: Case control study with 30 HT patients (mean age 52.37 ± 10.52) on thyrosupressive therapy and 30 euthyroid healthy controls, matched for age, sex and educational level, were included. Measurement of TSH, FT4, anti-TPO antibodies, TSH-receptors antibodies was done. Evaluation of QoL was evaluated by QoL questionnaire—SF36. Mann-Whitney U test was used to compare means between groups.

Results: The duration of the hyperthyroidism in HT group was 16.9 ± 18.6 months. HT patients had lower TSH levels vs control (0.95 ± 1.43 vs 1.93 ± 0.98 mIU/L, $P < .001$) and higher FT4 (20.01 ± 8.46 vs 14.36 ± 2.17 pmol/L, $P = .020$). Patients in HT group reported worse physical functioning, physical role, general health, vitality, social functioning, emotional role and mental health. HT group also reported worse physical health—Dimension A (64.00 ± 18.13 vs 79.87 ± 11.93, $P < .001$), mental health—Dimension B (62.23 ± 17.81 vs 78.20 ± 13.87, $P < .001$) and Total SF35 score (64.73 ± 18.31 vs 81.07 ± 13.38, $P < .001$).

Conclusions: Patients with HT had statistically significantly worse quality of life compared to healthy control. Future studies with larger cohorts and in longer observation periods are needed to further explore quality of life in patients with hyperthyroidism during remission of the disease.

EP1465 - ECE_1162 - Adherence to levothyroxine in adult patients with primary hypothyroidism: a cross-sectional study

Rubel Lafaurie-Noriega[1], Maria Roa-Parra[1], Miguel Ochoa-Vera[1], Juan Sarmiento-Ramón[1,2] and Edwin Wandurraga-Sánchez[2]
[1]*Universidad Autónoma de Bucaramanga—UNAB, Bucaramanga, Colombia;* [2]*Bucaramanga, Colombia*

Introduction: Primary hypothyroidism is the most common form of thyroid hormone deficiency and is more prevalent in women. The treatment of choice is thyroid hormone replacement with levothyroxine; however, a high proportion of patients do not achieve adequate control, and adherence to medication is an important factor in achieving this.

Objective: To evaluate pharmacological adherence to levothyroxine and the factors associated with it, in patients with primary hypothyroidism treated at an endocrinology center in Colombia.

Methods: Cross-sectional study of adults (≥18 years) with primary hypothyroidism undergoing treatment for ≥3 months, attending an endocrinology clinic between December 2024 and July 2025. Patients who agreed to participate signed informed consent and completed a specific data collection form, in addition to the 8-item Morisky–Green scale for levothyroxine adherence. Sociodemographic and clinical variables were assessed; Fisher's exact test, the Mann–Whitney U test, and Pearson's chi-squared test were applied. Additionally, binary logistic regression was used to calculate crude odds ratios (OR). The analysis was performed using STATA/SE v14.0. This study was approved by an Ethics Committee.

Results: 318 patients were included, with a median age of 60 years (IQR 46-73) and a higher proportion of women (82.08%). Most lived in urban areas (94.03%), and the most frequent type of social security affiliation was payroll-based contributory health insurance (78.62%). Regarding levothyroxine adherence, 52.20% showed high adherence, 25.79% moderate adherence, and 22.01% low adherence, with no significant differences according to sex. The only two variables associated with not having high adherence to levothyroxine were: government-subsidized health insurance (OR = 3.96; 95% CI 2.00-7.83; $P < .000$) and generic brands of levothyroxine compared to commercial brands (OR = 2.24; 95% CI 1.42-3.54; $P = .001$). No statistically significant differences were found in adherence for the following variables: age, educational level, marital status, socioeconomic status, daily dose of levothyroxine, presence of comorbidities, use of other medications or polypharmacy (≥ 5 medications).

Conclusions: In a predominantly female urban sample, more than half of the patients with primary hypothyroidism showed high adherence to levothyroxine, with type of health insurance and medication brand being associated factors. It is recommended to strengthen strategies aimed at improving adherence in the low- and moderate-adherence groups, as this factor directly impacts disease control.

J. Strossmayer Osijek, Osijek, Croatia;* [6]*Department of Internal Medicine, General County Hospital Vinkovci, Vinkovci, Croatia;* [7]*Department of Medical Statistics, Epidemiology and Medical Informatics, School of Public Health Andrija Štampar, Zagreb, Croatia;* [8]*School of Medicine, University of Zagreb, Zagreb, Croatia*

Introduction: Daytime sleepiness is common in patients with Hashimoto's thyroiditis (HT) and may reflect both thyroid

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

dysfunction and the effects of levothyroxine (LT4) replacement therapy. Data on the relationship between daytime sleepiness and biochemical markers of thyroid function during LT4 therapy are limited. This study aimed to examine the effect of LT4 replacement therapy on thyroid function biomarkers in HT patients, stratified by daytime sleepiness.

Methods: The study included 115 patients with clinically, ultrasound, and laboratory-confirmed HT treated at a single center. Daytime sleepiness was assessed using the Epworth Sleepiness Scale (ESS), and patients were categorized as having normal (ESS $\leq$ 10) or increased (ESS $\geq$ 11) daytime sleepiness. Laboratory parameters analyzed included total cholesterol, triglycerides, HDL, LDL, iron, vitamin D, TPOAb, TgAb, TSH, fT3, and fT4.

Results: The median age was 41 years (IQR 33-50), and women comprised 92.2% of the sample ($n = 106$). LT4 therapy was used by 61.7% of patients, and 28.7% reported increased daytime sleepiness. The group without LT4 therapy included 30 patients with normal ESS and 14 with increased ESS, while the group on LT4 therapy included 52 patients with normal ESS and 19 with increased ESS. Among patients with normal daytime sleepiness, those receiving LT4 had significantly higher TSH concentrations than those not receiving LT4 (12.15 [IQR 8.75-17.15] vs 8.65 [IQR 6.48-13.48] mU/L; $Z = -2.393$; $P = .017$). In the same group, patients not receiving LT4 therapy had significantly higher fT3 concentrations than those receiving LT4 therapy (5.65 [IQR 4.90-6.15] vs 5.10 [IQR 4.40-5.68] pmol/L; $Z = -2.265$; $P = .023$). Among patients with increased daytime sleepiness, no statistically significant differences in the analyzed biochemical analytes were observed with respect to LT4 therapy.

Conclusions: In patients with Hashimoto's thyroiditis and normal daytime sleepiness, LT4 therapy is associated with higher TSH and lower fT3, while in those with increased daytime sleepiness, no such differences are observed. These results suggest a complex relationship among daytime sleepiness, thyroid function, and the effects of LT4 therapy, highlighting the need for individualized monitoring and treatment. These findings can be used to generate hypotheses for larger, longitudinal studies that could confirm these observations.

EP1467 - ECE_2122 - Microwave ablation as an alternative to radioiodine therapy for hyperthyroidism caused by an autonomously functioning thyroid nodule: clinical case

Aiste Stonyte[1], Ruta Dubeikaite[2], Aurimas Maclonis[2] and Raimonda Klimaite[3]

[1]Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Department of Radiology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania; [3]Institute of Endocrinology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania

Introduction: Microwave ablation (MWA) is advantageous for patients with autonomously functioning thyroid nodules (AFTNs) who are poor surgical candidates or wish to avoid surgery and radioiodine therapy (RAI). The procedure is well tolerated, with few major complications and mostly preserves thyroid function. In this young female with an AFTN, MWA highlights the evolving role of image-guided thermal ablation as a safe and effective therapy in selected patients and discusses its potential in the contemporary AFTN management.

Case report: A 19-year-old female patient was referred due to weight loss, palpitations, and sweating. Since 2022, she had been monitored for a thyroid nodule. In 2022, FNA of the left thyroid lobe nodule showed cystic degeneration. Thyroid scintigraphy with 99mTc demonstrated the presence of an autonomous adenoma.

Laboratory tests (2025-01-13): TSH: 0.20 (0.4-3.6 mU/L), FT4: 10.27 (7.87-20.3 pmol/L), FT3: 4.54 (3.34-5.14 pmol/L).

Thyroid ultrasound (2025-01-13): in the left lobe, a mixed nodule with septations measuring $3.9 \times 2.5 \times 3.8$ cm (volume of ~19.3 mL). Nodular thyroid, EU-TIRADS 3.

As an autonomous thyroid adenoma causing subclinical thyrotoxicosis was diagnosed, treatment was initiated. The patient was unable to comply with radiation safety requirements following radioiodine therapy. Therefore, MWA of the left thyroid lobe nodule was chosen.

MWA (2025-03-03): Under ultrasound guidance, an 18G MWA antenna ablated the left thyroid lobe nodule at 15W for 42 minutes using the "fluid-motion" technique.

Thyroid ultrasound post-MWA, follow-up: I (2025-03-04): a broad, heterogeneous post-ablation zone is seen with peripheral vascularity and fragmented vascularity at the lower pole.

II (2025-03-18): mixed nodule, markedly devascularized, measuring $3.8 \times 2.0 \times 2.9$ cm.

III (2025-06-20): The nodule decreased in size to $2.65 \times 1.49 \times 2.05$ cm. No mass is visible in the neck. The nodule is completely devascularized.

IV (2025-12-29): a nodule has decreased in size to $2.53 \times 1.43 \times 1.74$ cm (volume ~3.3 mL). The nodule is completely devascularized.

Laboratory follow-up: The thyroid hormone levels normalized after MWA. Thiamasole were discontinued.

Conclusions: MWA was an effective alternative to RAI in this 19-year-old patient with a autonomic thyroid adenoma, achieving significant nodule reduction, devascularization, and normalization of thyroid hormone levels. This case highlights MWA as a viable option for AFTN, particularly in patients ineligible for RAI and underscores the need for further studies to evaluate long-term outcomes.

EP1468 - ECE_2504 - Hidden in plain sight: rising encounters of thyrotoxic periodic paralysis

Zachary Pierrepont[1] and Brian Lee[2]

[1]University Hospital Birmingham NHS Trust, Birmingham, United Kingdom; [2]Sandwell & West Birmingham Hospitals NHS Trust, Birmingham, United Kingdom

Background: Thyrotoxic periodic paralysis (TPP) is a rare endocrine emergency presenting with acute flaccid weakness and hypokalaemia in the setting of thyrotoxicosis. Misdiagnosis as a neurological disorder is common. We report a recent case of TPP and compare it with a previous case two years earlier in the Acute Medical Unit of the same NHS Trust.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Case Presentation: Current case: A 41-year-old Chinese man presented with sudden bilateral lower-limb weakness (power 2/5), initially treated as a stroke. Serum potassium was 2.9 mmol/L. Thyroid tests showed thyrotoxicosis. MRI spine was normal. Weakness fully resolved after potassium replacement, and antithyroid therapy was started.

In comparison, a previous 27-year-old ethnic Chinese male, had presented two years earlier with more profound paralysis (power 1/5), severe hypokalaemia (1.5 mmol/L), and ECG features of hypokalaemia. He had marked thyrotoxicosis required critical care and antithyroid therapy and radioactive iodine treatment following recovery.

Discussion: These cases demonstrate the variable severity and heterogeneous thyroid aetiology of TPP. Although uncommon, the occurrence of two cases within two years in one Trust highlights the need for greater awareness—especially given increasing international migration from regions where TPP is more prevalent.

Conclusions: In any patient presenting with acute limb weakness and hypokalaemia, TPP should be considered. We recommend urgent thyroid function testing as a routine add-on in such cases. Earlier recognition in acute settings can prevent delays in treatment and reduce morbidity.

Table 1 Comparison of two TPP cases in one NHS trust.

Feature	Case 1	Case 2 (This Report)
Initial Presentation	Sudden bilateral weakness (1/5), Guillain-Barré syndrome/spine initially suspected	Sudden bilateral weakness (2/5), stroke alert
Potassium	1.5 mmol/L	2.9 mmol/L
ECG	U waves, prolonged QTc	Normal
Thyroid function Test on admission	FT4 48 (9-20 pmol/L)	FT4 19.2
	FT3 28.4 (2.4-6.0 pmol/L)	FT3 7.2
	TSH <0.01 (0.35-4.94 miu/L)	TSH <0.008
Thyroid Aetiology	Graves' disease	Toxic nodular goitre
Thyroid Antibodies	TSH-R Ab positive	TSH-R negative
	TPO positive	TPO positive
Thyroid Ultrasound	No nodules	U2 nodules
Management	IV Potassium, antithyroid therapy, critical care	IV Potassium, antithyroid therapy
Definitive Treatment	Radioactive iodine	Planned radioactive iodine

EP1470 - ECE_1560 - Late onset of slipped upper femoral epiphysis in adult as the initial presentation of undiagnosed primary hypothyroidism

Sushma Burri and Shemitha Rafique
Tunbridgewells Hospital, Tunbridgewells, United Kingdom

Background: Hypothyroidism in adults is typically characterized by symptoms such as fatigue, cold sensitivity, weight gain, and constipation. However, acquired hypothyroidism in children and adolescents can disrupt growth and development, leading to long-term complications if left undiagnosed. The condition can significantly affect height and bone maturation until puberty.

Case History: A 20-year-old male presented to the emergency department with a six-week history of worsening left hip pain. The patient, who had been highly active in sports, reported difficulty participating in activities since the age of 15. Hip pain began at 17. Initial X-ray of the left hip revealed a diagnosis of Slipped Upper Femoral Epiphysis (SUFE), a condition typically seen in boys aged 11-17 years, around puberty.

The patient had been born full-term with no significant childhood illnesses. His height was within normal limits until age 14, after which growth significantly slowed. His mid-parental height is 5′10″, and his brother is 5′9″. The patient also noted difficulty losing weight and feeling excessively cold.

Physical Examination: The patient had a puffy face, short neck, a slightly enlarged tongue (but able to close the mouth), and small hands. A thyroid examination was normal, but delayed relaxation of the ankle jerk was noted.

Investigations

- Blood Tests:
  - TSH: >100 mU/L
  - Free T4: <3.0 pmol/L
  - Cortisol: 452 nmol/L
  - TPO antibodies: 230 IU/mL
- X-ray (Hand and Wrist for Bone Age):
  - Chronological age: 20 years, 5 months
  - Bone age: Corresponds to a male skeletal age of approximately 16 years (based on the Greulich and Pyle method).

Diagnosis: Primary hypothyroidism with delayed skeletal maturation.

Management: The patient was started on Levothyroxine 200 mcg prior to surgery. He subsequently underwent left hip surgery (Left Hip Slipped Upper Femoral Epiphysis, cannulated screw pinning) when his Free T4 level had increased to >6 pmol/L. There were no complications in anaesthesia or surgery when operated with a FT4 of 6. His Levothyroxine dose was reduced to 100 mcg following surgery. He was discharged with a follow-up plan in endocrine Clinic.

EP1473 - ECE_3737 - The relationship between iron metabolism indicators and thyroid function in adolescents

Marianna Yuskiv and Alina Urbanovych
State Non-Profit Enterprise «Danylo Halytsky Lviv National Medical University», Lviv, Ukraine

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: Thyroid dysfunction may be accompanied by changes in iron metabolism, in particular, the levels of ferritin and hepcidin, a key regulator of its homeostasis. At the same time, the relationship between iron metabolism indicators and thyroid hormones in adolescents remains insufficiently studied, which determines the relevance of this research. Therefore, the aim of our research was to assess the correlations between iron metabolism markers and thyroid function indicators in adolescents.

Materials and Methods: The study involved 28 adolescents with established thyroid dysfunction. Participants were divided into 2 groups depending on the existing thyroid dysfunction: group 1—hypothyroidism on the background of autoimmune thyroiditis ($n = 16$, 57.14%, median age 14 [11.8; 15.3] years) and group 2—Graves' disease, thyrotoxicosis ($n = 12$, 42.86%, median age 12 [10.8; 15.3] years). All patients underwent determination of iron, hepcidin and ferritin levels.

Results: In adolescents with established thyroid dysfunction ($n = 28$), the median hepcidin level was 182.8 [139.5; 243.6] ng/mL (range: 91.09-394.68 ng/mL). Elevated hepcidin levels were found in 21.43% (95% CI: 8.51-38.22%) of children. The frequency of elevated hepcidin was significantly higher in children in group 2 compared to group 1—41.67% (16.54-69.40%) vs 6.25% (0.01-22.79%), $P = .02$. Reduced ferritin levels, as a marker of iron stores, were found in 42.86% (95% CI: 25.43-61.26%) of children; the median value was 14.5 [8.2; 25.8] ng/mL (min.–max.: 3.79-48.86 ng/mL). The median serum iron level in adolescents with thyroid dysfunction was 12.5 [5.8; 26.3] μmol/L (2.0-53.0 μmol/L) and in 64.29% (45.97-80.66%) of cases it deviated from the norm: in 39.29% (22.33-57.69%) it was reduced, in 25.00% (11.02-42.37%) it was increased. Iron below the norm was more often found in children of group 2—58.33% (30.60-83.46%), while elevated iron levels prevailed in group 1—37.50% (16.19-61.75%).

Conclusions: Our research demonstrated that adolescents with thyroid dysfunction had impaired iron metabolism, manifested by a decrease in ferritin in almost half of the examined and deviations in serum iron levels in most children. Elevated hepcidin levels are more often observed in children of group 2 (Graves' disease, thyrotoxicosis) and are associated with a reduced serum iron level. The identified relationships indicate the potential influence of iron metabolism regulators on thyroid function. The obtained data create the basis for further studies of the mechanisms of interaction of iron and thyroid hormones in adolescence.

EP1474 - ECE_3620 - Epidemiology and risk factors of hearing loss in thyroid eye disease (TED)

Jason Brant[1], Vinaya Manchaiah[2], Junjie MA[3], Juan Ayala-Haedo[3], Patricia Franco[3] and Haridarshan Patel[3]
[1]*University of Wisconsin School of Medicine and Public Health, Madison, United States;* [2]*University of Colorado School of Medicine, Aurora, United States;* [3]*Amgen Inc., Thousand Oaks, United States*

Introduction: Hearing loss has not been fully evaluated in large population-based cohorts, particularly in patients with thyroid eye disease (TED). Understanding the epidemiology of hearing loss in this population is crucial for optimizing patient management and reducing the disease burden. Here we aim to describe the epidemiology and risk factors of hearing loss in patients with TED, Graves' disease, and the general population.

Methods: A retrospective cohort study using a large US claims database (2014-2019) estimated the age- and gender-adjusted cumulative incidence, incidence rates (per 10 000 person-years), and prevalence of hearing loss. Multivariable Cox regression assessed the association of hearing loss with TED (reference: general population). Machine learning methodology was used to identify predictors of hearing loss.

Results: Cohorts included 38 723 patients in TED, 171 831 in Graves' disease, and >20 million in the general population. Hearing loss was high in TED (cumulative incidence: 2.8%; incidence rate: 142.2; prevalence: 4.6%), followed by Graves' disease (cumulative incidence: 2.0%; incidence rate: 92.0; prevalence: 3.0%), and the general population (cumulative incidence: 1.6%; incidence rate: 67.6; prevalence: 2.2%). The adjusted hazard ratio for hearing loss with TED was 1.6 (95% CI: 1.5, 1.7). Top predictors included age, gender, tinnitus, dyslipidemia, and ototoxic drug use (macrolide and NSAIDs).

Conclusions: TED was associated with a significantly higher risk of hearing loss than the general population.

Introduction: Certain detectable variants (pathogenic/likely pathogenic) in cancer predisposition genes, identified with a variant allele frequency (VAF) >40%, are considered potentially of germline origin and are reported in approximately 3%-17% of cases.

Methods: Comprehensive genomic tumor profiling was performed on tumor tissue sections (FFPEs Formalin-Fixed Paraffin-Embedded) from 35/42 patients with radioiodine-refractory

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

differentiated thyroid carcinoma (RAIR-DTC) within the Hellenic Network of Molecular Oncology (EDIMO). Next-Generation Sequencing (NGS) using Ion AmpliSeq technology was applied for the detection of oncogenic/potentially oncogenic single-nucleotide variants (SNVs) and insertions/deletions (Indels) across >500 genes, as well as clinically significant copy number variants (CNVs) involving large genomic regions.

Results: Variants with VAF > 40%, compatible with a potential germline origin, were identified in 21/35 patients (60%). Among these, 6 metastatic patients harboured variants in cancer predisposition genes including: *TERT* (44.34-53.42%, *N* = 4: 1 male, 3 females, of whom one with ovarian cancer and a concomitant *RAD51D* variant (44%) and one with both breast and ovarian cancer); *TSHR* (42.7%, *N* = 1); *ATM* (50.2%, *N* = 1); co-occurrence of *APC* (49.15%) and *TP53* (55.5%) in one patient. In 15/21 germline-origin variants with primarily pharmacogenomic relevance were identified (*DPYD*, *NQO1*, *CYP2D6*, VAF:42%-99%). Additionally, potentially clinically significant CNVs were detected in 6 patients (5 metastatic), involving the following genes: *CHEK2* (*N* = 2), *BRCA2* (*N* = 2), *RAD54L* (*N* = 1), *ATM* (*N* = 2), and *CHEK1* (*N* = 2).

Conclusions: NGS-based comprehensive genomic profiling of aggressive RAIR-DTC patients revealed a high prevalence of variants suggestive of germline origin in cancer predisposition genes. Confirmation of these variants in peripheral blood DNA is recommended (using Sanger sequencing for SNVs/Indels and MLPA (Multiplex Ligation-dependent Probe Amplification) for CNVs) to establish their somatic or germline origin.

Subsequent cascade screening within families enables targeted testing of relatives and individualized genetic counselling regarding the risk of additional malignancies beyond thyroid cancer. Identification of germline variants may guide surveillance strategies for early cancer detection and stratification of targeted therapeutic approaches.

EP1478 - ECE_1860 - Potential use of predictive molecular techniques in thyroid nodules with indeterminate cytology

Selena Rodriguez Fernandez, Kevin David Díaz Gorrín, Javier Panizo Fra, Paula Pérez, Óliver Quintero Rodríguez, Ana Paola Leon Ocando, Patricia Cabrera García, Itziar Aznar Ondoño, MacArena Sánchez-Gallego Alonso and Juan Ignacio Márquez De La Rosa
Endocrinology and Nutrition, Hospital Universitario de Canarias, San Cristóbal de La Laguna, Spain

Introduction: Fine-needle aspiration biopsy (FNAB) is the diagnostic method of choice for assessing malignancy risk in thyroid nodules. The Bethesda System is the standard for cytological classification. Indeterminate categories (III and IV) represent a diagnostic challenge. In recent years, molecular testing (ThyroidPrint® or mir-THYpe®Full) has emerged as a tool to improve risk stratification in indeterminate nodules and potentially reduce unnecessary surgeries.

Objective: To evaluate the management of Bethesda III and IV nodules and the potential impact of molecular testing in avoiding unnecessary surgical procedures.

Materials and Methods: An observational, analytical, retrospective study including 87 patients with thyroid nodule cytology classified as Bethesda I, III, or IV between January 2023 and December 2024 at the University Hospital of the Canary Islands.

Results: Cytological samples from 87 patients were analyzed: 2 Bethesda I, 59 Bethesda III, and 26 Bethesda IV. A second FNAB was performed in 59 patients, yielding: 2 Bethesda I, 15 Bethesda II, 17 Bethesda III, 23 Bethesda IV, 1 Bethesda V, and 1 Bethesda VI.

Therapeutic approach: Hemithyroidectomy in 31.6%, total thyroidectomy in 24.1%, pending surgery in 3.8%, ultrasound follow-up in 32.9%, and surgical reintervention for differentiated thyroid cancer in 1.3%. Overall, 60.8% underwent surgery and 39.2% were managed conservatively. Among 25 hemithyroidectomies, 2 (8%) were malignant. Among 19 total thyroidectomies, 4 (21.1%) were malignant. Of the 17 Bethesda III nodules, 7 were surgically treated, all benign. Of the 23 Bethesda IV nodules, 18 were surgically treated, with 2 malignant outcomes.

Conclusions: Among 45 non-diagnostic or suspicious FNABs, 7 were malignant (14%). Seventy-six percent of surgeries resulted in benign pathology, suggesting that 23 hemithyroidectomies and 15 total thyroidectomies could have been avoided (cost €3500-7000 per patient). With 40 candidates for molecular testing (cost €34 400-60 000), the potential savings would be approximately €200 000 over two years. These findings highlight the need to incorporate predictive molecular techniques such as ThyroidPrint® or Mir-THYpe® in Bethesda III and IV nodules.

Objective: Thyroid hormone treatment is the standard therapy for hypothyroidism, particularly in women. Concerns have been raised that exogenous thyroid hormone use may increase breast cancer risk, but evidence remains inconclusive. This study aimed to systematically review and synthesize observational evidence on the association between thyroid hormone treatment and breast cancer risk in women.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Design: We conducted a systematic review and meta-analysis of observational studies.

Methods: MEDLINE, EMBASE, and Web of Science were searched from January 1976 to February 2025. Eligible studies assessed breast cancer incidence in adult women receiving thyroid hormone treatment versus non-users. Pooled odds ratios (ORs) and hazard ratios (HRs) were calculated using meta-analytic models. Heterogeneity, publication bias, and certainty of evidence were assessed. PROSPERO ID: CRD42022348966.

Results: Four case-control studies including 221 254 women receiving thyroid hormone treatment and 4 385 666 controls were included. In the primary random-effects meta-analysis, thyroid hormone treatment was associated with an increased risk of breast cancer (OR 1.43, 95% CI 1.07-1.90; $I^2 = 94.3\%$). A secondary meta-analysis of five cohort studies reporting hazard ratios showed a pooled HR of 1.25 (95% CI 1.08-1.44; $I^2 = 82\%$). Funnel plots and Egger's test ($P = .054$) suggested no strong publication bias. The certainty of evidence was rated as moderate due to heterogeneity.

Conclusions: Thyroid hormone treatment is associated with a modest but statistically significant increase in breast cancer risk in women. While causality cannot be established, these findings underscore the need for careful risk–benefit evaluation, particularly in women with other breast cancer risk factors.

EP1480 - ECE_1613 - Diagnostic performance of ACR TI-RADS in cytologically indeterminate thyroid nodules: a multicenter retrospective study

José Vicente Gil Boix[1,2], Javier Bodoque-Cubas[3], Meritxell Viñes Raczkowski[4], Iñaki Argüelles Jiménez[5], Francisco Javier Maravall Royo[1,2], Virginia Patricia Morillo Maclas[2,6], Santiago Tofé Povedano[5,7] and Agustín Ángel Merchante Alfaro[1,2]

[1]Endocrinology and Nutrition, Hospital General de Castellón, Castellón de la Plana, Spain; [2]Universidad Jaume I, Castellón de la Plana, Spain; [3]Endocrinology and Nutrition, Hospital De Tortosa Verge De La Cinta, Tortosa, Spain; [4]Endocrinology and Nutrition, Hospital Comarcal de Inca, Inca, Spain; [5]Endocrinology and Nutrition, Hospital Universitario Son Espases, Palma, Spain; [6]Hospital Clínico Universitario de Valencia, Valencia, Spain; [7]Universitat de les Illes Balears, Palma, Spain

Introduction: Cytologically indeterminate thyroid nodules (Bethesda III-IV) represent a diagnostic challenge and often lead to surgery despite a relatively low malignancy rate. The usefulness of ultrasound risk stratification systems such as ACR TI-RADS in this subgroup remains controversial.

Objective: To evaluate the diagnostic performance of ACR TI-RADS classification and individual ultrasound features for predicting malignancy in Bethesda III-IV thyroid nodules.

Methods: We performed a multicenter retrospective study including 179 patients with Bethesda III-IV thyroid nodules who underwent surgery. Nodules were classified according to ACR TI-RADS by experienced investigators. Final histopathology was used as the reference standard. Diagnostic performance was evaluated for individual TI-RADS categories and for grouped cutoffs (TR4-5 vs TR1-3 and TR5 vs TR1-4).

Results: Of the 179 nodules, 60 (33.5%) were malignant. Malignancy rates increased across TI-RADS categories, reaching 62.5% in TR5 nodules (Table 1).

Table 1 ACR TI-RADS risk of malignancy.

	Malignancy ($n = 60$)	Benign ($n = 119$)	ROM
TR1	1 (1.7)	3 (2.5)	NE
TR2	1 (1.7)	2 (1.7)	NE
TR3	14 (23.3)	45 (37.8)	23.73%
TR4	29 (48.3)	60 (50.4)	32.58%
TR5	15 (25.0)	9 (7.6)	62.50%

Abbreviations: NE, Not estimable ($N < 10$); NPV, Negative Predictive Value; PPV, Positive Predictive Value; ROM, Risk Of Malignancy.

When TR4-5 was considered suspicious for malignancy, ACR TI-RADS demonstrated high sensitivity but limited specificity, with a positive predictive value of 38.9% and a negative predictive value of 75.8%. In contrast, using TR5 as the sole cutoff markedly increased specificity and positive predictive value, at expense of sensitivity (Table 2).

Table 2 Diagnostic performance of ACR TI-RADS using different malignancy cutoffs in Bethesda III-IV nodules.

TI-RADS cutoff	Sensitivity %	Specificity %	PPV %	NPV %
TR4-5 vs TR1-3	73.3 (62.1-84.5)	42.0 (33.2-50.8)	38.9 (29.9-47.9)	75.8 (65.6-85.9)
TR5 vs TR1-4	25.0 (14.0-36.0)	92.4 (87.7-97.1)	62.5 (43.3-81.7)	71.0 (63.9-78.1)

Data in brackets represent 95% confidence intervals.

Among individual ultrasound features, irregular or lobulated margins, taller-than-wide shape, and punctate echogenic foci were significantly associated with malignancy ($P < .05$).

Conclusions: In Bethesda III-IV thyroid nodules, ACR TI-RADS shows a pronounced trade-off between sensitivity and specificity depending on the selected cutoff. TR4-5 prioritizes sensitivity and captures most malignant nodules, whereas TR5 identifies a subgroup with high certainty of malignancy. However, the overlapping malignancy risk across categories suggests that ACR TI-RADS alone is insufficient for clinical decision-making, highlighting the need for complementary diagnostic approaches.

EP1481 - ECE_2804 - Clinical significance of anti-thyroglobulin antibody dynamics in differentiated thyroid cancer

Merve Şenay Özçalık, Deniz Türküm Atikcan, Ece Gül Köse Hamidi, Ozlem Turhan Iyidir, Asli Nar and Neslihan Başçıl Tütüncü

Endocrinology and Metabolism, Baskent University, Ankara, Türkiye

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: The prognostic value of baseline anti-thyroglobulin antibodies (anti-Tg) in differentiated thyroid cancer (DTC) remains controversial. While anti-Tg interferes with thyroglobulin measurements, its dynamic behavior during follow-up may provide clinically relevant prognostic information beyond baseline levels.

Methods: We retrospectively evaluated 62 patients with DTC diagnosed between 2000 and 2024 who had positive baseline anti-Tg levels. The mean age was 47.6 ± 14.1 years, and 77.4% were female. Patients were classified according to histopathological subtype and ATA risk stratification. Anti-Tg dynamics, including negativization at 24 months, radioactive iodine (RAI) treatment, and recurrence outcomes were analyzed. Associations between baseline anti-Tg levels, anti-Tg negativization, and long-term recurrence were assessed.

Results: Classic papillary thyroid carcinoma was the most frequent histopathological subtype (58.1%). According to ATA risk classification, 35.5% of patients were low risk, 17.7% low–intermediate risk, 25.8% intermediate–high risk, and 21.0% high risk. RAI therapy was administered to 82.3% of patients. At 24 months, anti-Tg negativization was achieved in 77.4% of cases. Lower baseline anti-Tg levels were significantly associated with anti-Tg negativization at 24 months ($P = .001$). Baseline anti-Tg levels were not independently associated with ATA risk category, histopathological subtype, or recurrence ($P > .05$). However, among 47 patients with at least 5 years of follow-up, persistent anti-Tg positivity at 24 months was significantly associated with recurrence ($P = .031$).

Conclusions: Baseline anti-Tg levels alone do not predict ATA risk classification or recurrence in differentiated thyroid cancer. In contrast, failure to achieve anti-Tg negativization at 24 months was significantly associated with recurrence during long-term follow-up. These findings highlight the importance of dynamic anti-Tg monitoring as a prognostic marker beyond static baseline measurements. However, these findings should be interpreted cautiously due to the limited number of recurrance events.

Abstract citation ID: lvag096.1656

EP1482 - ECE_3080 - The use of rapid on-site evaluation during thyroid fine needle aspiration might help improve samples representativity

Aurélien Schommers, Iulia Potorac, Pauline Delannoy, Laurent Vroonen, Daniela Betea, Sandrine Petignot, Anne-Sophie Chachati and Patrick Petrossians
Endocrinology, Université de Liège, CHU Liège, Liège, Belgium

Introduction: Thyroid fine needle aspiration (FNA) is routinely performed in thyroid nodular disease. It provides precious information about nodules' cellular constitution and can help therapeutic management, notably through the use of Bethesda classification. Unfortunately, this test encounters a significant number of non-diagnostic (class I) results, which leads to uncertainty in providing the most appropriate support and potentially increasing patients' anxiety. In our study, we were interested in appreciating the improvement of sample quality by checking the cellular content during FNA with the help of a microscope and using rapid on-site evaluation (ROSE) directly in the consultation room.

Design and Methods: We conducted a retrospective study on 297 (69 males, 228 females; mean ages 54 and 55 respectively) fine needle aspirations, made between 2017 and 2024. Ultrasound appearance according to EU-TIRADS classification were respectively 131 EU-TIRADS 3 (44%), 68 EU-TIRADS 4 (23%), and 98 EU-TIRADS-5 (33%). In group A (ROSE, 67 patients), FNA was performed by the same operator (Operator A), spreading out a drop of the sample over a microscope slide. Samples were coloured using Diff-Quick method, and cellularity was evaluated under a microscope. If the cellularity was insufficient, another aspiration was made. Group B (230 patients) comprises cases of FNA performed without microscopic quality-control by operator A and others.

Results: 9 samples were classified as non-diagnostic in group A (13%) against 118 in group B (51%), $P < .0001$. Looking at the samples taken by operator A ($n = 146$), ROSE procedure was performed in 67 cases whereas standard FNA procedure was used in 79 cases. 9 needle aspirations were classified as non-diagnostic in the first subgroup (13%) against 31 (39%) in the second one. $P < .0001$. The proportion of different EU-TIRADS nodules in groups A and B was not significantly different.

Conclusions: Our study suggests the use of microscope and ROSE during FNA might improve the yield of fine needle aspiration by reducing the number of non-diagnostic samples. This method would help reduce the overall number of repeated biopsy sessions and allow the practician to offer a more refined exploration of thyroid nodular disease.

EP1484 - ECE_3544 - Clinical, radiological, and pathological characteristics of NIFTP: a single-center experience

Ekin Yiğit Köroğlu[1], Cevdet Aydin[2], Caglar Keskin[1], Ayşegül Aksoy Altınboğa[3], Asiye Şafak Bulut[3], Buket Altun Özdemir[4], Oya Topaloglu[2], Reyhan Ersoy[2] and Bekir Cakir[2]
[1]*Endocrinology and Metabolism Diseases, Ankara Bilkent City Hospital, Ankara, Türkiye;* [2]*Endocrinology and Metabolism Diseases, Ankara Yıldırım Beyazıt University, Ankara, Türkiye;* [3]*Medical Pathology, Ankara Bilkent City Hospital, Ankara, Türkiye;* [4]*Breast and Endocrine Surgery, General Surgery, Ankara Bilkent City Hospital, Ankara, Türkiye*

Background: Non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) represents a borderline thyroid entity with indolent behavior. However, its preoperative characterization remains challenging due to overlapping cytological and radiological features with papillary thyroid carcinoma (PTC). This study aimed to comprehensively evaluate the clinical, ultrasonographic, cytological, pathological, and outcome characteristics of patients diagnosed with NIFTP.

Methods: We retrospectively analyzed 165 consecutive patients diagnosed with NIFTP between 2017 and 2023 at a tertiary referral center. Demographic data, thyroid function, autoimmunity, ultrasonographic features (EU-TIRADS, ATA risk stratification), fine-needle aspiration (FNA) cytology, surgical approach, pathological findings, and clinical outcomes were evaluated. Descriptive statistics were applied, and follow-up data were analyzed in patients with isolated NIFTP.

Results: The cohort showed marked female predominance (84.8%; female-to-male ratio 5.6:1) with a mean age of 50.0 ± 12.6 years. Most patients were euthyroid at diagnosis (69.1%),

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

while autoimmune thyroiditis was present in 26.7%. Median ultrasonographic nodule diameter was 1.8 cm, and the majority were classified as low risk by EU-TIRADS (73.3%) and ATA (73.9%). Predominant sonographic features included regular margins (83.6%), isoechogenicity (85.5%), and wider-than-tall shape (91.5%).

FNA was performed in 85.5% of patients, with indeterminate cytology (Bethesda III-V) observed in 46.8%, most commonly Bethesda III (33.3%). Nuclear atypia was the most frequent cytological feature (82.1%), with a mean of 3.25 ± 1.79 papillary carcinoma–type nuclear features per patient.

Total thyroidectomy was performed in 79.4% of cases. Median pathological tumor size was 1.2 cm, and microcarcinomas (≤1 cm) accounted for 47.3%. Concurrent PTC was identified in 41.2%, while 58.8% had isolated NIFTP. During a median follow-up of 26 months, isolated NIFTP patients ($n = 97$) demonstrated excellent outcomes with no lymph node metastasis or recurrence and a disease-free survival rate of 100%.

Conclusions: NIFTP predominantly presents with low-risk ultrasonographic features and indeterminate cytology but demonstrates excellent clinical outcomes when isolated. Awareness of its characteristic profile may help avoid overtreatment and support conservative management strategies.

EP1485 - ECE_1032 - Determinants of radioactive iodine therapy failure in hyperthyroidism: a multivariable analysis from a UK cohort

Enam Ruf[1], Sonia Akther[1], Abdelmajid Musa[1,2], Harshal Deshmukh[3] and Mohamed Malik[1]
[1]*Diabetes & Endocrinology, Scunthorpe General Hospital, Scunthorpe, United Kingdom;* [2]*endo&diabetes, Scunthorpe General Hospital, Scunthorpe, United Kingdom;* [3]*James Cook University, South Mackay, Australia*

Introduction: Radioactive iodine (RAI) has been a cornerstone in management of hyperthyroidism since 1940s. Despite being effective therapy, a proportion of patients fail initial therapy and require repeat treatment. This study aims to identify clinical and biochemical predictors of RAI failure.

Methods: Retrospective cohort study of 764 patients treated with RAI for hyperthyroidism between 2007 and 2023 at a UK District Hospital. Univariable analyses followed by multivariable logistic regression were performed to identify independent predictors of treatment failure. Predictor variables were selected based on clinical relevance and published literature. Biochemical analysis of serial post-RAI TFTs up to 12 months were included. Categorical variables were analysed as factors with clinically relevant reference categories, and continuous variables were included as linear terms. Missing data were handled using random forest–based imputation. Results are reported as odds ratios (OR) with 95% confidence intervals (CI), with statistical significance defined as $P < .05$.

Results: Of the 764 patients included; 44 (5.76%) experienced treatment failure. Mean age was 56.6 ± 15.1 years, and 26.6% were male.

On univariable analysis; male sex was associated with increased odds of treatment failure (OR 3.29, 95% CI 1.55-6.89, $P = .001$). Longer ATD treatment duration was protective, particularly ≥13 months (13-18 months: OR 0.06, 95% CI 0.006-0.57; >24 months: OR 0.10, 95% CI 0.02-0.48). Multinodular goitre was associated with higher failure risk compared with smooth texture (OR 4.85, 95% CI 2.06-11.44, $P < .001$). Six-week post-RAI TSH was significantly lower in patients who failed treatment (Mann-Whitney U = 1481, $P < .001$).

On multivariable analysis; current smoking independently predicted treatment failure (OR 4.35, 95% CI 1.36-15.22, $P = .016$) whilst ex-smoking did not show the same relation (OR 1.62, 95% CI 0.33-7.15, $P = .53$) when compared with never smoking. Small goitre size was strongly protective compared with no goitre (OR 0.04, 95% CI 0.005-0.23, $P < .001$). Multinodular goitre texture remained independently associated with treatment failure (OR 11.48, 95% CI 2.58-62.12, $P = .002$). Autoimmune aetiology showed a borderline association with increased failure risk (OR 3.44, 95% CI 0.90-15.44). Six-week post-RAI TFTs were not independently predictive in the multivariable model, although raised TSH demonstrated a borderline protective trend.

Conclusions: This study confirms established clinical predictors of RAI treatment failure, including smoking status and multinodular goitre morphology. Importantly, suppressed 6-week post-RAI TSH emerged as a novel early biochemical marker of treatment failure, supporting its role in early risk stratification and optimisation of follow-up strategies.

EP1487 - ECE_2528 - Etiological diagnosis of hypothyroidism after craniofacial radiotherapy

Fatma Ben Abdessalem, Taieb Ach, Imen Halloul, Wiem Saafi, Hamza Fekih, Ghada Saad and Yosra Hasni
Endocrinology, Hôpital Farhat Hached, Sousse, Tunisia

Introduction: Radiotherapy for craniofacial cancers often leads to various forms of thyroid dysfunction as a significant late complication. The aim of this study is to identify the different causes of hypothyroidism following external radiotherapy.

Materials and Methods: This was a cross-sectional study involving 22 patients treated with external radiotherapy who developed hypothyroidism during post-radiation follow-up.

Results: 22 patients—10 men and 12 women—who experienced hypothyroidism following craniofacial radiation therapy were included in the study. Of these, 21 had nasopharyngeal carcinoma and one had Hodgkin's lymphoma. Over an average of 12 months, a dose of 72 ± 2 Gray was administered. The average interval between the end of radiation therapy and the hypothyroidism diagnosis was four years. Six cases had central hypothyroidism, with an inappropriate TSH (4.5 ± 2 mIU/L) and an average FT4 level of 4.1 pg/mL. Peripheral hypothyroidism was present in 14 cases. Anti-thyroperoxidase antibody levels were ten times higher than normal in four patients. Low FT4 levels (4.6 pg/mL), inappropriate TSH levels (12 mIU/L and 0.32 mIU/L), and elevated anti-thyroperoxidase antibody titers (82 and 890 IU/mL) were found in two cases with a mixed origin.

Conclusions: Hypothyroidism is the most common thyroid disorder after radiotherapy. It may be peripheral, due to direct toxicity or autoimmune damage, or central, isolated or occurring as part of hypothalamic-pituitary injury, or mixed. Therefore, regular thyroid function monitoring is essential for the early detection of post-radiation hypothyroidism.

EP1488 - ECE_2677 - Association of thyrotoxic periodic paralysis with long-term risk of incident diabetes: a population-based cohort study

Gloria Hoi-Yee Li[1], Kelvin Ho[1], Kathryn Choon-Beng Tan[2], Elaine Yun-Ning Cheung[3] and Ching-Lung Cheung[2]
[1]*Department of Health Technology and Informatics, The Hong Kong Polytechnic University, Hung Hom, Hong Kong;* [2]*Department of Pharmacology and Pharmacy, The University of Hong Kong, Pokfulam, Hong Kong;* [3]*Department of Medicine and Therapeutics, The Chinese University of Hong Kong, CUHK Medical Centre, Sha Tin, Hong Kong*

Introduction: Thyrotoxic periodic paralysis (TPP) is a rare complication of thyrotoxicosis, characterized by episodes of muscle paralysis and hypokalemia. During acute attacks, patients with TPP were observed to develop hyperinsulinemia triggered by precipitating factors such as carbohydrate load. Compared to patients with thyrotoxicosis but not TPP (simple thyrotoxicosis), those with TPP exhibited higher insulin levels even after the resolution of paralytic episodes. In this study, we aimed to evaluate the association of TPP with the long-term risk of developing diabetes.

Methods: We conducted a retrospective cohort study using a representative electronic health record database in Hong Kong. Individuals with first TPP and simple thyrotoxicosis between 2002 and 2016 were identified, and followed until the development of incident diabetes, death, or end of study on 31 December 2021. Propensity score (PS) matching was used to balance the baseline characteristics, matching each individual with TPP history with up to four individuals with simple thyrotoxicosis. Cox proportional hazards model was applied to estimate the hazard ratio (HR) for incident diabetes among individuals with TPP history compared to those with simple thyrotoxicosis.

Results: Between 2002 and 2016, a total of 631 individuals developed incident TPP, while 16 240 developed simple thyrotoxicosis. Using the PS approach, 630 individuals with TPP were matched to 1654 individuals with simple thyrotoxicosis. Over a median follow-up of more than 11 years, the incidence rate of diabetes was 11.03 per 1000 person-years (95% confidence interval [CI]: 8.72-13.77) in the TPP group and 6.6 per 1000 person-years (95% CI: 5.51-7.85) in the simple thyrotoxicosis group. In time-to-event analysis, individuals with TPP history had significantly higher risk of incident diabetes compared to those with simple thyrotoxicosis (HR = 2.25; 95% CI: 1.61-3.14; $P < .001$). Sensitivity analyses restricted to individuals with at least 10 and 15 years of follow-up time yielded similar results (10-year follow-up: HR = 2.33; 95% CI: 1.55-3.51; $P < .001$; 15-year follow-up: HR = 2.18; 95% CI: 1.54-3.09; $P < .001$).

Conclusions: Individuals with TPP history exhibited a significantly higher long-term risk of developing diabetes compared to those with simple thyrotoxicosis. Regular monitoring for diabetes may be warranted in individuals with TPP history to facilitate early detection and timely intervention.

EP1490 - ECE_3131 - Use of liothyronine in combination with levothyroxine: real-world biochemical outcomes in a UK endocrine clinic

Muhammad Masroor Amjad[1,2], Muhammad Haroon Riasat[1], Samraiz Nafees[3], Khurram Qayyum[1], Rehmat Karim[1], Najeeb Shah[1] and Mohamed Malik[4]
[1]*Hull Royal Infirmary, Hull, United Kingdom;* [2]*Diabetes & Endocrinology, Hull Royal Infirmary, Kingston upon Hull, United Kingdom;* [3]*Scarborough General Hospital, Scarborough, United Kingdom;* [4]*Scunthorpe General Hospital, Scunthorpe, United Kingdom*

Combined Levothyroxine and Liothyronine (T4/T3) therapy in primary hypothyroidism remain a matter of debate, this study was designed to highlight the biochemical outcomes from real clinical practice.**Methodology:** Retrospective observational audit of electronic records from secondary care endocrine clinic in UK.

Participants: All adults receiving liothyronine in combination with levothyroxine for primary hypothyroidism under clinic follow up during the audit period ($n = 26$). Most participants were female (24/26, 92.3%) and aged 36-80 years, with primary autoimmune, post-radioiodine and postsurgical hypothyroidism predominating.

Interventions: Existing combination therapy was reviewed. For each patient, prior levothyroxine dose, TSH and weight were extracted together with current T4 and T3 doses, TSH, weight and duration on a stable regimen.

Main outcome measures: Primary outcome was the proportion of patients with TSH within the reference range (0.4-4.5 mU/L) on combination therapy. Secondary outcomes included TSH <0.4 or >4.5 mU/L, change in TSH and weight from monotherapy to combination therapy, time to stable TSH, and prescribed T4:T3 dose ratios.

Results: Before combination therapy, 17/26 patients (65.4%) had TSH >4.5 mU/L despite levothyroxine doses most commonly between 100 and 150 mcg daily. On combination therapy, 18/26 (69.2%) had TSH 0.4-4.5 mU/L, 4/26 (15.4%) had TSH <0.4 mU/L, and 4/26 (15.4%) had TSH >4.5 mU/L. Stable TSH was documented in 14/26 patients (53.8%); in 12/26 (46.2%) TSH remained unstable, suppressed, recently altered or showed only minimal improvement. Mean T4:T3 ratio was approximately 4:1, with wide inter-individual variability.

Conclusions: In this cohort, combination therapy was used in a small, predominantly female group with persistent biochemical abnormalities on levothyroxine alone and led to normalisation of TSH in around two thirds of patients. However, almost half did not achieve sustained biochemical stability and a sizeable minority had suppressed or elevated TSH, raising concerns in the context of guidance that does not recommend routine combination therapy and emphasises cautious dosing and regular review. These findings support tighter local criteria, more structured monitoring and clearer documentation of indications when prescribing liothyronine.

EP1491 - ECE_3615 - Dose is not the answer: rethinking refractory hypothyroidism

Diana Martiniuc[1,2], Otilia-Andreea Tarcau[1], Simina Plesca[1], Ingrid-Ioana Stafie[1,2], Viviana Adam[1,2], Anca Matei[1,2], Stefana Bilha[1,2], Alexandru Florescu[1,2] and Cristina Preda[1,2]
[1]*Endocrinology, "St Spiridon" Clinical Emergency County Hospital, Iași, Romania;* [2]*"Grigore T. Popa" University of Medicine and Pharmacy, Iași, Romania*

Levothyroxine (LT4) is the first-line therapy for hypothyroidism and is available in multiple formulations, including tablets, liquid formulations, and soft-gel capsules. Persistent hypothyroidism despite apparently adequate or high LT4 doses is frequently labelled as "refractory", although this term encompasses heterogeneous mechanisms, including poor adherence, incorrect administration, and gastrointestinal disease impairing levothyroxine bioavailability. Accurate differentiation between these entities is essential, particularly in patients requiring strict TSH control.

We report three female patients referred to a tertiary endocrine centre for severe hypothyroidism despite high-dose LT4 therapy. All patients underwent a levothyroxine absorption test based on administration of the usual daily LT4 dose, with serial measurements of total and free thyroxine, according to the protocol described by Prof. Philippe Caron and colleagues. A comprehensive evaluation for gastrointestinal, autoimmune, and pharmacological causes of impaired absorption was performed. LT4 formulation and route of administration were individualized based on test results. Two patients demonstrated preserved intestinal LT4 absorption (>60%) despite marked biochemical hypothyroidism, consistent with pseudo-malabsorption, most likely related to improper administration or functional non-adherence. In both cases, therapeutic education and transition to liquid LT4 led to normalization of thyroid function tests. The third patient, with a history of total thyroidectomy for papillary thyroid carcinoma, presented with severe hypothyroidism despite high-dose LT4 and a clinical requirement for TSH suppression. She exhibited true malabsorption, associated with chronic gastritis and hypergastrinemia. A combined strategy using oral LT4 with vitamin C to enhance gastric acidification, together with temporary rectal LT4 administration, successfully restored euthyroidism. Follow-up demonstrated maintenance of biochemical control on oral LT4 alone, suggesting reversible, pH-dependent malabsorption.

Refractory hypothyroidism represents a diagnostic signal rather than a final diagnosis. The daily-dose levothyroxine absorption test is a practical and informative tool to distinguish pseudo-malabsorption from true absorption impairment and to guide individualized therapy. While most patients exhibit functional causes, a minority present with genuine, potentially reversible malabsorption, a distinction of particular importance in patients with differentiated thyroid carcinoma.

EP1492 - ECE_3648 - Metformin in the management of thyroiddysfunction and carbohydrate metabolism disorders inpatients with diffuse toxic goiter and insulin resistance

Halyna Suslyk[1] and Orysia Lishchuk[1,2]
[1]*Endocrinology, University Clinic, Lviv, Ukraine;* [2]*Danylo Halytskyi Lviv National Medical University, Lviv, Ukraine*

Introduction: Subsequent clinical and experimental studies have shown that in thyrotoxicosis insulin interacts differently with target tissues, including the liver, muscles, adipose tissue, and endothelium. The degree of glucose intolerance and β-cell dysfunction correlates with the severity of diffuse toxic goiter. Hyperthyroidism is associated with hepatic insulin resistance, increased fasting plasma glucose, enhanced gluconeogenesis, and glycogenolysis. Thyroid hormones regulate key enzymes of carbohydrate metabolism, while metformin, a biguanide and the only insulin sensitizer approved by major diabetes associations, reduces hepatic glucose production and improves peripheral glucose uptake. Data on the effect of metformin on thyroid function remain limited.

The aim of the study was to assess carbohydrate metabolism and insulin resistance indices in patients with diffuse toxic goiter receiving metformin.

Materials and Methods: The study included 41 patients (30 women and 11 men, mean age 42.0 ± 0.9 years) with diffuse toxic goiter and insulin resistance. Examinations were performed at baseline and after 3 and 6 months of thyreostatic therapy with thyrozol combined with metformin. Thyroid function (TSH, free T4, free T3), carbohydrate metabolism parameters (glucose, HbA1c, insulin, C-peptide), and insulin resistance indices (HOMA-IR, HOMA-β, Caro index) were assessed. Statistical analysis was performed using Microsoft Excel and STATISTICA 6.0.

Results and Discussion: Thyrozol therapy led to a significant increase in TSH levels from 0.02 ± 0.00 to 1.75 ± 0.12 mMO/L ($P < .001$), with a further rise to 2.20 ± 0.03 mMO/L ($P < .05$) after adding metformin. Free T4 levels decreased from 4.46 ± 0.35 to 1.65 ± 0.06 ng/dL after thyrozol treatment and to 1.57 ± 0.05 ng/dL with combined therapy ($P < .001$). Free T3 levels also significantly decreased from 16.18 ± 1.07 to 3.48 ± 0.11 pg/mL and further to 3.28 ± 0.10 pg/mL ($P < .001$).

Combined therapy resulted in improved carbohydrate metabolism: fasting glucose decreased from 5.56 ± 0.15 to 5.20 ± 0.10 mmol/L ($P < .05$), insulin from 13.09 ± 0.54 to 11.53 ± 0.43 mMO/L ($P < .05$), and HOMA-IR from 3.30 ± 0.20 to 2.70 ± 0.14 ($P < .05$). A trend toward reduced HbA1c was observed.

Conclusions: Thyrozol therapy achieved euthyroidism in patients with diffuse toxic goiter and insulin resistance. The addition of metformin enhanced normalization of thyroid hormone levels and significantly reduced insulin resistance. Thyreostatic therapy alone did not fully eliminate insulin resistance, highlighting the benefit of combined treatment with metformin.

EP1493 - ECE_1099 - When antithyroid drugs fail: refractory amiodarone-induced thyrotoxicosis managed with plasmapheresis and surgery

Mohammad Zaid Seegoolam, Hao Wei Tan, Amit Allahabadia, Sabapathy Balasubramanian and Miguel Debono
Diabetes and Endocrinology, Sheffield Teaching Hospital NHS Foundation Trust, Sheffield, United Kingdom

Severe amiodarone-induced thyrotoxicosis (AIT) can be rapidly life-threatening, particularly when standard antithyroid therapy is contraindicated or ineffective.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

A 69-year-old man with a history of paroxysmal atrial fibrillation (pAF), treated with amiodarone for the past 3.5 years, presented with progressive exertional dyspnoea. Amiodarone had been discontinued by cardiology in June 2024 due to conduction abnormalities.

Initial thyroid function tests (TFTs) revealed a thyrotoxic profile showing a suppressed TSH < 0.02, FT4 > 100 and FT3:25.1. Autoantibody screening including TRAb and TgAb was negative.

Patient was commenced on carbimazole 40 mg OD (07/01/2025) subsequently escalated to 20 mg TDS (13/01/2025), and prednisolone 40 mg OD (23/01/2025) for suspected amiodarone-induced thyrotoxicosis (AIT). By late January, transaminitis was noted but therapy was continued. On 12/02/2025, with persisting hepatic dysfunction, carbimazole was reduced to 20 mg BD. Prednisolone was switched to dexamethasone 2 mg BD.

Therapy was optimised in accordance with the SPROG protocol (Sheffield Peri-operative Rapid Optimisation in Graves' disease, which comprises of Lugol's iodine, dexamethasone, cholestyramine, lithium, propranolol): with carbimazole and dexamethasone continued, bisoprolol switched to propranolol 40 mg TDS, and cholestyramine 4 g TDS added. At endocrine MDT review (14/02/2025), a switch to propylthiouracil (PTU) 150 mg TDS was recommended alongside adjunctive therapy and surgical referral. However, with worsening hepatic dysfunction (ALT 436 IU/L), PTU was discontinued and the regimen revised to Lugol's iodine 0.3 mL TDS, lithium, dexamethasone 2 mg BD, cholestyramine 4 g TDS, and maximal-dose propranolol. Despite five weeks of intensive inpatient management with the SPROG protocol and adjunctive measures, thyroid function remained abnormal (TSH < 0.02 mU/L, FT4 > 100 pmol/L).

Following haematology input, plasmapheresis was introduced as a bridging therapy to surgery. An initial course of 10 alternate-day sessions over three weeks achieved only transient biochemical improvement (FT3 5.1 pmol/L, FT4 53.2 pmol/L), with subsequent biochemical relapse. Escalation to daily plasmapheresis for a further week was required, and in total the patient received 17 sessions. This strategy enabled sufficient stabilization to permit a successful high-risk total thyroidectomy after three months of intensive therapy.

Postoperatively, the patient made a marked clinical recovery, with resolution of fatigue and breathlessness. He was commenced on levothyroxine 125 µg OD, titrated to 75 µg OD and was placed on a hydrocortisone taper, now maintained on 10 mg, 5 mg, 2.5 mg for secondary adrenal insufficiency

We propose plasmapheresis should be considered a viable bridge to surgery in refractory AIT when conventional strategies fail.

EP1494 - ECE_1473 - Thyrotoxic Hypokalemic Periodic paralysis and new-onset autoimmune diabetes: a rare, combined presentation

Osman Abdalrazag[1], Zambu Kyaw[2] and Zayd Merza[1]
[1]*Diabetes & Endocrinology Centre, Barnsley Hospital Nhs Foundation Trust, Barnsley, United Kingdom;* [2]*Barnsley Hospital Nhs Foundation Trust, Barnsley, United Kingdom*

Introduction: Thyrotoxic Hypokalemic Periodic paralysis (THPP) is a rare but potentially life-threatening complication of thyrotoxicosis, mostly associated with Graves' disease. It presents as episodic muscle weakness brought on by triggers like carbohydrate intake, exercise or stress. Insulin causes shifting of potassium intracellularly increasing the risk of hypokalaemia and complicating management in patients with coexisting autoimmune diabetes.

Case report: A 41-year-old Caucasian male presented with acute lower limbs weakness progressing over a day without sensory symptoms. Examination revealed no objective weakness or clinical features of hyperthyroidism. Investigations demonstrated mild hypokalaemia of 3.4 mmol/L, TSH < 0.01, a raised Free FT4 of 49.3 pmol/L, and FT3 of 18.9 pmol/L. TSH receptor antibodies were positive, supporting a diagnosis of Graves' disease, and treatment with carbimazole and propranolol was commenced, alongside oral potassium replacement, resulting in complete recovery of the weakness.

One month later, he re-presented with bilateral lower limb heaviness following a high-carbohydrate meal. Neurological examination showed normal power, tone, reflexes, and sensation. Blood tests showed recurrent hypokalemia of 2.9 mmol/L, FT4 33 pmol/L, ECG showed no significant abnormalities. Based on the clinical presentation and biochemical findings, a diagnosis of THPP was established. Intravenous potassium replacement resulted in rapid resolution of symptoms. A random glucose measured 16 mmol/L with an HbA1C of 53 mmol/mol, indicating previously undiagnosed diabetes.

Positive anti-GAD antibodies >2000 u/mL with negative islet A2 and ZnT8 antibodies were consistent with newly diagnosed autoimmune diabetes. His C-peptide of 1413 pmol/L was raised with a glucose of 16.8 mmol/L.

Conclusions: This case highlights the importance of considering THPP in patients presenting with acute episodic weakness, even in the absence of objective neurological or thyrotoxic features. Recognition of triggers such as high-carbohydrate intake is important. The coexistence of Graves' disease, hypokalemic periodic paralysis, and newly diagnosed autoimmune diabetes underscores the need for comprehensive endocrine evaluation.

EP1496 - ECE_3588 - Tocilizumab as second-line therapy in 67-year-old female with severe graves' orbitopathy and corticosteroid-induced cataract

Petros Papalexis[1], Vasiliki Siampanopoulou[2], Alexandros Lafioniatis[2], Georgia Tsirou[2], Varvava Chalmantzi[2], Despoina Tsopouzidou[2], Paschalia Bekiaridou[2] and Anna Angelousi[2]
[1]*First Department of Medicine, Unit of Endocrinology, Laiko General Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece;* [2]*Unit of Endocrinology, First Department of Internal Medicine, National and Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece*

Background/Introduction: Graves' orbitopathy (GO) is the most common extrathyroidal manifestation of Graves' disease and can be sight-threatening in severe cases. While corticosteroids are the first-line treatment, their use may be limited by adverse effects or therapeutic resistance, necessitating second-line interventions.

Purpose: To present a clinical case of Graves' orbitopathy treated with the monoclonal antibody tocilizumab in a female patient who developed steroid-induced cataract.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Methods: A 67-year-old female with a history of Graves' disease since 2020 and persistently positive thyroid-stimulating immunoglobulin (TSI) antibodies presented with progressive bilateral exophthalmos and active GO (Clinical Activity Score [CAS] of 4/7). Despite antithyroid treatment with unimazole, her TSI levels remained elevated. She was also receiving selenium supplementation. The patient had previously undergone high-dose corticosteroid pulse therapy but developed steroid-induced cataracts, precluding further steroid use. Orbital MRI confirmed bilateral extraocular muscle enlargement and mild optic nerve compression.

Results: Tocilizumab was initiated at a dose of 500-520 mg intravenously every four weeks for four cycles. The treatment was well tolerated and led to a reduction in CAS from 4/7 to 3/7. Hertel exophthalmometry measurements decreased from 24 mm to 21 mm. Follow-up orbital MRI demonstrated partial regression of extraocular muscle enlargement. Although TSI antibody titers declined post-treatment, they remained persistently positive.

Conclusions: Tocilizumab, an IL-6 receptor antagonist, is emerging as an effective second-line agent in corticosteroid-resistant GO. In this case, it resulted in modest clinical improvement without adverse effects. The case underscores the challenges of managing refractory GO and the potential need for a multimodal treatment approach.

EP1497 - ECE_2945 - Successful levothyroxine discontinuation in patients with a persistently normal TSH

David Fisher[1,2], Ori Adler[3], Tamar Freud[4], Howard Tandeter[4] and Merav Fraenkel[1,2]

[1]Endocrinology, Soroka, University Medical Center, Be'er Sheva, Israel; [2]Faculty of Health Sciences, Ben-Gurion University of the Negev, Be-er Sheva, Israel; [3]Internal Medicine B, Soroka, University Medical Center, Be'er Sheva, Israel; [4]Department of Family Medicine and Siaal Research Center for Family Medicine and Primary Care, Ben-Gurion University of the Negev, Be'er Sheva, Israel

Background: Levothyroxine is widely prescribed for subclinical and overt hypothyroidism yet in some patients the indication for lifelong therapy remains uncertain. This study assessed whether long-term levothyroxine therapy can be safely discontinued in patients with persistently normal thyroid function. Secondary objectives were to identify predictors of successful levothyroxine discontinuation.

Methods: This prospective cohort study included adults (≥18 years) treated with levothyroxine for ≥5 years who maintained a normal annual TSH for five consecutive years. Eligible patients were identified through a computerized search of electronic medical records of Clalit Health Services, Southern District. Exclusion criteria included prior thyroidectomy, radioactive iodine therapy, diagnosis of congenital hypothyroidism or women with childbearing potential.

After obtaining informed consent, demographic data and baseline clinical, biochemical (including anti-thyroid peroxidase (TPO) antibodies) and current levothyroxine dose were recorded. Levothyroxine was discontinued, and participants were followed for 24 weeks with thyroid function tests and clinical assessments for symptoms of hypothyroidism at 4, 10, 16, and 24 weeks.

Treatment was restarted if during follow-up one of the following occurred:

1. TSH >10 mIU/L and/or free T4 below the lower limit of normal
2. Symptoms of hypothyroidism developed

The primary outcome was resumption of levothyroxine. Hazard ratios (HRs) for levothyroxine reinitiation were calculated using Cox proportional hazards models.

Results: Eighty-three patients were enrolled (69 women, 83%), mean age 70.5 ± 9.1 years; 32 were anti-TPO seropositive, 45 were seronegative and in 6 patients antibody status was unavailable. As of January 2026, sixty-seven patients completed 24-weeks follow-up; 33 patients (49.3%) remained biochemically and clinically euthyroid. Thirty-four patients (50.7%) required levothyroxine resumption: 23 (34%) due to biochemical hypothyroidism and 11 (16.4%) due to clinical hypothyroidism (of these patients, 6 had subclinical hypothyroidism and 5 were biochemically euthyroid).

Mean time to levothyroxine resumption was 6.4 ± 4.8 weeks (median 4 weeks). Following multivariable analysis adjusted for age, sex, and duration of prior euthyroid status, only levothyroxine dose (μg/kg) at study entry independently predicted treatment resumption (HR 5.1, 95% CI 1.65-15.63; $P = .005$). No serious adverse events were observed.

Conclusions: Half of patients receiving long-term levothyroxine with biochemical control were able to discontinue therapy and remain euthyroid after 24 weeks. The need for treatment resumption occurred early in those who failed discontinuation and was predicted by a higher baseline levothyroxine dose at study entry. Supervised levothyroxine withdrawal is feasible and safe in selected patients and may reduce unnecessary long-term treatment.

EP1498 - ECE_1989 - Graves' disease in patient with thyroid hormone resistance

Jan Drugda, Pavel Cee and Filip Gabalec

4th Department of Internal Medicine, University Hospital Hradec Králové, Hradec Králové, Czech Republic

Introduction: Thyroid hormone resistance (RTH) is a rare condition in which peripheral tissues fail to respond appropriately to thyroid hormones due to defects in thyroid hormone receptor

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

signaling, most commonly caused by mutations in the thyroid hormone receptor beta (THRB) gene. This condition leads to elevated circulating thyroid hormone levels (fT4/fT3) with normal or even increased thyroid-stimulating hormone (TSH). Clinical manifestations vary depending on the degree of resistance across different tissues. Graves' disease, on the other hand, is a much more common cause of elevated thyroid hormones caused by autoimmune activation of the TSH receptor. The coexistence of both conditions in a single patient is extremely rare and presents a significant therapeutic challenge.

Observation: We present a case of a 22-year-old woman without significant comorbidities. She was referred by our obstetrician after delivering a child with hyperthyroidism. Her testing showed elevated thyroid hormones, suppressed TSH, and elevated TSH receptor antibodies (TRAb). Ultrasound revealed a slightly enlarged, inhomogeneous thyroid with marked hypervascularisation. Graves' disease was diagnosed, and propylthiouracil treatment was started. Six months after labour, we switched to thiamazole as she stopped breastfeeding. The thyreostatic treatment was more or less successful during the first year, with fluctuating TSH and fT4 levels requiring several dose adjustments. Nevertheless, the patient remained practically asymptomatic since the beginning.

In parallel, her son was at first also treated with propylthiouracil. After the maternal TRAb clearance period, the treatment was discontinued. The thyroid hormones remained elevated, but the TSH normalized, and then became even mildly elevated. The boy underwent genetic testing, and the THRB mutation (c.1313G>A) was confirmed. The same mutation was later confirmed in our patient as well. That led us to a difficult decision: whether to continue the thyreostatic treatment. We decided to continue the current dose of 30 mg of thiamazole daily, because of the lack of symptoms and TSH suppression (we know that it used to be normal in the first trimester screening). We decided to adjust the dosing based on symptoms rather than laboratory findings.

Overview: This case report describes a rare coexistence of thyroid hormone resistance (RTH) due to a THRB mutation and Graves' disease in a young woman. The case highlights the diagnostic and therapeutic challenges of managing Graves' disease in the presence of RTH and highlights the importance of prioritizing clinical symptoms over biochemical parameters when guiding treatment.

EP1499 - ECE_3014 - An atypical case of schmidt syndrome in a male without hyperpigmentation

Khadija Had, Hamza El Fekih[1], Wiem Saafi[2], Sawsen Nouira[1], Imen Halloul[2], Taieb Ach[2], Ghada Saad[2] and Yosra Hasni[1]
[1]Department of Endocrinology and Diabetology, Laboratory of Exercise Physiology and Pathophysiology (LR19ES09), Farhat Hached University Hospital, Sousse, Tunisia; [2]Department of Endocrinology and Diabetology, Farhat Hached University Hospital, Sousse, Tunisia

Introduction: Schmidt syndrome is rare autoimmune disease with an estimated prevalence ranging from 1.4 to 4.5 cases per 100 000 inhabitants. It may occur at any age but is uncommon in children and after the age of 60, and it predominantly affects middle-aged women.

Addison's disease is usually suspected in the presence of weight loss, hypotension, hypoglycemia, and cutaneous hyperpigmentation; however, hyperpigmentation may be absent, as illustrated in our patient.

Case report: A 35-year-old male presented with progressive asthenia worsening in the evening, anorexia, and weight loss of 6 kg over one month. Physical examination revealed blood pressure of 100/60 mm Hg, heart rate of 99 bpm, fasting blood glucose of 0.74 g/L. The patient exhibits no cutaneous hyperpigmentation and no melanotic macules of the oral mucosa. The diagnosis of primary adrenal insufficiency was confirmed by 8 a.m. serum cortisol level at 43 µg/L and ACTH levels raging from 30 to 35 pg/mL. The patient was treated with hydrocortisone leading to significant clinical improvement. Two months later, the patient presented with weight gain, asthenia, and constipation, with no goiter on physical examination. Thyroid function tests confirmed primary hypothyroidism with a TSH level of 48 mIU/L and positive anti-thyroid peroxidase antibodies at 59 IU/mL. Treatment with L-thyroxine was initiated, resulting in clinical and biological improvement. The patient was hospitalized multiple times for acute adrenal insufficiency, triggered by flu, with no skin hyperpigmentation observed after 5 years follow-up.

Discussion: Schmidt syndrome, defined by the association of Addison's disease with Hashimoto's thyroiditis, is known also as autoimmune polyglandular syndrome type 2. Addison's disease results from autoimmune destruction of the adrenal cortex resulting in an elevation of ACTH levels and its precursor, POMC, which stimulate melanocyte activity and cause melanoderma. However, hyperpigmentation may be absent in the very early stages of the disease, particularly when adrenal involvement is partial or when ACTH secretion is only moderately increased.

Additionally, genetic factors may contribute to the absence of hyperpigmentation, especially in individuals with very fair skin or reduced melanogenic responsiveness.

EP1501 - ECE_2356 - MEN2A more indolent than expected: a report of two cases

Leandro Augusto Silva, Andreia Martins Fernandes, Ana Rita Elvas, Joana Couto, Raquel G. Martins, Teresa Martins, Jacinta Santos and Fernando Rodrigues
Endocrinology Department, Portuguese Institute of Oncology of Coimbra, Coimbra, Portugal

Introduction: Multiple endocrine neoplasia type 2A (MEN2A) is defined by medullary thyroid carcinoma (MTC) and/or C-cell hyperplasia, pheochromocytoma and primary hyperparathyroidism. 2015 American Thyroid Association (ATA) risk categories guide surveillance and timing of thyroidectomy; recommends, in ATA-MOD carriers, surveillance from age 5 and consideration of thyroidectomy mainly based on basal calcitonin levels; however, there is no consensus threshold for prophylactic surgery. Val804Met and Cys611Tyr variants, classified as ATA-MOD are associated with very high penetrance of MTC. We report two MEN2A asymptomatic carriers who remain disease-free under surveillance.

Case 1: Male, carrier of a pathogenic *RET* Cys611Tyr variant identified through family screening for MEN2A. At 73 years, biochemical

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

evaluation showed serum calcitonin <2 pg/mL (<14.3). Neck ultrasound detected two right-lobe thyroid nodules (7 and 8 mm, EU-TIRADS-4) and two right supraclavicular lymph nodes (11 and 15 mm); fine-needle cytology of the larger lymph node was negative for epithelial neoplastic cells and calcitonin in needle washout <2.0 pg/mL. Underwent active surveillance. At the last follow-up (age 82) he remained asymptomatic with normal examination; labs showed serum calcitonin 0.77 pg/mL and calcium, parathyroid hormone and plasma metanephrines within reference. Ultrasound demonstrated the previously nonspecific lymph nodes.

Case 2: Male, evaluated for a family history of MEN2A, at 72 years. Initial testing showed serum calcitonin 1.8 pg/mL, and three unsuspected micronodules in neck ultrasound. Familial variant Val804Met was identified. Prophylactic thyroidectomy was not pursued based on age, serum markers and ultrasound, surgical risk and patient preference. At the last assessment (age 81) he remained asymptomatic with an unremarkable examination; laboratory workup showed serum calcitonin 10.50 pg/mL and calcium, parathyroid hormone and plasma metanephrines within reference. Ultrasound demonstrated stable thyroid nodules (10 mm, EU-TIRADS-3).

Conclusions: Emerging data argue for re-appraisal of risk classification and management of 2015 ATA MTC guidelines, questioning the premise that prophylactic thyroidectomy is mandatory for all *RET* variant carriers. Active surveillance can be a safe strategy for selected carriers; however, robust data is needed to define optimal surveillance intervals, biomarkers and imaging triggers for intervention, maintaining a balance between safety and overtreatment.

EP1503 - ECE_3981 - Why add contrast in thyroid ultrasound: what perfusion curves can tell us

Andreea Bena, Stefania Bunceanu and Stoian Dana
Endocrinology, Internal Medicine 2nd, Universitatea de Medicină și Farmacie Victor Babeș, Timișoara, Romania

Background: Contrast-enhanced ultrasound (CEUS) allows dynamic, real-time evaluation of thyroid nodule microvascularization. While qualitative enhancement patterns are commonly used, quantitative analysis of time–intensity curves (TIC) may offer objective perfusion biomarkers that improve lesion characterization.

Objective: To illustrate the potential role of TIC-derived CEUS parameters in differentiating benign from malignant solitary thyroid nodules, using example data aligned with trends reported in the literature.

Methods: CEUS examinations were performed in 78 solitary thyroid nodules from 49 patients, with standardized cine acquisition and global region-of-interest (ROI) analysis. Quantitative TIC metrics included time parameters—arrival time (AT), rise time (RT), time to peak (TTP), fall time (FT), and mean transit time (mTT)—as well as amplitude and combined parameters: peak intensity (PKI), area under the curve (AUC), wash-in AUC (WiAUC), wash-out AUC (WoAUC), ascending slope (AS), descending slope (DS), slope ratio (SR), and mean TIC (mTIC). Nodule classification (benign vs malignant) was based on standard reference assessment (cytology and/or histology with follow-up). Data are presented as illustrative examples for educational purposes.

Results: In this example dataset, malignant nodules demonstrated delayed enhancement kinetics and reduced perfusion magnitude compared with benign lesions. Median AT was longer in malignant nodules (13.2 s [IQR 11.7-15.0] vs 11.0 s [9.6-12.8], $P = .008$), along with a prolonged TTP (28.5 s [24.0-33.2] vs 24.1 s [20.8-27.9], $P = .012$). Peak enhancement was significantly lower in malignant nodules, reflected by reduced PKI values (19.0 [14.8-22.6] vs 27.4 [22.3-32.1], $P < .001$).

Perfusion burden indices followed a similar pattern, with lower WiAUC in malignant nodules (285 [230-345] vs 402 [330-480], $P < .001$), suggesting diminished microvascular perfusion. Slope-derived parameters showed additional discriminatory value: malignant nodules exhibited a lower AS (1.05 [0.82-1.33] vs 1.48 [1.12-1.86], $P = .004$) and a higher SR (1.21 [0.98-1.46] vs 0.93 [0.76-1.12], $P = .021$), indicating relatively faster wash-out in relation to wash-in.

Receiver operating characteristic analysis identified PKI as a strong single predictor of malignancy (AUC = 0.83), while a multiparametric model combining PKI, TTP, and WiAUC improved diagnostic performance (AUC = 0.88).

Conclusions: Quantitative TIC analysis in CEUS provides complementary information on thyroid nodule perfusion dynamics. Parameters reflecting enhancement timing and magnitude—particularly PKI, TTP, and AUC-derived indices—illustrate how multiparametric CEUS assessment may enhance thyroid nodule characterization beyond qualitative imaging alone.

EP1504 - ECE_1653 - Thyroid nodule microwave ablation. First 100 cases in Romania

Emin Mammadov
Regina Maria Private Healthcare Network, Bucharest, Romania

Background: Microwave ablation (MWA) is a modern minimally-invasive technique using thermal ablation for outpatient treatment of benign and some malignant thyroid nodules, as well as parathyroid adenomas and metastatic lymph nodes. We report our experience with first 100 cases of MWA for thyroid nodules in Romania.

Methods: Retrospective analysis of the first 100 thyroid nodule MWA procedures performed in Romania. All MWA procedures were performed using cooled antenna 16G or 17G with a microwave generator manufactured by ECO Microwave. We followed our patients for at least 1 year after the procedure.

Results: Of 100 MWA procedures, 46 were performed for solitary non-functioning nodules, 30 for multinodular goitre, 24 for AFTN (autonomously functioning thyroid nodules) or toxic multinodular goitre.

The mean volume of nodules was 15.76cc (SD = 22.29) before ablation. Average ablation time was 6.7 minutes, average power used was 24.8 W.

The mean volume reduction rate (VRR) was 46% at 1-month, 61.4% at 3-month, 70.1% at 6-month and 79.4% at 12-month follow-up.

The VRR of at least 90% was seen in 4 patients at 3 months, 9 patients at 6 months and 17 patients at 12 months. Only 2 nodules had VRR less than 50% (mean 47.9%) at 12-month follow-up.

Minor complications included some bruising and post-procedural pain or local discomfort, controlled with non-

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

steroidal anti-inflammatory drugs. One patient with AFTN had transient post-procedural thyrotoxicosis, two patients developed transient dysphonia, no other significant complications.

Most patients who experienced compressive symptoms before ablation, had significant improvement at 1 month post ablation. All patients with AFTNs had their thyroid function normalized at 1 month, except for the aforementioned patient who developed transient thyrotoxicosis.

Conclusions: Thyroid nodule MWA is a safe and efficient treatment option for thyroid nodules, reducing volume and controlling thyroid function in case of AFTN or toxic multinodular goitre.

EP1507 - ECE_3270 - Rare case of Graves' disease with concomitant thyroid cancer and TED developed after RAI

Anna Somogyi[1], István Molnár[1], Bernadett Ujhelyi[2], Erika Szántó[3], Endre V. Nagy[1], Eszter Berta[1] and Miklós Bodor[1]

[1]Department of Medicine, Division of Endocrinology, University of Debrecen, Debrecen, Hungary; [2]Department of Ophthalmology, University of Debrecen, Debrecen, Hungary; [3]Department of Oncoradiology, University of Debrecen, Debrecen, Hungary

Introduction: Although Graves' disease (GD) is associated with an increased risk of thyroid malignancy, the concomitant occurrence of thyroid eye disease (TED) and thyroid cancer is rare. In our case, thyroidectomy was performed for GD, and differentiated thyroid carcinoma was diagnosed incidentally. Following radioiodine ablation, the patient developed new-onset TED. The pathogenesis of TED is not yet fully clarified however, literature data suggest that hypothyroidism preceding radioiodine therapy as well as the use of recombinant human TSH (rhTSH) as an alternative method may influence disease activity. This effect is thought to be mediated by activation of signalling pathways via TSH receptors expressed on orbital fibroblasts.

Case Presentation: A 44-year-old female patient with smoking history presented to the emergency department in February 2024 with sinus tachycardia, dysphagia and weight loss. Laboratory investigations revealed suppressed TSH, elevated TSH receptor antibodies (TRAb), and normal thyroid peroxidase antibody levels. Ultrasound examination demonstrated findings consistent with thyroiditis. Based on these results, Graves' disease was diagnosed, and thiamazole therapy was initiated.

Due to compression symptoms, total thyroidectomy was performed in August 2024, followed by hormone replacement with levothyroxine 100 µg daily. Histopathological examination revealed diffuse goiter and bilateral papillary microcarcinomas (one in each lobe). Consequently, after a 4-week levothyroxine withdrawal, the patient received 3700 MBq radioiodine ablation in December 2024. Follow-up examinations showed no residual thyroid or tumor tissue.

In early 2025, the patient developed diplopia accompanied by discomfort and tearing of the right eye. Ophthalmological assessment and ^{99m}Tc-DTPA (diethylenetriaminepentaacetic acid) SPECT/CT demonstrated bilateral, right-dominant, moderately active TED. Laboratory tests confirmed euthyroidism with elevated TRAb levels and normal thyroglobulin concentrations. Over the subsequent months the patient underwent a 12-week course of intravenous methylprednisolone therapy followed by retrobulbar irradiation, resulting in only transient improvement. Diplopia recurred one month after completion of steroid therapy.

Conclusions: The development of TED after total thyroidectomy may have been significantly influenced by hypothyroidism prior to radioiodine therapy and by the patient's ongoing smoking. It remains unclear whether the use of recombinant human TSH or prophylactic steroid administration would have resulted in a more favorable outcome. Further management options include rituximab or teprotumumab therapy as well as orbital surgery.

EP1508 - ECE_3693 - Riedel's thyroiditis associated with retroperitoneal fibrosis: a case presentation

Georgios Kostopoulos[1], Evangelia Makri[1], Georgios Tikos[1], Evangelia Katsiki[2], Dimitrios Deligeorgakis[3], Elpida Skouvaklidou[3], Christina Adamichou[3] and Zoe Efstathiadou[1]

[1]Endocrinology, Hippokration General Hospital, Thessaloniki, Greece; [2]Thessaloniki, Greece; [3]4th Department of Internal Medicine, Hippokration General Hospital, Thessaloniki, Greece

Background: Riedel thyroiditis (RT) is a rare, chronic fibro-inflammatory disorder of the thyroid, with challenging diagnosis and management. Although its exact aetiology is unknown, emerging evidence suggests RT is part of the spectrum of IgG4-related disease. Its coexistence with retroperitoneal fibrosis is uncommon but clinically significant, potentially reflecting multisystem involvement that requires prompt recognition.

Case Presentation: A 34-year-old male with autoimmune hypothyroidism on levothyroxine presented with a painless, progressively enlarging anterior neck mass and low-grade fever. His symptoms started 8 months before and initial evaluation suggested subacute thyroiditis; however, the patient lacked typical hormonal and ultrasonographic features and no improvement was noted upon glucocorticoid therapy.

On examination, he had a hard goiter with mild compressive symptoms. He was euthyroid on levothyroxine with elevated CRP and ESR. Ultrasound showed a diffusely enlarged, hypoechoic, hypovascular thyroid. RT was suspected. Fine-needle aspiration was nondiagnostic; core needle biopsy revealed fibrous tissue and inflammatory cells without thyroid follicles, raising suspicion for RT, while IgG4 immunohistochemistry was negative. Plasma IgG4 levels were also found within limits.

Cross-sectional imaging was ordered to assess for extrathyroidal fibrosis, but, at that time, the patient did not proceed due to personal reasons During follow-up, he developed acute lower abdominal pain radiating to the right testicular region. Imaging revealed a large right-sided retroperitoneal fibro-inflammatory mass encasing the distal abdominal aorta, inferior vena cava, iliac vessels, and right ureter, causing hydronephrosis and right renal cortical thinning—findings consistent with retroperitoneal fibrosis, likely IgG4-related. Following rheumatology assessment, the patient received high-dose intravenous methylprednisolone followed by rituximab and underwent right ureteral stent placement without complete resolution of hydronephrosis.Thyroid mass has partially regressed.

Conclusions: This case illustrates the rare coexistence of RT and retroperitoneal fibrosis, supporting a systemic

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

fibroinflammatory pathophysiology even in the absence of IgG4 positivity. Early recognition and multidisciplinary management by endocrinologists and rheumatologists are crucial to guide appropriate therapy.

EP1510 - ECE_1566 - Relation of irisin to insulin sensitivity in overweight/obese hypothyroid patients

Marwa Salah
Faculty of medicine, Alexandria University, Internal Medicine, Endocrine, Alexandria, Egypt

Background/Aim: Thyroid hormones and irisin, an exercise-induced adipo-myokine, modulate thermogenesis and energy metabolism. Given conflicting data on irisin in obesity and hypothyroidism, we evaluated the effects of adiposity and hypothyroidism on irisin levels and their relationships with insulin resistance.

Patients & Methods: In this cross-sectional study, ninety individuals were classified as follows: Group I: newly diagnosed hypothyroid overweight/obese ($n = 30$), Group II: treated hypothyroid overweight/obese ($n = 20$), Group III: euthyroid overweight/obese ($n = 20$), and Group IV: euthyroid lean controls ($n = 20$). Anthropometrics, thyroid function, glycemic, lipid profiles, and serum irisin levels were assessed. Group comparisons, correlations, and logistic regression were evaluated.

Results: Irisin levels were lower in obese groups (I-III) compared to controls ($H = 35.169$, $\mathbf{P < .001}$), with no difference between newly diagnosed and treated hypothyroid obese patients. In the total cohort, irisin correlated positively with FT3 ($\mathbf{P < .001}$) and FT4 ($\mathbf{P = .006}$), and negatively with TSH ($\mathbf{P = .007}$). Irisin correlated inversely with BMI, waist circumference, and waist-to-hip ratio (all $\mathbf{P < .001}$). In subgroup analyses, irisin correlated negatively with HOMA-IR in treated hypothyroid obese individuals ($P = .021$) and euthyroid obese individuals ($\mathbf{P = .026}$). In multivariable regression, **lower irisin was independently associated with obesity (OR 0.970, 95% CI 0.952-0.988, $\mathbf{P = .001}$)**

Conclusions: Circulating irisin is downregulated in obesity and linked to insulin resistance, while its relationship with hypothyroidism is less consistent. Irisin may serve as a metabolic, rather than thyroid-specific, biomarker, potentially useful for identifying obesity-related insulin resistance.

Keywords irisin, hypothyroidism, obesity, insulin resistance, HOMA-IR, thyroid hormones

EP1511 - ECE_1966 - Factors associated with the control of primary hypothyroidism in Northeastern Colombia

Maria Roa-Parra[1], Rubel Lafaurie-Noriega[1], Miguel Ochoa-Vera[1], María Luna-González[1], Juan Sarmiento-Ramón[1,2] and Edwin Wandurraga-Sánchez[2]
[1]*Universidad Autónoma de Bucaramanga—UNAB, Bucaramanga, Colombia;* [2]*Bucaramanga, Colombia*

Introduction: Primary hypothyroidism is the most common thyroid disease worldwide, with estimated prevalences of 3.8%-4.6%. Treatment consists of hormone replacement therapy, primarily with levothyroxine; however, 35%-60% of patients do not achieve adequate control. Several factors can influence TSH control; however, few studies have comprehensively evaluated these factors at the national level.

Objective: To identify factors associated with the control of primary hypothyroidism in a sample of Colombian adult patients.

Methods: Cross-sectional study including adult patients with primary hypothyroidism treated at an endocrinology referral center for more than 3 months. Variables included sociodemographic, paraclinical (serum TSH), clinical, and levothyroxine adherence, assessed using the 8-item Morisky–Green scale. The following tests were used for bivariate analysis: Fisher's exact test, the Mann–Whitney U test, and Pearson's chi-squared test. Prevalence ratios (PRs) were estimated using generalized linear models and Poisson models. This study was approved by the Ethics Committee of the Autonomous University of Bucaramanga.

Results: Of 318 patients evaluated (median age 60 years [IQR 46-73]; 82.08% women), 59.43% achieved hypothyroidism control (TSH 0.4-4.0 mU/L). The median levothyroxine dose was 1.20 mcg/kg/day (IQR 0.86-1.53), primarily using Eutirox (48.43%) or generics (46.23%). Men exhibited significantly higher TSH levels than women (4.0 vs 2.79 mIU/L; $P = .028$).

Factors associated with poorer control of hypothyroidism included: male sex (PR 0.73; 95% CI 0.54-0.98, $P = .039$), government-subsidized health insurance (PR 0.71; 95% CI 0.51-0.98, $P = .036$), overweight (PR 0.81; 95% CI 0.66-0.99, $P = .043$), and high-dose levothyroxine defined as >1.9 mcg/kg/day (PR 0.47; 95% CI 0.27-0.79, $P = .005$). Factors associated with better control of hypothyroidism were: levothyroxine brand with a PR 1.47 for Eutirox (95% CI 1.20-1.80, $P < .001$) and a PR 1.86 for Synthroid (95% CI 1.45-2.40, $P < .001$) in comparison with generic brands; and medication adherence with PR 2.16 for moderate (95% CI 1.30-3.58, $P = .003$) and PR 3.82 for high adherence (95% CI 2.43-6.02, $P < .001$) in comparison with low adherence.

Conclusions: The diversity in sociodemographic, clinical, and therapeutic factors associated with the control of primary hypothyroidism highlights the importance of a comprehensive approach focused on education, adherence, and appropriate prescribing.

Abstract citation ID: lvag096.1677

EP1514 - ECE_3561 - HLA class I and II allele distribution between Graves' disease patients in an Albanian population

Dorina Ylli[1], Megi Lekbello[2], Erkena Shyti[3], Violeta Hoxha[2], Donika Kasemi[3], Marjeta Kermaj[2], Zamira Ylli[2] and Genc Sulcebe[3]
[1]*Endocrinology, Internal Disease, University of Medicine Tirana, Tirana, Albania;* [2]*University of Medicine Tirana, Tirana, Albania;* [3]*Research Center of Biotechnology and Genetics, Tirana, Albania*

Background: Graves' disease (GD) is an autoimmune thyroid disorder with a strong genetic background, in which the human leukocyte antigen (HLA) region plays a central role in disease susceptibility. HLA associations with GD show marked population-specific variability, and no comprehensive HLA association studies have been reported for the Albanian population for GD.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Methods: We performed a case–control study in an Albanian population including 223 adult subjects who underwent HLA genotyping. Sixteen patients were diagnosed with Graves' disease, and 207 subjects served as controls. High-resolution HLA typing was available for class I (HLA-A, B, C) and class II (HLA-DRB1, HLA-DQB1) loci. Allele frequencies were compared between GD patients and controls using Fisher's exact test. Odds ratios (OR) with 95% confidence intervals were calculated.

Results: Significant differences in HLA class II allele distribution were observed between Graves' disease patients and controls. HLA-DRB1*16:01 was more frequent in GD patients compared with controls ($P = .01$), and HLA-DQB1*05:02 also showed increased frequency in GD patients ($P = .02$). However, after correction for multiple testing, these associations did not remain statistically significant, although the direction and magnitude of the effects were preserved. No significant differences were observed for HLA-A or HLA-C allele distributions.

Conclusions: In this Albanian cohort, Graves' disease was associated with differences in HLA class II allele distribution, particularly involving DRB116:01 and DQB105:02. These associations did not withstand correction for multiple testing, likely reflecting limited statistical power due to the small number of Graves' disease cases. Nevertheless, the observed trends are biologically plausible and consistent with the role of HLA class II mediated immune mechanisms in GD. Larger studies are required to confirm these findings and to better define population specific genetic susceptibility patterns.

EP1515 - ECE_3953 - Thyroid tissue stiffness as a marker of disease evolution in subacute thyroiditis

Andreea Bena, Stefania Bunceanu, Roxana Pui, Monica Simina Mihuta and Stoian Dana
Endocrinology, Internal Medicine 2nd, Universitatea de Medicină și Farmacie Victor Babeș, Timișoara, Romania

Background: Subacute thyroiditis (SAT) is a self-limiting inflammatory thyroid disease with variable clinical and imaging manifestations. Conventional ultrasound typically reveals hypoechoic, heterogeneous areas, while ultrasound elastography allows quantitative assessment of thyroid tissue stiffness, potentially reflecting inflammatory activity and disease evolution.

Methods: We prospectively followed 35 patients diagnosed with subacute thyroiditis, monitored longitudinally using conventional ultrasound and elastography. Fifteen patients had a positive history of SARS-CoV-2 infection, while 20 were COVID-19 negative. All patients underwent baseline clinical, biochemical, and ultrasound evaluation, followed by elastographic assessment at 1, 3, and 6 months. Thyroid vascularity was classified according to the Schultz scale. Elasticity index values were recorded as median and interquartile range (IQR).

Results: At baseline, all patients presented with clinical or subclinical hyperthyroidism at various stages. Conventional ultrasound showed a heterogeneous thyroid parenchyma with hypoechoic areas in all cases except four, which displayed a normal ultrasound appearance. According to the Schultz classification, 9 patients (25.7%) were classified as grade 1 vascularity, 18 patients (51.4%) as grade 2, and the remaining 8 patients (22.9%) as grade 3. Thyroid nodules were identified in 7 patients.

Approximately 45% of patients ($n = 16$) required corticosteroid therapy during the disease course. No statistically significant differences were observed between patients who required corticosteroids and those who did not, in terms of elastographic parameters ($P = .23$).

At initial evaluation, the median thyroid elasticity index was 128 kPa (IQR: 112-146). A progressive decrease in tissue stiffness was observed over time, with significant improvement at 1 and 3 months. At 6 months, normalization of elastographic values occurred in 34 out of 35 patients; one patient experienced disease recurrence with persistently elevated stiffness values.

At the 1-month follow-up, a moderate, statistically significant positive correlation was observed between thyroid-stimulating hormone (TSH) levels and the elasticity index (Spearman's rho = 0.42, $P = .01$). A stronger correlation was found between the elasticity index and C-reactive protein levels (rho = 0.48, $P < .001$), suggesting a close relationship between tissue stiffness and inflammatory activity.

Conclusions: Thyroid elastography reflects dynamic changes in tissue stiffness during the evolution of subacute thyroiditis and correlates with biochemical and inflammatory markers. Elastographic assessment may represent a valuable non-invasive tool for monitoring disease activity and recovery in patients with SAT.

EP1520 - ECE_1651 - First 830 thyroid core-needle biopsies (CNB) in Romania. Patient satisfaction questionnaires and complications analysis

Emin Mammadov[1], Dana Terzea[2] and Mihai Ciprian Stoicea[1]
[1]Regina Maria Private Healthcare Network, Bucharest, Romania; [2]CI Parhon National Institute of Endocrinology, Bucharest, Romania

Background: Core-needle biopsy (CNB) is a valuable option to investigate a thyroid nodule, offering possibility of histological rather than cytological evaluation. However, it is still seen as a sophisticated and potentially dangerous investigation. We report our data regarding results, complications and patient satisfaction with CNB.

Methods: Retrospective analysis of the first 830 thyroid nodule CNBs performed in Romania. All CNBs were performed using 18G semi-automatic biopsy instruments. We used the Korean Thyroid Association reporting system (KTA-CNB) for histology reports.

Results: Of 830 CNBs, there were only 6 non-diagnostic results (0.7%).

Among nodules which previously underwent FNA (fine-needle aspiration), CNB offered a conclusive result (either benign or malignant, KTA II, V and VI categories) in 69% of Bethesda 1, 75% of Bethesda 3, 53% of Bethesda 4 nodules. There were no non-diagnostic results in these nodules.

We performed on average 2.1 passes per lesion. There were no major complications (none of complications required hospitalisation), some minor adverse events were limited to bruising, perithyroidal hematoma (1.6%), anxiety and panic attacks (1.1%) and pain during or after procedure (1.2%). Five patients (0.6%) developed transitory hoarseness which resolved spontaneously in 20-90 minutes.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

150 patients completed a questionnaire at the end of procedure. Based on their responses, the anxiety level decreased from 5.1 (out of 10) to 0.92, pain level at the time of introduction of local anaesthesia was 2.3 (out of 10), during sampling was 0.93 and decreased to 0.57 after finishing procedure.

82% of patients declared CNB to be better or much better than they were expecting. 72% of patients who previously underwent FNA, also declared CNB to be better or much better.

All patients declared they would recommend or strongly recommend CNB to someone who got recommendation for thyroid biopsy.

Conclusions: The CNB is a safe and reliable diagnostic procedure for thyroid nodules. It offers very low chance of non-diagnostic results, as well as clarification of diagnosis in case of non-diagnostic or inconclusive FNA.

CNB is a procedure which improves patient experience by reducing the number of procedures needed to make a clinical decision.

CNB is well-tolerated and recommended by the patients who underwent this procedure.

Background: *TSHR* gene variants have been identified in a range of thyroid tumors, yet their prevalence, clinical significance, and relevance for molecular testing remain unclear. This study aimed to assess the prevalence and allelic frequency of *TSHR* variants in a large cohort of benign, low-risk neoplasms, and malignant thyroid tumors and to examine their association with histopathology and patient age.

Methods: A total of 1141 fresh-frozen thyroid tumor samples (589 malignant carcinomas, 78 low-risk neoplasms, and 442 benign tumors) from 204 pediatric (<18 years) and 937 adult patients were analyzed. DNA was extracted and analyzed for *TSHR* exon 10 variants (NM_000369.5) using next-generation sequencing (Illumina MiSeq). Library preparation was performed using the Nextera XT and SeqWell ExpressPlexTM 2.0 kits. Variants were classified according to their predicted functional impact.

Results: A total of 13 *TSHR* variants were detected in 42 thyroid tumors from 41 patients (35 females, 6 males). Histology of *TSHR*-positive tumors included 33 (78.6%) benign tumors, 3 (7.1%) papillary thyroid carcinomas (PTCs), 3 (7.1%) follicular thyroid carcinomas (FTCs), and 3 (7.1%) low-risk neoplasms. Among these patients, 14 (34.1%) were pediatric (<18 years) and 27 (65.9%) were adults. The most frequent variants were M453T (10 tumors: 6 benign, 1 low-risk neoplasms, 1 PTC, 2 FTC), F631L (5 tumors: 4 benign, 1 FTC), and D633Y (5 benign tumors), with D633Y observed exclusively in pediatric patients. Only five variants (M453T, Q489*, L512R, I541V, F631L) were detected in low-risk neoplasms or malignant tumors, the I541V and the Q489* were each detected once, alongside known causal variants. M453T and F631L showed a higher allelic frequency (>40%) in malignant tumors (3 FTC and 1 PTC) than in benign tumors. Several additional variants (S425I, I486F, I568T, D619G, I630L, T632I, and D633H) were detected exclusively in benign tumors.

Conclusions: *TSHR* variants were detected across benign, low-risk neoplasms, and malignant thyroid tumors in both pediatric and adult patients. Most were associated with benign lesions, while some occurred in low-risk neoplasms and malignant tumors, occasionally alongside known driver alterations and at higher allelic frequencies. These findings underscore the potential importance of allelic frequency in interpreting *TSHR* variants, and further studies are needed to clarify their biological and clinical significance.

EP1522 - ECE_1091 - Sublingual ectopic thyroid: two cases including malignant transformation

Mirona Dinca[1], Dana Tilici[1], Daniela Ioana Iulia Greere[1], Ruxandra Costinescu[1], Beatrice Grecu[1], Adina-Ioana Onofrei[1], Arnautu Ana Maria[2], Claudia Alexandra Nacea[1] and Diana Paun[1]

[1]The University Emergency Hospital Bucharest, Bucharest, Romania; [2]Endocrinology, University Emergency Hospital Bucharest, Bucharest, Romania

Background: Ectopic thyroid tissue is a rare congenital anomaly caused by abnormal migration of the thyroid gland during embryogenesis. The lingual region represents the most frequent location, while malignant transformation of ectopic thyroid tissue is exceptionally rare. Clinical presentation is often nonspecific, leading to diagnostic delay, especially in patients with congenital hypothyroidism and poor treatment adherence.

Cases: We present two cases of sublingual ectopic thyroid tissue with distinct clinical manifestations. The first case is a 24-year-old woman with congenital hypothyroidism who discontinued levothyroxine therapy for more than 10 years. She was

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

admitted for abdominal and chest pain associated with pyrosis. Laboratory evaluation revealed severe hypothyroidism (TSH >100 μIU/mL). Cervical ultrasound showed absence of thyroid tissue in the anterior neck. Technetium-99m pertechnetate scintigraphy followed by SPECT/CT demonstrated radiotracer uptake at the sublingual level, confirming ectopic thyroid tissue. Levothyroxine replacement therapy was reintroduced, with significant clinical and biochemical improvement, and surgical management was postponed.

The second case involves a 54-year-old male smoker with a history of congenital hypothyroidism and long-term treatment discontinuation, admitted for hematemesis, dysphonia, and progressive dysphagia. Biochemical evaluation showed severe hypothyroidism (TSH >48 μIU/mL, low FT4 and FT3). Upper gastrointestinal endoscopy revealed a large, intensely vascularized tumor at the base of the tongue. Cervical ultrasound did not reveal eutopic thyroid tissue, while scintigraphy and SPECT/CT confirmed the diagnosis of sublingual ectopic thyroid. After preoperative embolization of the feeding arteries, surgical excision was performed. Histopathological examination revealed poorly differentiated papillary thyroid carcinoma arising in ectopic thyroid tissue. Levothyroxine dose was increased, and the patient was referred for radioiodine therapy.

Conclusions: These cases illustrate the wide clinical spectrum of sublingual ectopic thyroid tissue and highlight the exceptional risk of malignant transformation. Awareness of this entity and appropriate use of functional imaging are essential for accurate diagnosis and management. Long-term follow-up is crucial in patients with congenital hypothyroidism, particularly in those with poor treatment adherence.

EP1523 - ECE_2140 - Refractory hypothyroidism after radioactive iodine therapy for Graves' disease: the combined effect of TSH receptor–blocking antibodies and impaired levothyroxine absorption

Birgul Kirel[1,2], Merve Akkaş[3], Zeren Barış[4], Özben Işıklar[5], Evin Kocaturk[5], Murat Yılmaz[1], Zeynep Karkın[1] and Göknur Yorulmaz[6]

[1]Pediatrics, Pediatric Endocrinology, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Türkiye; [2]Pediatric Endocrinology, Eskisehir Osmangazi University Hospital, Eskisehir, Türkiye; [3]Pediatric Endocrinology, Eskişehir Osmangazi University Faculty of Medicine, Eskisehir, Türkiye; [4]Pediatrics, Pediatric Gastroenterology, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Türkiye; [5]Medical Biochemistry, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Türkiye; [6]Internal Medicine, Endocrinology, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Türkiye

Introduction: Refractory hypothyroidism is a rare and challenging condition in which biochemical and/or clinical improvement cannot be achieved despite standard levothyroxine (LT4) therapy. Here, we present a patient who developed hypothyroidism following radioactive iodine (RAI) therapy for Graves' disease and failed to respond despite very high doses of oral thyroid hormone replacement.

Case Presentation: A 16-year-old female patient diagnosed with Graves' disease failed to achieve remission after approximately one year of antithyroid drug therapy and subsequently received RAI treatment. After the development of hypothyroidism, LT4 therapy was initiated and the dose was gradually and carefully increased over a period of approximately 10 months up to 6 μg/kg/day; however, no biochemical response was obtained. The patient was positive for TSH receptor–blocking antibodies, while tests for celiac disease and stool examinations for malabsorption were negative. The thyroxine absorption test also showed no response. Liothyronine (T3) at a dose of 50 μg/day was added for one month, but no improvement was observed.The patient had no history of additional medication use, and poor compliance as well as analytical laboratory errors were excluded. Upper gastrointestinal endoscopy revealed chronic gastritis and *H. pylori* infection. Despite appropriate *H. pylori* eradication therapy, the patient remained unresponsive to oral treatment. Therefore, intravenous LT4 was administered for four days at a dose of 100 μg/day. Following this treatment, free T4 levels increased from 0.61 ng/dL to 0.95 ng/dL and TSH levels decreased from 95 μIU/mL to 69 μIU/mL.To enhance gastric absorption, vitamin C supplementation, a lactose-free diet, and oral liquid LT4 at a dose of 200 μg/day were reintroduced. With this treatment approach, euthyroidism was achieved.

Conclusions: In conclusion, both TSH receptor–blocking antibodies and impaired LT4 absorption due to chronic gastritis and *H. pylori* infection were identified in this patient with autoimmune thyroid disease. This case highlights the diagnostic difficulties and therapeutic options in the management of refractory hypothyroidism.

EP1524 - ECE_2432 - Severe hyperkalemia in a hypothyroid patient presenting to the emergency department: a case of Autoimmune Polyendocrine Syndrome type 2

Nikoloz Tepnadze[1], Tamaz Mgaloblishvili[1], Nino Gvajaia[1], Salome Kaldani[2], Mariam Bardadze[2], Ana Khvedelidze[2], Tamar Didbaridze[3] and Karen Grigoryan[4]

[1]Endocrinology, Tbilisi State Medical University, Tbilisi, Georgia; [2]Tbilisi State Medical University, Tbilisi, Georgia; [3]Department of Microbiology, The First University Clinic of Tbilisi State Medical University, Tbilisi, Georgia; [4]Endocrinology, Tbilisi State Medical University, Tbilisi State Medical University The First University Clinic, Tbilisi, Georgia

Background: Schmidt syndrome, also known as Autoimmune Polyendocrine Syndrome type 2, is a rare condition characterized by the coexistence of autoimmune hypothyroidism and primary adrenal insufficiency. This case highlights the diagnostic challenges and clinical features of Schmidt syndrome in a patient with existing thyroiditis.

Case Presentation: A 32-year-old woman with a known history of Hashimoto's thyroiditis, treated with 150 μg of L-thyroxine, presented to the emergency department with severe fatigue and weakness. She had stopped her thyroid medication 6 months prior due to persistent nausea. On presentation, laboratory tests showed severe hyperkalemia (7 mmol/L) and elevated creatinine (200 μmol/L), with no genitourinary symptoms. Despite initial treatment for hyperkalemia, her potassium levels fluctuated.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Clinically, the patient was conscious and hemodynamically stable (HR-90/min, BP-115/90 mmHg) with generalized hyperpigmentation noted on physical examination.

Her medical history was significant for an emergency admission four months earlier due to shock, severe weakness, and unexplained hyperpigmentation. Blood cortisol levels were sampled, and hydrocortisone (100 mg) was administered empirically prior to results. Glucocorticoid therapy was subsequently continued**.** Her TSH was markedly elevated (95 mIU/L), and ACTH levels were also found to be elevated, cortisol level was significantly low, given the recurrent hyperkalemia, characteristic pigmentation, and autoimmune background, primary adrenal insufficiency was strongly suspected indicating primary adrenal insufficiency. Further testing revealed elevated renin levels and low aldosterone, supporting the diagnosis of concomitant Addison's disease. Given the recurrent hyperkalemia, characteristic pigmentation, and autoimmune background, primary adrenal insufficiency was strongly suspected.

Investigations: Hormonal evaluation demonstrated profoundly decreased serum cortisol (0.553 µg/dL) with markedly elevated ACTH (1925 pg/mL), confirming primary adrenal insufficiency. Aldosterone was decreased with elevated renin (134 µIU/mL), consistent with mineralocorticoid deficiency. Additional findings included hyponatremia (Na^+ 125 mmol/L), severe hypothyroidism with elevated TSH (95.25 mIU/L) and decreased free T4 (0.378 ng/dL), elevated anti-thyroid peroxidase antibodies (343 IU/mL), and elevated 21-hydroxylase antibodies (131 U/mL), confirming autoimmune etiology.

Conclusions: Schmidt syndrome should be considered in patients with autoimmune hypothyroidism who present with unexplained fatigue, hyperkalemia, and hyperpigmentation. Hypothyroidism alone does not cause hyperkalemia; therefore, severe electrolyte disturbances should prompt evaluation for Addison's disease. Early recognition of Schmidt syndrome with corticosteroid therapy and lifelong adrenal–thyroid monitoring is essential to prevent adrenal crises and misdiagnosis.

EP1526 - ECE_1696 - The potential autoimmune thyroid effect of daratumumab treatment

Hana Matijaca[1], Klara Brčić[1], Fran Petričević[1,2], Ana Matijaca[3,4], Petar Gaćina[1,5] and Zvjezdana Genzić[1]
[1]*Department of Haematology, University Clinical Hospital Sisters of Mercy, Zagreb, Croatia;* [2]*Department of Haematology, Sisters of Charity Hospital, Zagreb, Croatia;* [3]*Department of Endocrinology, Diabetes, Diseases of metabolism and Clinical Pharmacology, Clinical Hospital Dubrava, Zagreb, Croatia;* [4]*Endocrinology and Diabetes, Clinical Hospital Dubrava, Zagreb, Croatia;* [5]*Faculty of Stomatology, University of Zagreb, Zagreb, Croatia*

Background: The human anti-CD38 monoclonal antibody daratumumab is currently licensed for the treatment of the plasma cell malignancy, multiple myeloma (MM). Beside targeting and eliminating malignant plasma cells, it also affects various immune cells, leading to complex immunomodulation, ultimately boosting the immune response against the cancer. However, the immune response can induce autoimmune reaction affecting the thyroid gland.

Aim: To determine if the cohort of the MM patients treated with daratumumab-containing regimens had differences in thyroid laboratory tests (TSH, FT4, anti-TPO) compared to patients treated without daratumumab.

Methods: A single-center retrospective observational analysis at Sisters of Mercy University Clinical Hospital (Zagreb, Croatia) was conducted in 43 MM patients with available thyroid laboratory data (TSH, fT4 and anti-TPO). The patients were categorized into two groups based on treatment exposure (group A daratumumab-containing therapy, $n = 19$; group B no daratumumab therapy, $n = 24$). The patients with previously known thyroid dysfunction were excluded.

Results: Group A received daratumumab-containing regimens: DRD ($n = 12$, 63.2%), Dara-VMP ($n = 3$, 15.8%), Dara-VCD ($n = 2$, 10.5%), Dara-VRD ($n = 2$, 10.5%). In group B VRD was used in 16 patients (66.67%), all other regimens (KRD, MPT, RD, IRD, VRD-lite, KD, VCD, VD) occurred in 1 patient (each 4.17%). The two groups were broadly comparable in age (Mean ± SD: 72.05 ± 6.05 vs 69.29 ± 7.78 years) and sex distribution (males $n = 12$, 63.2%; $n = 15$, 62.5% in group A and B, respectively). Median [IQR] time of treatment exposure was 10 [44] months in group A and 3.5 [25.5] months in group B. Most patients had TSH within the normal range (0.79-4.79 mIU/L). Median TSH was higher in group A (2.55[2.01] mIU/L) than in group B (1.51[1.31] mIU/L). ln (TSH) between-group difference was borderline ($P = .049$). FT4 did not differ between groups ($P = .501$). Median anti-TPO was higher in group A (42.9[11] kIU/L) than in group B (16.55[33.75] kIU/L); anti-TPO values differed between groups ($P = .001$). All values were below ULN (85.8 kIU/L).

Conclusions: Anti-TPO was higher in the daratumumab group and TSH showed borderline difference with higher values in daratumumab group, although values remained within the reference range. FT4 was similar between groups. This could suggest a potential subclinical autoimmune effect of daratumumab treatment. Limitations include retrospective design, small sample size, variable timing of thyroid testing, and potential confounding by other anti-myeloma therapies. Larger prospective studies with serial thyroid testing are needed to confirm these findings.

EP1527 - ECE_2459 - Atypical Graves' orbitopathy with elevated serum IgG4: a report of two cases

Evangelia Makri, Georgios Kostopoulos and Foteini Adamidou
Endocrinology, Hippokration General Hospital of Thessaloniki, Thessaloniki, Greece

Background: Graves' orbitopathy (GO) presents with heterogenous clinical, serological, and radiological features. Occasional atypical presentations may overlap with IgG4-related ophthalmic disease (IgG4-ROD). Shared characteristics may create significant diagnostic uncertainty and therapeutic challenges.

Case Presentations: We describe two patients with atypical Graves' orbitopathy raising the suspicion of IgG4-ROD.

Case 1: A 53-year-old female presented with right upper eyelid discomfort and edema while euthyroid. Initial thyroid-stimulating immunoglobulins (TSI) and thyroid

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

autoantibodies were negative. Orbital MRI demonstrated normal extraocular muscles with an ill-defined T2 hyperintense enhancing lesion of the right lacrimal gland, suggestive of dacryoadenitis. Lacrimal gland biopsy revealed sparse IgG-positive plasma cells and few IgG4-positive cells, with an IgG4/IgG ratio <2%, excluding IgG4-related dacryoadenitis. Despite multiple courses of intravenous methylprednisolone, the patient developed progressive unilateral exophthalmos, eyelid edema, lid lag, and gaze-evoked pain. One year later, TSI became positive, and hyperthyroidism developed. Repeat imaging showed extraocular muscle edema, dacryoadenitis, mild apical crowding, and bilateral proptosis. Additional immunosuppression with mycophenolate mofetil led to marked clinical improvement, although eyelid edema persisted in the context of ongoing smoking.

Case 2: A 70-year-old was referred by the Neurology service for evaluation of diplopia at lateral gaze without soft tissue inflammation. Hyperthyroidism with elevated serum TSI and IgG4 levels was found. Orbital MRI demonstrated bilateral enlargement and enhancement of the superior and inferior rectus muscles predominantly, with increased orbital fat. The patient was treated with intravenous methylprednisolone pulses and intraorbital corticosteroid injections, resulting in complete resolution of diplopia despite persistent radiological abnormalities. No systemic involvement was documented.

Conclusions: These cases illustrate that uncommon presentations of GO may raise the suspicion of IgG4-ROD. The distinction in the absence of early thyroid autoimmunity is difficult, and tissue biopsy is necessary. In case of elevated serum IgG4 and GO, follow-up for systemic disease is prudent.

EP1530 - ECE_3398 - BRAF mutation and tumor growth kinetics during active surveillance of papillary thyroid microcarcinoma

Ki-Hyun Baek
Seoul, South Korea

Background: We investigated tumor-volume doubling time (TVDT) during active surveillance of papillary thyroid microcarcinoma (PTMC) and reviewed clinical factors including BRAF mutation associated with tumor progression.

Methods: Patients with papillary thyroid microcarcinoma (PTMC) who deferred surgery for more than one year after diagnosis between 2014 and 2021 and were followed until 2023 were enrolled. Inclusion criteria were papillary thyroid carcinoma confirmed by fine-needle aspiration cytology (Bethesda categories V-VI), maximal tumor diameter ≤1 cm, and available BRAF mutation testing.

Results: A total of 85 patients were included. The median age was 49 years, and 63 patients (74%) were female. The positivity rate for BRAF mutation was 51% in the study cohort, and 16 patients (19%) showed rapid-growing disease, defined by a TVDT of less than five years. The median follow-up duration was 4.4 years, and 23 patients (27%) underwent surgery after a median of 3.2 years. When TVDT groups were analyzed using logistic regression, sonographic features with microcalcification were associated with tumor growth in binary regression (odds ratio for the group combining slowly and rapid-growing disease was 2.80 [95% CI 1.09-7.22], $P = .033$), and BRAF mutation was associated with rapid-growing disease in multinomial regression (odds ratio for rapid-growing disease was 4.58 [95% CI 1.11-18.94], $P = .036$).

Conclusions: BRAF mutation is presumed to be associated with tumor progression and may help predict growth of PTMC. Genetic testing including BRAF testing may help distinguishing rapid-growing thyroid cancer.

EP1531 - ECE_3420 - Thyroid lymphoma case series: sonographic "pseudothyroiditis" and the role of core biopsy

Nuphar Vinegrad[1,2] and Uri Yoel[1,2]
[1]*Endocrinology, Soroka, University Medical Center, Be'er Sheva, Israel;* [2]*Ben-Gurion University of the Negev, Beer Sheva, Israel*

Introduction: Thyroid lymphoma is an exceptionally rare malignancy, representing <5% of thyroid cancers and ~2.5% of all lymphomas. It typically presents as a rapidly enlarging neck mass, often masquerading as benign goiter or aggressive carcinoma. Recent 2025 population-based data from the Tokyo Cancer Registry and the SEER database indicate that while histology-specific management significantly improves survival, diagnostic delays remain common. We present five cases highlighting the unique sonographic appearance of thyroid lymphoma and the critical role of core-needle biopsy (CNB) in avoiding unnecessary surgery.

Case Series: Five patients (median age 55, range 21-85; 3M/2F) presented with rapidly growing goiters (1-5 months duration) and compressive symptoms. Point-of-care ultrasound (POCUS) consistently revealed a distinctive "pseudothyroiditis" pattern: a markedly enlarged, heterogeneous, hypoechoic thyroid without distinct nodules, often mimicking thyroiditis despite discordant laboratory markers.

- **Patient 1 (50M):** Known Hashimoto's; initial FNA showed reactive lymphocytes. Open biopsy confirmed Diffuse Large B-cell Lymphoma (DLBCL). Treated with R-CHOP and thyroidectomy; achieved complete remission (CR).
- **Patient 2 (67F):** Poorly controlled hypothyroidism; Misdiagnosed as sub-acute thyroiditis. Ultrasound-guided CNB confirmed DLBCL. Achieved CR with R-CHOP alone.
- **Patient 3 (55M):** Large goiter and cervical lymphadenopathy. FNA was inconclusive (medullary vs lymphoproliferative). Open biopsy confirmed Low-grade Follicular Lymphoma. Achieved CR with Anti-CD20 + Bendamustine.
- **Patient 4 (21M):** Thyroid appeared normal except for islands of "thyroiditis-like" tissue and lymphadenopathy. FNA was Bethesda III; CNB diagnosed Stage IV Hodgkin Lymphoma. Successfully treated with ABVD.
- **Patient 5 (85F):** Elderly patient with aggressive B-cell lymphoma confirmed via Tru-cut (CNB). Rapidly initiated R-CHOP therapy.

Discussion: These cases emphasize that thyroid lymphoma frequently presents with a "pseudothyroiditis" sonographic appearance and a rapidly growing goiter, which, when paired with an inconclusive FNA, often leads to diagnostic delay or radical surgery. Our series aligns with recent literature suggesting that while age ≥70 and DLBCL histology are predictors of poorer

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

outcomes, early diagnosis via CNB facilitates rapid initiation of chemo-immunotherapy. This shift toward CNB (Cases 2, 4, 5) allowed for definitive diagnosis without the morbidity of diagnostic thyroidectomy.

Conclusions: Thyroid lymphoma should be suspected in any rapidly enlarging goiter exhibiting a "thyroiditis-like" sonographic pattern, especially when FNA is non-diagnostic. Core biopsy serves as a vital, minimally invasive tool for definitive classification, enabling excellent prognostic outcomes through modern multimodal therapy.

EP1532 - ECE_1005 - Comparison of efficacy of Liothyronine (T3) 50 mcg + Levothyroxine (T4) combination therapy Vs T3 25 mcg + T4 therapy vs T4 therapy alone on body weight in patients with hypothyroidism followed for 6 months

Vishal Gupta and Vaishali Teli
Diabetes and Endocrinology, VG-ADVANTAGE Diabetes Thyroid & Endocrine Center, Mumbai, India

Aim & Objectives: Compare the efficacy of Liothyronine (T3) 50 mcg/day + Levothyroxine (T4) combination therapy Versus T3 25 mcg/d+T4 combination therapy Versus T4 therapy alone on clinical parameters (weight-kg [W], BMI-kg/m^2, systolic BP mm of Hg {SBP}/Diastolic BP {DBP}, Lipid Profile-mg/dl (TC, LDL, TG, HDL), highly sensitive C-reactive protein-mg/L (hs-CRP) & Thyrotropin stimulating hormone-mIU/L (TSH) evaluated every 2-3 months over 6 months period.

Methodology: Between Mar' 24-May '24, 414 patients receiving 50 mcg T3, 25 mcg T3 & T4 for autoimmune hypothyroidism were analysed retrospectively. They were divided into 3 groups & propensity score matched.

Group 1: (G1) 50 pt's received T3{50 mcg} + T4 therapy,
Group 2: (G2) 189 pt's received only T4 Therapy &
Group 3: (G3) 175 pt's received T3 {25 mcg} + T4 therapy.

Data Analysis: Baseline characteristics of G1 vs G2 vs G3 groups were analysed using descriptive statistics. Categorical variables were described by frequencies and %, and continuous variables by using {mean ± SD}. Paired t test & unpaired t test was used to compare groups. P value <.05 was considered significant (S).

Results: Baseline (B) characteristics: G1 ($n = 50$), G2 ($n = 189$), and G3 ($n = 175$) were well-matched: TSH [G1 (4.86 ± 3.66) vs G2 (5.96 ± 10.33) vs G3 (8.00 ± 19.47) μIU/mL, $P = .261$] except for Weight [G1 (87.61 ± 19.13) vs G2 (69.99 ± 13.82) vs G3 (74.89 ± 17.27) kg, $P < .001$], DBP [G1 (85.22 ± 9.03) vs G2 (77.72 ± 9.60) vs G3 (81.70 ± 10.88) mmHg, $P < .001$].

Average Age: Age [G1 (39.94 ± 9.45) vs G2 (43.01 ± 10.52) vs G3 (40.33 ± 11.69) years]

G1 (B to 6 months): S reduction W, BMI, TSH, TC; LDL-C.
G2 (B to 6 months): S reduction in SBP, TSH, TC, LDL-C, TG.
G3 (B to 6 months): S reduction in W, BMI, TSH, TC, LDL-C.

Differences between G1 & G2 & G3 at 6 months: TSH [G1 (3.59 ± 3.59) vs G2 (4.47 ± 10.51) vs G3 (5.98 ± 19.74), $P = .479$]. S reduction seen in hsCRP [G1 (2.01 ± 4.37) vs G2 (0.12 ± 2.75) vs G3 (−0.06 ± 2.22); $P < .001$], W [G1 (2.63 ± 4.78) vs G2 (0.58 ± 6.00) vs G3 (1.13 ± 2.95); $P = .026$] favouring G1.

Conclusions: T3 (50 mcg)/T4 combination therapy significantly reduced body weight & hsCRP in comparison to only T4 therapy & T3 (25 mcg)/T4 combination therapy, while having no negative impact on BP.

EP1533 - ECE_2812 - Graves' orbitopathy remission after autologous stem cell transplantation in a patient with multiple myeloma

Veronika Špačková, Jakub Radocha, Pavel Cee and Filip Gabalec
IV Department of Internal Medicine, University Hospital Hradec Králové, Hradec Králové, Czech Republic

Introduction: Endocrine orbitopathy is the most common extrathyroidal manifestation of Graves' disease, characterized by an autoimmune attack on retro-orbital tissues. It significantly impairs quality of life. In severe cases can even be sight-threatening, so proper and timely therapy is crucial. Treatment primarily targets immune system suppression or modulation through different drugs and strategies.

Observation: We present the case of a 68-year-old patient with common comorbidities such as arterial hypertension and dyslipidaemia, but most importantly, with a history of multiple myeloma. She was presented to our department with Graves' disease complicated by orbitopathy. The patient exhibited typical manifestations of thyrotoxicosis alongside classic orbital involvement, including proptosis, swollen eyelids, and redness of the eyes. Given the severity and activity of the orbitopathy, treatment had to be initiated. We started thyrostatic treatment, followed by intravenous glucocorticoid pulses. At the same time, she was diagnosed with a relapse of multiple myeloma. In parallel to our treatment, she underwent chemotherapy consisting of bortezomib, lenalidomide and dexamethasone followed by an autologous haematopoietic stem cell transplant with melphalan conditioning. Throughout corticotherapy and chemotherapy, the patient showed a slight improvement in orbital symptoms. However, soon after stem cell transplant, the patient was completely relieved of symptoms and the orbitopathy seemed to be clinically inactive. The patient also achieved an ongoing complete remission of multiple myeloma. She tolerated the combined immunosuppressive therapy without major infectious or other complications.

Conclusions: This case shows the immunological reset achieved through high-dose corticotherapy, chemotherapy, and stem cell rescue. These addressed both active hematologic malignancy and autoimmune thyroid disease with Graves orbitopathy. This rare coincidence was beneficial in the management of thyroid eye disease. This highlights the importance of multidisciplinary coordination. In this case, the collaboration between the endocrinology, haematology, and ophthalmology teams was essential for success.

EP1534 - ECE_2132 - Papillary thyroid carcinoma—a rare case of vanishing tumor after fine-needle aspiration cytology

Mariana Agapito Fonseca[1], Teresa Alegria Neto[1], Catarina Isabel Lopes[1], Miguel António Duarte[1], Marta Vaz Lopes[1,2], Mariana De Griné Severino[1,2], Ana Gomes[1,2], Ana Paula Barbosa[1,2] and Ema Lacerda Nobre[1,2]

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

[1]ULS Santa Maria, Endocrinology, Diabetes and Metabolism Department, Lisbon, Portugal; [2]Lisbon, Portugal

Background: Fine-needle aspiration cytology (FNAC) is an effective diagnostic tool in thyroid nodular disease, contributing to differentiation between benign and malignant lesions. Procedural complications are rare. However, the trauma caused by puncture may result in morphological changes in the nodules, expressed in variable forms, from infarction to completely replacing it (vanishing tumors). This happens in 1%-2% of papillary thyroid carcinomas (PTC) submitted to FNAC, with resultant difficulty in the interpretation of histopathologic material.

Case Report: A 47-year-old woman presented in primary care with unspecific cervical discomfort. She had no evidence of thyroid dysfunction, compressive symptoms, personal history of head and neck radiation or family history of thyroid cancer. Thyroid ultrasound showed a 30 mm isoechoic nodule with regular margins on the left lobe (EUTIRADS-3) and a 9 mm solid, markedly hypoechoic, non-oval and irregular nodule on the right lobe (EUTIRADS-5), without suspicious lymph nodes. She was referred to Endocrinology and FNAC was performed. The left lobe EUTIRADS-3 nodule was benign and the right lobe EUTIRADS-5 nodule was consistent with PTC. The multidisciplinary team decided for total thyroidectomy. The procedure had no complications. Gross pathology showed the known benign nodule on the left lobe. On the right lobe, there was only a 5 mm dark-brown nodule, without any viable PTC tissue. Immunohistochemistry was not performed. Facing the absence of carcinoma tissue, the cytology specimen was reviewed by an independent pathologist, who confirmed the preoperative diagnosis of PTC. Given the definitive confirmation of PTC on cytology and the absence of residual malignant cells in histology, a diagnosis of vanishing PTC was made, most likely due to infarction induced by FNAC.

Conclusions: This case illustrates that recognition of vanishing thyroid tumors, along with reassessment of the FNAC specimen, is pivotal for a correct diagnosis. The biggest challenge now lies on the follow-up of this patient, since there are no guidelines on further management of vanishing thyroid tumors. Since it was a microcarcinoma and patient was submitted to total thyroidectomy, prognosis seems to be highly favorable.

EP1535 - ECE_2977 - Thyroid eye disease and myasthenia-myositis-myocarditis overlap syndrome: a cluster of rare immune-related adverse events secondary to pembrolizumab

Maria del Mar Garcia Gonzalez, Vanessa Triviño Yannuzzi, Isabel Huguet, Luyi Zeng, Laura Rambla Aguilar, Natalia Salvador Peiro, Marta Leon del Campo, Mikaela Zubillaga, Maria Llavero Valero, Olalla Meizoso-Pita, Alberto García Piorno, Elena Carrillo Lopez, Iciar Martin Timon, Inmaculada Moreno-Ruiz and Cristina Sevillano-Collantes
Endocrinology, Hospital Universitario Infanta Leonor, Madrid, Spain

A 72-year-old male was diagnosed in June 2024 with Stage IV(pT2N3M0) well-differentiated squamous cell carcinoma of the penis, treated with total penectomy and urethrostomy. Adjuvant chemotherapy combined with Pembrolizumab was initiated (1st cycle:07/2024, 2nd cycle:08/2024). Subsequently, maintenance of Pembrolizumab was started in 12/2024 after dermal metastases were observed in the scrotum. He was admitted on 01/31/2025 due to right eyelid ptosis, without dyspnea, dysphonia, diplopia, or motor deficits. Neurological examination revealed right eye ptosis, normal oculomotor movements, no sensory or motor alterations. Initially, a myasthenic syndrome in the context of immunotherapy was suspected due to the symptoms and positive anti-AChR antibodies (5.49 nmol/L).

During the etiological study, the following were observed: TSH: 107.28 µU/mL (0.35-5.5); free-T4: <0.20 ng/dl (0.77-1.76); Anti-TPO antibodies: 1289 UI/mL (<60); TSH receptor antibodies: <0.80 U/L(<1.75); and Anti-thyroglobulin antibodies: 113.30 UI/mL (<1.30). Previous studies were reviewed: TSH:0.01 µU/mL and free-T4: 2.93 ng/dl in 10/2024; thyroid function had been normal in 03/2024 and 08/2024. The assessment is consistent with chronic autoimmune thyroiditis/Hashimoto's thyroiditis precipitated by immunotherapy, with an initial phase of thyrotoxicosis followed by overt hypothyroidism. Treatment with levothyroxine was started reaching a total dose of 112 mcg.

Given the presence of eyelid ptosis and thyroid dysfunction, an orbital MRI was requested due to suspicion of thyroid eye disease. Results showed: signs of bilateral proptosis with increased fat space in the intra and extra-axial compartments, without focal or diffuse thickening of the orbital musculature and no abnormalities in the optic nerves. Thyroid eye disease was confirmed in the context of autoimmune hypothyroidism precipitated by immunotherapy. The patient showed progressive improvement and stability with eyelid asymmetry but no signs of fatigability, leading to discharge on 02/17/2025.

He was readmitted on 03/14/2025 due to motor deficits in the bulbar, cervical, and proximal limb territories, with clinical signs of fatigability. Given the positive anti-AChR results, generalized Myasthenia Gravis(MGFA IVb) was suspected, and Prednisone 1 mg/kg/day was initiated. Laboratory tests revealed elevated troponins (1336 pg/mL, normal<60), elevated CPK (1306 U/L), and hypertransaminasemia (ALT 70 mg/dl, normal <49; AST 115 mg/dl, normal <37), consistent with myocarditis, myositis, and Myasthenia Gravis overlap syndrome secondary to immunotherapy.

While these conditions are rarely reported individually, this is the first case report describing the concomitant occurrence of thyroid eye disease in the context of Hashimoto's thyroiditis and the overlap syndrome of myocarditis, myositis, and Myasthenia Gravis secondary to immune checkpoint inhibitors, to the best of our knowledge.

[4]University of Georgia, T'bilisi, Georgia; [5]David Agmashenebeli University of Georgia, T'bilisi, Georgia; [6]Ivane Javakhishvili Tbilisi State University, Tbilisi, Georgia; [7]Caucasus University, T'bilisi, Georgia

Background: Achieving stable euthyroidism in patients with Hashimoto's thyroiditis may be challenging despite regular levothyroxine therapy. Gastrointestinal factors, dietary habits, and prior bariatric surgery can significantly affect levothyroxine absorption.

Case Presentation: A 36-year-old female bank employee presented with fatigue, generalized weakness, mild weight gain (≈2 kg over one year), cold intolerance, and morning facial edema. She had a 6-year history of Hashimoto's thyroiditis treated with levothyroxine 50 µg/day. Family history was positive for autoimmune hypothyroidism. Four years earlier, she had undergone sleeve gastrectomy for obesity. She was a non-smoker and did not consume alcohol.

Physical examination revealed a BMI of 27.5 kg/m^2, blood pressure 118/75 mmHg, and heart rate 62 bpm. Facial puffiness, dry skin, and emotional lability were noted. The patient reported regular morning consumption of fiber-rich food (bran prepared with milk).

Laboratory evaluation showed mildly elevated TSH (4.8 mIU/L), FT4 at the lower limit of normal, and markedly increased anti-TPO antibodies (190 IU/mL). Inflammatory markers, vitamin D, ferritin, and vitamin B12 levels were within normal ranges. Thyroid ultrasound demonstrated hypoechoic focal areas and hypovascularization.

Despite several levothyroxine dose adjustments, TSH levels fluctuated between 0.15 and 5.8 mIU/L. The main clinical concerns were progressive weight gain and deterioration of well-being.

Management and Outcome: Levothyroxine dose was increased by 12.5 µg, and the timing of administration was changed to bedtime, at least three hours after the last meal. After six weeks, TSH decreased to 2.9 mIU/L, and the patient reported improved energy levels and overall well-being.

Conclusions: In patients with a history of bariatric surgery and specific dietary habits, the efficacy of levothyroxine may depend not only on the dose but also on the timing of administration. An individualized therapeutic approach is essential to achieve stable euthyroidism.

EP1540 - ECE_1061 - SPECT/CT textural features in differentiated thyroid cancer recurrence prognosis after radioiodine treatment

Sema Alieva[1], Alexey Trukhin[1], Tatyana Belotserkovskaya[1], Mikhail Maltsev[2], Almaz Manaev[2], Sergey Serzhenko[1], Konstantin Slashchuk[1] and Marie Reinberg[1]
[1]Moscow, Russia; [2]National Research Nuclear Institute "MEPhI", Moscow, Russia

Background: modern medical image analysis methods today include radiomics approaches, but implementation in practice across is still complicated. Promising field for textural features application is single-photon emission computed tomography combined with computed tomography (SPECT/CT). In this study we developed a diagnostic model for assessing differentiated thyroid cancer (DTC) recurrence based on SPECT/CT findings after radioiodine therapy (RIT), using texture features.

Materials and Methods: analysed group of patients includes 53 patients with DTC from 18 to 92 years: 24 with complete biochemical and structural remission after RIT; 29 with structural or biochemical recurrence after one or more courses of RIT and/or radioiodine refractoriness. First step in textural features extraction was manual expert lesion localization was performed with volume-of-interest (VOI) mask creation $3\times3\times3$-$11\times11\times11$ voxels centered on the maximum count voxel. Gray-level co-occurrence matrix, gray-level run-length matrix and gray-level size zone matrix matrices derived from created SPECT/CT all created masks. Count in voxels normalised to 128 and 256 scales.

Results: Best logistic regression model for metastatic lesions recurrence $\log\frac{p}{1-p} = 1.609x_1 - 0.730x_2 + 1.037x_3 + 1.553x_4 + 0.671x_5 - 0.855$ demonstrates AUC of 0.92 (0.78-1.00), where x_1—DiscretisedIntensitySkewness_11_128, x_2—NormalisedZoneSize NonUniformity_9_128, x_3—IntensityHistogramMeanAbsolute Deviation_5_128, x_4—DiscretisedIntensitySkewness_11_256, x_5—IntensityHistogramMeanAbsoluteDeviation_5_256. Numbers 5, 9, 11 are stand for mask size, 128 and are stand for normalization scale. Model for residual thyroid tissue reccurance (close tissue localization), due to cross textural contamination, shows low prediciton effectivness AUC 0.63 (0.53-0.69).

Conclusions: SPECT/CT textural features demonstrate high prognostic power for metastatic lesions recurrence and may be used for additional risk stratification. The effect of textural contamination limit application of method in residual thyroid tissue. Textural feature analysis has high potential for DTC radioiodine therapy personalization and should be compared to absorbed dose methods.

EP1541 - ECE_1614 - Radiofrequency ablation as a minimally invasive treatment for recurrent papillary thyroid carcinoma: a four-case experience

Maria Chrysoula Tatarida Palla[1], Aspasia Drosou[1], Georgia Samakidou[1], Olga Tsantarlioti[1], Nikoletta Mirtsou[1], Eleni Kotsi[1], Sotiroula Adamidou[1], Fani Chaikali[1], Demosthenes Mazarakis[1], Achilleas Meskos[1], Pyrros Gkousis[2], Anna Drakopoulou[1], Victoria Kaltzidou[1], Eirini Veniou[1] and Myrsini Gkeli[2]
[1]Endocrinology, Metaxa Cancer Hospital Piraeus, Athens, Greece; [2]Radiology, General Hospital "Agios Savvas", Athens, Greece

Papillary thyroid carcinoma (PTC) accounts for approximately 80%-85% of all thyroid cancers, with cervical lymph node metastases (CLNM) occurring in 40%-90% of patients. Although surgery and radioactive iodine (RAI) therapy remain the first-line treatments for recurrent PTC and nodal metastases, many patients become unsuitable for further surgery due to multiple prior operations, challenging lymph node locations, or poor clinical condition. Ultrasound-guided radiofrequency ablation (US-RFA) has emerged as a minimally invasive alternative, offering effective local control with fewer complications compared with reoperation.

We present four patients with recurrent PTC who had previously undergone multiple surgeries with lymph node dissections and

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

received more than one course of RAI therapy. All subsequently developed cervical lymph node metastases deemed unresectable because of their location or high surgical risk. Each patient was treated with US-RFA, and clinical, biochemical, and imaging outcomes were evaluated, including lymph node volume reduction and serum thyroglobulin (Tg) levels during follow-up. All four patients demonstrated substantial remission following RFA. Lymph node volume reduction rates reached approximately 74% at the first follow-up and progressed to as high as 95% at 6-12 months after treatment. Serum Tg levels decreased in all patients during follow-up, reflecting a favorable biochemical response.

Although surgery and RAI remain the standard first-line therapies for recurrent PTC, many patients are not candidates for further surgical intervention. RFA represents a promising minimally invasive alternative that provides effective local control and biochemical improvement. However, further research is needed to define optimal patient selection and long-term outcomes.

EP1542 - ECE_2367 - Impact of thyroid autoantibodies on the prognosis of differentiated thyroid cancer: a retrospective analysis

Sinem Başak Tan Öksüz, Hilal Güngör, Murat Erdogan, Sevim Güllü, Rıfat Emral, Özgür Demir, Asena Gökçay Canpolat and Mustafa Sahin
Department of Endocrinology and Metabolism, Ankara University School of Medicine, Ankara, Türkiye

Objective: Thyroid autoantibodies (TAAs) are detected in approximately one-quarter of patients with differentiated thyroid cancer (DTC). Although persistent or rising anti-thyroglobulin (anti-Tg) is accepted as an indicator of recurrence, whether TAAs and thyroid autoimmunity detected at diagnosis affect thyroid cancer behavior remains controversial. This study aimed to investigate whether TAA positivity detected at diagnosis influences DTC recurrence and survival.

Methods: Clinical and pathological data of 275 patients followed for DTC at the Department of Endocrinology and Metabolism, Ankara University Faculty of Medicine between 2005 and 2020 were retrospectively evaluated. Patients were grouped according to anti-Tg and anti-thyroid peroxidase (anti-TPO) antibody status at diagnosis. Anti-Tg and anti-TPO levels were measured by electrochemiluminescence immunoassay in all patients.

Results: Of the 275 patients included, the median age was 43 years (17-79), and 77.1% were female. The mean follow-up duration was 8.9 ± 5.6 years, with recurrence observed in 5.5%, distant metastasis in 2.5%, and DTC-related death in 2.2% of patients. Lymphocytic thyroiditis was present in 35.6% of patients. TAA-positive patients had significantly lower age at diagnosis ($P = .047$), higher preoperative TSH levels ($P = .038$), and markedly higher frequency of lymphocytic thyroiditis ($P < .001$). Stimulated thyroglobulin levels were significantly lower in the TAA-positive group ($P < .001$). However, no significant differences were found between the two groups regarding tumor size, histopathological features, lymph node metastasis, disease stage, risk groups, or recurrence rates ($P > .05$). Multivariate analysis identified lymph node metastasis (OR:2.12, $P = .002$), advanced stage disease (Stage IV OR:10.23, $P < .001$), and high-risk group (OR:4.28, $P < .001$) as independent predictors of recurrence.

Conclusions: TAA positivity alone does not predict DTC recurrence. Recurrence risk assessment should be based on objective factors such as lymph node metastasis, disease stage, and risk stratification. Preoperative TAA positivity may be misleading by causing lower thyroglobulin measurements in the postoperative period.

Abstract citation ID: lvag096.1696

EP1544 - ECE_2767 - Immunohistochemical features of multiple parathyroid gland disease in sporadic primary hyperparathyroidism and MEN-1 syndrome

Hanum Bagirova, Rustam Salimkhanov, Tatiana Kokorina, Anna Eremkina and Natalia Mokrysheva
Endocrinology Research Centre, Moscow, Russia

Background: Multiglandular parathyroid disease (MGD) occurs in both sporadic primary hyperparathyroidism (PHPT) and multiple endocrine neoplasia type 1 (MEN-1) syndrome. These conditions can exhibit overlapping clinical and morphological features, complicating their differentiation, especially when genetic testing is unavailable or inconclusive. Immunohistochemical (IHC) analysis may offer valuable additional insights into the patterns of parathyroid involvement.

Aim: To compare the IHC profiles of MGD in sporadic PHPT (MEN-) and MEN-1-associated disease (MEN+), with a particular focus on menin expression.

Materials and Methods: A cohort of 47 patients with MGD was analyzed, including 20 with sporadic PHPT (MEN−) and 27 with MEN-1 syndrome (MEN+). IHC was performed on all tumor samples received from the patients using a panel of 8 markers: PTH, Ki-67, chromogranin A, synaptophysin, parafibromin, menin, CaSR, and VDR. Staining intensity, cellular distribution, and interglandular variability were compared between groups.

Results: Distinct IHC patterns were observed between the MEN+ and MEN- groups. Loss of nuclear menin expression was the most prominent finding, detected in 97% (85/88) of MEN+ samples. In contrast, preserved nuclear menin expression was seen in the majority of MEN- cases (67%, 30/45), establishing it as the most reliable discriminator between the groups.

Synaptophysin expression was positive in 31% of MEN− samples vs 28% of MEN+. However, MEN-1-associated lesions exhibited more uniform synaptophysin expression across multiple glands within individual patient, whereas sporadic cases showed greater interglandular variability.

The Ki-67 was generally low in both groups, with more homogeneous expression in MEN+ lesions and greater variability in MEN− cases. Chromogranin A expression was preserved in both cohorts, tending toward more diffuse staining in MEN+ and more focal positivity in MEN− lesions. Parafibromin expression was largely retained, although MEN+ lesions more frequently displayed heterogeneous nuclear staining. Expression of CaSR and VDR showed greater heterogeneity or reduction in MEN+ lesions.

Conclusions: MEN-1-associated MGD is marked by near-universal loss of menin expression and high IHC concordance

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

across glands. In contrast, sporadic MGD typically shows retained menin expression and more pronounced interglandular heterogeneity. Assessment of menin expression may serve as a useful adjunctive tool for the morphological differentiation between MEN-1 and sporadic MGD.

Abstract citation ID: lvag096.1697

EP1545 - ECE_1248 - Severe post–radioactive iodine thyroiditis causing thyroid storm and rapid-onset hypothyroidism in a young man with Graves' disease: a biphasic and iatrogenically amplified course

Aung Kaung Sett Hein[1], Rawia Adoma[2], Nini Nagyha Binti Nordin[2,3] and Oraizi Jafery[2]
[1]University Hospital North Durham, Durham, United Kingdom; [2]Bedford Hospital, Bedford, United Kingdom; [3]Medical Department, Bedford Hospital, Bedfordshire, United Kingdom

Radioiodine (RAI-131) is a standard treatment for Graves' hyperthyroidism, with hypothyroidism usually developing gradually over 8-16 weeks.[1] Following RAI, a minority of patients (1%-5%) can develop radiation-induced thyroiditis,[2] leading to a transient surge in thyroid hormone levels. Thyroid storm after RAI is rare, and the rapid progression to severe hypothyroidism is even more uncommon. Careful clinical assessment and close biochemical monitoring are essential for accurate diagnosis and management.

A 23-year-old man with Graves' disease who previously developed neutropenia on carbimazole has been maintained on propylthiouracil (PTU). Following RAI in May 2025, he developed destructive thyroiditis with extreme thyrotoxicosis (Free T4 >100 pmol/L) and clinical thyroid storm, requiring high-dose PTU and steroid therapy. Six weeks later, while still on PTU 100 mg three times daily, he transitioned rapidly into marked hypothyroidism (Free T4 1.5 pmol/L, TSH 63 mIU/L) with profound fatigue and cold intolerance. Stopping PTU led to gradual biochemical improvement. This case highlights an uncommon sequence of severe post-RAI thyrotoxicosis followed by abrupt, profound hypothyroidism, with persistent PTU use likely intensifying the transition. Following radioactive iodine (RAI) therapy, it is important that antithyroid medications are appropriately withdrawn and in cases of patients continuing on PTU, TFTs should be checked every 2-4 weeks to detect rapid changes.[3]

EP1546 - ECE_1720 - Clinical remission of pretibial myxedema in a female patient with thyroid eye disease after tocilizumab treatment

Georgios Boutzios and Anastasia Nikolopoulou
Department of Pathophysiology, National and Kapodistrian University of Athens, Outpatient Clinic of Autoimmune Endocrinopathies, Athens, Greece

Introduction: Pretibial myxedema is an infrequent extrathyroidal manifestation of Graves' disease, mostly occurring in the presence of orbitopathy, with its prevalence at 0,15 per 10 000 persons with Graves' orbitopathy (GO). Similarly to the pathophysiology of GO, pretibial myxedema lesions result from fibroblast-derived glycosaminoglycans accumulation in the dermis after immune stimulation of fibroblasts from circulating cytokines and thyroid stimulating immunoglobulins (TSI). Its current management consists of topically administered corticosteroids, with variable response rates.

Case presentation: A 52-year-old woman presented with eyelid edema, redness of the conjunctiva and pretibial myxedema. She was diagnosed with Hashimoto thyroiditis in 2004 and there was a disease transformation to Graves' disease with GO in 2021. She had previously received two cycles of intravenous corticosteroids and a total thyroidectomy, achieving clinical remission after the second cycle of intravenous corticosteroids. On clinical examination, she had inactive GO as defined by a 7-point Clinical Activity Score (CAS) of 2/7, while she exhibited proptosis (20 mm in the right and 21 mm in the left eye, measured by Hertel exophthalmometer), inconstant diplopia, bilateral lagophthalmos and dry eye, suggesting moderate-to-severe disease. Dermopathy lesions located in the pretibial area of lower extremities and were nodular, painful, firm in palpation, erythematous, with non-pitting edema. She was clinically and biochemically euthyroid, with positive anti-thyroid peroxidase antibodies and high TSI levels. On orbital MRI, enlargement of all extraocular muscles with pathological intravenous contrast enhancement, indicative of active inflammation, was revealed. Given all the above, treatment with tocilizumab at a dose of 8 mg/kg every four weeks for four cycles was initiated. A complete resolution of the lesions was observed in the 5 weeks post- treatment. Reduction in CAS to 1/7 and diminution TSI levels could indicate a disease- modifying effect. Proptosis and lagophthalmos showed no improvement, while no side effects were reported and the patient remained euthyroid. In her follow—up visit, six months after tocilizumab last dose, GO remained inactive, with no pretibial myxedema recurrence and stable TSI levels.

Conclusions: This case highlights tocilizumab's efficacy for the management of inflammation in the context of steroid-resistant GO with concurrent pretibial myxedema as shown by a clinical and biochemical response.

EP1547 - ECE_3276 - Efficacy and safety of intrathyroidal dexamethasone injections in severe subacute thyroiditis—a single center cohort study

Magdalena Stasiak[1], Magdalena Rosińska[1], Bartłomiej Stasiak[2], Renata Michalak[1] and Arkadiusz Zygmunt[1]

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

[1]Department of Endocrinology and Metabolic Diseases, Polish Mother's Memorial Hospital—Research Institute, Łódź, Poland; [2]Lodz University of Technology, Łódź, Poland

Clinically severe or recurrent subacute thyroiditis frequently requires high cumulative doses of systemic steroids. Such therapy is associated with high risk of steroid-related complications.

The aim of the study was to assess efficacy and safety od intrathyroidal dexamethasone and lidocaine injections (DLI) in comparison to standard oral steroid therapy.

Methods: A total number of 60 patients were included in the study, among whom 30 were treated with DLI (study group, SG) and 30 were treated with standard protocol of oral prednisone therapy (control group, CG).

In all SG patients, a dose of 4 mg of dexamethasone with 1 mL of 2% lidocaine, was injected into each affected thyroid lobe. On the basis of the obtained clinical and biochemical results, doses were repeated every 2-5 days, as required. Before and after injections, as well as after therapy completion, the following parameters were measured: pain severity, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), thyroid stimulating hormone (TSH), free thyroxine (FT4) and free triiodothyronine (FT3). The total steroid dose required for complete remission and the therapy duration was considered primary endpoint of the study. Additionally, the frequency of recurrence and of persistent hypothyroidism in SG and CG were compared.

Results: Excellent rapid and long-term response was observed in all SG patients, with no side effects except for injection-related discomfort. After the first injection, in all SG patients pain decrease from 4-8 to 2-5 points in the numerical rating scale—NRS, as well as improvement in ESR, CRP, and thyroid parameters were observed. The mean number of doses required for total recovery were 6.83 ± 2.88, median 7, with a mean dose of dexamethasone for a total recovery 49.7 mg. The longest therapy period was 43 days, mean 26.4 days. In CG, the mean therapy period was 118.9 days and a mean dose of oral prednisone was 1702.17 mg, which is equal to 255.23 mg of dexamethasone ($P < .0001$). Three cases of recurrence (10%) were observed in both of SG and CG. Persistent hypothyroidism occurred in three patients (10%) in SG and in five patients (16.6%) in CG.

Conclusions: The efficacy and safety of DLI in SAT therapy were excellent and the method was demonstrated to be significantly more beneficial than standard oral steroid therapy, which is especially important for patients with high risk of steroid-related complications.

EP1552 - ECE_1224 - Marked thymic hyperplasia and widespread lymphadenopathy in a patient with thyroid storm due to Graves' disease

Htet Htet Aung[1,2], Neelam Khalid[1] and Rahat Tauni[1]
[1]Endocrine and Diabetes, West Hertfordshire Teaching Hospitals NHS Trust, Watford, United Kingdom; [2]Endocrine and Diabetes, West Hertfordshire NHSTrust, Watford, United Kingdom

We present the case of a 21-year-old woman who presented with symptoms of tonsillitis and tachycardia. She had a strong family history of thyrotoxicosis and hypothyroidism in first-degree relatives. Biochemical investigations revealed severe thyrotoxicosis, and carbimazole was commenced. Thyroid eye disease and strongly positive TSH receptor antibodies confirmed **Graves' disease**. Ten months later, she presented with **tonsillar abscess** complicated by *Staphylococcus epidermidis* bacteraemia, requiring emergency incision and drainage, followed by antibiotics. Despite progressive escalation of carbimazole to 60 mg daily, thyrotoxicosis worsened, and FT4 rose by more than 60% in three months. Due to concerns of non-compliance and features consistent with thyroid storm, she was admitted for emergency **total thyroidectomy.** Preoperative optimisation included intravenous prednisolone, propranolol, propylthiouracil and Lugol's iodine. Preoperative CT chest & neck demonstrated a diffuse goitre without retrosternal extension but revealed **marked thymic enlargement and mediastinal lymphadenopathy**. She underwent successful total thyroidectomy, and histology showed mild lymphocytic thyroiditis with focal non-necrotising granulomatous inflammation, possibly sarcoidosis. A CT chest, abdomen and pelvis was performed on the recommendations of thyroid multidisciplinary team (MDT) demonstrated marginal residual thymic enlargement without lymphadenopathy. MRI chest later revealed marked regression of the thymic enlargement compared with prior imaging, supporting the diagnosis of **thymic hyperplasia associated with Graves' disease**. No radiological features of sarcoidosis were identified on either imaging. Patient remains well on Levothyroxine replacement and is under endocrine follow-up.

Thymic hyperplasia associated with Graves' disease is a rare entity but is under-recognised as chest imaging is not routinely performed unless retrosternally extended goitre is suspected. As imaging becomes more accessible, clinicians should remain cognisant of this rare association of Graves' disease. In our case, thymic hyperplasia seems to be marked with presence of lymphadenopathy which is even rarer. We postulate that it may have been contributed to by the preceding tonsillar infection. Thymic enlargement typically resolves following definitive treatment and resolution of thyrotoxicosis. Clinicians should consider the differential diagnosis of thymic hyperplasia in patients with Graves' disease if chest or neck imaging is performed; however, it is critical to avoid unnecessary intervention/s due to benign and reversible nature of the disease. MDT approach involving radiologists, surgeons, pathologists and endocrinologists is necessary in decision making.

EP1555 - ECE_1633 - Balancing efficacy and safety in antithyroid therapy: a case of carbimazole-induced agranulocytosis

Thaalitha Naidu Suranthiran Naidu, Masliza Hanuni Mohd Ali and Wan Mohd Hafez Wan Hamzah
Medical Department Hospital Kemaman, Ministry of Health, Terengganu, Malaysia

Antithyroid drug–induced agranulocytosis represents a rare yet potentially catastrophic idiosyncratic reaction. It most frequently manifests within the first three months of therapy and is potentiated by higher cumulative drug exposure or underlying genetic susceptibility. We report a case of early-onset carbimazole-induced agranulocytosis complicating the management of severe Graves' disease.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

A 32-year-old man with a one-year history of progressive thyrotoxic symptoms, including chronic diarrhoea, palpitations, heat intolerance, and postural tremors, was diagnosed to have Graves' disease complicated by thyroid eye disease at a private centre. Initial thyroid biochemistry demonstrated extreme thyrotoxicosis (free T4 >154.8 pmol/L, T3 >30.8 pmol/L, TSH 0.01 mIU/L), prompting initiation of methimazole 20 mg twice daily with verapamil. Within 4 days, he re-presented to our district hospital with febrile illness, profound lethargy, gastrointestinal disturbance, and escalating palpitations. Clinical assessment revealed marked agitation, bilateral fine tremors, a diffuse non-tender goitre, exophthalmos, temperature 37.5 °C, atrial fibrillation (heart rate 140-170 bpm) with rapid ventricular response. Biochemical indices confirmed persistent severe thyrotoxicosis (T4 of >100 pmol/L with suppressed TSH levels) and concomitant mild mixed hepatocellular–cholestatic transaminitis (ALT 78 U/L, ALP 198 U/L).

He was managed emergently for thyroid storm with high-dose propylthiouracil, non-selective beta-adrenergic blockade, Lugol's iodine, and intravenous hydrocortisone, resulting in substantial clinical stabilisation. The patient was discharged with carbimazole 30 mg daily and propranolol. However, eight days later, he was readmitted with high-grade fever (38 °C) and palpitations despite confirmed treatment adherence. Haematological evaluation revealed profound agranulocytosis (TWC 4×10^9/L, absolute neutrophil count 0.09×10^9/L, Hb 14 g/dL, platelet count 256×10^9/L), consistent with antithyroid drug–induced agranulocytosis. Carbimazole was immediately withdrawn, and he was commenced on broad-spectrum intravenous antimicrobials, granulocyte colony-stimulating factor, Lugol's iodine, with beta-blockade. Inflammatory markers were elevated (CRP 45 mg/L), blood cultures remained sterile, and serial full blood counts demonstrated prompt marrow recovery in 3 days (TWC 10.77×10^9/L, ANC 2.52×10^9/L).

He was subsequently discharged with oral ciprofloxacin, cholestyramine, Lugol's iodine, and propranolol. Close outpatient surveillance and repeat thyroid function testing were planned.

This case underscores the formidable risk of rapid, potentially fatal hematological toxicity with antithyroid therapy, even at standard doses. Clinicians must maintain a heightened index of suspicion for agranulocytosis in any patient presenting with fever, malaise, or constitutional symptoms during the early phase of antithyroid therapy, and alternative therapeutic strategies for thyrotoxicosis should be promptly considered in the setting of drug intolerance.

EP1556 - ECE_2129 - Can resistance to I-131 in differentiated thyroid cancer regress after treatment with tyrosine kinase inhibitors?

Vakaris Kaminskas[1], Aiste Stonyte[1] and Raimonda Klimaite[2]
[1]*Lithuanian University of Health Sciences, Kaunas, Lithuania;* [2]*Institute of Endocrinology, Medical Academy, Lithuanian University of Health Sciences, Kaunas, Lithuania*

Introduction: Between 5%-15% of patients with differentiated thyroid cancer (DTC) and 50% of patients with metastatic DTC are resistant to radioactive iodine (RAIR). Patients with RAIR-DTC metastatic disease have the poorest prognosis—their 10-year survival is below 10%. Although tyrosine kinase inhibitors (TKIs) provide effective treatment options for RAIR-DTC, most patients remain incurable, and disease progression occurs over time.

Clinical Case: A 68-year-old man underwent thyroidectomy at LUHS Kaunas Clinics in 2013; confirmed follicular thyroid carcinoma (pT3NxMx). Radioactive iodine treatment was administered.

In autumn 2018, the patient developed gluteal pain; MRI showed S2-S5 metastases. S2-S3 laminectomy confirmed follicular thyroid carcinoma, followed by 30 Gy palliative radiotherapy. In winter 2019, the third I-131 course showed minimal uptake, and CT revealed a large destructive S2-S3 lesion. A right renal lesion detected in May 2019 was resected, confirmed as papillary renal cell carcinoma type I.

In late 2021, a newly detected pathological lymph node near the right kidney was treated with stereotactic radiotherapy. By May 2022, disease progressed with thyroid lodge changes, lung metastases, possible liver metastasis, enlarged paracaval lymph nodes, and sacral involvement; biopsies confirmed Hürthle cell thyroid carcinoma. Lenvatinib, started in June 2022, induced initial regression of lung metastases and the lymph node metastases.

By spring 2025, no new metastases were seen, but fluid accumulation developed. Lenvatinib withdrawal due to nephrotic syndrome led to tumor progression, with increased thyroid mass, pain, and rising thyroglobulin (306 → 1000 µg/L).

A fourth I-131 course was given to assess restored sensitivity, but post-therapy scintigraphy again demonstrated no significant uptake. Concurrent CT revealed persistent disease. The findings indicate a lack of restored RAI sensitivity, confirming ongoing RAI-refractory disease.

Conclusions: This case illustrates a patient with metastatic, RAIR-DTC who initially showed structural response to lenvatinib but did not regain significant iodine avidity. Lenvatinib withdrawal due to nephrotoxicity led to rapid tumor progression, highlighting the temporary nature of systemic control and confirming the patient's continued RAI-refractory status. This case underscores the limited potential for restoring I-131 sensitivity in advanced DTC.

EP1560 - ECE_1619 - Mild-to-moderate basal hypercalcitoninemia with different histology findings after thyroidectomy: a single-centre case study

Zoran Gluvic[1,2], Vladimir Samardzic[1], Milena Lackovic[1], Marija Sinik[1], Bojan Joksimovic[1], Milos Marinkovic[1], Ilinka Popovic[1], Lidija Kojic[1], Sonja Zafirovic[3], Milan Obradovic[3] and Esma R. Isenovic[3]
[1]*Department of Endocrinology, Faculty of Medicine, Zemun Clinical Hospital, University of Belgrade, Belgrade, Serbia;* [2]*Endocrinology, Zemun Clinical Hospital, Belgrade, Serbia;* [3]*Laboratory for Radiobiology and Molecular Genetics, Institute of Nuclear science "Vinca", National Institute of Republic of Serbia, University of Belgrade, Belgrade, Serbia*

Mild-to-moderate increases in basal calcitonin (bCT) levels pose diagnostic challenges. To enhance accuracy in diagnosing medullary thyroid carcinoma (MTC), the calcium stimulation test (CST) is employed. Currently, age and gender-specific stimulated calcitonin (sCT) *cut-off* levels are used, underscoring the complexity of interpretation in clinical practice.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

We present a case study of 5 patients aged 42-74 years (4 females and one male) with a mild-to-moderate increase in bCT levels, ranging from 13 to 165 pg/mL, detected during thyroid nodular disease workup. Except for the patient who presented with the highest bCT level (165 pg/mL), all other patients were referred for a CST. The sCT values were: 168, 568, >2000, and >2000 pg/mL. The entire group of patients experienced total thyroidectomy, resulting in diverse postoperative histological findings. The first two patients were diagnosed with follicular adenoma, and Thyroid Follicular Nodular Disease (TFND) coexisted with C-cell hyperplasia (CCH). Patients exhibiting enhanced sCT levels (>2000 pg/mL) were diagnosed with papillary thyroid microcarcinoma (mPTC), and medullary thyroid carcinoma (MTC) coexisted with mPTC. A parathyroid adenoma was histologically verified in a patient with a bCT level of 165 pg/mL who was not tested with CST.

Mild-to-moderate basal hypercalcitoninemia warrants comprehensive evaluation, with the CST as the gold standard. The observed sCT responses align with follicular and C-cell malignancies. When sCT response appears evident but clinically insignificant, benign causes must be ruled out. Failure to demonstrate increased sCT response during CST necessitates investigation for neuroendocrine tumors.

Keywords basal hypercalcitoninemia, calcium stimulation test, stimulated calcitonin, thyroidectomy

EP1562 - ECE_1745 - Probiotics and antioxidants as a synergistic immunomodulatory therapy in autoimmune thyroiditis

Federica Riccobene[1,2] and Luciana Carmen Nitoi[3,4]
[1]*Faculty of Medicine and Pharmacy, "Dunărea de Jos" University, Galati, Romania;* [2]*Facoltà di Medicina "Dunarea De Jos", Enna, Italy;* [3]*Medical Clinical Department, "Dunarea de Jos" University, Galati, Romania;* [4]*"St. Apostol Andrei" Clinic Emergency Hospital, Galati, Romania*

Background: Autoimmune thyroiditis represents a group of chronic inflammatory disorders characterized by aberrant immune activation and loss of self-tolerance, leading to progressive thyroid inflammation and destruction. The most common forms, Hashimoto's thyroiditis (HT) and Graves' disease (GD), involve both genetic and environmental factors, including the intestinal microbiota. Through the gut–thyroid axis, the microbiota regulates thyroid function and dysbiosis may promote autoimmunity. Probiotics can restore microbial balance and modulate the Th17/Treg lymphocyte ratio, while antioxidants such as vitamin C and selenium may enhance these immunomodulatory effects by reducing oxidative stress.

Objectives: To evaluate the efficacy of probiotics combined with the antioxidants vitamin C or selenium as adjunctive therapy in autoimmune thyroiditis, assessing their effects on immunological and endocrine parameters.

Design: A cross-sectional and prospective study was conducted in 48 patients treated with *OMNi-BiOTiC® Stress Repair*, containing nine human-derived bacterial strains of *Lactobacillus* and *Bifidobacterium*. The study sample included 30 patients with HT (62.5%), managed with levothyroxine and 18 with GD (37.5%) under treatment with thiamazole. According to disease type and adjunctive supplementation with probiotics combined with either vitamin C or selenium, patients were stratified into four subgroups.

Methods: Serum concentrations of thyroid-stimulating hormone (TSH), free thyroxine (FT4), anti-thyroid peroxidase antibodies (anti-TPO), anti-thyroglobulin antibodies (anti-TG) and anti-thyrotropin receptor antibodies (TRAb) were measured at baseline and after six months of treatment. Statistical analysis was performed using SPSS 18.0, with a 95% significance level.

Results: After six months of treatment, both HT subgroups demonstrated a reduction in mean TSH levels accompanied by an increase in FT4 concentrations. Anti-TG titres decreased significantly, while changes in anti-TPO titres were modest. At baseline, all GD patients had TSH concentrations below the reference range; after six months, approximately 90% of participants in both treatment groups achieved normalization, a change that was statistically significant. Additionally, TRAb values decreased significantly at six months, particularly in the group receiving probiotics and vitamin C.

Conclusions: Probiotics, particularly combined with vitamin C, demonstrated potential immunomodulatory effects in autoimmune thyroiditis, especially among patients with GD.

EP1563 - ECE_1863 - Should subclinical hypothyroidism always be treated with thyroid hormone?

Barbara Bordacs, Krisztina Kupai and Zsuzsanna Valkusz
Department of Endocrinology, University of Szeged, Internal Medicine, Szeged, Hungary

Introduction: Hypothyroidism is a common disease, especially among women, with a prevalence of around 20%. The treatment of mild and subclinical hypothyroidism is controversial. Initiating pharmacotherapy has a long-term impact on patients's lives, so choosing the right indication is a challenge for clinicians. Selenium is necessary for the synthesis of thyroid hormones, and myo-inositol signaling pathways have a positive effect on the course of many autoimmune and endocrine diseases. The immunomodulatory effect of vitamin D3 has been known for a long time. In our study, we aimed to provide our patients with primary care in the form of dietary supplements in order to prolong or possibly avoid the introduction pharmacotherapy.

Patients and Methods: Our single-center study included 60 newly diagnosed hypothyroid patients (age: 48.7 ± 14.9 years, mean $\pm$ SD) who had not previously received thyroid hormone replacement therapy. For 6 months, we administered a dietary supplement containing 83 µg of selenium and 600 mg of myo-inositol daily, together with 2000 IU of vitamin D3. From the laboratory values, TSH levels were determined at baseline and at least 6 months after treatment. The two values were statistically compared using a T-test.

Results: The therapy used in the study significantly reduced the TSH levels after at least 6 months (6.28 ± 3.4 vs 4.3 ± 2.9; $P < .001$).

Summary: Our results show a significant improvement in thyroid function with the use of a combined agent. By stimulating endogenous hormone synthesis, the initiation of pharmacotherapy could be avoided.

EP1564 - ECE_2302 - Metabolic health and obesity phenotypes and thyroid autoimmunity in euthyroid individuals

Hye Jeong Kim
Seoul, South Korea

Background: Thyroid autoimmunity is a complex condition in which genetic and environmental factors interact to trigger an autoimmune response against the thyroid. This study aimed to investigate the association between metabolic health and obesity phenotypes and thyroid autoimmunity in euthyroid individuals.

Methods: We included participants aged ≥20 years from the National Health and Nutrition Examination Survey (2001-2002, 2007-2008, 2009-2010, and 2011-2012) with thyroid autoantibody results and normal thyroid function. Participants were categorized into four groups based on their metabolic health and obesity phenotypes: metabolically healthy non-obese (MHNO), metabolically unhealthy non-obese (MUNO), metabolically healthy obese (MHO), and metabolically unhealthy obese (MUO). Thyroid autoimmunity was defined as anti-thyroid peroxidase antibody positive and/or anti-thyroglobulin antibody positive. Weighted multiple logistic regression models estimated odds ratios (ORs) for thyroid autoimmunity, adjusting for confounders.

Results: The prevalence of MHNO, MUNO, MHO, and MUO phenotypes was 26.8%, 41.1%, 4.8%, and 27.3%, respectively. The prevalence of thyroid autoimmunity differed by groups (8.8% in MHNO, 12.9% in MUNO, 10.8% in MHO, and 10.2% in MUO; $P = .02$). The MUNO group had a significantly higher risk of thyroid autoimmunity compared with the MHNO group, even after adjusting for confounding variables, including sex, age, race/ethnicity, and smoking [adjusted OR 1.45; 95% confidence interval (CI), 1.06-1.99; $P = .02$]. In the subgroup analyses, the MUNO group had a significantly higher risk of thyroid autoimmunity compared with the MHNO group, particularly among younger individuals under 60 years (adjusted OR 1.73; 95% CI, 1.22-2.47; $P < .01$) and non-Hispanic White individuals (adjusted OR 1.66; 95% CI, 1.12-2.46; $P = .01$).

Conclusions: In euthyroid individuals, the MUNO phenotype was associated with an increased risk of thyroid autoimmunity. Further studies are needed to clarify causality and underlying mechanisms.

EP1565 - ECE_2326 - Management of severe Graves' disease in a patient with antithyroid drug intolerance

Nino Tedoradze
Endocrinology, Caucasus Medical Center, Tbilisi, Georgia

Background: Antithyroid drugs (ATDs) are the first-line treatment for Graves' disease; however, their use may be limited by adverse effects such as allergic reactions and hepatotoxicity. In these situations, definitive therapy with radioactive iodine or surgery becomes necessary. Achieving euthyroidism before thyroidectomy is essential to minimize perioperative risk. When ATDs are contraindicated, potassium iodide represents an effective alternative for short-term preoperative management.

Case Presentation: We report the case of a 26-year-old woman with a 3-year history of Graves' disease who developed severe thyrotoxicosis after discontinuation of antithyroid therapy. Reintroduction of methimazole resulted in an allergic reaction, prompting a switch to propylthiouracil (PTU) combined with prednisone and a beta-blocker. During PTU therapy, the patient developed a second allergic reaction characterized by skin rash, edema, and pruritus, accompanied by elevated liver transaminases (hypertransaminasemia). Consequently, PTU was discontinued.

On admission, the patient presented with marked weakness, dyspnea, tachycardia, emotional lability, weight loss, arterial hypertension, tremor, and exophthalmos. Laboratory evaluation revealed severe thyrotoxicosis (TSH 0.008 mIU/L, FT4 53 pmol/L, FT3 >20 pg/mL), elevated TSH receptor antibodies (30.87 IU/L), increased liver enzymes, and elevated IgE levels. Thyroid ultrasound demonstrated a diffuse goiter with a total thyroid volume of 72 cm^3.

Management and Outcome: Given intolerance to both methimazole and PTU, definitive treatment options were considered. In view of the large goiter size, severe hyperthyroidism, and presence of Graves' orbitopathy, total thyroidectomy was selected. Preoperative preparation was achieved with potassium iodide drops administered for 14 days, resulting in successful attainment of a euthyroid state. The patient subsequently underwent an uncomplicated total thyroidectomy.

Conclusions: This case illustrates the complexity of managing Graves' disease in patients with allergic reactions and intolerance to antithyroid medications. When both methimazole and PTU are contraindicated, potassium iodide can serve as an effective short-term therapy to achieve euthyroidism prior to surgery. Total thyroidectomy is a safe and definitive treatment option in patients with severe hyperthyroidism, large goiter, and Graves' orbitopathy.

EP1568 - ECE_2013 - A multifocal differentiated high grade thyroid carcinoma in a young female patient with Hashimoto thyroiditis

Georgios Boutzios[1], Anastasia Nikolopoulou[1], Christos Doudakmanis[2] and Gerasimos Tsouroufl is[2]
[1]*Department of Pathophysiology, National and Kapodistrian University of Athens, Outpatient Clinic of Autoimmune Endocrinopathies, Athens, Greece;* [2]*Second Department of Propaedeutic Surgery, Medical School, National and Kapodistrian University of Athens, Athens, Greece*

Introduction: Differentiated high grade thyroid carcinoma (DHGTC) is a new classification of thyroid cancer introduced in 2022 by WHO. It is an aggressive type of tumor that retains a well-differentiated architecture and cytology but is characterized by invasive properties, increased mitotic counts and tumor necrosis. Its prevalence is low, representing <3% of all thyroid cancers, it is mostly seen in older individuals and it has a female preponderance.

Case presentation: We present a 34-year-old Caucasian female, smoker, with a disease-free medical history, with a suspicious thyroid nodule on the upper pole of the left thyroid lobe, in a routine neck ultrasonography. The nodule was 12 mm in

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

diameter, hypoechoic with irregular margins and calcifications. Biochemically, she was euthyroid with positive thyroglobulin antibodies and negative calcitonin levels. The patient underwent a FNAB and the lesion was characterized as suspicious for malignancy (Bethesda Category VI).

The patient underwent a total thyroidectomy with central neck compartment dissection. Pathological examination of a specimen of the upper pole of the left thyroid lobe showed evidence of papillary thyroid carcinoma of the follicular type with papillary and mainly follicular pattern, while revealing isolated clusters of solid neoplastic cells infiltrating the thyroid capsule, mild mitotic activity, focal necrosis and important inflammatory infiltration in the cancer focus. Moreover, in a tissue specimen of the lower pole of the right thyroid lobe, a microscopic focus of encapsulated papillary thyroid carcinoma of the follicular type without capsule extension was addressed. The rest of the thyroid parenchyma revealed chronic lymphocytic thyroiditis. None of the seventeen exerted lymph nodes were invaded by neoplastic cells leading to the diagnosis of multifocal differentiated high-grade thyroid carcinoma with papillary follicular and solid growth pattern, pathological stage mT1b, N0, with focal capsule invasion. After thyroid surgery, the patient was treated with Radioactive Iodine.

Conclusions: DHGTC is associated with aggressive clinicopathological features and poor clinical outcome, similar to poorly differentiated thyroid cancer. Early diagnosis seems to be crucial for the patient's outcome.

EP1569 - ECE_2328 - A rare complication of untreated thyrotoxicosis: thyrotoxic periodic paralysis

Banu Ocak[1], Hakan Ömer Karataş[2], Hülya Karadağ[3] and Murat Tuğcu[3]

[1]*Department of Internal Medicine, Marmara University Faculty of Medicine, İstanbul, Türkiye;* [2]*Department of Internal Medicine, Van Gürpınar State Hospital, Van, Türkiye;* [3]*Department of Internal Medicine, Division of Nephrology, Marmara University Faculty of Medicine, İstanbul, Türkiye*

Background: Thyrotoxic hypokalemic periodic paralysis (THPP) is a rare but potentially life-threatening complication of thyrotoxicosis, characterized by episodic hypokalemia and acute flaccid muscle weakness. The underlying pathophysiology involves increased Na^+/K^+-ATPase activity in the hyperthyroid state, leading to an intracellular shift of potassium rather than true potassium depletion. Genetic susceptibility, including mutations affecting skeletal muscle inward-rectifying potassium (Kir) channels, has also been implicated. THPP predominantly affects young adult males and is commonly precipitated by strenuous physical activity, emotional stress or high-carbohydrate intake. In this context, the present case aims to draw attention to thyrotoxic hypokalemic periodic paralysis as an important endocrine cause of acute paralysis.

Methods: Case presentation

Case Presentation: A 27-year-old male presented to the emergency department with sudden-onset, symmetrical weakness of both lower extremities. Neurological examination revealed bilateral proximal muscle weakness graded 3/5, while sensory and cranial nerve examinations were normal. Vitals showed sinus tachycardia with 112 beats/min and blood pressure of 135/70 mmHg. Laboratory testing revealed significant hypokalemia (2.6 mmol/L) and electrocardiography revealed repolarization abnormalities consistent with hypokalemia. Oral and intravenous potassium replacement was initiated under cardiac monitoring.

Further history revealed recurrent self-limited episodes of muscle weakness over the preceding year, previously evaluated in neurology and physical medicine clinics. Neuroimaging and electromyography had been unremarkable. Renal function was normal and there was no evidence of gastrointestinal or renal potassium loss, medication use, or reduced oral intake. The patient reported intermittent palpitations and an unintentional weight loss of approximately 10% over the past year.

Although the patient denied a known thyroid disorder at presentation, review of prior medical records revealed abnormal thyroid function tests obtained one year earlier, with incomplete follow-up due to relocation. Repeat testing revealed thyrotoxicosis consistent with autoimmune thyroid disease (TSH <0.003 mIU/L; free T3: 7.55 ng/L; free T4: 2.76 ng/dL; anti-thyroid peroxidase antibody: 594 IU/mL; TSH receptor antibody: 20 IU/L). Thyroid ultrasonography showed increased vascularity and pseudonodular changes.

Based on clinical and biochemical findings, THPP due to Graves' disease was diagnosed. Complete clinical recovery occurred within hours after potassium replacement, methimazole and propranolol therapy was initiated. The patient has remained asymptomatic during follow-up.

Conclusions: THPP is an uncommon manifestation of thyrotoxicosis and may present as the initial clinical feature, particularly in young men. This case highlights the importance of careful assessment of hyperthyroid symptoms in the emergency setting. Early recognition of the underlying endocrine disorder can facilitate appropriate management and help prevent recurrent paralytic episodes.

Abstract citation ID: lvag096.1710

EP1570 - ECE_3856 - Amiodarone-induced thyrotoxicosis associated with papillary thyroid cancer: diagnosis and treatment difficulties

Melania Balas, Ioana Golu, Plotuna Iulia-Ştefania, Daniela-Georgiana Amzar, Oriana Pelineagra, Oana Popa, Ana-Silvia Corlan and Mihaela Maria Vlad

2nd Internal Medicine, "Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania

Case presentation: A 57-year-old patient was diagnosed with atrial fibrillation in 2022, treated with amiodarone for 2 years (no thyroid ultrasound was performed, thyroid function was normal during monitoring). In November 2023 he was referred to Endocrinology Department with weight loss, palpitations (recurrent atrial fibrillation), sweating and insomnia. The laboratory evaluation confirmed amiodarone-induced thyrotoxicosis (AIT) with suppressed TSH, increased serum FT4, normal FT3, negative antithyroid and TSH-receptor antibodies, negative inflammatory markers.

Thyroid ultrasound revealed normal volume, moderately hypoechoic parenchyma, decreased vascularization. In both lobes, in the posterior region, solid nodules were described, 8.7/9.4/

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

10 mm on the left, respectively 9.2/12.2/11.5 mm on the left, with similar features: marked hypoechoic, "taler than wide" shape, irregular borders, absent intranodular vascularity, microcalcifications, absent halo (TIRADS 5). Thyroid scintigraphy Tc^{99m} showed very low uptake in the thyroid tissue.

Shear-wave elastography found mean IE of 51.5 Kpa of the right nodule, respectively 36 kPa of the left nodule. Contrast-Enhanced Ultrasound (CEUS) showed lower enhancement compared to surrounding tissue. Antithyroid drugs were administered with favorable response.

As the patient was under anticoagulant treatment, fine-needle aspiration biopsy (FNAB) was postponed. FNAB performed in both nodules was reported as suspicious for malignancy (Bethesda category V).

After euthyroidism was achieved, total thyroidectomy was performed in December 2024, confirming the diagnosis of multifocal papillary thyroid carcinoma (PTC), with conventional and Warthin-like features (pT1bN1M0). ^{131}I ablation with 3.7 GBq was performed, with no abnormal uptake at total body scan. During follow-up, stimulated serum thyroglobulin levels were below 0.04 ng/mL, with negative antithyroglobulin antibodies. Under treatment with levothyroxine, TSH values are maintained slightly suppressed, with normal serum thyroid hormones.

Discussion: Although rare, cases of papillary thyroid cancer associated with AIT (mainly type 2), has been reported. The main issue is to distinguish AIT types and to treat thyroid dysfunction accordingly, as PTC can coexist, leading to diagnosis pitfalls.

Managing PTC in an AIT patient can be challenging, due to the high iodine content of amiodarone, its long half-life, factors that may hinder radioactive iodine treatment.

EP1572 - ECE_1014 - Transient hyperthyroid Graves' disease following subacute thyroiditis: a case report

Yotsapon Thewjitcharoen[1], Veekij Veerasomboonsin[2], Soontaree Nakasatien[1] and Thep Himathongkam[1]
[1]*THEPTARIN Diabetes, Thyroid and Endocrine Center, Vimut-Theptarin Hospital, Bangkok, Thailand;* [2]*Radiology, Vimut-Theptarin Hospital, Bangkok, Thailand*

Background: There have been reports on subacute thyroiditis, Graves' disease and Hashimoto's thyroiditis following COVID-19 infection. Appearance of overt autoimmune thyroid disease (AITD) following subacute thyroiditis is very rare. It is also uncommon for subacute thyroiditis to progress to either Graves' disease or Hashimoto's thyroiditis. In previous case reports, most patients had negative baseline thyroid antibodies, so that the autoimmune process was postulated to have been triggered by the release of antigenic material from the inflamed thyroid gland. Herein, we report an interesting case of hyperthyroid Graves' disease following post COVID-19 infection subacute thyroiditis.

Clinical case: A 40-year-old woman presented with palpitation and 4-kilogram weight loss within 1 month following tenderness in her neck. No family history of AITD was reported. One month earlier, she experienced thyroid tenderness after flu-like symptoms. The patient was not tested for COVID-19 at that time. She was treated with oral prednisolone 20 mg/day with presumptive diagnosis of subacute thyroiditis. Her symptoms rapidly improved within 24 hours and oral prednisolone was tapered-off within 2 weeks. However, she developed hyperthyroid symptoms one month later. Physical examination revealed a heart rate of 120 beats/minute and a normal size, non-tender thyroid gland without evidence of orbitopathy. TFT showed serum TSH <0.01 μIU/mL (normal value 0.27-4.20 μIU/mL), FT4 2.8 ng/dL (normal value 0.9-1.7 ng/dL), total T3 218 ng/dL (normal value 60-177 ng/dL), negative anti-Tg but positive anti-TPO titers. Thyroid ultrasonography showed slightly enlarged heterogeneous thyroid gland with mild hypervascularity. Serum TSH receptor antibody (TRAb) was positive at 4.9 IU/L (normal value <1.7 IU/L). Oral methimazole 15 mg per day was given and then tapered to 5 mg per day. At 7 months later, the patient discontinued methimazole by herself from weight gain and feelings of tiredness. Repeated serum TRab turned to negative result with normal TFT. At 2 years later, the patient was still in remission.

Conclusions: The development of Graves' disease after the resolution of subacute thyroiditis is an uncommon condition but had been reported occasionally in previous studies. This case emphasized the need for careful follow-up during steroid treatment and long-term surveillance for thyroid dysfunction.

EP1573 - ECE_2630 - Thyroid-stimulating immunoglobulin in Graves' disease: association with biochemical disease severity and real-world monitoring practices

Win Lei Yin[1], Blaise Emery[1], Therese Michael[2], Angharad Shore[2] and Thinzar Min[1]
[1]*Department of Endocrinology, Swansea Bay University Health Board, Swansea, United Kingdom;* [2]*Laboratory Medicine, Swansea Bay University Health Board, Swansea, United Kingdom*

Background: Thyroid autoantibodies are recommended as first-line investigations in the differential diagnosis of hyperthyroidism. Thyroid-stimulating immunoglobulin (TSI) is increasingly used to support the diagnosis of Graves' disease and has potential value in predicting treatment response. This study aimed to: (1) evaluate whether TSI level at diagnosis correlates with the biochemical severity of Graves' disease, and (2) assess the extent to which TSI is routinely measured during the treatment course.

Methods: We conducted a retrospective observational study of patients diagnosed with Graves' disease who had a positive TSI between January 2023 and December 2024 within Swansea Bay University Health Board. Demographic data, TSI results at or around diagnosis, thyroid function tests at baseline and at 12-month follow-up, and the number of repeat TSI measurements were collected.

Results: A total of 130 patients (mean age 48 ± 19 years; 79% Female) were included. All patients were treated with carbimazole at variable doses. Baseline biochemical measurements showed: median Free T4 FT4:37.8 pmol/L; median Free T3 15.1 pmol/L and median TSI: median 4.20 IU/L. TSI levels at diagnosis correlated positively with biochemical severity: TSI vs FT4: $r = 0.55$, $P < .001$ and TSI vs FT3: $r = 0.49$, $P < .001$ ($n = 129$). At 12 months, 93 (71%) patients remained on antithyroid medication 30 (23%) remained thyrotoxicosis (12 had low TSH, and 18 had suppressed TSH). 19 (14%) patients achieved biochemical euthyroidism and were off antithyroid therapy at

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

the 12-month assessment. Only 10 of 130 patients underwent repeat TSI testing during treatment.

Conclusions: Higher TSI levels at diagnosis are moderately correlated with biochemical severity in Graves' disease. Despite its recognised diagnostic and prognostic value, repeat TSI measurement was infrequently performed in routine practice. The low proportion of patients achieving treatment-free euthyroidism at 12 months highlights the need for improved tools to guide treatment duration. More consistent longitudinal use of TSI may enhance clinical decision-making and support personalised management strategies in Graves' disease.

Abstract citation ID: lvag096.1713

EP1574 - ECE_2545 - Nonspecific increase of thyroglobulin in a patient with papillary thyroid carcinoma

Agnieszka Suligowska and Aldona Kowalska
Skarzysko-Kamienna, Poland

Case Presentation: A 36-year-old woman with a history of multinodular goiter was referred for further evaluation after a suspicious focal lesion was identified on ultrasound.

On 11 June 2011, she underwent total thyroidectomy with prophylactic central compartment lymph node dissection. Histopathological examination confirmed a papillary thyroid carcinoma of the right thyroid lobe measuring 9 mm in greatest diameter, classified as pT1a. One metastatic lymph node was identified in the central compartment, with a metastatic focus measuring 2 mm (pN1a). On 20 July 2012, she received ablative treatment with 2700 MBq of radioactive iodine (^{131}I). Post-therapy whole-body scintigraphy showed no abnormal iodine uptake outside the thyroid bed. During the initial follow-up period, the patient demonstrated an excellent response to treatment. She was maintained on levothyroxine therapy aimed at TSH suppression and remained clinically stable for several years.

During long-term follow-up, a gradual increase in serum Tg levels was observed. Basal Tg rose to 0.9 ng/mL, and stimulated Tg reached 3.0 ng/mL. Repeated ultrasound examinations of the thyroid bed and cervical lymph nodes revealed no suspicious lesions or lymphadenopathy. In view of the biochemical evidence suggestive of persistent or recurrent disease, the patient was qualified for whole-body scintigraphy.

The whole-body scintigraphy revealed an unexpected focus of increased radioiodine uptake located in the left pelvic region. Subsequent SPECT/CT imaging precisely localized the uptake to a lesion within the left ovary.

Further evaluation with pelvic magnetic resonance imaging (MRI) demonstrated a well-defined 16 × 11 mm lesion in the left ovary with thin septations, while the right ovary contained a 13 × 9 mm lesion with imaging characteristics consistent with a fibroma.

The patient was referred for gynecological surgery, and bilateral ovarian lesions were surgically excised. Histopathological examination confirmed the diagnosis of mature cystic teratomas, with thyroid tissue present in the left ovarian lesion. Following surgical removal of the ovarian tumors, serum Tg levels returned to undetectable values, confirming that the elevated Tg levels were not due to recurrent thyroid carcinoma but rather to ectopic thyroid tissue within the ovarian teratoma.

Conclusions: We report a rare case of nonspecific Tg elevation in a patient with papillary thyroid carcinoma, caused by struma ovarii within an ovarian teratoma. This case underscores the importance of considering extrathyroidal sources of Tg when evaluating rising Tg levels in the absence of locoregional or distant recurrence. Accurate recognition can prevent unnecessary interventions and ensure appropriate management.

EP1581 - ECE_1050 - Unmasking pembrolizumab-induced hypothyroidism in a complex multimorbid renal tumour patient: a case report

Shadman Rahman, Muhammad Dalili, Sumaiya Kamal, Sameer Sighakoli and Kh Imranul Alam
Endocrine and Diabetes, Medway NHS Foundation Trust, Gillingham, United Kingdom

Background: Immune checkpoint inhibitors (ICIs), such as pembrolizumab, are increasingly employed in the treatment of advanced malignancies, including renal cell carcinoma. Thyroid dysfunction is a well-recognised immune-related adverse event (irAE) associated with ICIs, typically manifesting as transient thyrotoxicosis followed by hypothyroidism.[1] This case report highlights the development of overt hypothyroidism in a patient with previously normal thyroid function following pembrolizumab therapy.

Case Presentation: A 70-year-old male with multiple comorbidities—including ischemic heart disease, heart failure with reduced ejection fraction, chronic obstructive pulmonary disease (COPD), hypertension, atrial fibrillation, psoriasis, and a history of prostate cancer treated with robotic prostatectomy—was admitted with chest sepsis requiring inotropic support. Incidentally, two renal masses were identified on CT imaging, demonstrating heterogeneous enhancement, regional lymphadenopathy, and a suspected tumour thrombus extending into the renal vein and inferior vena cava. The patient subsequently underwent robotic right nephrectomy with excision of the tumour thrombus.

Postoperatively, pembrolizumab therapy was initiated. Baseline thyroid function tests were within normal limits (TSH: 0.45 mIU/L). However, within weeks of treatment initiation, the patient developed overt hypothyroidism, characterised by a markedly elevated TSH of 49.60 mIU/L and a low free T4 level of less than 3.2 pmol/L. Oral levothyroxine therapy was commenced, and the patient is currently under close monitoring with regular thyroid function tests and outpatient thyroid ultrasound evaluation.

Conclusions: Pembrolizumab-induced thyroid dysfunction is a common irAE, with hypothyroidism reported in up to 10% of patients.[2] The underlying pathophysiology may involve destructive thyroiditis or autoimmune mechanisms, even in individuals without prior thyroid disease. This case underscores the critical importance of routine thyroid function monitoring during ICI therapy. Early recognition and management of endocrine irAEs are essential to ensure the safe continuation of immunotherapy and optimise patient outcomes.[3]

EP1582 - ECE_3531 - Graves' disease after long-term levothyroxine-treated hypothyroidism

Lia Katcharava[1,2] and Salome Kalandadze[1]
[1]*New Hospitals, Tbilisi, Georgia;* [2]*Endocrinology, New Hospitals, Tbilisi, Georgia*

Background: Biochemical thyrotoxicosis in patients receiving levothyroxine is often attributed to over-replacement. However, persistence of suppressed thyrotropin (TSH) with elevated free thyroxine (FT4) and free triiodothyronine (FT3) after dose reduction and complete withdrawal should trigger prompt evaluation for a new hyperthyroid disorder. Rarely, patients previously treated for hypothyroidism may subsequently develop Graves' disease ("conversion"), creating a diagnostic pitfall.

Case presentation: A female patient diagnosed with primary hypothyroidism in 2020 remained clinically stable and biochemically euthyroid on levothyroxine 75 μg/day with regular monitoring. In December 2024, she developed symptoms suggestive of thyrotoxicosis; thyroid function tests demonstrated suppressed TSH with elevated FT4/FT3. Iatrogenic thyrotoxicosis was suspected and levothyroxine was reduced, then fully discontinued in January 2025. Despite cessation, repeated testing continued to show suppressed TSH with elevated FT4/FT3. The patient did not seek specialist care until April 2025, when she developed bilateral periorbital edema with mild proptosis, accompanied by palpitations, tremor, and diaphoresis. Thyroid ultrasound revealed no focal nodules. Anti-TPO and anti-TG antibodies were negative. TSH receptor antibodies (TRAb) were strongly positive (11 IU/L; assay reference <1.22 IU/L), confirming Graves' disease with early thyroid-associated orbitopathy.

Management and Follow-up: Methimazole therapy was initiated with symptomatic improvement and biochemical monitoring. Levothyroxine remained discontinued. Given ocular involvement, the patient was referred for ophthalmologic assessment and multidisciplinary management according to orbitopathy activity and severity.

Conclusions: Suppressed TSH in a patient receiving levothyroxine should not automatically be attributed to over-replacement. Persistence of thyrotoxicosis despite dose reduction and drug cessation—especially when orbital signs develop—should prompt immediate TRAb testing to confirm Graves' disease, avoid diagnostic delay, and ensure timely initiation of antithyroid therapy and coordinated ophthalmologic care.

Abstract citation ID: lvag096.1716

EP1583 - ECE_1839 - Exogenous T3 ingestion leading to T3 thyrotoxicosis

Ishara Ranathunga, Chandima Idampitiya and Fathima Pambinezhut
Endocrinology, North Cumbria University Hospitals Nhs Trust—Carlisle Library, Carlisle, United Kingdom

Background: T3 thyrotoxicosis due to exogenous triiodothyronine (T3) ingestion is a rare cause of hyperthyroidism, mimicking endogenous thyroid dysfunction. It results from intentional or accidental ingestion of T3 or T3 containing supplements leading to suppression of endogenous thyroxine production. Diagnosis can be challenging, requiring exclusion of endogenous causes and establishing exogenous ingestion. This case highlights the complexity of diagnosis of a patient with persistent T3 toxicosis who denied exogenous T3 use.

Case Report: A 45-year-old female was diagnosed to have thyrotoxicosis during investigations for persistent post-operative tachycardia following laparoscopic cholecystectomy in August, 2023. On further evaluation, she was noted to have typical thyrotoxic symptoms since March 2023. Examination revealed elevated blood pressure (160/105 mmHg), sinus tachycardia (heart rate 123 pbm), and a weight of 48 kg. She did not have a palpable goitre and any signs of thyroid eye disease. Investigations showed elevated T3 of >50 pmol/L with suppressed fT4 (fT4 2.7 pmol/L (11-22)), and TSH <0.02 mU/L (0.3-4.5). TRAb and TPO was negative, and biotin interference was excluded. Ultrasound showed a small thyroid and technetium uptake scan showed absence of thyroid uptake. Urine iodine was inconclusive. Normal pelvic ultrasound and pelvic MRI ruled out ectopic thyroid tissue. The imaging showed the presence of an undisclosed gastric band. Whole-body iodine scan showed increased uptake around the thyroid, but a repeat technetium scan confirmed absence of thyroid uptake. As the patient denied exogenous T3 use, she was initially treated with antithyroid medication and beta blockers. Subsequently due to absence of response, she was started on steroids and later on cholestyramine without any success. She was closely observed as an inpatient for exogenous use for 1 week without a confirmation. Despite denying exogenous T3/supplements use, persistently high T3 and discordant scans suggest undisclosed ingestion of T3 as the cause of her refractory thyrotoxicosis. Therefore, the above mentioned medications were discontinued.

Conclusions: This case emphasises the need to consider exogenous T3 ingestion in refractory thyrotoxicosis, particularly with discordant imaging. The failure of conventional antithyroid or steroid treatment highlights the importance of discontinuing ineffective therapies and pivoting to alternative treatment strategies, including counselling to encourage disclosure. Further exploration of the patient's lifestyle, dietary habits, and potential environmental exposures is essential to pinpoint the exogenous T3 source. This approach not only resolves the diagnostic enigma but also paves the way for tailored management, potentially preventing long-term complications and improving the patient's quality of life.

EP1584 - ECE_2222 - Carbimazole-induced systemic lupus erythematosus complicating the management of Graves' disease: a rare but serious association

Hafiz Awais Javed, Haris Marath, Daisy Beard, Jayamalee Jayaweera, Arooj Zulfiqar and Amna Zeeshan
Endocrinology, West Suffolk Hospital, Bury St Edmunds, United Kingdom

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Background: Graves' disease and systemic lupus erythematosus (SLE) are autoimmune conditions that predominantly affect young women. While Graves' disease is organ-specific, SLE is a multisystem autoimmune disorder with diverse clinical manifestations. Drug-induced lupus erythematosus (DILE) is classically associated with medications such as hydralazine, procainamide, and isoniazid; however, antithyroid drugs are rarely implicated.

Case Presentation: We report the case of a 44-year-old female presented with new-onset atrial fibrillation resistant to standard rate-control therapy, pyrexia and classical features of thyrotoxicosis, including palpitations, unintentional weight loss, and fine tremors. Biochemical testing confirmed severe thyrotoxicosis (TSH < 0.02 mIU/L, fT4 69.6 pmol/L). A Burch–Wartofsky score of 55 was highly suggestive of thyroid storm. She was treated with intravenous beta-blockade and steroids, oral propylthiouracil, and Lugol's iodine, resulting in marked clinical improvement. She was discharged on carbimazole 10 mg twice daily with a tapering course of prednisolone.

Four weeks later, she was re-admitted with persistent fever and flu-like symptoms. She remained febrile with a persistently elevated C-reactive protein despite antiviral therapy and broad-spectrum antibiotics. Investigations for pyrexia of unknown origin, including blood and urine cultures and cross-sectional imaging, were unremarkable. Autoimmune testing showed positive ANA, Anti dsDNA, anti-Ro, and anti-histone antibodies, supporting a diagnosis of carbimazole-induced SLE.

Carbimazole was switched to propylthiouracil, and oral prednisolone 20 mg daily was initiated, resulting in rapid resolution of fever and arthralgia. Hydroxychloroquine was later introduced for ongoing disease control. Subsequent evaluation revealed significant proteinuria, and renal biopsy confirmed class III lupus nephritis, necessitating treatment with mycophenolate mofetil.

Discussion: This case demonstrates a rare but serious complication of carbimazole therapy. The coexistence of Graves' disease and drug-induced SLE presents diagnostic and therapeutic challenges, particularly when persistent systemic symptoms are misattributed to infection or relapse of thyrotoxicosis.

Conclusions: Clinicians should recognise carbimazole as potential trigger for drug induce lupus and maintains a high index of suspicion for autoimmune pathology in patients who develop unexplained systemic symptoms. Early recognition, prompt withdrawal of the offending drug, and appropriate immunosuppressive therapy can result in favourable outcomes.

EP1586 - ECE_3112 - Ectopic papillary thyroid carcinoma of the lateral neck: an unusual presentation

Milena Brkic[1,2,3], Tade Popovic[1], Ljiljana Tadic Latinovic[4], Aleksandra Markovic[1] and Zoran Dakic[5]

[1]Medical Faculty, Banja Luka, Bosnia and Herzegovina; [2]School of Medicine, University of Banja Luka, Banja Luka; [3]Faculty of medicine University of Banja Luka, Banja Luka, Bosnia and Herzegovina; [4]Institute of Pathology, University Clinical Centre of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina; [5]Thoracic Surgery Department, University Clinical Centre of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina

Introduction: The presence of thyroid tissue outside its normal anatomical location, between the second and fifth tracheal rings, is defined as ectopic thyroid tissue. Approximately one to three percent of ectopic thyroid tissue is located in the lateral neck. Most cases are asymptomatic and considered benign.However, lateral neck ectopic thyroid tissue may also represent metastatic disease from an occult primary thyroid carcinoma, making accurate diagnosis challenging.

Case presentation: A 36-year-old male presented for microwave ablation of a large right-lobe thyroid nodule after five years of ultrasound surveillance. Progressive growth had been documented, and surgery was recommended, but the patient opted for minimally invasive treatment. Repeated fine-needle aspiration of the right-lobe nodule showed benign cytology, thyroid function tests were normal, and no cervical lymphadenopathy was detected. Clinical examination revealed a palpable right thyroid mass causing compressive symptoms and cosmetic concerns. Ultrasound demonstrated a parenchymatous-colloid nodule measuring $3.1 \times 4.1 \times 2.5$ cm in the right lobe, a 0.2 cm micronodule in the left lobe, and an enlarged left lateral cervical lymph node with microcalcifications, highly suspicious for malignancy.

During microwave ablation in November 2024, fine-needle aspiration of the suspicious lymph node suggested papillary carcinoma, possibly arising from ectopic thyroid tissue. In February 2025, right lobectomy with excision of lateral neck tissue and lymph node dissection was performed. Histopathology confirmed a benign right-lobe nodule and papillary carcinoma of conventional and follicular variants originating from ectopic thyroid tissue, with microscopic lymphatic invasion and no vascular invasion.Postoperative evaluation revealed elevated serum thyroglobulin levels of 123.6 ng/mL. Computed tomography identified enlarged lateral cervical lymph nodes. Completion thyroidectomy and removal of metastatic lymph nodes were performed. Histology demonstrated a 0.2 cm papillary microcarcinoma in the left thyroid lobe and metastases in three of eleven lymph nodes, while remaining thyroid tissue showed nodular colloid goiter. Follow-up computed tomography and whole-body scintigraphy were normal. The patient received radioactive iodine therapy I-131 150 mCi.

Conclusions: Ectopic thyroid carcinoma of the lateral neck is a rare but clinically important entity. Papillary microcarcinoma, despite its small size, may exhibit aggressive behavior and requires careful evaluation. Thermal ablation enabled early detection, appropriate surgical management, and adjuvant therapy, resulting in a favorable oncological outcome and long-term disease control. This case highlights the importance of multidisciplinary assessment, imaging, and histopathological correlation in complex thyroid disease presentations in clinical practice.

Keywords papillary microcarcinoma, thyroid nodule, ectopic thyroid tissue

EP1588 - ECE_3284 - Thyroid hormone transporter defect (Allan-Herndon-Dudley syndrome)—a rare syndrome masquerading as dyskinetic cerebral palsy: a case report

Iryna Lastivka

Bukovinian State Medical University, Chernivtsi, Ukraine

Topicality: Allan-Herndon-Dudley syndrome (AHDS) (ORPHA:59) (synonym monocarboxylate transporter 8 (MCT8) deficiency) is a

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

syndrome caused by mutations in the *SLCI6A2* gene (Xq13.2), which encodes MCT8, which acts as a thyroid hormone (TH) transporter. Since MCT8 is crucial for the transport of TH across the blood-brain barrier and into neurons, its deficiency leads to intellectual disability and thyroid dysfunction. It occurs only in males. It's diagnosed by clinical signs, changes in serum TH levels, and DNA diagnostics.

Objective: To present a case of Thyroid Hormone Transporter Defect in a child.

Methods: TH assay by immunochemiluminescent method; whole-exome sequencing.

Clinical case: A 7-month-old boy from the 3rd pregnancy on the background of polyhydramnios, third delivery at 39 weeks. Birth weight 2500 g (−3σ), length—47 cm (−3σ). Intrauterine growth retardation, symmetrical variant. Complaints of convulsions, restlessness, crying. Children (females) from two previous pregnancies are healthy. At birth—hypotension, difficulties with feeding; at 2 month—tremor, restlessness, sleep-wake disorder; at the age of 2 months—tremor, restlessness, sleep-wake disorder; at the age of 6 months—spasticity with hyperreflexia, clonus and dystonic movements of the face, neck and distal extremities. At the age of 7 months—weight 6300 g (−2σ), length—62 cm (−3σ).

Phenotype: apathy, slow reaction, hypotrophy, open mouth, short upper lip, ear deformity, right eye converging slant, constant chin tremor. He does not hold head, does not sit, positive Moro reflex, increased muscle tone. Weakness of neck muscles, hypertonicity of limbs, retroflexion of head, microcephaly, poor motor coordination are detected. Laboratory: cholesterol—2.2 mmol/L; TH: TSH—5.0 μM IU/mL (normal: 0.3-4.0 μM IU/mL); T4—7.8 pmol/L (normal: 9.0-20.0 pmol/L). Thyroid ultrasound—without abnormalities. EEG: diffuse abnormalities with focal sharp waves in the parieto-occipital-temporal region; Brain MRI: bilateral dilatation of the ventricular system and delayed myelination. Whole-exome sequencing of the child and parents: a mutation c.330C>A, p.(Cys110*) was detected in the hemizygous variant in the *SLC16A2* gene (NM_006517.5) of maternal origin.

Conclusions: Allan-Herndon-Dudley syndrome or MCT8 transporter deficiency is a rare syndrome that should be considered in male infants with idiopathic hypotension and weakness. The diagnosis of SAHD is based on the determination of a complex of indicators (T3, T4 and TSH) of thyroid function. Cytogenetic diagnostic methods allow to verify the diagnosis at an early age.

Abstract citation ID: lvag096.1720

EP1589 - ECE_3574 - A rare hematologic emergency during treatment of hyperthyroidism: a clinical case

Nuno Faria, Rita Ribeiro, Patrícia Brito, Adriana de Sousa Lages, Maria Joana Santos, Olinda Marques and Catarina MacHado
Endocrinology department, Unidade Local de Saúde de Braga, Braga, Portugal

Background: Antithyroid drugs remain the first-line treatment for Graves' disease, with methimazole preferred for its efficacy and safety profile. Agranulocytosis is an extremely rare but potentially life-threatening adverse effect, occurring in <0,5% of patients. Early recognition is critical to avoid serious infectious complications and uncontrolled thyrotoxicosis.

Case Description: We describe a case of a previously healthy 39-year-old woman with newly diagnosed Graves' disease [TSH <0.008 μUI/mL, free T4 2.57 ng/dL (0.89-1.76), TRAb 1.79 UI/L (<0.55)], who was started on methimazole 15 mg/day. A previous history of other autoimmune diseases and smoking were excluded.

One month later, she presented to the emergency department with fever (39.7°C), odynophagia, and malaise. Examination revealed a tender goiter and bilateral tonsillar hypertrophy with asymmetric bulging. Laboratory testing showed severe leucopenia (1000/mm^3) with neutropenia (100/mm^3), elevated C-reactive protein (299.9 mg/L; <5.0), and a peritonsillar abscess on cervical CT. Thyroid function had partially improved [TSH 0,011uUI/mL; free T4 1,8 ng/dl; free T3 6,02 pg/mL (2,3-4,2)].

Methimazole was immediately discontinued, and broad-spectrum antibiotics and corticosteroids were initiated. Due to the risk of cross-reactivity, propylthiouracil was avoided. Given the risk of thyroid storm in the absence of antithyroid therapy and the need for definitive treatment, Lugol's solution (10 drops every 8 hours) and propranolol (40 mg twice daily) were introduced for thyrotoxicosis control before total thyroidectomy. Other causes of agranulocytosis were excluded, namely renal or hepatic impairment or viral infections. No microbiological agents were isolated in the collected blood samples.

After recovery of the neutrophil count and normalization of thyroid hormone levels (free T4 0,921 ng/dl; free T3 2,96 pg/mL), total thyroidectomy was performed without complications. Postoperatively, the patient developed transient hypoparathyroidism with mild hypocalcemia, which resolved with calcium carbonate and calcitriol. She was discharged on levothyroxine 88 ug/day and remains euthyroid.

Conclusions: This case underscores the rarity and severity of methimazole-induced agranulocytosis and the challenges in managing hyperthyroidism when this complication occurs. Early drug withdrawal, infection control, and prompt preoperative stabilization of thyrotoxicosis are crucial to prevent thyroid storm. Definitive surgery, once hematologic recovery is achieved, remains the safest curative option.

EP1590 - ECE_1907 - Indole-3-carbinol as a potential protective agent—lipid peroxidation determination in porcine thyroid after Fenton reaction damage and application of molecular docking

Anna Skoczyńska[1], Michał B. Ponczek[2], Jan Stępniak[1] and Małgorzata Karbownik-Lewińska[1,3]
[1]*Department of Endocrinology and Metabolic Diseases, Medical University of Łódź, Łódź, Poland;* [2]*Department of General Biochemistry, University of Łódź, Łódź, Poland;* [3]*Polish Mother's Memorial Hospital—Research Institute, Łódź, Poland*

Objectives: Indole-3-carbinol is a known dietary supplement and naturally occurs in vegetables like broccoli, cabbage, cauliflower, kale, kohlrabi, mustard greens, belonging to the cruciferous family *(Brassicaceae)* and exhibiting medicinal activities. The thyroid is an endocrine gland, which is a good example of an organ, where intense redox reactions occur. The aims of this research are the evaluation of the influence of indole-3-carbinol wide range of concentrations on membrane lipid peroxidation

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

caused by Fenton reaction substrates ($FeSO_4$ and H_2O_2) in porcine thyroid homogenates and application of molecular docking with homology modelling in case of indole-3-carbinol possible interactions with known antioxidative enzymes, ie, superoxide dismutase (SOD) and glutathione peroxidase (GPx).

Methods: To determine lipid peroxidation products, ie, malondialdehyde+4-hydroxyalkenals (MDA+4-HDA), a spectrophotometric assay was used. The Fenton reaction substrates were used in the following concentrations: 1200, 600, 300, 150, 75, 37.5, 18.75, 9.375, 4.687, 2.343, 0.0 μM for $FeSO_4$ and 5.0 mM for H_2O_2. Indole-3-carbinol was used in the following concentrations: 20.0, 10.0, 5.0, 1.0, 0.5 and 0.0 mM. Additionally, *in silico* molecular docking to isoforms of antioxidative enzymes, such as SOD and GPx of human and pig was performed using SwissDock (https://www.swissdock.ch/) with AutoDock Vina algorithm. Porcine SOD and GPx homology models were generated in SwissModel based on human SOD and GPx isoforms as PDB templates.

Results: Indole-3-carbinol showed dual activity that depends on the concentration of iron ions and the indole derivative itself. This indole derivative showed antioxidant activity across its entire concentration range, particularly against $FeSO_4$ concentration equal to 18.75 μM. On the other hand, indole-3-carbinol enhanced stimulatory effect of $FeSO_4$ (1200-300 μM) on lipid peroxidation. The pro-oxidant activity of indole-3-carbinol was also observed at two highest its concentrations, when the antioxidant was used alone. Results of *in silico* molecular docking suggest that indole-3-carbinol does not interact with SOD and GPx at lower concentrations. At higher concentrations used in the *in vitro* homogenate experiments, nonspecific partial inhibition of SOD or GPX cannot be excluded, which may contribute to reduced endogenous ROS scavenging.

Conclusions: Dual nature of indole-3-carbinol relies on its anti- and pro-oxidant properties and is consistent with literature reports. Although our results do not clearly confirm any interaction between indole-3-carbinol and superoxide dismutase and glutathione peroxidase, non specific partial inhibition of these enzymes cannot be excluded, contributing to reduced endogenous ROS scavenging. Therefore, additional research is needed to determine the specific mechanism of action of indole-3-carbinol in thyroid cells.

EP1591 - ECE_2886 - Assessment of BRAF V600E-mutated circulating tumour DNA in papillary thyroid microcarcinoma

Emilia Niedziela[1,2], Kinga Hińcza-Nowak[3], Justyna Miłek-Krupa[3], Iwona Palyga[1,2], Agnieszka Walczyk[1,2], Danuta Gąsior-Perczak[1,2], Janusz Kopczyński[4], Artur Kowalik[3,5] and Aldona Kowalska[1,2]

[1]Department of Endocrinology, Holy Cross Cancer Center, Kielce, Poland; [2]Collegium Medicum, Jan Kochanowski University, Kielce, Poland; [3]Department of Molecular Diagnostics, Holy Cross Cancer Center, Kielce, Poland; [4]Department of Tumor Pathology, Holy Cross Cancer Center, Kielce, Poland; [5]Division of Medical Biology, Jan Kochanowski University, Institute of Biology, Kielce, Poland

Background: Papillary thyroid microcarcinoma (PTMC) is a tumour ≤1 cm with a generally favourable prognosis. Management options include surgery, percutaneous ablation or active surveillance, based on clinical risk and patient preference. To date, the role of molecular assessment in the risk stratification and clinical decision-making of PTMC is limited due to insufficient evidence. Although the *BRAF* V600E mutation is detected in up to 70% of PTMC, previous studies have reported conflicting results on this mutation as a risk factor. Detection of *BRAF* V600E-mutated circulating tumour DNA (ctDNA), reflecting the release of mutated DNA from tumour cells and potentially indicating more aggressive tumour biology, may therefore be investigated as a potential marker of disease risk.

Aim: The aim of this study was to investigate the clinical utility of detection of *BRAF* V600E-mutated ctDNA in plasma as a minimally invasive adjunct to the primary diagnosis of PTMC.

Methods: This prospective, single-center study was conducted between 2021 and 2024. Patients with focal thyroid lesions who were scheduled for total thyroidectomy were enrolled. Blood samples of 10 mL were collected during the perioperative period and subsequently centrifuged. The plasma was frozen and biobanked. Plasma samples from patients with confirmed *BRAF* V600E-positive PTMC were tested for the presence of circulating nucleic acids. Positive samples were further tested for the *BRAF* V600E mutation using digital droplet PCR (ddPCR). The reference test was the detection of the *BRAF* V600E mutation in tumour tissue using real-time PCR. Patients diagnosed with other malignant tumours were excluded from the final analysis. The obtained results were correlated with clinical data.

Results: 19 plasma samples from patients with *BRAF* V600E-positive PTMC were included in the final analysis. All patients had stage I PTMC. Median time from blood sampling to surgery was 26 days (IQR: 9-35). The median size of a tumour was 7 mm (IQR: 5-8.5). No plasma samples were positive for *BRAF* V600E-mutated ctDNA.

Conclusions: The assessment of circulating tumour DNA does not seem to be a suitable test to supplement the diagnosis of PTMC, presumably due to low release of free DNA into circulation.

Abstract citation ID: lvag096.1723

EP1592 - ECE_1203 - Is statin use linked to thyroid cancer? What does NHANES show?

Christos Savvidis, Vasiliki Tsiama, Stella Proikaki, Konstantinos Belis, Efthymia Kallistrou, Dimitra Ragia, Dimitra Motsiou and Ioannis Ilias

Department of Endocrinology, Hippokration Hospital, Athens, Greece

Introduction: The use of statins and its relation to thyroid cancer have been under continuous research with somewhat conflicting findings; however, evidence also leans toward a potential protective effect rather than harm.

Aim: To assess statin use in relation to thyroid cancer using the NHANES data.

Methods: Data from NHANES 2013-2020 were analyzed (*n*: 35 706, 1:1 gender ratio). NHANES is a continuous, nationally representative program, which runs in the U.S.. The program monitors the health and nutritional status of the U.S. population through interviews, physical examinations, and laboratory tests. Statin use was recorded ($n = 3643$, all medications combined) as was thyroid cancer history (all histologies, $n = 59$). Statistical analysis

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

was done with logistic regression and the chi square test; associations between thyroid cancer history, age, gender and reported statin use were assessed.

Results: Thyroid cancer history was positively linked ($P < .05$) to age (weakly, Nagelkerke R2:0.065), female gender (OR: 1.311-3.201) and statin use (OR: 0.739-1.933), but for the latter, the confidence intervals of the OR were not significant.

Discussion: The number of thyroid cancer cases was small ($n = 59$); this may limit definitive epidemiologic conclusions. Many recent large-scale observational data suggest that statin use is not associated with an increased risk of thyroid cancer; studies even suggest that statin use may even confer a protective effect. The protective effect may be related to the known anti-proliferative and pro-apoptotic effects of statins on thyroid cancer cells, as well as their ability to modulate metabolic pathways linked to cancer risk. However, some studies have reported an increased risk, particularly in women: patient-specific factors, statin type, dosage, and duration of use might influence outcomes. Limitations of existing studies include their retrospective design, potential confounding, and reliance on administrative data for diagnoses; all these factors necessitate cautious interpretation.

Conclusions: This work is congruous with previous smaller studies that suggested a possible increased risk of thyroid cancer with statins' use. However, larger studies have reported negative associations, indicating that statin use may reduce thyroid cancer risk. This is corroborated by mechanistic studies, which have shown that statins exert anti-cancer properties on thyroid cells. Additional research is needed to conclusively establish this.

EP1594 - ECE_3384 - Subject: anaplastic thyroid carcinoma: clinical presentation, diagnosis and management in a four-case series

Charikleia Paschalidi[1], Anna-Maria Papadopoulou[2], George Papastergiou[2], Marina Sassi[3], Akrivi Kostopoulou[3], Danai Georgakopoulou[1], Athina Markou[1], Athanasios Fountas[1] and Labrini Papanastasiou[1]

[1]Unit of Endocrinology and Diabetes, General Hospital of Athens "G. Gennimatas", Athens, Greece; [2]Otolaryngology, General Hospital of Athens "G. Gennimatas", Athens, Greece; [3]Pathology, General Hospital of Athens "G. Gennimatas", Athens, Greece

Introduction: Anaplastic thyroid carcinomas (ATC) is a rare tumor usually presented at an advanced stage and characterized by aggressive behavior and poor prognosis. Current best practices consist of radical surgery combined with postoperative radiotherapy and chemotherapy. For BRAF*V600E*-positive tumors, targeted BRAF inhibitors are available.

Objective: We report on a series of four cases of patients with ATC presented in our clinic between 2023-2025.

Case reports: 1st case

A 69-year-old male underwent total thyroidectomy due to a large thyroid nodule. Histology showed poorly differentiated thyroid carcinoma. He presented a month later with locally advanced disease, causing airway obstruction necessitating emergency tracheostomy. The CT scan showed pulmonary metastases (stage IVC). New histological examination revealed ATC positive for BRAF mutation. Treatment with dabrafenib-trametinib was initiated combined with ERBT and chemotherapy. Three months later, the patient developed rare metastases to the right pulmonary artery and left ventricle. He passed away three months after disease progression.

2nd case

A 90-year-old male presented to the outpatient department with a three-month history of coarseness and cough. Thyroid ultrasound revealed a 3-cm nodule with cytology positive for ATC. PET-FDG scan was negative for metastatic disease (stage IVB), and the patient underwent total thyroidectomy. Histology confirmed the diagnosis of ATC positive for BRAF mutation. The patient was treated with dabrafenib—trametinib and refused to undergo radiotherapy or chemotherapy. He passed away four months after the diagnosis.

3rd case

A 73-year-old female underwent total thyroidectomy due to a nodule with cytology positive for papillary carcinoma. During the surgery, a large thyroid nodule was discovered, extensively infiltrating the surrounding tissues. Histology showed ATC, while molecular profiling showed an HRAS mutation. A PET-FDG scan one month later revealed metastatic disease (stage IVC). Due to the absence of specific targeted therapy, she received standard radiotherapy and chemotherapy which was complicated by radiation-induced esophagitis.

4th case

A 73-year-old female with a history of advanced dementia presented to the emergency department with a progressively enlarging cervical mass. FNB confirmed the diagnosis of ATC. Imaging revealed an enlarged cervical mass and multiple pulmonary nodules (stage IVC). Given the patient's poor clinical condition and the advanced stage of disease, a palliative approach was decided. The patient died within a month.

Conclusions: The management of ATC remains challenging due to its rapid progression and limited response to conventional therapies. These cases underscore the need for early diagnosis, multidisciplinary approach, and molecular profiling to guide personalized therapy.

EP1596 - ECE_3482 - Herpetic keratitis complicating thyroid eye disease: a report of two rare cases

Dionysios Vrachnis[1], Grigoris Effraimidis[1,2], Nektarios Adamopoulos[1], Athanasios Kasotas[1], Maria Galani[1], Eleni Georgiou[1], Ioannis Gkountios[1], Anastasia-Konstantina Sakali[1], Apostolia Pouliou[1], Stefanos Tamouridis[1], Maria Apostolopoulou[1,2] and Alexandra Bargiota[1,2]

[1]Department of Endocrinology and Metabolic Diseases, University General Hospital of Larissa, Larissa, Greece; [2]Faculty of Medicine, Department of Endocrinology and Metabolic Diseases, School of Health Sciences, University of Thessaly, University General Hospital of Larissa, Larissa, Greece

Introduction: Thyroid Eye Disease (TED) is an autoimmune inflammatory disease of the orbit that primarily affects the extraocular muscles, orbital adipose tissue, and surrounding soft tissues. Herpes simplex virus (HSV) keratitis may lead to exposure keratopathy with epithelial breakdown and corneal ulceration, potentially resulting in sight-threatening visual loss.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Case 1: A 71-year-old woman with a 35-year history of Graves' disease and post-thyroidectomy hypothyroidism presented with moderate-to-severe TED, with symptoms of two months' duration. One month prior to her visit to our clinic, she had been diagnosed with herpetic keratitis in the left eye. Slit-lamp examination revealed a central corneal scar with old fibrosis. For TED, intravenous glucocorticoid (IVGC) therapy was administered (cumulative dose of 4.5 g of methylprednisolone over 12 weeks), resulting in improvement of TED symptoms and she also received topical and therapy for herpetic keratitis, with concomitant clinical improvement.

Case 2: A 74-year-old man presented to our clinic with a recent diagnosis of Graves' disease and moderate-to-severe TED, with symptoms of three months' duration. Two months prior to his visit to our clinic, he had been diagnosed with herpetic keratitis in the right eye. IVGC therapy was administered (cumulative dose of 4.5 g of methylprednisolone over 12 weeks),leading to significant improvement of TED and he had topical therapy and oral acyclovir for his h keratitis, with associated improvement on slit-lamp examination.

Discussion: TED is a challenging condition to manage and may become more complex when herpetic keratitis coexists. Clinical manifestations of TED include tear film instability, proptosis with dry eye symptoms, eyelid retraction, restricted ocular motility, and impaired Bell's phenomenon, all of which contribute to ocular surface destabilization and corneal exposure. Patients with active TED are at increased risk of developing corneal infections, including herpetic or bacterial keratitis, and in severe cases, corneal ulceration with potential visual impairment. When initiating IVGC therapy, clinicians should be mindful of the risk of HSV reactivation. Regular slit-lamp examination is essential for evaluating disease activity and detecting corneal complications.

EP1597 - ECE_1134 - Variable clinical manifestations of thyroid carcinoma associated with struma ovarii; role of serum thyroglobulin

Ho-Cheol Kang[1], Jeehee Yoon[1], Ji Yong Park[1], A Ram Hong[1], Young Sang Lyu[2], Jin Woo Jung[3] and Hee Kyung Kim[1]
[1]Division of Endocrinology and Metabolism, Department of Internal Medicine, Chonnam National University Medical School, Chonnam University Hwasun Hospital, Hawsun, South Korea; [2]Division of Endocrinology and Metabolism, Department of Internal Medicine, Chosun University School of Medicine, Gwangju, South Korea; [3]Division of Endocrinology and Metabolism, Department of Internal Medicine, Wonkwang University Scholl of Medicine, Iksan, South Korea

Introduction: Struma ovarii (SO) is a specialized form of ovarian teratoma in which more than 50% of the tumor is composed of thyroid tissue, and malignant transformation is extremely rare. Owing to its rarity and the fact that most cases are initially managed in gynecology, SO associated with thyroid carcinoma has been reported only sporadically in the form of individual case reports or small series. We report three cases of thyroid carcinoma associated with SO managed at a single tertiary referral center.

Patients: The first patient, a 51-year-old woman who underwent total thyroidectomy for papillary thyroid carcinoma (PTC) showed persistently elevated thyroglobulin (Tg) levels despite negative neck and chest imaging. PET-CT revealed an adnexal mass, and surgery confirmed SO; her Tg normalized and remission was maintained for three years.

The second patient, a 65-year-old woman, was diagnosed with PTC arising in SO after oophorectomy. Subsequent total thyroidectomy revealed occult papillary carcinoma in the thyroid. Her postoperative serum Tg decreased to 18.4 ng/mL and became undetectable following radioiodine ablation (RAI). she remained in remission for four years. The third patient, a 37-year-old woman, had SO with peritoneal strumosis but no malignant cells. Small enhancing pelvic lesions persisted postoperatively, and total thyroidectomy revealed multiple PTCs (5 mm and 2 mm). Her postoperative serum Tg was 13.3 ng/mL, and she was scheduled to receive RAI.

Conclusions: These cases demonstrate the heterogeneous clinical spectrum and diagnostic challenges of thyroid carcinoma coexisting SO. Unexplained serum Tg elevation after thyroidectomy warrants evaluation for ectopic thyroid tissue, including SO, and can aid in determining the need for RAI.

EP1601 - ECE_1326 - Diagnostic challenges of TSH–FT4 discordance: a case of TSHoma with Graves' disease and a case of chronic TSH elevation with uncertain origin

Guan-Ho Chen and Chih-Yuan Wang
Division of Metabolism and Endocrinology, National Taiwan University Hospital, Taipei, Taiwan

Background: Discordant TSH and FT4 levels represent a major diagnostic challenge, particularly when pituitary lesions, evolving autoimmunity, or chronic TSH elevation coexist. We report two contrasting cases illustrating different mechanisms of pituitary–thyroid axis dysregulation.

Methods: Clinical, biochemical, autoimmune, imaging, and TRH stimulation data were reviewed longitudinally.

Results: Case 1 demonstrated persistently elevated or high-normal thyroid hormone concentrations accompanied by inappropriately non-suppressed TSH, consistent with a TSH-secreting microadenoma. Several years later, new-onset Graves' disease emerged, producing abrupt thyrotoxicosis while TSH remained unsuppressed. Case 2 exhibited more than a decade of markedly elevated TSH with only mild reductions in FT4, minimal symptoms, and a small pituitary lesion. An exaggerated TRH response supported primary thyroid dysfunction but did not fully exclude subtle pituitary dysregulation.

Conclusions: These cases highlight the complexity of interpreting TSH–FT4 discordance and the limitations of TRH stimulation in long-standing abnormalities. Integrating longitudinal biochemical trends, evolving autoimmunity, and pituitary imaging is essential for distinguishing primary from central mechanisms.

EP1602 - ECE_2092 - Rapid malignant transformation of long-standing multinodular goiter into anaplastic thyroid carcinoma

Jezdancher Watti
Gyöngyösi Bugát Pál Hospital, Gyöngyös, Hungary

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Anaplastic thyroid carcinoma (ATC) is a rare, highly aggressive malignancy, frequently arising in elderly patients with pre-existing benign thyroid disease. It is characterized by rapid local progression, early distant metastases, and dismal prognosis. Early recognition of warning symptoms is critical.

A 78-year-old woman with a >30-year history of non-toxic multinodular goiter and multiple cardiovascular comorbidities presented with a 3-month history of progressive left-sided neck enlargement, dysphagia, hoarseness, dyspnea, and stridor, accompanied by weight loss. Physical examination revealed a firm, fixed cervical mass (~15 cm) with airway deviation. Laboratory tests showed euthyroidism and normocytic anemia.

Contrast-enhanced neck and chest CT demonstrated a markedly enlarged thyroid with a heterogeneous solid mass (68 × 76 mm axial, 96 mm craniocaudal) arising from the left lobe, displacing the trachea and laryngeal structures, with retrosternal extension. Multiple bilateral pulmonary nodules consistent with metastases and right-sided pulmonary embolism were identified. No overt tracheal lumen obstruction was present, but significant airway compromise was evident clinically.

Fine-needle aspiration cytology and ultrasound-guided core biopsy revealed high-grade undifferentiated carcinoma consistent with anaplastic thyroid carcinoma.

Immunohistochemistry demonstrated broad cytokeratin positivity (CK8/18) with negative TTF-1, PAX8, BRAF, pan-TRK, and HER2. PD-L1 expression was strikingly high (CPS 100; TPS 100%).

Given ECOG performance status 2, extensive locoregional disease, pulmonary metastases, and acute pulmonary embolism, curative treatment was not feasible. The patient received anticoagulation (LMWH) and palliative hypofractionated radiotherapy to the thyroid mass (5 × 4 Gy) for airway protection and symptom relief. A nasogastric feeding tube was placed to secure nutrition. Multidisciplinary tumor board recommended further oncologic evaluation for systemic therapy; molecular profiling was initiated.

This case highlights the catastrophic malignant transformation of long-standing multinodular goiter into ATC, presenting with rapidly progressive airway-threatening disease, distant pulmonary metastases, and thromboembolic complications. Red-flag symptoms—rapid neck mass growth, dysphagia, hoarseness, and stridor—in patients with benign thyroid disease mandate urgent evaluation. The exceptionally high PD-L1 expression underscores the potential role of immunotherapy in selected ATC patients. Despite modern multimodal approaches, ATC remains a devastating disease, emphasizing the need for early detection and personalized therapeutic strategies.

Abstract citation ID: lvag096.1729

EP1603 - ECE_3734 - Levothyroxine-induced agranulocytosis: an exceptional adverse effect in a patient with congenital heart disease

Zaynab Ezzahoum[1,2], Nassim Essabah Haraj[1,2], Malak Iggar[1,2], Siham El Aziz[1,2] and Asma Chadli[1,2]
[1]*Endocrinology, Diabetology, Metabolic Diseases and Nutrition Department, Ibn Rochd University Hospital, Casablanca, Morocco;* [2]*Clinical Neuroscience and Mental Health Laboratory, Faculty of Medicine and Pharmacy, Hassan II University-Casablanca, Casablanca, Morocco*

Introduction: Levothyroxine is widely used in the management of hypothyroidism. Its adverse effects are predominantly cardiovascular or metabolic. Hematologic complications, particularly neutropenia or agranulocytosis, are exceptionally reported. We present a case of central neutropenia potentially induced by levothyroxine, in the context of concomitant medication use, with a review of possible mechanisms.

Case Report: A 26-year-old patient with Tetralogy of Fallot, not indicated for surgical correction, followed for inflammatory anemia, was admitted for a prolonged febrile syndrome evolving over three months, without an evident infectious focus. Initially treated with ceftriaxone 2 g/day, laboratory tests revealed hypothyroidism, and levothyroxine at 12.5 µg/day was initiated. After 15 days, severe agranulocytosis was observed (absolute neutrophil count: 240/mm^3). Discontinuation of levothyroxine led to gradual improvement in hematologic parameters (ANC: 11 620/mm^3), suggesting a probable drug-related origin. The imputability of levothyroxine was retained (I3B2), although this effect is exceptionally described.

Conclusion: This case highlights the need to consider levothyroxine as a rare but possible cause of central agranulocytosis, particularly in combination with other medications. Rigorous hematologic monitoring may be warranted in the presence of infectious signs during thyroid hormone replacement therapy.

EP1604 - ECE_1490 - Prevalence of hypothyroidism and its association with metabolic parameters in patients with metabolic syndrome: a retrospective cross-sectional study

Mariami Azirashvili and Lia Pertaia
Endocrinology Department, Consilium Medulla Multiprofile Clinic, Tbilisi, Georgia

Background: Metabolic syndrome is a complex cardiometabolic condition characterized by dyslipidemia, hypertension, and impaired glucose metabolism. Thyroid hormones play a key role in lipid and energy homeostasis, and thyroid dysfunction may exacerbate metabolic abnormalities. The coexistence of thyroid dysfunction and metabolic syndrome may therefore contribute to increased cardiometabolic risk; however, data on their association in routine clinical practice remain limited.

Aim: To determine the prevalence of overt and subclinical hypothyroidism in patients with metabolic syndrome and to compare selected metabolic parameters between euthyroid and hypothyroid individuals.

Methods: This retrospective cross-sectional observational study included 70 patients diagnosed with metabolic syndrome. Patient data were extracted from electronic medical records of the Multiprofile Clinic "Consilium Medulla" in Tbilisi, Georgia.

Metabolic syndrome was defined according to the NCEP ATP III criteria. Due to the unavailability of waist circumference measurements, metabolic syndrome was diagnosed in patients meeting at least three of the four available ATP III criteria.

Hypothyroidism was defined as a serum thyroid-stimulating hormone (TSH) level >3.8 mIU/L. Both overt and subclinical hypothyroidism were included; overt hypothyroidism was defined by elevated TSH with reduced free thyroxine (FT4), whereas subclinical hypothyroidism was defined by elevated TSH with normal FT4.

Metabolic parameters were compared between euthyroid and hypothyroid patients. Data distribution was assessed using the

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Shapiro–Wilk test; between-group comparisons were performed using the independent samples t-test or the Mann–Whitney U test, as appropriate. A *P*-value <.05 was considered statistically significant.

Results: The median age was 52 years (IQR 40-64), and 40 patients (57.1%) were male. Hypothyroidism was present in 31 patients (44.3%, 95% CI: 33.2-55.9), including 15 with subclinical hypothyroidism and 16 with overt hypothyroidism. Compared with euthyroid patients, those with hypothyroidism had significantly higher low-density lipoprotein (LDL) cholesterol levels ($P = .027$) and lower diastolic blood pressure ($P = .017$). No statistically significant differences were observed in other metabolic parameters (Table 1).

Conclusion: Hypothyroidism was common among patients with metabolic syndrome and was associated with higher LDL cholesterol levels and lower diastolic blood pressure. Routine assessment of thyroid function may help identify patients with an unfavorable cardiometabolic profile in this population.

Table 1 Comparison of metabolic parameters between euthyroid and hypothyroid patients.

Metabolic parameter	*P*-value
BMI	0.986[a]
Fasting glucose	0.221[a]
Triglycerides	0.321[a]
HDL cholesterol	0.471[a]
LDL cholesterol	**0.027**[b]

EP1605 - ECE_1086 - Performing hemithyroidectomy for nodular and unilateral multinodular euthyroid goiters

Farida Saidova[1], Oruc Shahsuvarov[1], Rasim Huseynov[1], Shahla Alakbarova[1], Aygun Mayilova[1], Nizami Muradov[2] and Natavan Aliyeva[3]
[1]Endocrine Surgery, Scientific Center of Surgery named M.A.Topchubashov, Baku, Azerbaijan; [2]Anesthesiology and Reanimatology, Scientific Center of Surgery named M.A.Topchubashov, Baku, Azerbaijan; [3]Radiology, Scientific Center of Surgery named M.A.Topchubashov, Baku, Azerbaijan

The aim of the study is to evaluate the results of hemithyroidectomy for nodular and unilateral multinodular euthyroid goiter.
Material and Methods: Total of 98 patients, aged 20-74 years with nodular (46) and unilateral multinodular euthyroid goiter (52) who had undergone hemithyroidectomy, were examined (women – 80.6%, men – 19.4%). Most of patients were women aged 41-50 years (30.6%). All patients underwent hemithyroidectomy (removal of the one lobe and isthmus). The majority (73.5%) of patients were follow-up within 4-5 years after surgery.

Results and Discussion: In patients with nodular and unilateral multinodular euthyroid goiter who underwent hemithyroidectomy, the following was observed low recurrence rates (4.3% and 11.5%, respectively). The incidence of postoperative hypothyroidism compensated by replacement therapy after hemithyroidectomy for NEG and MNEG is 19.6% and 21.2%, respectively. The quality of life was much better for patients after hemithyroidectomy, than for patients who underwent radical surgeries: 84.8% of patients with NEG and 78.8% of patiens with unilateral MNEG did not require burdensome hormone therapy. However, patients with hypothyroidism need a low level of postoperative replacement therapy. A comparison of levothyroxine levels taken by patients with NEG and MNEG after hemithyroidectomy revealed a non-significant ($P > .05$) difference between the groups, consistent to 36.1 ± 4.4 μg and 40.9 ± 5.1 μg, respectively. Risk factors for the development of recurrence of MNEG include the patient's young age, the duration of follow-up, the absence of replacement therapy, the presence of a hereditary genesis of the disease and lymphoid infiltration. Factors predisposing to the development of postoperative hypothyroidism include lymphoid infiltration of the glandular tissue, the duration of follow-up hereditary genesis of the disease.

Findings: Performing a hemithyroidectomy for NEG and unilateral MNEG is the optimal volume of surgery. However, the choice of this procedure for unilateral MNEG is a joint decision between the surgeon and the patient, made, taking into account risk factors for recurrence and postoperative hypothyroidism are determined individually for each patient.

EP1606 - ECE_2617 - Thyroid storm at onset-an uncommon first presentation of Graves disease

Muhammad Dalili[1], Shadman Rahman[1], Sarah El-Toukhy[1], Hussam Khalifa[1], Jayalekshmi Leena[1], Jaspal Kallah[2], Thomas Yau[2] and Sameer Sighakoli[1]
[1]Diabetes and Endocrine, Medway Maritime Hospital, Gillingham, United Kingdom; [2]Medway Maritime Hospital, Gillingham, United Kingdom

Introduction: Graves' disease is an autoimmune disorder causing hyperthyroidism through antibodies that stimulate levothyroxine (T4) and triiodothyronine (T3) production.[1] It typically presents with palpitations, weight loss, tremors, and sweating.[2] While thyroid storm is a rare complication of Graves' disease, its occurrence as the first clinical manifestation is exceptionally uncommon.[3] Therefore, a detailed history, thorough examination and holistic approach are essential for diagnosis, management, and follow-up.[2]

Case: A 62-year-old woman with a background of hypertension, T2DM, COPD, OSA, and HF presented with acute-onset confusion, shortness of breath, chest and abdominal pain, and vomiting. Examination revealed GCS 14/15, hypoxia and signs of decompensated cardiac failure.

ABG on 4 L of oxygen demonstrated T1RF. Chest radiography showed features consistent with pulmonary oedema (Figure 1). Blood investigations revealed AKI-1 and an elevated BNP (Table 1). CT of the head and abdomen/pelvis were unremarkable.

The patient was transferred to the critical care unit in view of multi-system involvement. A thyroid function test demonstrated a hyperthyroid picture (Table 1). The Burch–Warsofsky Point Scale score was 80, highly suggestive of thyroid storm. Thyroid ultrasonography demonstrated features

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

of thyroiditis (Figure 2). ECHO showed preserved EF.

The patient was started on carbimazole, intravenous hydrocortisone, and beta-blocker. The patient's symptoms improved clinically, and repeat thyroid function tests on day 6 showed biochemical improvement, with positive TSH receptor antibodies (Table 2).

The patient continued to improve and was discharged after two weeks with a plan for repeat thyroid function testing in two weeks and follow-up in endocrinology and arrhythmia clinics.

Conclusion: This case illustrates the rare occurrence of thyroid storm as the initial presentation of Graves' disease and underscores the critical importance of timely diagnosis and appropriate management in the intensive care setting due to the high mortality rate of this endocrine emergency.

Figure 1

EP1607 - ECE_2876 - The role of the free triiodotyronine to free thyroxine ratio in the differential diagnosis of thyrotoxicosis: a cross-sectional study

Saieehwaran Menon[1], Sy Liang Yong[1], Abdullah Shamshir Abd Mokti[2] and Vijiya Mala Valayatham[2]
[1]Hospital Tengku Ampuan Rahimah Klang, Klang, Malaysia; [2]Institut Endokrin, Hospital Putrajaya, Putrajaya, Malaysia

Thyrotoxicosis is a clinical state of excessive thyroid hormone action arising from diverse etiologies and accurate differentiation of these causes is essential for optimal management. Advanced diagnostic modalities, such as thyrotropin receptor antibody (TRAb) assay and ultrasonography are not often accessible in resource-limited settings, underscoring the need for cost-effective alternatives. Emerging evidence suggests that the free triiodothyronine to free thyroxine (FT3/FT4) ratio may serve as a potential biomarker for distinguishing the causes of thyrotoxicosis.

This study aimed to compare the FT3/FT4 ratio among patients with different etiologies of thyrotoxicosis and to correlate these findings with autoantibodies. A cross-sectional study was conducted among patients aged ≥18 years with newly diagnosed thyrotoxicosis recruited from Hospital Tengku Ampuan Rahimah, Hospital Banting, Klinik Kesihatan Pelabuhan Klang and Klinik Kesihatan Pandamaran. All participants underwent thyroid function testing (ie, FT3, FT4 and thyroid-stimulating hormone (TSH)) and autoantibody assays (ie, TRAb and anti-thyroid peroxidase antibody (anti-TPO)). Receiver operating characteristic (ROC) curve was performed to evaluate the discriminatory value of FT3/FT4 ratio in Graves' disease, Hashimoto's disease and thyroiditis. A total of 58 patients were recruited from February to December 2025. Of these, 58.6% were diagnosed with Graves' disease, 22.4% with thyroiditis, and 19.0% with Hashimoto's disease. FT3 levels in patients were significantly higher in Graves' disease (Median 16.8 pmol/L; Interquartile range (IQR) 10.9-25.7) compared with Hashimoto's disease (Median 10.6 pmol/L; IQR 6.9-15.2) and thyroiditis (Median 6.6 pmol/L; IQR = 5.2-9.6) ($P < .001$). A similar trend was observed for FT4 levels ($P < .001$). However, the FT3/FT4 ratio did not differ significantly between Graves' disease, Hashimoto's disease and thyroiditis ($P > .05$). ROC curve analysis revealed limited discriminatory ability of the FT3/FT4 ratio, with area under the curve (AUC) ranging from 0.503 to 0.720. Notably, its discriminatory ability improved when stratified by FT4 levels. At FT4 of 30-49 pmol/L, the FT3/FT4 ratio showed good discriminatory ability in distinguishing Hashimoto's disease from thyroiditis

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

(AUC = 0.958, 95% CI = 0.837-1.000; $P = .019$), with 100% sensitivity and 83.3% specificity at a cutoff of 0.2884. In addition, the FT3/FT4 ratio showed no significant correlation with TRAb or anti-TPO.

In conclusion, while the overall discriminatory value of the FT3/FT4 ratio is limited, it may still provide adjunctive diagnostic insight in selected biochemical contexts, complementing established immunologic investigations.

EP1609 - ECE_3740 - Unusual case of concomitant papillary thyroid cancer and malignant choroidal melanoma

Vitali Vashakidze, Tea Khurodze, Ana Pruidze, Basa Gegeshidze and Elisabed Pkhaladze
Tbilisi, Georgia

Introduction: Papillary thyroid carcinoma (PTC), the most common malignant thyroid neoplasm, accounts for approximately 1% of newly diagnosed malignancies and is predominantly found in females. Melanoma is the type of cancer that develops from melanin-producing cells, and in 3-4% can arise in the eyes. The PTC increases the risk of melanoma by 1.8-fold. Recent studies revealed that the coincidence of these two malignancies has various probable mechanisms and can be associated with BRAF and BRCA-1-associated protein (BAP1) gene mutations. Although the coexistence in the same patient is uncommon, the occurrence can have significant implications for the patient's clinical presentation, diagnostic evaluation, and treatment approach.

Case Presentation: A 65 years old caucasian female was diagnosed with thyroid papillary cancer. She was asymptomatic and was found to have right thyroid mass on routine neck ultrasound exam—classified as TIRADS V, euthyroid state, and negative antithyroid antibodies confirmed with lab. Tests. FNAC findings were consistent with papillary carcinoma, Bethesda class VI.

The patient's Past medical history was remarkable for arterial hypertension, prediabetes (treated with Ace inhibitor in combination with Thiazide diuretic, metformin 750 mg, and atorvastatin 20 mg), and left-sided nephrectomy due to nephrolithiasis with hydronephrosis in 2018. Her family history was significant with paternal bladder carcinoma and maternal diabetes mellitus. The patient's social history was negative for cigarette smoking or alcohol use.

The patient underwent thyroidectomy and left-sided lymphadenectomy. Pathologic report demonstrated papillary carcinoma without lymphovascular invasion. After thyroidectomy, 50-mCi I-131 was administered, and levothyroxine suppressive treatment was started.

Six months later, the whole-body scan didn't show any evidence of an abnormal radioiodine-avid lesion throughout the body. Regular checkups and scans every six months for the first two years excluded the recurrence of TPC. But for the past two months patient started complaining about seeing left-sided flashes of light, noticing floating objects (photopsia, metamorphopsia). She was referred for eye exam and imaging tests, clinical and imaging features were consistent with the diagnosis of left eye malignant choroidal melanoma. Soon after, left globe enucleation and implant replacement were performed.

At this time, the patient is in good health and under continuous medical supervision.

Conclusion: In this unique case report, we present a patient demonstrating papillary thyroid carcinoma and malignant choroidal melanoma. With some evidence in favor of associations between the two cancers, the case illustrates the importance of routine follow-up and active surveillance.

Abstract citation ID: lvag096.1735

EP1610 - ECE_2160 - Tōku Ara OraNGA* (TAONGA): development and testing of a thyrotoxicosis model of care co-designed with Indigenous whānau

Jade Tamatea[1,2], Taisha Abbott[1], Matire Harwood[1] and Marianne Elston[1,2]
[1]*University of Auckland | Waipapa Taumata Rau, Auckland, New Zealand;* [2]*Endocrinology Department, Te Whatu Ora Waikato/Health New Zealand, Hamilton, New Zealand*

Introduction: Unfair, unjust healthcare inequities are experienced by many Indigenous populations.[1] In Aotearoa/New Zealand, Indigenous healthcare inequities have long been documented, more recently including in thyrotoxicosis.[2] Healthcare design is an important determinant impacting inequities.

Objectives: Grounded in Indigenous (kaupapa Māori) methodology,[3] *Tōku Ara OraNGA* (TAONGA)* is an Indigenous-led four-staged mixed-methods project, setting out to work alongside *whānau* (Māori patients and families) to reimagine thyrotoxicosis services.

Methods: *Whakatakatū* (Stage 1 – Research foundation) established governance and responsibility relationships, and mapped available quantitative evidence of ethnic inequities in thyrotoxicosis in Aotearoa/New Zealand. *Kōrero mai, kōrero atu* (Stage 2 – Qualitative) added narrative of thyrotoxicosis care via thematic analysis within a kaupapa Māori paradigm of four focus groups with whānau and stakeholders. Grounded in reciprocity, Stage 3 – model of care co-design—shared earlier findings within three facilitated *wānanga* (workshops) to identify action areas (define/engage) and allow 'no-limit' solutions (test/finalise). Informed by both CONSIDER[4] and CONSORT[5] statements, a pilot of clinical care (Stage 4) delivered in partnership with a local Indigenous community health provider will test this model of care.

Results: Indigenous governance and responsibility relationships informed all four stages. A metaphoric river summarises the 'patient journey map' of quantifiable Māori thyrotoxicosis inequity information from epidemiology to outcomes. Stage 2 presents seven themes in an Indigenous flower conceptualisation: (a) recognisably Māori care, (b) differential experiences, (c) system access, (d) autonomy, (e) *whānau*/family, (f) communication, and (g) reciprocal relationships. Co-design *wānanga* developed a model of care incorporating six design features: (a) the foundational right to high quality healthcare, (b) safe environments, (c) support services, (d) staff development, (d) reciprocal relationships, and (e) resources. Conditional ethical approval means a clinical pilot will soon begin with feasibility findings able to be presented. Additionally, collaborative approaches to dissemination have developed whānau-informed outputs.

Conclusion: Indigenous-led research can facilitate power-sharing with *whānau*/families, supported by knowledgeable stakeholders,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

to create healthcare responsive to diverse Indigenous realities. It is imagined this will translate to better healthcare experiences and outcomes that could reach beyond thyroid care.

* *"Tōku Ara Oranga"–translating to 'My wellness path'*

EP1611 - ECE_2041 - National prevalence of thyroid disorders in North Macedonia: marked female predominance in a population-based registry study

Ana Talevska[1,2], Zaklina Cagoroska[3], Emilija Antova[4], Lisa Zottarelli[5], Colton Daniels[6], Larisa Ozeryansky[7], Sunil Thankam[7] and Ivica Smokovski[8]

[1]Internal Medicine, Klinicka Bolnica Dr Trifun Panovski, Bitola, North Macedonia; [2]Faculty of Medicine, Skopje, North Macedonia; [3]eHealth Directorate, Ministry of Health, Skopje, North Macedonia; [4]Medicinski Fakultet, Skopje, North Macedonia; [5]University of Tennesse, College of Social Work, Knoxville, United States; [6]Saint Mary's University, San Antonio, United States; [7]Univ Health System Inc., Knoxville, United States; [8]Univerzitet Goce Delchev-Medicinski Fakultet, Shtip, North Macedonia

Background: Thyroid disorders are among the most prevalent endocrine conditions worldwide, yet national-level epidemiological data from Southeast Europe remain limited. The Republic of North Macedonia has a history of iodine deficiency and recent concerns regarding changing dietary patterns, underscoring the need for comprehensive population-based data.

Objective: To estimate the national prevalence of thyroid disorders and to evaluate sex-, age-, and residence-specific patterns using data from the National e-Health System (NeHS).

Methods: A population-based cross-sectional analysis was performed using anonymized data from the NeHS, a nationwide electronic health platform integrating records from all levels of care. Individuals with recorded ICD-10 codes E00–E07 as of October 31, 2024 were identified. Prevalence estimates were calculated using official population denominators from the State Statistical Office and stratified by sex, age group, and urban or rural residence. Associations were assessed using odds ratios (ORs) with 95% confidence intervals (CIs).

Results: Among a total population of 1 836 713 individuals, 269 690 had a documented thyroid disorder, corresponding to an overall prevalence of 14.68%. Prevalence was substantially higher in women than in men (24.36% vs 4.85%), with a pronounced female predominance observed across all age groups and residential settings (overall OR 6.32; 95% CI 6.25-6.38). Thyroid disorder prevalence increased with age in both sexes, peaking in individuals aged 60-79 years (21.87%). Higher prevalence was observed in urban compared with rural areas (17.07% vs 10.85%). Hypothyroidism (ICD-10 E03) was the most frequent diagnosis, affecting 9.74% of the total population.

Conclusions: This first national-level registry-based study from North Macedonia demonstrates a high population burden of thyroid disorders with a marked and persistent female predominance and clear age- and residence-related patterns. These findings highlight substantial sex-specific disparities in thyroid disease and emphasize the importance of targeted screening and public health strategies in Southeastern Europe.

EP1612 - ECE_2310 - When thyroid function is normal: MRI-guided diagnosis and management of endocrine orbitopathy

Maria Mathiopoulou and Maria Pisimisi

Hospital of Uster, Switzerland, Zurich, Switzerland

Background: Euthyroid endocrine orbitopathy (euthyroid thyroid-associated orbitopathy, TAO) represents a diagnostically challenging subset of thyroid eye disease, characterized by classical orbital manifestations in the absence of overt thyroid dysfunction. Atypical clinical presentations and normal thyroid biochemistry frequently delay diagnosis and increase the risk of irreversible visual complications. Advanced imaging, particularly orbital magnetic resonance imaging (MRI), has emerged as a critical tool for accurate disease characterization and risk stratification in this population.

Pathophysiology: Despite euthyroidism, disease mechanisms largely mirror Graves' orbitopathy and are driven by autoimmune activation of orbital fibroblasts, leading to excessive glycosaminoglycan accumulation, tissue edema, and remodeling of extraocular muscles and orbital fat. This immune-mediated process distinguishes euthyroid TAO from infectious, vascular, granulomatous, and infiltrative orbital disorders that may present with overlapping clinical features.

Diagnostic Approach and Imaging: Diagnosis remains one of exclusion and requires careful integration of clinical, laboratory, and imaging findings, particularly in patients with atypical muscle involvement or absent restrictive motility patterns. Orbital MRI plays a central role in this context due to its superior soft-tissue contrast, enabling reliable differentiation between active inflammatory disease (muscle edema, increased T2 signal intensity, and contrast enhancement) and inactive fibrotic disease. MRI is also uniquely suited for assessing tendon involvement, typically spared in TAO, and for identifying apical crowding and early dysthyroid optic neuropathy through direct visualization of optic nerve compression. While computed tomography remains valuable for anatomical detail and quantitative assessment of orbital structures, MRI provides critical functional and prognostic information that directly influences management decisions. Hybrid imaging modalities,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

such as SPECT/CT, may further complement anatomical imaging by assessing inflammatory activity in selected cases.

Clinical Implications and Management: Accurate MRI-based assessment of disease activity informs therapeutic strategy, supporting timely initiation of immunosuppressive therapy in active disease and appropriate surgical planning in fibrotic or sight-threatening stages. Given the risk of insidious optic nerve compromise, longitudinal imaging and structured follow-up are essential, even in patients with initially mild symptoms.

Conclusion: Euthyroid endocrine orbitopathy is an under-recognized but clinically significant entity with potential for serious visual morbidity. Incorporation of orbital MRI into diagnostic and prognostic pathways enhances diagnostic confidence, improves differentiation from mimicking conditions, and enables activity-guided, individualized management. These advantages support a central role for MRI in contemporary care models for euthyroid TAO and highlight its relevance for endocrinologists managing complex orbital disease.

EP1613 - ECE_2424 - Fixed point observation of thyroid abnormalities after nuclear power plant explosions induced by giant earthquakes and thsunami

Takao Kunori[1,2]
[1]Surgery, Iwaki-city Medical Center, Thyroid Clinic, Iwaki City, Japan; [2]Surgery, Iwaki-city Medical Center, Iwaki, Japan

Background: Our clinic is located 45 km south of Tokyo Electric Fukushima Daiichi nuclear power plant (NPP), which exploded in East Japan Disaster (2011). Highest air dose was recorded as 20 micro Sievelt in our hospital. Significant number of pediatric thyroid cancer has been detected in this area, but not confirmed significant relation with the NPP accidents by DNA analysis. While adult data has not been sufficiently published. We reviewed pre- and post outpatient data of thyroid clinic to find NPP effects.

Patients and Methods: 7463 patients (2007-2025), age 54 ± 17 (3-96); female 83.7%), were examined. Chronological data: 5 terms were compred; group A, 2007-2010 (pre); B, 2011-14 (post1); C, 2015-2018 (post2); D, 2019-2022 (post3); E, 2023-2025 (post4). Disease: Nodular goiter was 2523 (solid), 1003 (cyst). Hyperthyroidismm (HY) was 1783 and Hashimoto (HA) was 531. Hormonal assay: Tg, anti-thyroglobulin (aTg), thyroid peroxidase antibody (TPO), anti-TSH receptor antibody (TSH-R) and thyroid stimulating antibody (TS). Diagnostic tools: Ultrasonography(US) and fine needle aspiration (FNA); classified 2(benign)-5(cancer). Signifiance was determined by Kai2 test or student-t test; probability (p) less than 0.05 was judged as significant.

Results: (1) Disease (%): Group A ($n = 559$); solid 40%, cyst 18%, HY 35%, HA 7.7%. Group B ($n = 616$); solid 40%, cyst 20%, HY 27%, HA 7.5%. Group C ($n = 451$); solid 40%, cyst 21%, HY 29%, HA 11%. Group D ($n = 55$); solid 47%, cyst 15%, HY 28%, HA 11%. Group E ($n = 345$); solid 48%, cyst 10%, HY 32%, HA 11%.

(2) Changes of autoimmunity*: TPO positive patients slightly increased from 23%(B), 25%(C), 33%(D), 40%(E) . aTg positive patients showed no particular changes; 33%(B), 25%(C), 28%(D), 35%(E). *Data of group A was not used by technical reason.

(3) Cytology(malignancy%): 9% (A) to 6%(B), 9%(C), 4%(D), 8%(E).

Conclusion: There was no observable changes in patients' analysis. These data suggest that the adverse effects of NPP accidents were as small as negligible.

Abstract citation ID: lvag096.1739

EP1615 - ECE_3412 - Urinary and serum iodine status and its association with inflammatory markers in a cohort of Romanian pregnant women

Robert Badan[1], Corina Delia[2,3], Ioana-Maria Crasan[2], Anisoara Cimpean[2], Alexandra Ichim[3], Mirela Daniela Haidautu[3], Beatrice Radu[2], Bogdan Pascu[3] and Elena Ionica[2]
[1]Giurgiu County Emergency Hospital, Giurgiu, Romania; [2]Departament of Biochemistry and Molecular Biology, University of Bucharest, Bucharest, Romania; [3]Laboratory of Biochemistry, National Institute for Mother and Child Health "Alessandrescu-Rusescu", Bucharest, Romania

Although salt iodisation programs are implemented in many countries, iodine deficiency among pregnant women persists in several regions of Romania and remains a significant public health concern. During pregnancy, the maternal thyroid must increase hormone production to meet both maternal and foetal requirements, particularly in the first trimester when the foetus depends entirely on maternal thyroxine (T4) (Spina et al., 2023; Pendersen et al., 1993).

The aim of this study was to evaluate urinary and serum iodine levels across pregnancy and to explore associations with inflammatory markers in a cohort of Romanian pregnant women. A total of 121 women were included and stratified by trimester: first ($n = 43$), second ($n = 42$), and third ($n = 36$). Urinary iodine concentration (UIC), serum iodine, thyroid function parameters (TSH, FT4), iron status, renal function markers (creatinine, urea), and inflammatory indices (C-reactive protein [CRP], white blood cell count [WBC]) were assessed. Iodine status was compared across trimesters, and Pearson correlation analyses, visualised in heatmaps, were performed to examine relationships between iodine measures and biochemical parameters in the overall cohort and within each trimester.

Analysis of a preliminary subset of 32 women showed a progressive decline in iodine status with advancing gestation. The median UIC decreased from 174 μg/L in the first trimester to 112 μg/L in the third trimester, and a higher proportion of women in late pregnancy fell below the World Health Organisation adequacy threshold of 150 μg/L. Serum iodine levels also declined in the third trimester compared with early pregnancy, although this difference did not reach statistical significance because of substantial interindividual variability. Thyroid function parameters remained largely stable, with no significant correlations between iodine measures and TSH or FT4.

Overall, UIC showed only weak associations with inflammatory markers across the entire cohort. However, in the third trimester, UIC showed a stronger positive correlation with CRP ($r \approx 0.6$) and aligned with WBC in heatmap analyses. These associations appeared to be driven by a small number of individuals with concurrently elevated iodine and inflammatory markers, potentially reflecting acute inflammatory states or recent supplementation. Mild to moderate iodine deficiency was prevalent, particularly in late gestation, despite universal salt iodisation.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

These findings underscore the importance of continuous monitoring of iodine status during pregnancy and support targeted strategies to ensure adequate iodine intake throughout gestation.

Abstract citation ID: lvag096.1740

EP1618 - ECE_2364 - Skin hyperpigmentation as a clinical manifestation of isolated hypothyroxinemia: a case report

Oleksandra Zavalniuk and Ilona Rudnieva
National Medical University named after O.O. Bogomolets, Kyiv, Ukraine

Introduction: Isolated hypothyroxinemia is defined as a reduction in free thyroxine levels with normal thyroid-stimulating hormone (TSH) and has long been considered a condition without clear clinical manifestations. However, accumulating evidence suggests that even with normal TSH, thyroid hormone deficiency at the tissue level may have clinical significance, including effects on skin status and pigment metabolism. Of particular interest is the role of iodine deficiency as a leading factor in the development of isolated hypothyroxinemia in women, as well as its possible association with hyperpigmentation of exposed skin areas. Clinical observations showing regression of pigmentation following correction of iodine status highlight the importance of a broader view of the clinical manifestations of this condition.

Aim of the Study: To present a clinical case illustrating a possible association between isolated hypothyroxinemia and skin hyperpigmentation and to evaluate the effect of iodine ицsupplementation.

Materials and Methods: A 35-year-old woman presented with progressive forehead hyperpigmentation lasting six months. Laboratory evaluation included prolactin, TSH, free thyroxine (fT4), vitamin D, and ferritin levels. TSH and prolactin levels were within the reference range, while fT4 was at the lower limit of normal. VitaminD, ferritin, and thyroid ultrasound findings were normal. Thyroid ultrasound was performed. Prophylactic potassium iodide was administered at a dose of 150 μg/day for six months.

Results: After six months of iodine supplementation, complete regression of forehead hyperpigmentation was observed, and euthyroid status was confirmed.

Conclusion: This case demonstrates that isolated hypothyroxinemia related to iodine deficiency may present with subtle cutaneous manifestations, such as forehead hyperpigmentation, which can be reversed with appropriate iodine supplementation. The findings emphasize the need to consider tissue-level thyroid hormone deficiency in women, even when TSH is normal, and highlight the clinical relevance of preventive iodine correction. Further experience with additional patients is needed to better understand the prevalence and spectrum of cutaneous manifestations in this condition.

Abstract citation ID: lvag096.1741

EP1621 - ECE_3888 - Ectopic mediastinal thyroid: a case report

Marta Almeida, Miguel Marques, Daniel Duarte, H. Francisca, Ricardo Capitão and Maria Carlos Cordeiro
Unidade Local de Saúde de Almada-Seixal, Almada, Portugal

Introduction: Ectopic thyroid tissue (ETT) is a rare developmental anomaly caused by abnormal embryological migration of the thyroid gland. Mediastinal involvement represents an uncommon presentation among ectopic thyroid cases. We present a case of multinodular ectopic mediastinal thyroid tissue discovered incidentally in a patient with prior hemithyroidectomy.

Case Presentation: A 55-year-old woman with a history of left hemithyroidectomy performed 10 years prior for colloid goiter presented with fatigue, mild dysphagia, cough, and recent-onset snoring following an upper respiratory infection. She had been maintained on levothyroxine 25 mcg with normal thyroid function. Family history was negative for thyroid malignancy and head/neck radiation exposure. Physical examination revealed 5 kg weight loss and night sweats without fever.

Investigations: Laboratory studies demonstrated euthyroid status (TSH 1.58 mIU/L, free T3 2.90 pg/mL, free T4 1.26 ng/dL) with undetectable calcitonin (2 pg/mL). Chest computed tomography revealed a well-defined, heterogeneous, contrast-enhancing mass in the superior anterior mediastinum measuring 51 × 38 × 46 mm, posterior to the manubrium sterni. The mass demonstrated multiple hypodense nodular areas. The residual right thyroid lobe appeared reduced in size with an apparent cleavage plane from the mediastinal lesion. Differential diagnosis included ectopic thyroid tissue vs thymoma.

Thyroid scintigraphy with Tc-99m pertechnetate confirmed diffuse hyperfunctioning of the right thyroid lobe and demonstrated anomalous uptake in the mediastinal mass corresponding to the CT findings. The mediastinal lesion showed heterogeneous tracer distribution consistent with multinodular ectopic thyroid tissue.

Management and Outcome: The patient was referred to thoracic surgery and underwent successful surgical resection without complications. Histopathological examination confirmed ectopic thyroid tissue. Separate fragments revealed involutional thymic tissue. The diagnosis of primary ectopic mediastinal thyroid was established, with no evidence of malignancy. After one year of follow-up, the patient showed complete resolution of all symptoms.

Conclusion: This case illustrates the diagnostic challenge of mediastinal masses in patients with thyroid disease history. Mediastinal ectopic thyroid tissue should be considered in the differential diagnosis of anterior mediastinal masses, particularly when scintigraphy demonstrates radiotracer uptake. The combined use of CT imaging and thyroid scintigraphy was essential for establishing an accurate preoperative diagnosis. Surgical resection remains the treatment of choice for symptomatic ectopic mediastinal thyroid. This case underscores the importance of maintaining a high index of suspicion for ectopic thyroid tissue, even in patients with prior thyroid surgery, as ectopic tissue may function independently of the orthotopic gland.

EP1622 - ECE_2158 - Psychological distress in women with autoimmune thyroiditis assessed using GHQ-28 and the Hamilton Depression Rating Scale

Marcin Nosal
Collegium Medicum, Jan Dlugosz University, Częstochowa, Poland

Background: Autoimmune thyroiditis (AIT) is a endocrine disorder in women and is increasingly recognized as a condition associated not only with hormonal imbalance but also with

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

inflammation, and psychological distress. Neuropsychiatric symptoms may persist even in euthyroid patients.[1-6]

Objective: This study aimed to evaluate general mental health and depressive symptoms in women with autoimmune thyroiditis using standardized psychometric tools.

Materials and Methods: Women diagnosed with AIT were assessed using the General Health Questionnaire (GHQ-28) to evaluate anxiety, and depression. Depressive symptom severity was measured with the Hamilton Depression Rating Scale (HAM-D). Coping strategies were additionally analyzed using the Brief COPE questionnaire.

Results: Participants showed significantly elevated GHQ-28 scores, indicating reduced psychological well-being, particularly in the domains of anxiety. HAM-D results revealed to depressive symptoms in a substantial proportion of patients, independent of thyroid hormone levels. Greater depressive severity was associated with fatigue, and subjective disease burden. Less adaptive coping strategies were more common among patients with increased psychological distress.

Conclusions: Women with autoimmune thyroiditis frequently experience clinically relevant psychological symptoms that are not fully explained by endocrine dysfunction. The combined use of GHQ-28 and HAM-D allows effective identification of patients at risk for depression. These findings support the need for routine psychological screening and an integrated psychoneuroendocrine approach in the management of autoimmune thyroid disease.

EP1624 - ECE_1645 - A rare overlap of Graves' disease and atypical subacute thyroiditis: a diagnostic and therapeutic challenge

Mariam Bulashvili, Ia Kavtiashvili and Nino Zavrashvili
Tbilisi Institute of Medicine, Tbilisi, Georgia

Introduction: Graves' disease is an autoimmune disorder that causes hyperthyroidism and is managed with antithyroid drugs, radioiodine therapy, or surgery. Subacute thyroiditis is a self-limiting inflammatory condition, often post-viral, that rarely coexists with Graves' disease. When present together, their clinical and biochemical overlap can complicate diagnosis and management.

Case Presentation: A 24-year-old male with a 5-year history of Graves' disease presented in January 2025 with significant weight loss (8-9 kg over 3 weeks), tremor, anxiety, tachycardia (100-130 bpm) and hypertension (140/85 mmHg). He had been on regular methimazole therapy, with relapses upon cessation. Although thyroidectomy was recommended two years prior, it was not pursued. At the presentation, the patient was taking methimazole 20 mg/day for the past five weeks. Laboratory evaluation revealed suppressed TSH <0.005 μU/mL, markedly elevated FT4 > 7.77 ng/dl (0.9-1.7), and FT3 3.25 ng/dl (0.26-0.44), Anti-TSHR 1.4 IU/l, consistent with thyrotoxicosis. CBC and CRP were normal. Thyroid ultrasound showed an enlarged thyroid (volume 60 cm^3). Methimazole was increased to 40 mg/day, and propranolol 40 mg three times daily was initiated.

After 20 days, follow-up testing showed persistent hyperthyroidism: TSH < 0.005 mIU/mL, FT4 > 7.77 ng/dl (0.9-1.7), FT3 1.8 ng/dl (0.26-0.44). The disproportionately elevated FT4/FT3 ratio raised suspicion of destructive thyroiditis. The patient reported a recent mild upper respiratory infection with sore throat and mild fever. A diagnosis of atypical subacute thyroiditis superimposed on Graves' disease was suspected, and methylprednisolone 32 mg/day was added to the regimen, which led to significant clinical improvement within 24 h.

By February 2025, the patient achieved a euthyroid state (FT4 1.66 ng/dl, FT3 0.2 ng/dl). Methimazole and methylprednisolone dosages were reduced. In March 2025, total thyroidectomy was performed successfully. The patient is on levothyroxine replacement therapy.

Conclusion: This case underscores a rare overlap of Graves' disease and subacute thyroiditis. Recognizing atypical thyroid function patterns, such as a high FT4/FT3 ratio, recent viral symptoms, and initiating corticosteroid therapy facilitate recovery and prepare patients for definitive treatment.

Abstract citation ID: lvag096.1744

EP1626 - ECE_2261 - Association between body mass index and ultrasound-derived thyroid parameters

Nino Turashvili[1,2]
[1]*Tbilisi State Medical University and Ingorokva Clinic of High Medical Technologies, Tbilisi, Georgia;* [2]*New Vision University, Tbilisi, Georgia*

Background: The relationship between obesity and thyroid morphology remains incompletely understood. Evidence regarding associations between body mass index (BMI) and ultrasound-derived thyroid parameters is limited, and potential sex-specific differences have not been fully clarified.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Aim: To investigate the association between BMI and thyroid ultrasound parameters in adults and to evaluate whether these associations differ between men and women.

Methods: This retrospective cross-sectional study included 152 adults aged 18-75 years. BMI was calculated using standard anthropometric measurements. Thyroid ultrasound examinations were performed to assess thyroid volume (cm^3), number of thyroid nodules, and size of the dominant thyroid nodule (mm). Thyroid volume was interpreted according to established upper reference limits. Thyroid-stimulating hormone (TSH) levels were within the normal range in all participants.

Associations between BMI and thyroid ultrasound parameters were assessed using Pearson's correlation coefficients. A P-value $< .05$ was considered statistically significant. Analyses were conducted in the overall population and separately in men and women.

Results: In the overall study population, BMI showed a weak but statistically significant positive correlation with thyroid volume ($r = 0.174$, $P = .032$). No significant associations were observed between BMI and thyroid nodule number or dominant nodule size (Table 1).

Table 1 Correlations between BMI and thyroid ultrasound parameters in the overall study population ($n = 152$).

Comparison	Pearson r	*P*-value
BMI vs thyroid volume	0.174	.032
BMI vs number of thyroid nodules	0.040	.625
BMI vs dominant nodule size	−0.033	.686

In analyses conducted separately in men and women, BMI was not significantly associated with thyroid volume, thyroid nodule number, or dominant nodule size (Tables 2 and 3).

Table 2 Correlations between BMI and thyroid ultrasound parameters in men ($n = 31$).

Comparison	Pearson r	*P*-value
BMI vs thyroid volume	0.235	.203
BMI vs number of thyroid nodules	−0.124	.507
BMI vs dominant nodule size	−0.265	.150

Table 3 Correlations between BMI and thyroid ultrasound parameters in women ($n = 121$).

Comparison	Pearson r	*P*-value
BMI vs thyroid volume	0.162	.077
BMI vs number of thyroid nodules	0.075	.416
BMI vs dominant nodule size	0.022	.809

Conclusions: Higher BMI was associated with a modest increase in thyroid volume in the overall population, while no associations were observed with thyroid nodular characteristics. These findings suggest that excess body weight may predominantly influence diffuse thyroid enlargement rather than focal nodular changes. Further studies are needed to clarify underlying mechanisms.

Abstract citation ID: lvag096.1745

EP1627 - ECE_3102 - Therapeutic management and outcomes of dysthyroid orbitopathy

Rekik Mona[1], Yoldez Ben Jemaa[1], Kmar Maaloul[1], Imene Kaibi[1], Nabila Rekik Majdoub[2] and Trigui Amira[1]
[1]*Habib Bourguiba Hospital, Sfax, Tunisia;* [2]*Hôpital Universitaire Hédi Chaker, Sfax, Tunisia*

Purpose: To evaluate therapeutic strategies and clinical outcomes of patients with dysthyroid orbitopathy, with particular emphasis on medical and surgical management and their impact on visual and functional prognosis.

Methods: We conducteed a retrospective study in Habib Bourguiba Hospital including patients diagnosed with dysthyroid orbitopathy and who were managed according to disease severity and activity. Therapeutic modalities were analyzed, including topical treatment, systemic corticosteroid therapy following EUGOGO recommendations, specific thyroid management in collaboration with endocrinology, and surgical intervention when indicated. Visual acuity, clinical signs, recurrence, complications, and long-term outcomes were assessed during follow-up.

Results: A total of nine patients with dysthyroid orbitopathy were included in the study. Medical treatment was the mainstay of management. Topical therapy using lubricants and intraocular pressure lowering agents was prescribed in 44.4% of patients. Systemic corticosteroid therapy was required in 33% of cases due to moderate-to-severe active disease. One patient with compressive optic neuropathy received high-dose intravenous methylprednisolone (1 g/day for three consecutive days), followed by oral tapering, while two patients were treated with weekly intravenous pulses according to EUGOGO protocols. Specific thyroid therapy was administered concomitantly in collaboration with endocrinology department in all patients with thyroid dysfunction. Surgical orbital decompression was performed in one patient presenting with compressive optic neuropathy and significant visual field loss. The mean follow-up duration was 10 months (range: 0-30 months). Final visual acuity remained stable in 77.8% of cases, improved in 11.1%, and worsened in 11.1%. Overall clinical evolution was favorable in 77.8% of patients, with complete recovery and no sequelae. However, recurrence occurred in 22.2% of cases, and residual sequelae were observed in 55.6%, including exposure keratopathy, ocular hypertension, and optic neuropathy (11.1%).

Conclusion: Appropriate therapeutic management of dysthyroid orbitopathy, guided by disease activity and severity, allows favorable outcomes in the majority of patients. Early initiation of systemic corticosteroids and timely surgical intervention in selected cases are crucial to prevent irreversible visual impairment. Long-term follow-up remains essential to detect recurrences and manage late complications.

EP1629 - ECE_3607 - Effectiveness of iodine prophylaxis evaluated through iodine status in children and young adults living in residential care facilities in Lodz

Ewelina Sośnierz[1], Przemysław Śliwka[1], Dorota Kowalik-Zakrzewska[1], Sara Aszkiełowicz[1,2], Sylwester Smoleń[3], Marcin Pakosz[3], Alina Niewiadomska[4], Renata Stawerska[1,2], Anna Łupińska[1,2], Andrzej Lewiński[1] and Arkadiusz Zygmunt[1]

[1]Department of Endocrinology and Metabolic Diseases, Polish Mother's Memorial Hospital-Research Institute, Lódź, Poland; [2]Department of Developmental Age and Adult Endocrinology, Medical University of Lodz, Łódź, Poland; [3]Laboratory of Mass Spectrometry, Faculty of Biotechnology and Horticulture, University of Agriculture in Krakow, Kraków, Poland; [4]Laboratory Diagnostics Center, Polish Mother's Memorial Hospital-Research Institute, Łódź, Poland

Introduction: Poland is currently regarded as a country with sufficient iodine supply at the population level. However, iodine prophylaxis is a process whose effectiveness is influenced by numerous external factors; therefore, continuous monitoring of its efficacy is necessary. The aim of our study was to evaluate the effectiveness of the iodine prophylaxis model implemented in Poland since 1997.

Methods: We assessed urinary iodine concentration (UIC) in children and young adults from residential care facilities in central Poland. A total of 157 participants were examined in 2019, and 132 participants in 2023-2024. The participants were aged 6-20 years. The results were compared with goitre prevalence assessed on the basis of thyroid volume measured by ultrasound, as well as the thyroid volume–to–body surface area ratio (V/BSA). This ratio allows for a more reliable assessment of thyroid volume.

Results: The median urinary iodine concentration (UIC) was 237.04 ± 72.82 μg/dm^3 before creatinine normalisation and 89.49 ± 98.91 μg/g creatinine after normalisation. Based on unadjusted WHO cut-off values, 64% of participants had adequate or above-requirements iodine intake, while 24% exhibited mild iodine deficiency and 9% had moderate to severe deficiency. Using WHO cut-offs adjusted for the median creatinine concentration of the cohort, 53% of children had adequate or above-requirements iodine status, whereas 10% had excessive UIC, 31% had mild deficiency and <6% had moderate to severe deficiency. The median V/BSA ratio was 3.30 mL/m^2 (range: 1.14-15.72 mL/m^2). According to WHO reference standards, goitre prevalence was low (<5%), indicating no evidence of iodine-deficiency–related thyroid enlargement at the population level. Creatinine-normalised UIC was higher in boys than in girls (91.81 ± 108.86 vs 84.75 ± 82.16 μg/g creatinine). Small to moderate negative correlations were observed between UIC and body weight ($r = -0.351$; $P < .001$), BMI ($r = -0.231$; $P < .001$), BSA ($r = -0.407$; $P < .001$), thyroid volume ($r = -0.263$; $P < .001$) and V/BSA ($r = -0.138$; $P = .020$). When stratified by sex and age, younger children exhibited higher creatinine-normalised UIC, with a weak but significant negative correlation between UIC and age ($r = -0.153$; $P = .011$). Significant differences between age groups were observed ($P < .001$).

Conclusions: The iodine prophylaxis programme implemented in Poland remains effective at the population level, as reflected by adequate median urinary iodine concentrations and a low prevalence of goitre among children and young adults. These findings support the classification of Poland as a country with sufficient iodine supply.

EP1630 - ECE_3818 - Graves' disease: ultrasonographic changes at diagnosis vs euthyroid state

Juan de Dios Barranco Ochoa, María Sánchez-Prieto Castillo, Marina Soria Becerra and Ana Segarra Balao

Endocrinology and Nutrition, Complejo Hospitalario de Jaén, Jaén, Spain

Introduction: Thyrotoxicosis is defined as the clinical state resulting from excess thyroid hormone levels. When caused by increased thyroid gland activity, it is termed hyperthyroidism, with Graves' disease (GD) being the most frequent etiology. The diagnosis of non-nodular hyperthyroidism may be challenging, as gold-standard diagnostic tests—such as thyroid scintigraphy and thyrotropin receptor antibodies (TRAb)—often involve delays. Thyroid ultrasonography allows bedside assessment and provides valuable diagnostic information.

Objectives: To evaluate ultrasonographic differences in patients with Graves' disease at diagnosis compared with the euthyroid state.

Materials and Methods: A prospective observational study was conducted including patients diagnosed with Graves' disease. GD was defined as primary hyperthyroidism with positive TRAb levels (>2 IU/mL) or diffuse uptake on thyroid scintigraphy in cases with negative or indeterminate TRAb results.

Biochemical evaluation (TSH, free T4, and TRAb) and thyroid ultrasonography were performed at the time of diagnosis. Ultrasonography was repeated after normalization of thyroid hormone levels. Clinical and laboratory data were recorded, along with qualitative ultrasonographic features (thyroid volume, echogenicity, and vascular pattern) and quantitative parameters, including peak systolic velocity of the inferior thyroid artery (ITA-PSV), measured both at diagnosis and at euthyroidism. Thyroid scintigraphy was performed in patients with suspected GD and negative or indeterminate TRAb results. Statistical analysis was carried out using SPSS version 25®.

Results: A total of 37 patients with Graves' disease were included, with a mean age of 44.4 ± 2.2 years; 33 were women (89%). Goiter was present in 91.7% of patients, and 91.9% reported symptoms of hyperthyroidism. At diagnosis, mean laboratory values were: TSH 0.03 ± 0.02 mIU/L, free T4 3.72 ± 1.61 ng/dL, and TRAb 9.47 ± 13.08 mIU/L.

On ultrasonography, increased thyroid volume was observed in 91.7% of patients, while decreased echogenicity was present in all cases. Regarding vascular patterns, increased thyroid vascularization (patterns 2 and 3) was observed in 97.3% of patients at diagnosis, compared with 71% at the euthyroid state.

Patients with Graves' disease showed statistically significant differences in ITA-PSV between diagnosis and euthyroidism (78.8 ± 20.1 cm/s vs 49.7 ± 12.8 cm/s; $P = .012$). The mean time to achieve normalization of thyroid hormone levels was 7.25 ± 1.6 months.

Conclusions: Thyroid ultrasonography is an essential tool in the management of hyperthyroidism. Measurement of inferior thyroid artery peak systolic velocity may serve as a useful marker for disease monitoring in Graves' disease.

EP1631 - ECE_3859 - The prevalence of thyroid nodules in correlation with anthropometric and metabolic factors in euthyroid adult patients

Edlira Hoxha[1,2], Anila Shuka[1] and Arben Mitrushi[1]
[1]*Endocrinology, Morphology Department, Medicine University, Spacialty Polyclinic Nr.3, Tirana, Albania;* [2]*Endocrinology, Medicine Faculty, Specialty Polyclinic Nr.3, Medicine University, University of Medicine, Tirana, Albania*

Thyroid nodules are common in clinical practice. They begin like discrete lesions inside of structure of the gland that can be differentiated by radiological examinations. Most of them are benign and asymptomatic for the patient followed by normal hormonal balance. Epidemiologic studies have shown the prevalence of palpable thyroid nodules 5% in women and 1% in men living in iodine-sufficient countries. In contrast, high resolution ultrasound can detect 19%-65% of the thyroid nodules with higher frequencies in women and the elderly.

Genesis of nodules can be influenced by genetics and environmental factors. Most common risk factors in thyroid nodules are: age (high risk in children, adults under 30 years old and over 60 years old), iodine deficiency, history of radiation exposure or head/neck radiotherapy, smoking or alcohol, family history of thyroid cancer or MEN2. The recent studies have shown that high TSH values (those too in upper-normal range) is an important factor that influences nodules development. As well metabolic syndrome is related with a higher prevalence of thyroid nodules, especially in obese patients.

The aim of our study is to evaluate the prevalence of thyroid nodules and the association between thyroid hormone levels and anthropometric and metabolic parameters in the presence of this nodules in euthyroid adult subjects.

This is a prospective study during a period of one year, that includes 100 patients of the Specialty Polyclinic Nr.3 in Tirana, Albania. The patients came to control for another health disease like cardiovascular or diabetes mellitus type 2. We evaluated thyroid hormone levels like: TSH, FT4, FT3 and antithyroid peroxidase antibody. Also we evaluated the anthropometric and metabolic parameters.

Results: The prevalence of thyroid nodules was almost 30% among the patients. Female gender, TSH levels in the upper normal range, thyroid volume were independent risk factors for thyroid nodules. Metabolic syndrome (like obesity, Hypertension, dyslipidemia, insulin resistance) was associated the elevated thyroid volume and nodules prevalence.

EP1632 - ECE_2352 - Amiodarone-induced thyrotoxicosis: a case report

Oumaima Dimassi, Ines Bayar, Ilef Guirar, Rawen Jaziri, Sana Abid, Ekram Hajji, Bilel Ben Amor, Héla Marmouch, Hanene Sayadi and Inès Khochteli
Department of Endocrinology and Internal Medicine, Fattouma Bourguiba University Hospital, Monastir, Tunisia

Introduction: Amiodarone is the most commonly used antiarrhythmic agent. It can lead to thyroid disease through two main mechanisms: intrinsic drug effects and the side effects due to its high iodine content. We report the case of amiodarone-induced thyrotoxicosis (AIT) with cardiothyrotoxicosis.

Observation: A 66-year-old male patient with cardiovascular and metabolic history (well-controlled hypertension, two episodes of acute coronary syndrome at the ages of 53 and 58, requiring the placement of drug-eluting stents, an ischemic stroke at the age of 61, prediabetes, and chronic kidney disease (stage 3A)).

At the age of 64, the patient was started on Amiodarone due to supraventricular tachycardia. Clinical examination upon admission showed: Grade 1 obesity; brisk deep tendon reflexes; heart rate at 120 beats per minute; no ocular signs; non-palpable thyroid. Electrocardiogram: rapid atrial fibrillation at 120 bpm.

Laboratory Tests: TSH at 0.15 µUI/mL; FT4 at 17 pmol/L; neutrophil count at 5400; negative anti-thyroperoxidase and anti-TSH receptor antibodies. Cervical ultrasound: thyroid of normal size; no thyroid nodules. Thyroid scintigraphy: “blank” result.

The patient was started on methimazole 20 mg/day and propranolol 40 mg/day, followed by prednisolone 30 mg/day, with good clinical and biological improvement, suggestive of type 2 AIT. However, type 3 (mixed type) cannot be ruled out.

Conclusion: Determining the type of AIT is crucial for better management. Although its treatment is complex, particularly due to “mixed” forms, euthyroidism is restored in the majority of cases with medical treatment.

Abstract citation ID: lvag096.1750

EP1634 - ECE_3104 - When cervical nodes speak first: two cases of papillary thyroid microcarcinoma revealed by lymphadenopathy

Assia Azzoune
Faculty of Medicine, Blida, Algeria

Introduction: The appearance of cervical lymphadenopathy is a real challenge for the doctor due to its varied benign or malignant etiologies; it can rarely reveal a previously asymptomatic papillary thyroid microcarcinoma which remains the most common cancer of the thyroid, accounting for up to 70% of cases. Ultrasound and cytology are crucial for diagnosis.

Cases:

1st case: a women 35 years old came to consult for a sensation of laryngeal tickling. She was stable. The cervical palpation reveals adenopathy of right lymph node chain III with a small right thyroid nodule. The thyroid and inflammatory tests were normal. Cervical ultrasound confirmed the presence of 01 cm lymphadenopathy as well as the 08 mm thyroid nodule classified EUTIRADS 4, cytology study finds malignant cellularity (Bethesda V) completed by a total thyroidectomy with lymph node dissection confirming the presence of a papillary thyroid carcinoma with lymph node metastasis.

2nd case: Mrs. A. L., 45 years old with overweight (BMI = 29 kg/m^2) consulted for left cervical discomfort. The patient was stable without any change in general condition or fever, cervical palpation revealed cervical lymphadenopathy of the left lymph node chain IV confirmed on cervical ultrasound which also showed an appearance of thyroiditis with 07 mm isthmic nodule classified

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

EUTIRADS 5. Biologically; antiTPO antibodies were positive. The aspiration cytology was malignant and the total thyroidectomy confirmed the presence of a papillary carcinoma on the isthmic nodule with lymph node metastasis on a background of Hashimoto's thyroiditis.

Discussion: The tumoral origin of cervical lymphadenopathy is predominantly represented by lymphomas and metastases from cancers of the upper aerodigestive tract. In 25% of cases, it is caused by thyroid carcinoma, particularly papillary thyroid carcinoma.[1] Cystic metastases from thyroid cancer have been reported in one out of ten cases, typically in individuals around 30 years of age.[2] The lymph node mass is usually solitary, most often located in levels IIa and III.[3] Thyroid abnormalities are identified during the diagnostic work-up in 75% of cases, mainly through cervical ultrasound followed by cytological confirmation.[4] The primary thyroid tumor is generally small—5.5 mm on average in a French series—with capsular involvement in 69% of cases.[5]

Conclusion: Through these two cases, we report an uncommon clinical situation in which the diagnosis of a papillary thyroid microcarcinoma was revealed by lymph node metastases. This highlights the importance of a thorough diagnostic work-up, which must systematically include cervical ultrasonography.

EP1635 - ECE_3137 - Metabolic dysfunction–associated steatotic liver disease as the initial presentation of subclinical hypothyroidism

Marin Pecani[1] and Paola Andreozzi[2]
[1]*Department of Experimental Medicine, Sapienza University of Rome, Tirana, Albania;* [2]*Policlinico Umberto I University Hospital, Sapienza University of Rome, Rome, Italy*

Introduction: Metabolic dysfunction–associated steatotic liver disease (MASLD) is the most common chronic liver condition, with a worldwide prevalence of over 30% in adults. Most individuals with MASLD are asymptomatic, therefore, the diagnosis is often made incidentally through imaging studies or when elevated liver enzymes are detected. MASLD can be associated with subclinical hypothyroidism, particularly of autoimmune origin, and these two may conditionally exacerbate insulin resistance, dyslipidemia, or hepatic steatosis.

Case Report: A 35-year-old man (body mass index [BMI] 30.5 kg/m^2) was referred for further assessment after routine health screening revealed elevated liver enzymes. He reported fatigue and a gradual weight gain of 10 kg over the past four years, a sedentary lifestyle with long hours in the office, lack of exercise, and frequent consumption of refined carbohydrate-rich food and sweetened drinks. He denied alcohol use and smoking. Family history was positive for type 2 diabetes and hypertension. Physical examination showed central obesity (waist circumference 103 cm) and mildly elevated blood pressure (124/83 mmHg). Laboratory tests revealed increased levels of aspartate transaminase (AST, 53 U/L) and alanine transaminase (ALT, 61 U/L), fasting plasma glucose (FPG) 96 mg/dL, glycated hemoglobin (HbA1c) 5.7%, and dyslipidemia (total cholesterol 246 mg/dL, triglycerides 175 mg/dL, and HDL cholesterol 43 mg/dL). Viral hepatitis serology was negative. Thyroid function tests showed an elevated TSH (10.2 µIU/mL) with normal free T4 (0.98 ng/dL) and free T3 (2.5 pg/mL), along with positive anti-TPO antibodies (156 IU/mL), supporting the diagnosis of primary subclinical hypothyroidism. An ultrasound exam demonstrated grade 2 hepatic steatosis, and vibration-controlled transient elastography ruled out clinically significant fibrosis (stiffness 5.3 kPa). A diagnosis of MASLD, obesity, and autoimmune subclinical hypothyroidism was made. The patient was advised on calorie restriction, adherence to a Mediterranean diet, and regular exercise and started on levothyroxine. At six months, he achieved a 6 kg weight loss, TSH (2.4 µIU/mL), normalization of liver enzymes, and improved HbA1c (5.3%) and lipid profile.

Conclusion: MASLD and subclinical hypothyroidism have similar metabolic abnormalities that lead to metabolic dysfunction and increased cardiovascular disease risk. Therefore, timely diagnosis and effective treatment, including lifestyle modification and targeted therapy, are essential to prevent progression to advanced liver disease and systemic complications.

Abstract citation ID: lvag096.1752

EP1638 - ECE_1306 - Primary thyroid lymphoma: a case series from a tertiary care centre in Northern India

Prashant Hubballi, Subhash Yadav and Bibhuti Bhusan Mohanta
Endocrinology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India

Introduction: Primary thyroid lymphoma (PTL) refers to a lymphoma which involves the thyroid gland with or without involving regional neck lymph nodes but without contiguous spread or distant metastases from other areas of involvement at the time of diagnosis. PTL is a very rare entity, necessitating accurate and early diagnosis, as its management is very much different from that of other neoplasms intrinsic to the thyroid.

Aims and Objective: In this study, we report cases of primary thyroid lymphoma for which we analysed clinical, pathological, and treatment aspects to contribute to a better understanding of this rare neoplasm

Materials and Methods: Cases diagnosed from 2014 to 2024 (10 years)were retrieved and clinical details were noted. Immunohistochemistry (IHC) was performed for immunophenotyping, and cases were classified according to the World Health Organization 2022 classification of haematolymphoid neoplasms

Results: Sixteen patients with PTL were identified, with mean age of 63.5 years (range 34-93 years) including ten males. Duration of symptoms ranged from 2-12 months with most common symptom being rapidly progressing painless goitre. Thyroid Peroxidase (TPO) antibody was positive in 8 patients. Diffuse large B cell lymphoma was most frequent type of NHL found and most commonly it was of nongerminal centre type. In immunochemistry, CD 20 was most common marker found (13 patients) and one pt had CD3 positivity for T cell lymphoma. 11 patients received R-CHOP regimen and one patient underwent left hemithyroidectomy. Five patients expired and four patients improved

Discussion and Conclusion: PTL is a very rare entity amongst lymphomas and even rarer in Indian population as there is lack of considerable data. PTL is rare, accounting for 5% of all thyroid neoplasms and 1%-2% of extranodal lymphomas. These tumours usually present with painless neck mass that rapidly increases in size

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

with/without compressive symptoms. The mean age of presentation is at 6th-7th decade of life, and a female predominance has been noted. DLBCL accounts for 50%-70% of all cases and 60%-90% arise in a background of Hashimoto's thyroiditis. Early diagnosis in the form of histopathological evaluation supplemented by immunochemistry is the gold standard for the diagnosis of PTL. Combined chemoradiotherapy (R-CHOP regimen/E-SHAP) appears to be the best treatment modality, irrespective of histological type, as PTL are considerably radiosensitive too. Overall survival rates with combination therapy are very good (more than 90%), and recurrence rates as low as 7.7% have been reported.

Abstract citation ID: lvag096.1753

EP1641 - ECE_2433 - When the eyes lead the diagnosis: Marine-Lenhart syndrome with subclinical hyperthyroidism and unilateral exophthalmos

Teodora Nastasa[1], Nada Akad[1,2], Anca Matei[1,2], Georgiana Constantinescu[1,2], Alexandru Florescu[1,2] and Stefana Bilha[1,2]
[1]*Saint Spiridon County Hospital, Iaşi, Romania;* [2]*"Grigore T Popa" University of Medicine and Pharmacy, Iaşi, Romania*

The coexistence of hyperfunctioning thyroid nodules is estimated to occur in 0.26%-4.1% of patients with Graves disease (GD), a clinical entity referred to as Marine–Lenhart syndrome (MLS). Due to its rarity, clear diagnostic criteria and standardized therapeutic management strategies have not yet been established.

We present the case of a 47-year-old woman referred for right upper eyelid retraction, right unilateral exophthalmos, diffuse conjunctival congestion and minimal bilateral chemosis. Contrast-enhanced cranio-cerebral CT and MRI were performed for orbitopathy assessment, revealing no significant pathological abnormalities on imaging, thus ruling out potential causes of proptosis.

Laboratory evaluation revealed negative anti–thyroid peroxidase antibodies (TPOAb) and anti–TSH receptor antibodies (TRAb), with positive thyroid-stimulating immunoglobulins (TSI) and subclinical hyperthyroidism, characterized by borderline TSH levels and normal free-T4 concentrations. Thyroid ultrasound revealed two nodular lesions, a microcyst and a TI-RADS 3 thyroid nodule, within a diffusely heterogeneous, hypoechoic thyroid parenchyma, with an overall normal thyroid volume and vascularisation. Thyroid scintigraphy with technetium-99m pertechnetate ($99mTcO_4$) demonstrated a hyperfunctioning nodule, accounting for approximately 32% of total thyroid uptake.

The patient was diagnosed with type 1 MLS, associated with moderate inactive (CAS 2) thyroid eye disease (TED). Any active therapeutic interventions were postponed given the rare condition of subclinical hyperthyroidism status, inactive TED and the absence of cervical compressive symptoms. Clinical, biochemical and imaging follow-up were recommended.

At subsequent evaluation, a >50% increase in nodular volume was observed, along with progression of ultrasound features to a TI-RADS 5, with a maximum diameter at the borderline threshold for fine-needle aspiration biopsy (FNAB). FNAB was performed, leading to a Bethesda II cytological result. TSH was within normal limits (TSH = 1.06 mUI/mL). Follow-up in 6 months was recommended.

This case highlights a type 1 MLS presentation with moderate, inactive thyroid eye disease and only subclinical biochemical hyperthyroidism, justifying close clinical, biochemical and imaging monitoring. Clinically significant orbitopathy may occur even when classical thyroid autoimmunity markers (TRAb, TPOAb) are negative, with TSI positivity supporting the autoimmune background.

Abstract citation ID: lvag096.1754

EP1642 - ECE_2510 - When the skin reveals the diagnosis: pretibial myxedema in Graves' disease

Hakan Ömer Karataş[1] and Banu Ocak[2]
[1]*Internal Medicine, Van Gürpınar State Hospital, Van, Turkey;* [2]*Marmara University School of Medicine, Marmara University Pendik Research and Education Hospital, Internal Medicine, İstanbul, Turkey*

Background: Graves' disease is a multisystem autoimmune disorder with cardiovascular, neuropsychiatric and dermatological manifestations that may result in fragmented evaluation across multiple specialties and lead to delayed diagnosis. In such settings, cutaneous manifestations may serve as a unifying clinical clue that prompts reassessment of the overall clinical picture. The aim of this case is to illustrate the diagnostic value of pretibial myxedema in patients with fragmented multisystem presentations of Graves' disease.

Methods: Case presentation.

Case Presentation: A 47-year-old woman was referred to our outpatient clinic by her family physician for evaluation of progressive pretibial and ankle edema. Over the preceding year, she experienced restlessness, anxiety, sweating and weight loss along with tremor, leading to consultations across multiple specialties. She had been followed by psychiatry for 18 months with a diagnosis of anxiety disorder and treated with selective serotonin reuptake inhibitors (SSRI). She also presented repeatedly to the emergency department with palpitations and fever, where sinus tachycardia was documented on electrocardiograms and empirical antibiotic treatments were administered. Neurological evaluation for progressive tremor and neuropathic pain included electromyography demonstrating entrapment neuropathy and cranial imaging, which was unremarkable, after which levodopa was empirically initiated with a preliminary diagnosis of Parkinson's disease.

Physical examination revealed bilateral non-pitting edema over the pretibial regions and dorsal ankles, warm and moist skin and fine tremor. Resting heart rate was 115 bpm. Cardiac, renal, hepatic and venous evaluations did not identify an alternative cause for edema. Laboratory evaluation showed suppressed thyroid-stimulating hormone (0.0001 μIU/mL), markedly elevated free triiodothyronine (22.2 ng/L) and free thyroxine (5.61 ng/dL) with increased thyroid-stimulating immunoglobulin levels. Thyroid ultrasonography demonstrated diffuse enlargement with heterogeneous parenchyma.

Graves' disease was diagnosed and treatment with methimazole and propranolol was initiated. With treatment, autonomic symptoms resolved, free thyroxine levels normalized and pretibial myxedema showed regression, while previously prescribed SSRI and levodopa therapies were discontinued. The patient remains clinically stable under ongoing outpatient follow-up.

Conclusion: Pretibial myxedema is an uncommon but specific manifestation of Graves' disease with a clear pathophysiological basis in autoimmune fibroblast activation and glycosaminoglycan deposition in the dermis and subcutaneous tissue. It should be recognized not merely as a late or rare finding but as a valuable diagnostic clue that may precede or outshine other features of

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

thyrotoxicosis. This case underscores the importance of careful physical examination and early consideration of thyroid dysfunction in patients with fragmented multisystem presentations to prevent diagnostic delay, unnecessary investigations and polypharmacy.

EP1643 - ECE_3146 - Emotional regulation and existential well-being in women with autoimmune thyroiditis: findings based on CECS and LAP-R

Marcin Nosal
Collegium Medicum, Jan Dlugosz Uniwersity, Częstochowa, Poland

Background: Autoimmune thyroiditis is a chronic disorder affecting not only physical health but also existential functioning. Persistent symptoms, uncertainty regarding disease progression, and treatment contribute to distress and reduced quality of life. Emotional suppression and impaired meaning-making may play an important role in adaptation to chronic illness. This study aimed to assess emotional regulation patterns and existential attitudes in women with autoimmune thyroiditis using the Courtauld Emotional Control Scale (CECS) and the Life Attitude Profile–Revised (LAP-R).[1-6]

Materials and Methods: Women with autoimmune thyroiditis were evaluated using the CECS, measuring suppression of anxiety, and depressed mood, and the LAP-R, assessing purpose in life, existential coherence, life acceptance, and attitudes toward death. Additional tools, including Brief COPE and PSSI-5, supported interpretation of emotional functioning and coping styles.

Results: Participants demonstrated increased emotional suppression, particularly in anxiety and sadness. Higher CECS scores were associated with lower existential fulfillment, reduced sense of life meaning, and poorer psychological adaptation. Women showing stronger emotional inhibition reported greater subjective disease burden and less effective coping, indicating a link between emotional suppression and reduced existential well-being.

Conclusions: Emotional regulation and existential factors play an important role in autoimmune thyroiditis. Combined use of CECS and LAP-R offers valuable insight beyond standard endocrine evaluation. Psychological interventions focused on emotional expression, meaning-making, and adaptive coping may improve patient and quality of life.

EP1644 - ECE_3464 - When “definitive” isn’t final: late recurrence of Graves’ disease after total thyroidectomy

Zin Tun, Saira Yousaf, Sarishka Singh, Denise Tapa and Hassan Ibrahim
Diabetes and Endocrinology, Cambridge University Hospitals, Wolfson Diabetes & Endocrinology Centre, Cambridge, United Kingdom

Introduction: Radioactive iodine (RAI) and total thyroidectomy are established definitive treatments for Graves’ disease, with total thyroidectomy offering rapid and durable control of hyperthyroidism. Recurrence of Graves’ disease following complete thyroidectomy is considered exceptionally rare and is usually attributable to residual or ectopic thyroid tissue rather than failure of the surgical approach itself. We present a rare case of late recurrent Graves’ thyrotoxicosis occurring more than a decade after total thyroidectomy.

Case Presentation: A 57-year-old female with a history of refractory Graves’ disease underwent total thyroidectomy in 2008. She subsequently developed hypothyroidism and was stabilised on 125 µg of levothyroxine once daily.

In 2022, after fourteen years of stability, the patient presented with classic thyrotoxic symptoms including insomnia, palpitations, heat intolerance, diaphoresis, and 3 kg weight loss. She also reported dry skin and gritty eyes. Despite reducing levothyroxine dose gradually to 25 µg daily she remained biochemically thyrotoxic. Review of her records revealed subclinical hyperthyroidism dating back to 2019.

Thyroid stimulating immunoglobulin (TSI) level has been persistently more than 40 IU/L (normal < 0.56 IU/L). A thyroid ultrasound identified 8 mm residual thyroid tissue in the left lower thyroid bed. Fine needle aspiration confirmed benign thyroid tissue (Thy2). A technetium uptake scan revealed multiple foci of uptake in the neck (13 mm anterior to the cartilage, a small 5 mm right paratracheal nodule and 2 small nodules in the left thyroid bed).

Levothyroxine was discontinued and carbimazole 10 mg daily was commenced. While thyroid function tests initially normalised the persistently high TSI levels prompted a transition to a block and replace regimen. MRI of the orbits ruled out active thyroid eye disease.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Repeat surgery was deemed clinically inappropriate after discussion with the ENT team. Patient was offered radioactive iodine, but she expressed a preference for long term medical management.

Conclusion: Recurrence of thyrotoxicosis following total thyroidectomy is a rare but significant complication. This case demonstrates the challenges of managing a persistent autoimmune drive despite surgical intervention. High TSI titres necessitate long term vigilance as even minimal residual tissue can grow over time and become hyper-functional under sustained autoimmune stimulation. Imaging with ultrasound and uptake scans is essential for localising remnants.

EP1645 - ECE_3586 - Comparative analysis of inflammatory biomarkers in women with hypothyroidism and diminished ovarian reserve

Fotima Makhmudova[1,2] and Khurshida Nasirova[2]
[1]Tashkent, Uzbekistan; [2]Tashkent State Medical University, Tashkent, Uzbekistan

This study empirically investigated the relationship between thyroid function and ovarian reserve in women of reproductive age, incorporating key hormonal markers and inflammatory indicators. A one-way Analysis of Variance (ANOVA) was conducted to compare three distinct groups: the control group (practically healthy women, $n = 20$), women with decreased ovarian reserve (DOR) and hypothyroidism ($n = 40$), and women with DOR and euthyroidism ($n = 40$). Data on Thyroid-Stimulating Hormone (TSH), Anti-Müllerian Hormone (AMH), Follicle-Stimulating Hormone (FSH), C-reactive protein (CRP), Complement C3, and Ceruloplasmin were analyzed. Significant differences were observed across groups for TSH ($F(2,97) = 54.245$, $P < .001$), AMH ($F(2,97) = 323.365$, $P < .001$), CRP ($F(2,97) = 101.497$, $P < .001$), Complement C3 ($F(2,97) = 34.264$, $P < .001$), and Ceruloplasmin ($F(2,97) = 46.734$, $P < .001$). Post-hoc analyses revealed significantly higher TSH and lower AMH in the group with DOR and hypothyroidism compared to both the control group and the group with DOR euthyroidism. CRP, Complement C3, and Ceruloplasmin were also markedly elevated in the DOR with hypothyroidism group, suggesting an inflammatory component. FSH and age did not show significant inter-group differences. These findings underscore the critical impact of thyroid dysfunction on ovarian reserve and highlight the potential role of inflammatory markers in compromised reproductive health.

Keywords thyroid function, ovarian reserve, hypothyroidism, diminished ovarian reserve, infertility

EP1646 - ECE_1678 - Potential use of tocilizumab in glucocorticoid-resistant Thyroid Eyes Diseases

Tatsiana Mokhort[1], Ksenia Palavinkina[2], Alena Mokhort[1] and Natalia Likharad[3]
[1]Endocrinology, Belarusian State Medical University, Minsk, Belarus; [2]Minsk City Clinical Endocrinology Center, Minsk, Belarus; [3]Endocrinology, 1th City Clinical Hospital, Minsk, Belarus

Objective: to evaluate the efficacy of tocilizumab (TZM) in the treatment of glucocorticoid-resistant Thyroid eyes Diseases (TED)

Materials and Methods: 7 female patients with glucocorticoid-resistant TED were observed on the background of compensated Graves' disease (6) and 1 with compensated hypothyroidism after surgical treatment of Graves' disease. Treatment with TZM (8 mg/kg, intravenously, once a month No. 3) was initiated after a course of pulse therapy with methylprednisolone (total dose 8000-13 500 mg) without significant clinical effect with a score of 4-5 points on a 7-point CAS scale. After a course of TZM treatment, all patients subjectively assessed changes in their quality of life, indicating significant improvement after 1-3 months. The CAS scores returned to normal (up to CAS 1) in all patients. The disappearance of spontaneous pains, pain when trying to look up, redness of the eyelids and conjunctiva, swelling of the eyelids, caruncle/plica inflammation, and chemosis was noted. At the same time, there was an improvement in vision, a decrease in intraocular pressure, and a significant decrease in the manifestations of diplopia (only 1 patient retained Gorman type 2 diplopia). When assessing the tolerability of treatment, 1 patient had an infection, and 2 patients had neutropenia, which had no significant effect on the treatment. With the consent of the patients, visual changes of the eyes are presented before and after TZM therapy.

Conclusion: The effectiveness of TZM in reducing CAS in patients with glucocorticoid-resistant TED has been demonstrated, which allows it to be used for the activity of TED manifestations.

EP1650 - ECE_1167 - Correlation between iron deficiency in women with autoimmune thyroiditis depending on the functional status of the thyroid gland

Ilona Rudnieva[1], Iuliia Komisarenko[1], Galyna Mykhalchyshyn[1], Nazarii Kobyliak[1,2] and Viktoriia Yerokhovych[1]
[1]Bogomolets National Medical University, Kyiv, Ukraine; [2]Medical Laboratory CSD, Kyiv, Ukraine

Introduction: Iron is an essential micronutrient for sustaining vital physiological functions. It plays a key role in oxygen transport, energy metabolism, as well as in the functioning of the immune and nervous systems.

According to the World Health Organization, iron deficiency is the most widespread micronutrient disorder globally: approximately

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

30% of the population has anemia, predominantly due to iron deficiency. Women of reproductive age are particularly vulnerable, with up to 40% showing signs of iron depletion.

Women with autoimmune thyroiditis (AIT) are at an even higher risk of developing iron deficiency due to several contributing factors: chronic inflammation, impaired micronutrient absorption, and frequently associated hypothyroidism, which suppresses erythropoiesis.

Therefore, investigation the relationship between iron levels and thyroid function in women with AIT is relevant for early detection of latent deficiency and prevention of related complications.

Aim of the Study: To assess the presence of latent iron deficiency in women diagnosed with autoimmune thyroiditis, taking into account the functional status of the thyroid gland.

Materials and Methods: The study involved 50 female patients aged till 18-73 years, all of them had a confirmed the autoimmune thyroiditis. All participants underwent laboratory testing, which included the determination of ferritin levels (as an indicator of iron stores), as well as thyroid-stimulating hormone (TSH), free thyroxine (fT4), and free triiodothyronine (fT3) levels, using the immunochemiluminescence method for venous blood samples.

Results: Latent iron deficiency (reduced ferritin without overt anemia) was identified in 40% of the examined patients. Among them:

- 13 women (26%) were under 49 years of age;
- 3 women (6%) were over 49 years of age.

Among reproductive-age women with confirmed iron deficiency:

- 3 women (6%) had AIT with overt primary hypothyroidism;
- 4 women (8%) had AIT with subclinical hypothyroidism;
- 6 women (12%) had AIT with euthyroid status.

Among women over 49 years of age:

- 1 patient (2%) had AIT with overt hypothyroidism;
- 1 (2%) had subclinical hypothyroidism;
- 1 (2%) had euthyroidism.

Conclusions: 1. Latent iron deficiency was identified in 40% of women with autoimmune thyroiditis, indicating a high prevalence of this condition in the studied population. 2. The highest proportion of iron deficiency was observed among women of reproductive age—26%. 3. Most cases of iron deficiency occurred in patients with the euthyroid form of AIT—12%, suggesting that this subgroup may be underdiagnosed due to the absence of obvious thyroid dysfunction.

EP1651 - ECE_3381 - Pembrolizumab-induced secondary adrenal insufficiency and thyroid dysfunction

Tamara Janic[1], Luka Ciric[1], Mirjana Stojkovic[1,2], Bojan Markovic[1], Nata Joksimovic[1], Jovana Babic[1], Biljana Nedeljkovic Beleslin[1,2], Jasmina Ciric[2] and Milos Zarkovic[1,2]
[1]Department of Thyroidology, Clinic of Endocrinology, Diabetes and Diseases of Metabolism, University Clinical Centre of Serbia, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Belgrade, Serbia

Pembrolizumab is a monoclonal antibody that blocks the programmed death receptor-1 (PD-1) on T cells and prevents cancer cells expressing PD-L1 ligand from using this pathway for suppression of the host immune system. It is successfully used for the treatment of various malignancies. Pembrolizumab allows T-cell reactivation leading to a more potent antitumor immune response. T-cell overactivity due to increased proliferation and a Th1/Th2 balance shift may cause autoimmune-driven destruction of endocrine tissues with or without autoantibody-mediated dysfunction. We present a 67-year-old male with a history of BRAF-negative metastatic melanoma with unknown primary, which was diagnosed by the examination of an enlarged cervical lymph node. Treatment with pembrolizumab was started and stable partial response achieved. After the fourth cycle of treatment (after 3 months), an increased level of FT4 was found (28 pmol/L), with suppressed TSH and undetectable TPOAb. A thyroid ultrasound showed a few spongiform micronodules. The treatment with low dose of methimazole was started in local hospital. After four months (eleven cycles of treatment) the patient presented to the emergency department due to extreme fatigue, hypotension, nausea and weight loss. Serum cortisol measured sporadically during the treatment was normal, but at the time of presentation a significant decrease of cortisol (38 nmol/L) and ACTH (1.8 ng/L) was found. Also, hypothyroidism on 5 mg of methimazole was registered, with FT4 5.95 pmol/L and TSH 94 mIU/L, undetectable TPOAb and TRAb 2.2 U/L (normal < 1.75). The treatment with hydrocortisone and levothyroxine was successfully introduced. Except for slightly higher FSH, gonadal hormones were normal. Aldosterone was 2.7 ng/dl, renin 1.5 uIU/mL, both normal. Although TgAb was transitory found slightly increased, only TRAb remained permanently 2.2 U/L for 20 months until now, with normal thyroid hormones on 37.5 mcg of levothyroxine. Among pembrolizumab-induced endocrinopathies the most common is thyroiditis, mostly presented as thyrotoxicosis followed by long-term hypothyroidism. Hypophysitis may lead to central hypothyroidism, secondary adrenal insufficiency and hypogonadism. Primary adrenal insufficiency and diabetes mellitus type 1 are rare complications. Since those conditions may be life-threatening, regular monitoring of thyroid hormones, cortisol and glucose levels during and after the treatment with pembrolizumab is essential.

EP1652 - ECE_3575 - Unilateral Graves' disease: a case report

Chayma Besrour[1], Wiem Helali[2], Hiba Bettaieb[3], Manel Boudokhane[3], Rim Bourguiba[2] and Syrine Bellakhel[2]
[1]Endocrinology, Internal Security Forces Hospital Marsa, Tunis, Tunisia; [2]Internal Medecine, Internal Security Forces Hospital Marsa, Tunis, Tunisia; [3]Rhumatology, Internal Security Forces Hospital Marsa, Tunis, Tunisia

Introduction: Graves' disease is an immune system condition that affects the thyroid gland and responsible for an excess of hormones production that causes hyperthyroidism. Usually it affects the entire thyroid gland, only few cases reported the involvement of one lobe.

Case Presentation: Herein we report the case of 31-year-old female patient ,with no medical history , who consulted for weight loss, palpitations and asthenia for 2 months. Clinical examination

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

showed no abnormalities in the cervical area. Laboratory investigations confirmed thyrotoxicosis with suppressed thyroid stimulating hormone < 0.001 μU/L. Anti-TSH receptor antibodies were negative. Neck Ultrasound showed a right thyroid lobe enlarged and heterogeneous with increased vascularization ,and left lobe were both normal in size. A Tc99m pertechnetate thyroid scan showed an enlargement of the right thyroid lobe with diffuse intense uptake, whereas the left lobe was totally suppressed. A diagnosis of unilateral Graves' disease was made. The patient was treated with methimazole.

Discussion: Anti-TSH receptor antibodies are the classic autoantibodies that mimic TSH role, and they're present in almost 90 % of Graves' disease case.

Some patients can initially test negative despite having thyrotoxicosis but they may convert later on, suggesting timing or assay sensitivity issues or difference in structural or local expression of sodium-iodide symporters.

EP1657 - ECE_1650 - Multiparametric ultrasound–based algorithm for evaluating overt thyrotoxicosis in diffuse thyroid disorders

Stefania-Alexandra Bunceanu[1], Bena Andreea[2], Roxana Pui[1,3] and Stoian Dana[2]
[1]*Department of Doctoral Studies, Victor Babes University of Medicine and Pharmacy, Timisoara, Romania;* [2]*Timisoara, Romania;* [3]*Endocrinology, Spitalul Clinic Judetean de Urgenta Timisoara, Timisoara, Romania*

Introduction: Thyrotoxicosis, defined as an excess of circulating thyroid hormones, encompasses a heterogeneous group of disorders, most commonly related to diffuse thyroid disease (DTD). In current clinical practice, distinguishing hyperfunctional etiologies, particularly Graves' disease (GD), from destructive causes such as subacute thyroiditis, hashitoxicosis, postpartum thyroiditis, or drug-induced thyroiditis remains challenging. This diagnostic uncertainty can delay accurate diagnosis and prompt treatment initiation. The aim of this study was to improve etiologic discrimination in thyrotoxicosis by implementing a multiparametric ultrasound (MPUS) algorithm.

Methods: This prospective study was conducted between January 2022 and January 2024 in a specialized endocrinology center in Timișoara, Romania. A total of 100 patients with newly diagnosed thyrotoxicosis were enrolled, alongside 25 controls. All participants underwent a stepwise MPUS assessment, including B-mode ultrasound, shear-wave elastography (SWE), and spectral Doppler evaluation. Contrast-enhanced ultrasound (CEUS) was reserved for cases in which the etiology remained uncertain after the preceding steps. For each pathology subtype, the reference standard was established using biochemical markers and/or confirmatory tests, in accordance with current guideline recommendations.

Results: Among 125 participants, 25 were controls and 100 were diagnosed with DTD. The MPUS algorithm provided definitive etiologic classification in 98/100 DTD cases. At the initial assessment, B-mode hypoechogenicity showed good performance for identifying DTD (ROC AUC = 0.810). As the second step of the proposed algorithm, SWE revealed markedly increased parenchymal stiffness in subacute thyroiditis (SWE > 52 kPa; $P < .001$; ROC AUC = 0.990). Subsequently, spectral Doppler reliably separated GD from destructive thyrotoxicosis using inferior thyroid artery peak systolic velocity measurements; a cut-off of 54.8 cm/s identified GD (ROC AUC = 0.962; $P < .001$), whereas destructive disorders typically measured < 32.7 cm/s. Finally, CEUS correctly classified 26/28 equivocal cases; hyperfunctioning etiologies showed shorter time-to-peak and higher peak enhancement than destructive patterns. Using quantitative time–intensity curve thresholds: washout AUC (WoAUC) > 1867, wash-in AUC (WiAUC) > 205.8, and mean time–intensity curve (mTIC) > 12, CEUS discriminated hyperfunctioning disease with 88.2% sensitivity, 100% specificity, and 92.9% overall accuracy.

Conclusion: The proposed MPUS algorithm integrating grayscale ultrasound, SWE-based stiffness assessment, spectral Doppler, and selective quantitative CEUS demonstrated high diagnostic performance for etiologic classification in this cohort. If confirmed in larger prospective studies, this approach may facilitate earlier etiologic diagnosis, guide targeted management, and reduce reliance on radionuclide scintigraphy.

EP1659 - ECE_1015 - Warthin-like papillary thyroid carcinoma associated with BRAF V600E and TERT promoter mutations: a case report

Yotsapon Thewjitcharoen[1], Waralee Chatchomchuan[1], Ekgaluck Wanothayaroj[1], Veekij Veerasomboonsin[2] and Somboon Keelawat[3]
[1]*THEPTARIN Diabetes, Thyroid and Endocrine Center, Vimut-Theptarin Hospital, Bangkok, Thailand;* [2]*Radiology, Vimut-Theptarin Hospital, Bangkok, Thailand;* [3]*Pathology, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand*

Background: Warthin-like Papillary Thyroid Carcinoma (WL-PTC) is a rare subtype of PTC, officially recognized as a distinct entity since 2017. It is characterized by the presence of papillary architecture with prominent lymphocytic stroma within fibrovascular core, resembling the Warthin tumor of the salivary gland. WL-PTC typically carries an excellent prognosis. However, due to its rarity, molecular profiling in WL-PTC remains limited. We present an unusual case of WL-PTC with coexisting *TERT* and *BRAF V600E* mutations.

Clinical Case: A 56-year-old Thai woman with no known underlying disease presented with left thyroid nodule for 6 months without other symptoms. Ultrasound showed a large heterogeneous hypoechoic nodule involving the entire left lobe (2.4 × 1.9 × 3.3 cm) and an ill-defined hypoechoic nodule in the right lobe (1.4 × 0.9 × 1.7 cm). Fine-needle aspiration (FNA) at left lobe yielded a Bethesda class V result. The patient underwent total thyroidectomy with lymph node dissection at another hospital. Histopathological examination revealed WL-PTC in the left lobe and Noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) in the right lobe. Given the favorable prognosis of both tumors, the patient was advised against radioactive iodine (RAI) therapy. However, she sought a second opinion regarding the need for RAI. A follow-up neck ultrasound revealed multiple sub-centimeters, suspicious cervical lymph nodes (LNs) metastasis. Repeated neck exploration with modified radical neck dissection was subsequently performed. Pathology confirmed metastatic PTC with oncocytic features inside LNs (7/37 nodes). Molecular analyses for *BRAF* V600E and *TERT* promoters (C228T

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

and C250T) were detected by pyrosequencing technique. High-dose RAI ablation (150 mCi) was administered and the patient recovered well without recurrent disease at 24 months later.

Conclusions: WLPTC is an uncommon subtype of papillary thyroid carcinoma, accounting for less than 0.2% of all PTCs but with generally good prognosis. However, LNs metastasis with aggressive molecular alterations such as BRAF V600E and TERT mutations should be considered and thoroughly evaluated to guide treatment decisions. Further investigations are required to elucidate the prognostic impact of coexisting *BRAF* V600E and *TERT* mutations in this rate tumor subtype.

EP1662 - ECE_3427 - Morphological features of thyroid dysfunction during combined therapy for breast cancer

Makhbuba Azimova and Khurshida Nasirova
Endocrinology, Tashkent State Medical University, Tashkent, Uzbekistan

Breast cancer (BC) is one of the most common malignancies among women worldwide and requires multimodal treatment approaches. Combined therapy, including chemotherapy, hormone therapy, and targeted treatment, significantly improves survival; however, it is often accompanied by systemic adverse effects. Thyroid dysfunction represents an important complication that may worsen patients' quality of life and reduce treatment tolerance. The study of morphological and functional changes in the thyroid gland during combined therapy for breast cancer remains clinically relevant.

Purpose: To evaluate morphological, laboratory, and clinical manifestations of thyroid dysfunction in patients with breast cancer undergoing combined therapy, taking into account tumor histological grade, molecular subtype, and proliferative activity.

Materials and Methods: The study included 136 patients with histologically confirmed breast cancer treated with combined therapy between 2021 and 2024. Thyroid function was assessed by measuring serum levels of thyroid-stimulating hormone (TSH), free thyroxine (fT4), free triiodothyronine (fT3), and anti-thyroid peroxidase antibodies (anti-TPO). Cytomorphological examination of the thyroid gland was performed in 14 patients using fine-needle aspiration biopsy specimens obtained from thyroid nodules after four cycles of chemotherapy and/or within 30 days after completion of combined treatment. Morphological evaluation included nuclear atypia, karyopyknosis, proportion of binucleated cells, and apoptotic index. Immunohistochemical analysis of breast tumor tissue assessed estrogen and progesterone receptor status, HER2/neu expression, and Ki-67 proliferation index.

Results: Patients receiving combined therapy demonstrated significantly elevated TSH levels and reduced fT4 and fT3 concentrations compared with the control group ($P < .001$). Higher TSH levels and lower fT4 values were observed in patients with invasive breast cancer compared to ductal carcinoma in situ, suggesting early manifestations of subclinical hypothyroidism. Morphological analysis revealed destructive changes in thyroid tissue, including nuclear atypia and increased apoptotic activity, predominantly after multiple chemotherapy cycles. Clinical manifestations of thyroid dysfunction were more frequent in patients with luminal B subtype and high proliferative activity (Ki-67 > 35%), including palpitations, neck discomfort, apathy, and sensation of a "lump" during swallowing. No statistically significant association was found between histological tumor grade (G1–G3) and severity of thyroid dysfunction.

Conclusion: Thyroid dysfunction in breast cancer patients undergoing combined therapy is more closely associated with molecular tumor subtype and proliferative activity than with histological tumor aggressiveness. These findings support the necessity of regular thyroid function monitoring in patients with breast cancer, particularly those with aggressive molecular subtypes, to ensure timely detection and correction of endocrine disorders.

EP1664 - ECE_3925 - Rapidly enlarging thyroid nodule in an asymptomatic patient from an endemic goiter region: a case report

Ivanna Zaliska
Emergency Department, Ivano Frankivsk City Central Clinical Hospital, Ivano Frankivsk, Ukraine

Background: Thyroid nodules are common, particularly in endemic goiter regions. Environmental factors, including potential radiation exposure following the Chernobyl disaster, as well as challenges in healthcare access during the ongoing war in Ukraine, highlight the importance of early detection and monitoring. Incidentally detected thyroid nodules may demonstrate rapid growth and require timely evaluation.

Case Description: An asymptomatic female patient was referred by her primary care physician for thyroid ultrasonography during routine evaluation. Initial imaging revealed a small thyroid nodule. During follow-up, the nodule demonstrated rapid enlargement, raising suspicion for malignancy. The patient subsequently underwent total thyroidectomy, followed by radioiodine therapy as part of postoperative management.

Conclusion: This case highlights the importance of careful monitoring of incidentally detected thyroid nodules, particularly in high-risk regions. Rapid growth may necessitate surgical intervention and multidisciplinary management. Early detection and coordinated care remain essential to ensure optimal patient outcomes.

Abstract citation ID: lvag096.1766

EP1665 - ECE_3582 - Influence of ethnicity on prevalence of hypothyroidism in women with gestational diabetes and its relationship with metabolic parameters and pregnancy outcomes

Laura Vitale[1], Pamela Senesi[1,2], Guido Adda[2], Anna Ferrulli[1,2] and Livio Luzi[1,2]
[1]*Department of Biomedical Science for Health, University of Milan, Milan, Italy;* [2]*Department of Endocrinology, Nutrition and Metabolic Diseases, IRCCS Multimedica, Sesto San Giovanni, MI, Italy*

Background: Hypothyroidism and diabetes mellitus (DM) are the most common endocrine disorders in pregnancy and are associated with increased perinatal and postnatal morbidity. Adequate levothyroxine replacement and optimal glycaemic control reduce adverse pregnancy outcomes. The aetiology of hypothyroidism in pregnancy differs by ethnicity; for instance, iodine deficiency is more common in northern Asian populations, whereas

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

autoimmune thyroiditis predominates among Caucasians, albeit with exceptions. As ethnicity may affect incidence of both hypothyroidism in pregnancy (HP) and gestational diabetes mellitus (GDM), this study aims to evaluate its impact on type of hypothyroidism, glycaemic metabolism and pregnancy outcomes.

Materials and Methods: 105 women of different ethnicities [35 Caucasian (C), 35 North African (NA) and 35 Asian (A)] with GDM were included and the following parameters were retrospectively analysed:

- pre-existing hypothyroidism or HP,
- risk factors for GDM (maternal age, pre-gestational BMI, family history of DM, previous GDM),
- metabolic parameters [fasting glucose, glycated haemoglobin (HbA1c), oral glucose tolerance test (OGTT)],
- delivery characteristics (labour induction, caesarean section).

Results: Pre-existing hypothyroidism was more prevalent in Asian women (mostly secondary to autoimmune thyroiditis in our cohort), whereas Caucasians developed HP more frequently (C 26%, A 5%, NA 8%; $P = .055$), and exhibited higher HbA1c levels when compared with C without HP (33.00 ± 2.87 vs 30.05 ± 5.89 mmol/mol). Baseline fasting glucose values during OGTT were significantly higher in groups A and NA compared with group C (A vs C, $P = .02$; NA vs C, $P = .03$). Groups NA and A showed a trend toward higher HbA1c levels (NA 35.0 ± 4.8, A 34.3 ± 3.7, C 31.91 ± 3.5 mmol/mol; NA vs C $P = .003$, A vs C $P = .014$) and higher pre-gestational BMI compared with group C (NA 27.7 ± 0.9, A 25.9 ± 0.7, C 25.4 ± 1.1 kg/m^2; $P = .07$).

Conclusions: Higher rate of HP and higher HbA1c levels in group C suggests a negative impact of hypothyroidism on glucose metabolism. Lower fT4 and higher TSH levels may interfere with insulin synthesis and secretion and may induce insulin resistance by reducing peripheral insulin sensitivity due to excessive glucose–fatty acid cycling, which impairs insulin-mediated increases in blood flow to insulin-sensitive tissues.

Higher maternal age emerged as a major GDM risk factor in Caucasians, while higher pre-gestational BMI played a predominant role in groups A and NA, consistent with higher glycaemic parameters that demonstrate a greater tendency towards insulin resistance in these two groups. Family history of DM and previous GDM were confirmed as ethnicity-independent risk factors. No significant differences in delivery outcomes were observed.

Abstract citation ID: lvag096.1767

EP1667 - ECE_3765 - HLA allele associations with Hashimoto's thyroiditis in Albanian patients

Dorina Ylli[1], Megi Lekbello[1], Erkena Shyti[2], Marjeta Kermaj[1], Violeta Hoxha[1], Donika Kasemi[2], Zamira Ylli[1] and Genc Sulcebe[2]
[1]*University of Medicine Tirana, Tirana, Albania;* [2]*Research Center of Biotechnology and Genetics, Tirana, Albania*

Background: Hashimoto's thyroiditis (HT) is the most common autoimmune thyroid disease and is strongly influenced by genetic susceptibility, particularly within the human leukocyte antigen (HLA) region. Population specific data on HLA related risk and protection remain limited in Southeast Europe and particularly in Albania.

Methods: We performed a case control study including 50 patients diagnosed with Hashimoto's thyroiditis (diagnosis based on positive thyroid autoantibodies (anti-TPO and/or anti-Tg) and/or characteristic ultrasound features) and 208 controls. High-resolution HLA typing was performed for class I (HLA-A, B, C) and class II (HLA-DRB1, HLA-DQB1) loci. Allele frequencies were compared using Fisher's exact test, and odds ratios (OR) were calculated.

Results: Marked differences in HLA class II allele distribution were observed between patients and controls. The HLA-DQB1*03:01 allele was significantly overrepresented in Hashimoto patients (OR ≈ 8.25, $P < .001$), representing the strongest disease association. The HLA-DQB1*02:01 allele was also significantly associated with HT (OR ≈ 3.17, $P = .009$). At the DRB1 locus, DRB1*12:01 showed a significant association with disease susceptibility (OR ≈ 13.2, $P = .024$). Several alleles, including DRB1*14:01, were more frequent among controls than patients, however, these differences did not reach statistical significance, indicating a possible but unconfirmed protective effect.

Conclusions: This study identifies strong associations between Hashimoto's thyroiditis and specific HLA class II risk alleles in the Albanian population, while also suggesting the presence of potentially protective alleles that did not reach statistical significance. These findings emphasize the complex role of HLA class II variants in both susceptibility and protection in autoimmune thyroid disease and support the need for larger population studies.

EP1668 - ECE_1130 - Thyroid dysfunction due to chronic stress caused by military operations

Yana Kocherzhynska-Halis
Family Doctor's Office, Odesa, Ukraine

For thousands of years, humans have lived in a dynamic environment full of potential dangers. While fear and stress were crucial for the survival of our ancestors, today they are largely considered harmful factors that threaten both our physical and mental health. The hypothalamus plays a crucial role in initiating hormonal responses to stressful stimuli through the hypothalamic-pituitary-adrenal (HPA) axis. Connected to the prefrontal cortex and limbic structures, especially the amygdala and hippocampus, the hypothalamus acts as a central hub, integrating the physiological aspects of the stress response. However, in addition to the well-known role of the hypothalamic-pituitary-thyroid (HPT) axis, the hypothalamus can also involve the hypothalamic-pituitary-thyroid (HPT) and hypothalamic-pituitary-gonadal (HPG) axes, as well as through the secretion of growth hormone, prolactin, dopamine, and oxytocin. Experimental studies in animals and humans illustrate the effects of various forms of stress on the thyroid gland and the regulation of thyroid hormone (TH) through the thyrotropic multi-loop control loop. The hypothalamic-pituitary-thyroid (HPT) axis is part of the physiological stress system and mediates key regulators of metabolic activity during the stress response. Genetically predisposed individuals are more responsive to stressors, and their psychological response is greatly enhanced. This results in a significant increase in serum TH levels as soon as a negative stressor occurs. Physical stressors are used to induce psychological stress all of which affect thyroid function. In addition, somatic diseases can also affect the thyroid gland or be associated with thyroid dysfunction. Within the framework of observation in practice over the past year

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

11.2024-11.2025, 35 patients were examined for TSH levels, 30 women and 5 men, aged 30-65 years and a questionnaire was conducted on the impact of stress on their health. The survey included a clear framework for the occurrence of stress and the development of complaints that may have been associated with thyroid diseases. All patients who noted a significant deterioration according to the questionnaire during the war were sent for TSH control, according to the results of TSH level violations and further examination of patients, it was found: diffuse toxic goiter 12 patients, Autoimmune thyroiditis, including hypothyroidism in 9 patients. This work represents an analysis of previously conducted studies and observations in personal clinical practice of the impact of chronic stress caused by military operations on the development of thyroid dysfunction and the need for screening for the disease in countries where military operations are underway.

EP1670 - ECE_1101 - Reappraisal of the role of ultrasonography-guided fine needle aspiration biopsy in the management of autonomously hyperfunctioning thyroid nodules

Hee Kyung Kim[1], Ho-Cheol Kang[1,2], Jeehee Yoon[1], Ji Yong Park[1], A. Ram Hong[1], Sun Kyung Song[3] and Suk Bong Yun[4]

[1]Chonnam National University Medical School, Hwasun-gun, South Korea; [2]Division of Endocrinology and Metabolism, Department of Internal Medicine, Chonnam National University Medical School, Chonnam University Hwasun Hospital, Hawsun, South Korea; [3]Internal Medicine, Presbyterian Medical Center, Jeonju, South Korea; [4]Rehabilitation Medicine, Presbyterian Medical Center, Jeonju, South Korea

Background: Autonomously hyperfunctioning thyroid nodules are generally believed to have very low chances of malignancy. Clinical guidelines recommend not performing fine needle aspiration biopsy (FNAB) on these lesions irrespective of their size. However, a reappraisal of the need to perform FNAB is warranted because recent studies suggest the malignancy rate of toxic nodules may have been underestimated.

Methods: We reviewed patients with toxic nodules who visited Chonnam National University Hwasun Hospital from 2003 to 2023. A control group was selected from the population with nontoxic nodules who underwent FNAB in 2023. Laboratory tests and ultrasonographic findings of the nodules were analyzed.

Results: Toxic nodules were more likely to be single (77.8% vs 38.4%, $P < .001$) and larger (3.94 cm vs 1.78 cm, $P < .001$) compared to nontoxic nodules. Nontoxic nodules tended to exhibit ultrasonographic features associated with a higher malignancy risk (K-TIRADS 3: 28.0%, K-TIRADS 4: 28.4%, K-TIRADS 5: 42.0%) compared to toxic nodules (K-TIRADS 3: 55.6%, K-TIRADS 4: 42.6%, K-TIRADS 5: 1.9%). The malignancy rate was higher in nontoxic nodules (25.6% vs 3.7%, $P < .001$), but the malignancy rate in other nodules or the contralateral thyroid gland was similar (16.7% vs 9.2%, $P = .139$). This resulted in a malignancy rate of 16.7% for toxic nodules and 25.6% for nontoxic nodules ($P = .014$).

Conclusion: We believe that when deciding whether to perform FNAB for thyroid nodules, ultrasonographic findings should take priority over serum TSH levels.

Abstract citation ID: lvag096.1770

EP1671 - ECE_2171 - A network meta-analysis of the therapeutic efficacy for moderate to severe active thyroid-associated ophthalmopathy

Aihua Liu[1], Fanrui Meng[1], Yixin Gao[1], Haining Wang[1,2], Hongwei Gao[1] and Tianpei Hong[1]

[1]Beijing, China; [2]Endocrinology and Metabolic Disease, Peking University Third Hospital, Beijing, China

Objective: To evaluate the safety and efficacy of various treatment modalities for thyroid-associated ophthalmopathy through a network meta-analysis.

Methods: A literature search was conducted in multiple databases including PubMed, Web of Science, EMBASE, and Cochrane Library up to December 31, 2024, for randomized controlled trials involving patients with moderate to severe active thyroid-associated ophthalmopathy. The quality of the included studies was evaluated using the Cochrane Risk of Bias tool (RoB 2). Network meta-analysis based on the frequentist approach was performed using RevMan 5.3 and STATA 15.0 software. The primary outcome measures were overall response rate, clinical activity score (CAS), proptosis, palpebral fissure height, diplopia, and adverse reactions.

Result: Eventually, we included 26 eligible randomized controlled studies, involving a total of 1561 participants, covering a total of 16 intervention methods, including intravenous glucocorticoid injection (IVGC), oral glucocorticoid (OGC), retrobulbar glucocorticoid injection (TA), orbital radiotherapy (OR), somatostatin analogues (SSA), and biological agents such as tislelizumab, etc. Network analysis showed that tislelizumab outperformed the placebo in improving clinical activity scores, exophthalmos degree, and overall response rate. Glucocorticoid combined with statins and mycophenolate mofetil treatment could improve the exophthalmos degree, quality of life score, and diplopia score of patients.

Conclusion: Compared with no treatment, tiotropium bromide shows a significant effect in increasing the overall treatment response rate. The method of oral mycophenolate mofetil or statins combined with intravenous glucocorticoid administration is more effective in improving exophthalmos and diplopia in patients. Although some treatment methods have shown good effects in the treatment of thyroid-associated ophthalmopathy, the adverse reactions that occur raise safety concerns, and a more ideal balance between the efficacy and safety of the treatment methods needs to be sought.

EP1679 - ECE_3542 - Sex differences in agranulocytosis reporting among patients on antithyroid drugs: a retrospective EudraVigilance study

Aia Nana[1], Alexandru-Ioan Draghici[2], Ioana-Elena Tarabasanu-Mihaila[3], Mahir Khalil Ibrahim Jallo[4], Shatha Faisal Al Aqarbeh[5] and Rania Al-Mukhtar[6]

[1]Thumbay University Hospital, Ajman, United Arab Emirates; [2]Iuliu Hatieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania; [3]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [4]Department of Endocrinology, Thumbay University Hospital, Ajman, United Arab Emirates; [5]Near East University, Cyprus; [6]King's College London, London, United Kingdom

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: Agranulocytosis is a rare but serious adverse event of antithyroid drugs (ATDs). We decided to evaluate clinical outcomes and reporting patterns of agranulocytosis with methimazole (MMI), carbimazole (CBZ), and propylthiouracil (PTU) with an emphasis on gender disparities.

Methods: Individual Case Safety Reports (ICSR) of MMI, CBZ OR PTU use were extracted from EudraVigilance. Agranulocytosis was categorized using MEDRA Preferred Terms. The reports were classified by drug and sex. Overall and sex specific reporting disproportionality was evaluated using reporting odd ratios (ROR) with 95% confidence intervals, each drug being compared to a pooled group made out of the other members of the category. Clinical outcomes were summarized by drug (recovered, not recovered, fatal). Reporter type and geographical origin of reports (European Economic Area vs non-EEA) were described.

Results: Recovery was reported in 71% of methimazole, 74% of carbimazole, and 75% of propylthiouracil agranulocytosis cases. Fatal outcomes were uncommon, occurring in 4%, 5%, and 3% of cases, respectively.

Disproportionality analysis identified varying reporting patterns for agranulocytosis among antithyroid drugs. Carbimazole showed a significantly increased signal (ROR 1.15, 95% CI 1.03-1.29), whereas propylthiouracil was associated with a significantly lower signal (ROR 0.72, 95% CI 0.61-0.86). Methimazole showed no disproportional reporting overall (ROR 1.01, 95% CI 0.91-1.12).

Although limited by a low number of male cases, sex-stratified analyses showed potential differences in reporting patterns. Among males, no statistically significant disproportionality was observed. Carbimazole showed a numerically higher ROR (1.27, 95% CI 0.98-1.64), while methimazole showed a lower ROR that did not show statistical significance (0.80, 95% CI 0.63-1.01). Propylthiouracil showed no disproportional reporting (ROR 1.08, 95% CI 0.75-1.56).

Among females, carbimazole remained significantly associated with higher disproportionality reporting (ROR 1.15, 95% CI 1.01-1.31), propylthiouracil showed lower reporting (ROR 0.75, 95% CI 0.62-0.92), and methimazole showed no disproportionality (ROR 0.99, 95% CI 0.88-1.11).

Hospital care providers submitted 97% of the reports. Reporting from the European Economic Area accounted for 40% of methimazole, 78% of carbimazole, and 70% of propylthiouracil cases.

Conclusion: This EudraVigilance analysis revealed drug- and sex-specific differences in agranulocytosis reporting among antithyroid drugs. Carbimazole showed increased reporting and propylthiouracil decreased reporting, largely driven by female reports, while methimazole showed no signal. Most cases recovered and fatal outcomes were rare. Despite limitations of spontaneous reporting, these findings support drug- and sex-specific clinical vigilance.

EP1700 - LBA_ECE_1289 - Pituitary gigantism due to a novel AIP variant with an under-recognised ocular manifestation

Vishnou Mourougavelou[1,2,3], Erik Benyei[1], Panagiotis Drakos[1], Naz Raoof[4], Fresht Naomi[5], Anouk Borg[6] and Marta Korbonits[1,2]

[1]Faculty of Medicine and Dentistry, Queen Mary University of London, William Harvey Research Institute, Centre for Endocrinology, London, United Kingdom; [2]Department of Endocrinology, Barts Health NHS Trust—Barts & the London Hospitals, London, United Kingdom; [3]Barts Health NHS Trust, London, United Kingdom; [4]Department of Opthalmology, Barts Health NHS Trust—Barts & the London Hospitals, London, United Kingdom; [5]Department of Oncology, University College London Hospitals NHS Foundation Trust, London, United Kingdom; [6]Department of Neurosurgery, National Hospital for Neurology and Neurosurgery, London, United Kingdom

Background: Pituitary gigantism is typically caused by growth hormone (GH)-secreting pituitary neuroendocrine tumours. Germline heterozygous loss-of-function variants in the aryl hydrocarbon receptor-interacting protein (*AIP*) gene are the most common genetic cause and are associated with large, invasive tumours and relative resistance to first-generation somatostatin analogues.

Case Presentation: A 17-year-old male initially presented with a slipped capital femoral epiphysis. Despite a height exceeding 2 m, the diagnosis of gigantism was delayed by six months, during which he experienced rapid linear growth, headaches, and declining academic performance. While he had markedly elevated GH levels (>100 µg/L), his insulin-like growth factor-1 (IGF-1; 1.64× upper limit of normal [ULN]) was only modestly raised. This discordance was attributed to coexisting hypopituitarism, including secondary hypothyroidism, adrenal insufficiency, and hypogonadotropic hypogonadism (undetectable testosterone; bone age 14 years at a chronological age 18.5 years).

Magnetic resonance imaging demonstrated a 37 × 36 × 25 mm pituitary macroadenoma with cavernous sinus invasion and suprasellar extension compressing the anterior visual pathway. Initial treatment with first-generation somatostatin analogues achieved limited biochemical control (GH: 58.9 µg/L; IGF-1: 654 µg/L; 1.34x ULN). Following transsphenoidal surgery, histopathology revealed a sparsely granulated somatotrophinoma with a Ki-67 index of 1%-2% and a low mitotic index. There was a significant remnant within the cavernous sinus. GH (29.6 µg/L) and IGF-1 (540 µg/L, 1.11x ULN) levels improved but did not normalise.

Genetic testing identified a novel truncating *AIP* variant (c.259C>T; p.Gln87Ter). Postoperative management included escalating doses of pegvisomant (currently 270 mg/week), thyroxine, hydrocortisone, testosterone replacement, and subsequent proton beam radiotherapy. After radiotherapy, the patient developed eye pain, and an ophthalmological assessment diagnosed posterior (“foamy”) blepharitis, with preserved visual function, fields, colour vision, and normal intraocular pressures. This was attributed to acromegaly-related meibomian gland dysfunction rather than radiation exposure, and symptoms improved with topical treatment with eye drops.

Discussion: There are several learning points in this case:

1. Slipped capital femoral epiphysis is a well-described complication of childhood-onset GH excess.
2. Given his epiphysis was open, and he grew by 3 centimetres within the few months whilst awaiting surgery, the best postoperative medical treatment was deemed to be pegvisomant. Testosterone therapy would be the optimal solution, but it could cause an initial temporary growth acceleration.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

3. The ocular manifestation of posterior blepharitis seems to be under-recognised in patients with GH-excess.
4. Genetic testing helped us to make therapeutic decisions (early pegvisomant and proton beam therapy).

EP1701 - LBA_ECE_1166 - Clinicopathologic characteristics and recurrence risk factors in parathyroid carcinoma: a multi-institutional retrospective study in Korea

So Hee Lee[1], Yu-Mi Lee[2], Jae Hyun Park[3], Su-Jin Kim[4], Hyeok Jun Yun[5] and Jong Ju Jeong[6]

[1]Department of Surgery, Eunpyeong St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Seoul, South Korea; [2]Department of Surgery, Asan Medical Center, University of Ulsan College of Medicine, Seoul, South Korea; [3]Department of Surgery, Yonsei University Wonju College of Medicine, Wonju-si, Gangwon-do, South Korea; [4]Department of Surgery, Seoul National University Hospital, Seoul, South Korea; [5]Department of Surgery, Gangnam Severance Hospital, Seoul, South Korea; [6]Department of Surgery, Severance Hospital, Seoul, South Korea

Background: Parathyroid carcinoma is a rare endocrine malignancy, due to its rarity, prognostic factors and optimal surgical strategies remain incompeletely defined. This study aimed to evaluate clinicopathological characteristics and outcomes and to identify risk factors for recurrence.

Methods: We conducted a retrospective multicenter study across six tertiary hopitals in Korea. Patients without surgical treatments or those whose initial surgery was not performed at the respective institution were excluded. A total of 81 patients with pathologically confirmed parathyroid carcinoma between 1990 and 2024 were included. Clinicopathological data and outcomes were analyzed. Recurrence-free surgival was assessed, and Cox regression analysis was performed to identify risk factors for recurrence.

Results: The mean follow-up periods was 74.8 months. The mean age was 50.6 years, and 58% were female. Hypercalcemia was present in 81.5% of patients, while 17.3% were normocalcemic. Markedly elevated PTH levels (>1000 pg/mL) were observed in 38.5%. Primary hyperparathyroidism was present in 82.7% of patients, and 12.4% had secondary or tertiary hyperparathyroidism.

Ultrasonography detected 97.3% of cases, and MIBI scans were positive in 88.7%. Focused parathyroidectomy was performed in 77.8% of patients; among these, combined thyroidectomy was performed in 53.1% and central compartment neck dissection(CCND) in 50.6%. Subtotal or total parathyroidectomy was performed in 11.1% of patients, including concomitant thyroidectomy in 4.9%, CCND in 6.2%, and lateral neck dissection in 1.2%.

The mean tumor size was 28.4 mm. Capsular invasion was observed in 86.5%, including direct invasion into the thyroid gland in 19.8%. Vascular invasion was identified in 22.2%. Regarding the Ki-67 index, 12.4% of patients had values of 5%-10%, and 6.2% had values >10%. Most tumors were T1 (80.2%) and nodal metastasis was present in 4.9%. Synchronous distant metastasis was observed in 3 patients: two had lung metastases, and one had both lung and bone metastases.

During follow-up, eleven patients developed recurrence, most commonly in cervical lymph node(54.5%) and lung(63.6%). Nine patients undewent reoperation. Seven patients died during follow-up, including four disease-related death. The 5-year overall survival rate was 89.2% and 5-year disease-specific survival rate was 97.0%.

On multivariate analysis, lymph node metastasis was an independent risk factor for recurrence (HR 6.22, 95% CI 1.27-30.37, $P = .024$), while combined thyroidectomy showed a trend toward reduced recurrence risk but did not reach statistical significance.

Conclusion: Parathyroid carcinoma showed favorable long-term survival with a relatively low recurrence rate. Lymph node metastasis was the only independent predictor of recurrence, highlighting the importance of nodal assessment.

EP1703 - LBA_ECE_1126 - Improvement of symptomatic postprandial reactive hypoglycemia with a nutraceutical based on white mulberry, fenugreek, inulin, niacin, xhromium, zinc, and *Lactiplantibacillus plantarum* A7

Inmaculada Molinero-Marcos[1], Borja Santana-Ojeda[1], Sara Andrada-Diaz[2], Claudia Arnas-Leon[1,3], Ricardo Jose de Leon-Durango[1], Agnieszka Kuzior[3], Irene Hernandez-Hernandez[1], Carmen Acosta-Calero[4], Jennifer Maria Perez-Rivero[5] and Francisco Javier Martinez-Martin[1,3]

[1]Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Medical Advisory, Bioksan Naturalmente Juntos, Las Palmas de Gran Canaria, Spain; [3]Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain; [4]Cardiology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [5]Centro de Salud de Escaleritas, Las Palmas, Spain

Background and Objectives: Symptomatic postprandial reactive hypoglycemia is associated with hyperinsulinism and prior gastric surgery. Although rarely severe—except in occasional cases such as arrhythmia—it can significantly impair patients' quality of life. Current management includes dietary measures and, in some cases, off-label use of alpha-glucosidase inhibitors such as acarbose. These agents are effective in blunting postprandial hyperglycemia and reducing subsequent hyperinsulinemia, but their use is often limited by poor gastrointestinal tolerability.

White mulberry (*Morus alba*) contains 1-deoxynojirimycin, a potent competitive inhibitor of alpha-glucosidase. A nutraceutical has been developed combining a standardized white mulberry leaf extract, fenugreek (*Trigonella foenum-graecum*), inulin, *Lactiplantibacillus plantarum* A7, niacin, chromium, and zinc.

This study aimed to evaluate the tolerability and efficacy of this nutraceutical in patients with symptomatic postprandial reactive hypoglycemia, as well as its impact on quality of life.

Methods: We recruited patients diagnosed with symptomatic postprandial reactive hypoglycemia who had failed dietary management and had declined or were intolerant to treatment with acarbose. All participants presented documented symptomatic hypoglycemic episodes (<70 mg/dL), confirmed by capillary blood glucose measurements using test strips or continuous/

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

intermittent glucose monitoring. Patients were instructed to take one capsule of the nutraceutical daily before the main meal (usually lunch) with a glass of water. Episodes of hypoglycemia were registered and reported. Quality of life was assessed at baseline and after 3 months of treatment using the EuroQoL-5D-3L questionnaire.

Results: Fifteen patients were recruited (8 women; mean age 57 ± 9 years). Twelve had a history of gastric surgery (5 sleeve gastroplasty, 4 gastric by-pass, 2 fundoplication for reflux, 1 resection of gastric lymphoma), one had long COVID as a potential cause of reactive hypoglycemia, and two had prediabetes without another obvious cause. Five patients had previously received acarbose (off-label) with poor tolerance.

After 3 months of treatment, 12 out of 15 patients reported a clear clinical improvement. The frequency of hypoglycemic episodes decreased from 2.7 ± 1.2 to 0.3 ± 0.2 episodes per week (−89%, $P < .001$). Quality of life scores improved from 0.65 ± 0.12 to 0.84 ± 0.15 ($P = .008$).

Self-reported tolerability was excellent in 7 patients, good in 6, and acceptable in 2.

Conclusions: This nutraceutical was well tolerated and reduced symptomatic reactive hypoglycemia episodes by nearly 90%, significantly improving quality of life scores. Although originally designed for prediabetes and diabetes management, it may also represent a useful option in this therapeutic niche.

EP1704 - LBA_ECE_1301 - FDG-avid lipid-poor adrenal incidentaloma mimicking malignancy: a rare cortisol-secreting black adrenal adenoma

Eirini Melidou[1], Artemis Kyriakidou[1], Maria Grammatiki[1], Litsa Rakitzi[1,2], Triantafyllia Koletsa[3], Stylianos Apostolidis[4] and Kalliopi Kotsa[1]

[1]*Division of Endocrinology and Metabolism—Diabetes Center, 1st Department of Internal Medicine, Medical School, Aristotle University of Thessaloniki, AHEPA University Hospital, Thessalonki, Greece;* [2]*University Hospital AHEPA, Thessaloniki, Greece;* [3]*Laboratory of General Pathology and Pathological Anatomy, Aristotle University of Thessaloniki, Thessaloniki, Greece;* [4]*1st Propedeutic Surgical Department, Aristotle University of Thessaloniki, AHEPA University Hospital, Thessaloniki, Greece*

Objective: To report a rare case of a cortisol-secreting black adrenal adenoma detected during investigation of elevated carcinoembryonic antigen (CEA) levels.

Case Presentation: A 58-year-old woman with a history of total hysterectomy with bilateral salpingo-oophorectomy at age 47 for a uterine smooth muscle tumor of uncertain malignant potential (STUMP) was evaluated for persistently elevated CEA levels (12.3 ng/mL; reference < 6.5) detected during routine gastroenterological screening. Gastrointestinal endoscopy was normal. Computed tomography revealed a 22-mm left adrenal nodule and a thyroid nodule. Findings remained stable on follow-up imaging. 18F-FDG PET-CT demonstrated moderate metabolic activity in the thyroid nodule (SUV_{max} 3.2) and increased uptake in the adrenal lesion (SUV_{max} 7.3), raising suspicion of malignancy. Magnetic resonance imaging confirmed a 21 × 19 mm left adrenal mass without signal loss on chemical-shift sequences, consistent with a lipid-poor lesion and raising the possibility of metastatic disease. The patient was referred for endocrine evaluation. Hormonal assessment revealed hypercortisolism with abnormal suppression tests (overnight dexamethasone suppression test 1 mg: cortisol 20.5 μg/dL; low-dose dexamethasone suppression test: cortisol 21.27 μg/dL) and suppressed ACTH (<1.5 pg/mL), confirming ACTH-independent hypercortisolism. Twenty-four-hour urinary metanephrines and normetanephrines were normal, excluding pheochromocytoma, while renin, aldosterone and androgen levels were within normal limits. Clinically, the patient had hypertension, easy bruising and hair thinning without overt Cushingoid features. Thyroid ultrasound showed a 1.68-cm TIRADS-3 nodule with normal thyroid function and calcitonin. The patient underwent laparoscopic left adrenalectomy.

Follow-up: Postoperatively, hydrocortisone replacement was tapered and discontinued within two months. At follow-up visits at two and four months, blood pressure and hormonal parameters were normal. Histopathological examination confirmed an adrenocortical adenoma with intracytoplasmic lipofuscin deposition, consistent with a black adrenal adenoma. No malignant features were identified and Ki-67 <1% confirmed low proliferative activity.

Conclusion: Black adrenal adenomas are extremely rare benign tumors characterized by lipofuscin deposition. They are usually nonfunctioning adrenal incidentalomas, while cortisol or aldosterone secretion is uncommon. Because lipid-poor appearance and increased FDG uptake may mimic malignancy, careful endocrine evaluation and histopathological confirmation are essential. Surgical resection is curative and associated with excellent prognosis.

EP1705 - LBA_ECE_1103 - Wernicke's encephalopathy following GLP-1 receptor agonist use for weight loss: a case report

Anne Milligan[1] and Joseph Timmons[1,2]

[1]*University Hospital Wishaw, Lanarkshire, United Kingdom;* [2]*Glasgow, United Kingdom*

Wernicke's encephalopathy (WE) is a neurological emergency resulting from vitamin B1 (thiamine) deficiency. It's classic triad of symptoms -oculomotor dysfunction, ataxia and altered mental status- are present in only 16% of patients, making it a chronically under-diagnosed condition. Whilst WE is most commonly associated with chronic alcoholism, malnourishment (for example, starvation, extreme dieting, hyperemesis gravidarum and bariatric surgery) and hyper-catabolism (for example, cancer) are among other, far less recognised, states in which WE can develop. An emerging subgroup at risk of developing WE, is those taking glucagon-like peptide 1 receptor agonists (GLP-1RA). The therapeutic role of GLP-1RAs in obesity management has been increasingly recognised and endorsed over recent years. We will discuss a case of a patient presenting with non-specific neurological symptoms in the context of recent GLP-1RA use, and subsequent significant weight loss, who saw rapid resolution of symptoms with intravenous (IV) thiamine replacement. This case highlights the importance of nutritional supplementation with GLP-1RAs and the need for early consideration of a WE diagnosis in patients receiving GLP-1 receptor agonists, allowing prompt and sufficient treatment, and prevention of irreversible neurological damage.

EP1706 - LBA_ECE_1386 - The great masquerader: pheochromocytoma presenting as type 2 diabetes mellitus

Ricardo Jose de Leon-Durango[1], Borja Santana-Ojeda[1], Inmaculada Molinero-Marcos[1], Claudia Arnas-Leon[1,2], Alba Hernandez-Lazaro[1,3], Marta Sánchez[1], Agnieszka Kuzior[2], Carmen Acosta-Calero[4], Fabianna Genesi[5] and Francisco Javier Martinez-Martin[1,2]

[1]Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain; [3]Servei d'Endocrinologia i Nutricio, Parc Taulí Hospital Universitari, Sabadell, Barcelona, Spain; [4]Cardiology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [5]Centro de Salud de Arucas, Arucas, Las Palmas, Spain

Background: Catecholamine excess in pheochromocytoma can induce hyperglycemia occasionally mimicking type 2 diabetes mellitus (T2DM). Although typically symptomatic, some tumors remain clinically silent. We report an incidental, asymptomatic pheochromocytoma presenting as apparent type 2 diabetes, which remitted following tumor resection.

Case Presentation: A 56-year-old woman with a normal body mass index was referred to our Endocrinology Clinic following the incidental discovery of an indeterminate left adrenal mass on abdominal CT, performed during the evaluation of recurrent abdominal pain. The lesion measured 3.4 cm in maximum diameter, with a density of 30-40 Hounsfield units. The patient was normotensive, had no history of tremor or tachycardia, and showed no Cushingoid features.

Five years earlier, she had been diagnosed with T2DM, presenting with polydipsia, polyuria, and marked hyperglycemia. Latent autoimmune diabetes in adults (LADA) was excluded based on negative anti-GAD antibodies. Glycemic control had been acceptable (HbA1c 6.8%) with diet, regular exercise, metformin, sitagliptin, and a relatively high dose of basal insulin (approximately 0.75 U/kg), after failure to achieve adequate control without insulin.

Adrenal evaluation revealed a normal cortisol suppression test and normal aldosterone, renin, and aldosterone-to-renin ratio. However, plasma metanephrines and chromogranin A were markedly elevated (metanephrine 412 pg/mL, normetanephrine 335 pg/mL, chromogranin A 324 ng/mL). An MIBG scan confirmed a left pheochromocytoma without evidence of additional lesions. The tumor was successfully removed via robotic laparoscopic adrenalectomy without complications. Histopathological analysis confirmed a pheochromocytoma with low malignant potential (PASS score 3).

Postoperatively, the patient developed frequent hypoglycemic episodes, predominantly nocturnal. Basal insulin doses were progressively reduced and eventually discontinued, followed by withdrawal of sitagliptin and metformin.

Ten months after surgery, the patient remains asymptomatic, with normal plasma metanephrines and chromogranin A levels. Her diabetes has apparently remitted, with an HbA1c of 5.6% in the absence of pharmacological treatment.

Discussion: This case illustrates an atypical presentation of pheochromocytoma, lacking classical adrenergic symptoms and identified incidentally. Catecholamine excess (particularly in epinephrine secreting tumors, as in our case) can induce hyperglycemia through increased hepatic glucose production, impaired insulin secretion, and insulin resistance, thereby mimicking T2DM. The requirement for relatively high insulin doses despite normal BMI may represent a clinical clue. The marked improvement and eventual remission of diabetes following tumor resection support a causal relationship.

Conclusions: Pheochromocytoma should be considered in atypical or difficult-to-control diabetes. Recognition of this reversible cause of hyperglycemia is essential, as surgical treatment may lead to complete remission.

EP1707 - LBA_ECE_1349 - Uncontrolled hyperthyroidism mimicking pseudo-hypoandrogenism: SHBG-mediated peripheral androgen resistance in a male with poorly controlled Graves' disease

Inmaculada Molinero-Marcos[1], Borja Santana-Ojeda[1], Claudia Arnas-Leon[1,2], Ricardo Jose de Leon-Durango[1], Alba Hernandez-Lazaro[1], Agnieszka Kuzior[2], Carmen Acosta-Calero[3], Maria del Pino Perez-García[4], Paula Maria Fernandez-Trujillo-Comenge[1] and Francisco Javier Martinez-Martin[1,2]

[1]Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain; [3]Cardiology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [4]Family & Community Medicine, Centro de Salud San Gregorio, Telde, Las Palmas, Spain

Background: Uncontrolled hyperthyroidism robustly increases hepatic sex hormone-binding globulin (SHBG) synthesis via direct T3 stimulation, leading to elevated total testosterone with paradoxically normal or low free testosterone. This creates a state of functional peripheral androgen resistance (pseudo-hypoandrogenism) without primary hypogonadism, often overlooked and prompting unnecessary urologic investigations for androgen-secreting tumors.

Case Presentation: A male patient with Graves' disease diagnosed in 2022, marked by persistent non-adherence and loss to follow-up, was referred from Urology in September 2025 for persistently elevated total testosterone (>2× upper limit of normal) without virilizing features. Biochemical evaluation confirmed severe uncontrolled hyperthyroidism (free T4 3.07 ng/dL, TSH undetectable) without clinically evident ophthalmopathy. Total testosterone was markedly elevated, yet free testosterone remained within normal range; gonadotropins (LH/FSH) were normal, testicular ultrasound unremarkable, and tumor markers negative. SHBG was strikingly elevated, attributable solely to sustained thyrotoxicosis. The patient exhibited classic hyperthyroid symptoms (tachycardia, tremor) but was not receiving antithyroid therapy.

Discussion and Management: This presentation exemplifies SHBG-driven discordance in androgen profiling, where hyperthyroidism induces a reversible, functional hypoandrogenic state by sequestering testosterone. It averted invasive workup for neoplasm and highlighted the pitfalls of interpreting total

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

testosterone in isolation. Given poor adherence, absent active ophthalmopathy, and recurrent loss to follow-up, definitive radioiodine (^{131}I) therapy was recommended as the optimal strategy to achieve euthyroidism, normalize SHBG, restore physiologic androgen balance, and prevent future complications.

Conclusions: This case emphasizes two pivotal clinical pearls: (1) always contextualize elevated total testosterone with SHBG and thyroid status to avoid misdiagnosis of androgen excess; and (2) prioritize definitive ^{131}I ablation in non-adherent Graves' patients without contraindicating ophthalmopathy. Multidisciplinary endocrinology-urology collaboration proved essential in steering accurate diagnosis and targeted therapy.

EP1708 - LBA_ECE_1373 - Atypical presentation of acute thyroiditis masking recurrent laryngeal carcinoma—a case report

Radina Dimitrova[1], Zhenya Ruseva[1], Mira Siderova[1], Georgi Davidov[2], Rumen Nenkov[3] and Lyuben Stoev[4]
[1]*Second Department of Internal Medicine, Medical University of Varna, Clinic of Endocrinology and Metabolic Diseases, Varna, Bulgaria;* [2]*Department of Neurosurgery and ENT, Medical University of Varna, Clinic of ENT, Varna, Bulgaria;* [3]*Department of Surgery, Medical University of Varna, Clinic of Thoracic surgery, Varna, Bulgaria;* [4]*Department of General and Clinical Pathology, Forensic Medicine and Deontology, Medical University of Varna, Varna, Bulgaria*

Introduction: Acute thyroiditis usually manifests with sudden onset of fever, neck pain and tenderness. However, atypical painless forms pose substantial diagnostic challenges as they can resemble or coexist with regional malignancies. Here, we present a rare case of severe necrotizing thyroiditis that has masked a late recurrence of laryngeal cancer.

Case Report: A male patient presented with a rapid growing anterior neck mass, progressive dysphagia and dyspnea. Notably, the patient had a history of laryngeal carcinoma (pT2NxMx) treated surgically five years prior and deemed in remission. No neck pain or fever was reported.

Laboratory findings revealed markedly elevated inflammatory markers and constellations for thyrotoxicosis. Computed tomography (CT) revealed large polylobulated formation involving the entire thyroid gland (suspected abscess 30 × 71 × 82 mm). Due to diagnostic uncertainty, fine-needle biopsy (FNA) was performed, yielding a greenish, malodorous aspirate. Cytology demonstrated cells with marked signs of necrosis. Despite the aspirate's suspicious features and empiric triple antibiotic therapy, microbiology cultures remained sterile.

Due to the mechanical airway obstruction and high mediastinitis risk the patient underwent urgent surgery with team of thoracic and otorhinolaryngology specialists.

Intraoperatively, around 100 mL of thick purulent discharge was evacuated. Histopathology confirmed acute thyroiditis, with recurrent laryngeal carcinoma infiltrating left laryngeal part as an incidental finding.

Conclusion: This case highlights the potential for severe necrotizing thyroiditis to present without the classic "red flag" symptoms (fever, pain, tenderness). Concurrent or etiologic recurrent laryngeal carcinoma emphasizes the need for rigorous diagnostic evaluation in patients exhibiting obstructive symptoms. Sterile cultures despite purulent-appearing aspirate should prompt consideration of malignancy-associated necrosis over primary infection. Expedited surgical intervention is critical to avert airway compromise and delineate overlapping pathologies when clinical and microbiological data are discordant.

EP1709 - LBA_ECE_1124 - Tocilizumab in refractory pretibial myxedema: new therapeutic frontiers?

Silvia Corrias, Federica Diana, Francesca Sedda, Claudia Corda, Giuseppe Giannaccare, Stefano Mariotti, Francesco Boi and Giulia Lanzolla
Cagliari, Italy

Introduction: Pretibial myxedema (PTM), is a rare extrathyroidal manifestation of Graves' disease (GD), occurring in approximately 1%-4% of patients and with concomitant Graves' Orbitopathy (GO) present in nearly all reported cases. It presents as bilateral non-pitting edema of the pretibial region, occasionally accompanied by hyperkeratotic and hyperpigmented papules and plaques.

Case Report: We report the case of a GD female patient treated with total thyroidectomy in 2022. In November 2024, following the development of moderate-to-severe active GO, first-line therapy with high-dose intravenous glucocorticoids (ivGCs) was initiated. At baseline, the patient presented with bilateral proptosis of 25 mm, eyelid aperture of 18 mm, intermittent diplopia and CAS 6/7. Six months after ending treatment, partial response was observed: CAS improved to 4/7 and eyelid aperture reduced to 16 mm, while proptosis remained unchanged at 25 mm. However, at one-year follow-up, disease worsening was documented, with CAS returning to 5/7, persistent proptosis of 25 mm, eyelid aperture of 16 mm and inconstant diplopia in supraversion and lateroversion. Concurrently, the patient had developed bilateral PTM approximately 18 months after thyroidectomy, refractory to topical corticosteroids and occlusive bandaging.

Given the inadequate and non-sustained response of GO to first-line therapy, tocilizumab (8 mg/kg monthly infusion for 6 months) was initiated in July 2025. After 6 months of treatment, marked improvement in GO was observed: proptosis reduced to 23 mm (OD) and 22 mm (OS), eyelid aperture decreased to 13 mm, diplopia became intermittent, and CAS improved to 2/7. Notably, the patient reported rapid and significant improvement of PTM following the first infusion, with progressive marked reduction of edema and local symptoms confirmed at subsequent visits. No significant adverse events were recorded.

Discussion: The pathogenesis of PTM remains incompletely understood, but it is considered an autoimmune condition likely sharing key immunomediated mechanisms with GO. Interleukin-6 (IL-6) is a key pro-inflammatory cytokine implicated in GO pathogenesis, and tocilizumab, a monoclonal antibody targeting the IL-6 receptor, has demonstrated efficacy in moderate-to-severe active GO refractory to ivGCs. To our knowledge, this is the first reported case of PTM successfully treated with tocilizumab. Given the shared pathogenetic background of GO and PTM, IL-6 inhibition may represent an effective

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

therapeutic option not only for ivGC-refractory GO but also for refractory PTM, by targeting fibroblast activation and underlying autoimmune inflammatory cascade. Further studies are warranted to confirm the therapeutic role of tocilizumab in PTM and to define optimal treatment protocols.

Background: The optimal treatment of biopsy-proven cervical lymph node recurrence in differentiated thyroid cancer (DTC) has not been established. Although surgery is the preferred approach for structural disease, RAI therapy is used in selected patients. Comparative data on biochemical outcomes between these modalities remain scarce.

Methods: We conducted a retrospective cohort study of 104 adult patients with pathologically confirmed nodal recurrence of DTC treated between 2019 and 2025 at Ankara Bilkent City Hospital. Patients received either surgical resection ($n = 72$) or RAI therapy ($n = 32$) as the initial treatment. The primary outcome was anti-thyroglobulin antibody (AntiTg) negativity at 1 year; secondary outcomes included AntiTg status at last follow-up, need for additional treatment, and time to biochemical event.

Results: One-year AntiTg negativity was achieved in 22/32 patients (68.8%) in the RAI group and 49/72 (68.1%) in the surgery group ($P = 1.000$). AntiTg negativity at last follow-up was 74.1% vs 66.1% ($P = .628$). Additional treatment rates were similar (64.5% vs 71.4%, $P = .645$). Median 1-year Tg was 3.39 ng/mL (RAI) vs 1.17 ng/mL (surgery) ($P = .129$). Kaplan–Meier analysis showed no difference in time to AntiTg positivity (log-rank $P = .894$). On multivariable analysis, treatment modality was not associated with 1-year biochemical response (adjusted OR = 0.88, 95% CI 0.34-2.28), whereas baseline AntiTg negativity was the strongest predictor of response ($P < .001$).

Conclusion: In patients with biopsy-proven nodal recurrence of DTC, surgery and RAI yielded comparable biochemical outcomes. Baseline AntiTg status, rather than treatment modality, was the primary predictor of response. In selected patients with limited nodal disease, RAI may be a reasonable alternative to surgery, with AntiTg status serving as a key prognostic marker.

Table Primary and secondary outcomes according to initial treatment strategy.

Outcome	RAI *n*/*N* (%)	Surgery *n*/*N* (%)	RR (95% CI)	OR (95% CI)	*P* value
1-year AntiTg negativity (primary)	22/32 (68.8)	49/72 (68.1)	1.01 (0.76-1.34)	1.03 (0.42-2.53)	1.0
No additional treatment needed	20/31 (64.5)	50/70 (71.4)	0.90 (0.67-1.22)	0.73 (0.30-1.79)	.645
Last follow-up AntiTg negativity[a]	20/27 (74.1)	37/56 (66.1)	1.12 (0.84-1.50)	1.47 (0.53-4.08)	.628
1-year Tg level (ng/mL)	median (IQR)	3.39 (1.90-5.39)	1.17 (0.41-4.51)	-	.129

RR and OR presented with 95% CI.
Percentages based on available data. AntiTg negativity defined per institutional reference range.
Anti-tg, Anti-Thyroglobulin Antibodies; tg, Thyroglobulin.
[a]Most recent available follow-up measurement for each patient.

EP1713 - LBA_ECE_1229 - Adrenal adenoma causing apparent 21-hydroxylase deficiency: a case report of a non-classic congenital adrenal hyperplasia mimic

Sandra Urbina Solano[1], Marta Iturregui Guevara[1] and Mariana Jesús Gomes Porras[1,2,3]

[1]Endocrinology and Nutrition, Regional University Hospital of Málaga, Malaga, Spain; [2]Institute of Biomedical Research of Málaga (IIBIMA), BIONAND Platform, Málaga, Spain; [3]Biomedical Research Networking Center for Diabetes and Associated Metabolic Diseases (CIBERDEM), group CB07/08/0019, Málaga, Spain

We present the case of a 40-year-old man who consulted for a six-month history of gynecomastia and decreased libido, without medication use or apparent testicular abnormalities. Initial laboratory findings were consistent with hypogonadotropic hypogonadism (FSH 0.55 mIU/mL, LH 1.15 mIU/mL, estradiol 88 pg/mL, testosterone 1.22 ng/mL), with normal TSH and prolactin levels. Semen analysis and testicular ultrasound were unremarkable. Pituitary MRI showed no abnormalities.

Topical testosterone therapy was initiated, resulting in minimal clinical improvement. Follow-up laboratory testing at three months demonstrated further suppression of gonadotropins and testosterone (FSH 0.35 mIU/mL, LH 0.46 mIU/mL, estradiol 49 pg/mL, testosterone 1.01 ng/mL). Therapy was then switched to intramuscular testosterone every three weeks for 8 months. After a six-week washout period, hormone levels worsened (FSH < 0.3 mIU/mL, LH 0.50 mIU/mL, estradiol 97 pg/mL, testosterone 0.88 ng/mL). Intramuscular testosterone therapy was continued for eight months, and during the treatment, gynecomastia resolved, and

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

libido returned. After discontinuation, spontaneous normalization of serum testosterone levels (2.91 ng/mL) was observed, while 17-hydroxyprogesterone levels remained elevated (5.32 ng/mL).

An ACTH stimulation test demonstrated results consistent with non-classic congenital adrenal hyperplasia. An abdominal CT scan was performed to exclude neoplasia, which revealed a left adrenal lesion 26 × 29 mm with attenuation <10 HU, suggestive of an adrenal adenoma. Therefore, the most likely diagnosis was non-classic congenital adrenal hyperplasia with an associated adrenal lesion. However, negative genetic testing for variants in CAH-related genes leads to consideration of the possibility of an androgen-secreting adrenal tumor, a rare entity.

Finally, a left adrenalectomy was performed, and histopathological analysis confirmed an adrenal adenoma. Three months after surgery, serum 17-hydroxyprogesterone and androstenedione levels normalized. An ACTH stimulation test demonstrated recovery of normal 21-hydroxylase activity.

EP1717 - LBA_ECE_1183 - Effectiveness and safety of palopegteriparatide in clinical practice: a real-world experience from a Spanish region

Jorge González Prieto[1], Laura María Martín Flores[1], Jesús Manuel Morán López[2], Juan Manuel Parra Barona[3], Marelis Triana Borroto[4] and Francisco Morales Pérez[1]
[1]*Hospital Universitario de Badajoz, Badajoz, Spain;* [2]*Hospital Virgen Del Puerto, Plasencia, Spain;* [3]*Hospital De Mérida, Mérida, Spain;* [4]*Hospital Campo Arañuelo, Navalmoral de la Mata, Spain*

Introduction: Chronic hypoparathyroidism is a rare endocrine disorder characterized by hypocalcemia and impaired calcium-phosphate homeostasis, traditionally managed with oral calcium and active vitamin D. However, conventional therapy is often associated with poor biochemical control, fluctuations in serum calcium, and renal complications. Palopegteriparatide, a long-acting parathyroid hormone analog, has emerged as a novel therapeutic option, although real-world data remain limited.

Methods: This multicenter retrospective observational study included adult patients with chronic hypoparathyroidism treated with palopegteriparatide in routine clinical practice in Extremadura, Spain. Demographic, clinical, and biochemical data, including calcium-phosphate parameters, renal function, and treatment requirements, were collected before and after treatment initiation. Comparisons were performed using the Wilcoxon signed-rank test ($P < .05$).

Results: Eight patients were included (62% female), with a mean age of 52.4 ± 15.9 years and hypoparathyroidism duration of 13.3 ± 8.7 years. Baseline PTH was 5.81 ± 2.91 pg/mL and 25-hydroxyvitamin D 29.4 ± 12.0 ng/mL. Mean treatment duration with palopegteriparatide was 3.5 ± 1.5 months. Etiology was postsurgical in 75% and idiopathic in 25%. Indications for treatment were recurrent hypocalcemia (75%), renal impairment (50%), nephrolithiasis (37%), and prior hospitalizations due to calcium disturbances (25%).

Following treatment initiation, corrected calcium increased significantly from 7.77 ± 0.91 to 9.33 ± 0.56 mg/dL ($P = .017$), while no significant changes were observed in serum phosphorus (4.70 ± 0.99 to 4.24 ± 0.79 mg/dL; $P = .246$) or estimated glomerular filtration rate (76.0 ± 26.4 to 84.8 ± 24.6 mL/min/1.73 m^2; $P = .500$). Calcium carbonate requirements markedly decreased from 5962 ± 7277 to 275 ± 511 mg/day, and calcitriol was discontinued in all patients. After treatment optimization, normalization of corrected calcium and serum phosphorus was achieved in 100% of cases.

All patients (100%) reported high satisfaction after switching from conventional therapy to palopegteriparatide. Regarding safety, one patient experienced transient pruritus at the injection site, and 75% presented mild episodes of hypo- or hypercalcemia, all of which resolved without requiring emergency or hospital care.

Conclusions: Palopegteriparatide treatment in patients with chronic hypoparathyroidism was associated with rapid and effective normalization of calcium homeostasis, allowing discontinuation of conventional therapy. Despite the small sample size, a significant improvement in corrected calcium levels was observed, with consistent biochemical control achieved in all patients. Treatment was well tolerated and was associated with high patient satisfaction. These findings support palopegteriparatide as an effective and well-accepted therapeutic option in the management of hypoparathyroidism.

Abstract citation ID: lvag096.1784

EP1719 - LBA_ECE_1405 - Clinical case: resistance to thyroid hormone syndrome in a patient after treatment for papillary thyroid carcinoma

Viktoria Sadovskaya
Endocrinology and Metabolic Disorders, Fomin Clinic, Moscow, Russia

Background: Resistance to thyroid hormone (RTH) syndrome is a rare genetic disorder most commonly caused by mutations in the THRB gene. Diagnosing RTH in patients after thyroidectomy for thyroid cancer is challenging because the clinical picture of thyrotoxicosis during high-dose levothyroxine therapy may be misinterpreted as iatrogenic hyperthyroidism, while inappropriate dose reduction carries a risk of tumor progression.

Clinical Case: A 30-year-old female patient. She had a history of multinodular goiter; in January 2023, fine-needle aspiration biopsy revealed papillary thyroid carcinoma (pT1bN1M0). Total thyroidectomy with central lymph node dissection was performed, followed by radioactive iodine therapy (3700 MBq) in March 2023. After surgery she was started on levothyroxine replacement.

She complained of hair loss, hot flashes, and tachycardia. Attempts to adjust the levothyroxine dose were complicated by extreme fluctuations in TSH levels:

- on 88 µg/day, TSH was 49.06 µIU/mL;
- on 112-125 µg/day, TSH ranged from 15.7 to 1.25 µIU/mL.

Target TSH suppression (<0.1 µIU/mL) could not be achieved. While taking 125 µg/day, TSH was 1.23 µIU/mL and free T4 was elevated to 1.92 ng/dL, with normal levels of anti-TPO and anti-TG antibodies.

Given the discrepancy between high levothyroxine doses, failure to achieve adequate TSH suppression, and clinical signs of thyrotoxicosis, resistance to thyroid hormone was suspected. Genetic testing confirmed a mutation in the THRB gene, establishing the diagnosis of RTH.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusion: Resistance to thyroid hormone should be considered in post-thyroidectomy patients when target TSH suppression cannot be achieved with high levothyroxine doses and the clinical picture combines features of thyrotoxicosis with biochemically elevated free T4. Genetic confirmation helps avoid unnecessary dose escalation and reduces the risk of treatment-related adverse effects.

EP1720 - LBA_ECE_1145 - Booking HbA1c as a marker of preconception care delivery in women with type 2 diabetes: a service evaluation from a UK centre

Charlotte Jones, Fareeha Ikram, Dilawar Khan, Nomaira Hassan and Ammara Naeem
Croydon University Hospital, Diabetes and Endocrinology department, London, United Kingdom

Background: Optimising glycaemic control prior to conception is critical in reducing adverse maternal and neonatal outcomes in women with type 2 diabetes mellitus (T2DM). Despite clear national and international recommendations advocating structured preconception care, real-world delivery remains inconsistent. Recent evidence further highlights persistent gaps between guideline recommendations and clinical practice. We evaluated booking HbA1c as a pragmatic marker of preconception care effectiveness in our population.

Methods: We conducted a retrospective service evaluation of women with T2DM booked for antenatal care at a single UK centre over a 12-month period (August 2024—August 2025). Data were extracted from electronic health records, including demographics, preconception care indicators (documented counselling and 5 mg folic acid use), diabetes management, and HbA1c at booking and 28 weeks' gestation. Pregnancy outcomes, including gestational age at delivery and birthweight centiles, were also analysed.

Results: Forty-four pregnancies were identified. Mean maternal age was 33 years, with a diverse ethnic distribution (White 14%, Asian 29%, Black 29%, other 28%). Mean booking BMI was 32 kg/m^2.

Mean booking HbA1c was 60 mmol/mol, with only 10/44 (23%) achieving the recommended target of ≤48 mmol/mol. Booking took place between 5-20 weeks at an average of 9 weeks. Most women were on metformin, insulin, or a combination (27%, 11% and 34% respectively) with the remaining on diet (14%) or on other oral medication not recommended in pregnancy (14%) that were stopped at booking.

Evidence of preconception care was limited: 2/44 (5%) had documented preconception counselling, and 10/44 (23%) were recorded as taking 5 mg folic acid prior to conception.

Women with target booking HbA1c demonstrated more favourable outcomes, with a higher proportion of term deliveries (88% vs 69%) and infants with birthweight within the 10th–95th centile (100% vs 65%) compared to those above target.

Conclusions: This evaluation demonstrates substantial gaps in the delivery and documentation of preconception care for women with T2DM, reflected in suboptimal glycaemic control at booking. Although limited by sample size, our findings show a consistent signal towards improved perinatal outcomes in women achieving target HbA1c prior to pregnancy.

In the context of growing evidence highlighting deficiencies in preconception care uptake, our data reinforce the need for system-level interventions, including strengthened primary—secondary care collaboration, improved identification of women of reproductive age with type 2 diabetes, and accessible, funded preconception pathways. Booking HbA1c represents a simple and clinically meaningful metric to monitor and drive improvements in preconception care delivery.

EP1721 - LBA_ECE_1237 - Brown adipose tissue status modifies the dynamic proteomic response to cold exposure in humans

Filip Bossowski[1], Dominik Cysewski[2], Tomasz Kowalczyk[2], Magdalena Bossowska[1], Katarzyna Miniewska[3], Edyta Adamska-Patruno[4], Adam Krętowski[1] and Katarzyna Maliszewska[1]
[1]Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Bialystok, Bialystok, Poland; [2]Centre of Regenerative Medicine, Medical University of Bialystok, Bialystok, Poland; [3]Department of Medical Biochemistry, Medical University of Bialystok, Bialystok, Poland; [4]Clinical Research Centre, Medical University of Bialystok, Bialystok, Poland

Background: Brown adipose tissue (BAT) activation is a potential therapeutic target for metabolic disorders, yet the effects of BAT on the circulating proteome are not well characterized. This study examined whether BAT status is associated with a distinct baseline proteomic signature at rest and whether it alters the proteomic response to acute cold stimulation.

Methods: Twenty-five healthy, non-smoking Caucasian men (median age 25-28 years) were recruited and completed a standardized 120-minute cold exposure protocol. BAT activity was quantified by 18F-FDG PET/MR imaging. Participants were classified as BAT-positive (BAT(+), $n = 17$) or BAT-negative (BAT(−), $n = 8$) using a glucose uptake rate threshold of $>2.0\ \mu mol \cdot (100\ g)^{-1} \cdot min^{-1}$; groups were matched for age and BMI. Plasma samples collected at 0, 60, and 120 minutes were analyzed with a targeted proteomics panel. The assay used 804 stable-isotope-labeled standard reference peptides to quantify 582 human plasma proteins. Differential abundance was assessed with linear models using empirical Bayes moderation, testing baseline differences and BATxTime interactions.

Results: At baseline (0 min), no proteins differed significantly between groups after false discovery rate (FDR) correction, indicating that BAT status was not associated with a distinct baseline plasma proteomic signature at rest. In contrast, longitudinal analyses over 120 minutes identified BATxTime interaction effects consistent with BAT-dependent divergence during cold exposure. Thirty-three proteins showed a nominal BATxTime interaction ($P < .05$), with opposite-direction trajectories in BAT(+) versus BAT(−) subjects. Vinculin showed the strongest interaction (interaction FDR = 0.076): levels increased in BAT(+) subjects (log2FC approximately +5.6) but decreased in BAT(−) subjects (log2FC approximately −8.0) during cold exposure. Sensitivity analyses showed that these interaction effects persisted after adjustment for BMI.

Conclusions & Clinical Relevance: BAT status dictates a highly dynamic, rather than static, proteomic response to thermogenic stress. The extreme divergence of vinculin provides a direct, systemic readout of acute cytoskeletal remodeling and focal adhesion turnover occurring strictly in BAT(+) individuals during activation.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Clinically, rather than relying on radioactive imaging, tracking the plasma trajectories of vinculin and associated mechanotransduction proteins offers a novel foundation for the liquid biopsy-based therapeutic monitoring of BAT-activating pharmacotherapies in metabolic disease.

Abstract citation ID: lvag096.1787

EP1723 - LBA_ECE_1257 - Vanishing Testes Syndrome (VTS): emerging insights from a pediatric case series

Vasiliki Siampanopoulou[1], Sofia Lekka[2], Maria Tzoraki[2,3], Maria Kafetzi[4], Georgia Pepe[5] and Elpis Vlachopapadopoulou[2]

[1]Unit of Endocrinology, First Department of Internal Medicine, National and Kapodistrian University of Athens, Laiko General Hospital of Athens, Athens, Greece; [2]Department of Endocrinology, «P. and A. Kyriakou» Children's Hospital of Athens, Athens, Greece; [3]Endocrinology-Growth and Development, Children's Hospital "P. & A. Kyriakou", Athina, Greece; [4]Biochemical Department, «P. and A. Kyriakou» Children's Hospital of Athens, Athens, Greece; [5]Genekor Medical SA, Athens, Greece

Introduction: Congenital anorchia, also known as VTS, is a rare cause of primary hypogonadism in boys and is characterized by the absence of functional testicular tissue in individuals with a 46,XY karyotype. Early diagnosis is essential to ensure appropriate hormonal, surgical, and psychosocial management.

Objective: To present a case series of five pediatric patients with congenital anorchia and their management including pubertal induction and final height.

Methods: A retrospective study of five boys who presented with bilateral anorchia at a tertiary pediatric endocrinology clinic.

Results: All patients presented with normal penile size without hypospadias, shallow scrotum and non-palpable testes. Laboratory evaluation showed a 46,XY karyotype, consistent with 46XY,DSD, hypergonadotropic hypogonadism [median value of LH = 15.25 mIU/mL (min:10, max:202) and FSH = 119 mIU/mL (min:15, max:253) respectively] and undetectable testosterone levels. Median age at diagnosis was 14 months (min: 3, max: 40). Imaging did not reveal functional testicular tissue; in some cases, atrophic testicular remnants were detected, suggesting an intrauterine vascular event or torsion. Findings were confirmed by ultrasonography in all patients and by laparoscopy in two.

All patients received testosterone replacement therapy during puberty; median age of initiation: $12^{6/12}$ years (min: $11^{9/12}$ years, max: $14^{11/12}$ years), with a gradual dose titration, resulting in growth acceleration, normal penile size, and development of secondary sexual characteristics. Four patients reached their final height [median = 170 cm (min: 165, max: 172)], corresponding to the 5^{th}-25^{th} percentiles. One patient was below target height ($H_{final}/H_{target} = 169/178 \pm 5$ cm), while three were within their respective target height ranges (H_{final}/H_{target}: $172/178 \pm 5$ cm, $165/167 \pm 5$ cm, $171/176 \pm 5$ cm). One patient has not yet reached final height (chronological age: $11^{9/12}$), but is currently at the 75th percentile ($H_{current}/H_{target} = 153/170 \pm 5$ cm).

Testicular prostheses were placed in three patients at a median age of 16 years (min: 15, max: $17^{3/12}$ years). One patient is below the recommended age and one declined due to personal preferences. Whole exome sequencing (WES) was performed in one patient and did not identify pathogenic variants among the 118 genes included in the analyzed panel.

Conclusions: Congenital anorchia represents a heterogeneous condition with variable pathogenetic mechanisms. Systematic clinical and hormonal evaluation, combined with operative evaluation is essential for the diagnosis. This case series highlights the importance of early diagnosis and timely testosterone treatment to achieve normal pubertal development and growth. Nowadays, incorporating comprehensive genetic testing into the diagnostic approach for patients with vanishing testes syndrome is valuable to clarify the etiology and optimize management.

EP1724 - LBA_ECE_1232 - Genetically confirmed HNF1A-MODY with severe autoimmune β-cell failure: evidence for a true overlap phenotype

Ayse Nur Gul and Meliha Melin Uygur

Department of Endocrinology, Faculty of Medicine, Recep Tayyip Erdoğan University, Rize, Turkey

Background: Maturity-Onset Diabetes of the Young (MODY) is a monogenic form of diabetes characterized by non-autoimmune β-cell dysfunction, most commonly due to HNF1A mutations. In contrast, Type 1 Diabetes Mellitus results from immune-mediated β-cell destruction and is defined by the presence of pancreatic autoantibodies. These entities are traditionally considered mutually exclusive; however, emerging evidence suggests that overlapping mechanisms may occur, challenging the current classification paradigm.

Case Presentation: A 47-year-old man was diagnosed with diabetes at age 29 and initially classified as type 1 diabetes. He presented with weight loss without documented ketoacidosis. His body mass index was 28.6 kg/m^2. Family history revealed diabetes in multiple maternal relatives, suggesting a hereditary component. He was treated from diagnosis with basal–bolus insulin therapy using multiple daily injections (MDI). Despite long-term treatment, glycaemic control progressively deteriorated (HbA1c from 9.1% at diagnosis to 10.3% currently), and microvascular complications including diabetic retinopathy and peripheral neuropathy developed. Immunological evaluation showed strongly positive anti-glutamic acid decarboxylase antibodies (209 U/mL), while islet cell antibodies were initially positive but became negative during follow-up. Fasting C-peptide was <0.10 ng/mL, indicating near-complete β-cell failure. Genetic testing identified a pathogenic HNF1A mutation, confirming HNF1A-MODY. Sulfonylurea therapy was not initiated due to the severe insulin-deficient phenotype.

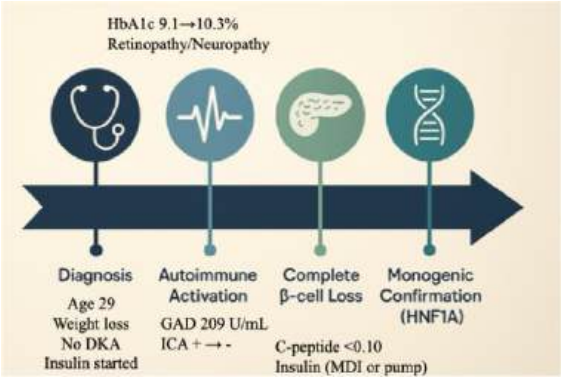
Discussion: This case demonstrates a true overlap between HNF1A-MODY and autoimmune diabetes, characterized by coexistence of a monogenic β-cell defect and profound immune-mediated β-cell destruction. Unlike classical HNF1A-MODY, which is associated with preserved endogenous insulin secretion and high sensitivity to sulfonylureas, this patient exhibited complete insulin deficiency and a clinical course indistinguishable from long-standing autoimmune diabetes. A plausible explanation is a sequential dual-hit mechanism, whereby chronic β-cell dysfunction due to HNF1A mutation increases cellular stress and immunogenicity, facilitating autoimmune activation in genetically susceptible individuals.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusion: Autoimmune diabetes does not exclude monogenic diabetes, even in genetically confirmed HNF1A-MODY. In patients with atypical features, strong family history, or discordant clinical progression, overlapping mechanisms should be considered. Recognition of this phenotype has important implications for diabetes classification, therapeutic decision-making, and genetic counselling, supporting a shift toward a more integrated, mechanism-based approach.

FEATURE	TYPICAL HNF1A-MODY	THIS CASE
Antibodies	Negative	Strongly positive
C-peptide	Preserved	Absent
Treatment	Sulfonylurea	Insulin
Course	Mild-progressive	Severe

Phenotypic Divergence Between Classical HNF1A-MODY and Overlap Diabetes.



Sequential Dual-Hit Model of β-Cell Failure.

Keywords HNF1A-MODY, autoimmune diabetes, overlap phenotype, monogenic diabetes

Abstract citation ID: lvag096.1789

EP1725 - LBA_ECE_1089 - A wolf in sheep's clothing: unmasking CAH in a "PCOS" patient with co-occurring POTS and Ehlers-Danlos syndrome

Rana Almudhammed[1,2]
[1]*Department of Biochemistry and Internal Medicine, Diyala College of Medicine, Private Clinic, Baghdad, Iraq;* [2]*Physiology and Internal Medicine, Diyala College of Medicine, Diyala, Iraq*

24 year old female presented with a five-year history of irregular menstrual cycles, oligomenorrhea alternating with menorrhagia, lower facial acne, and hirsutism. She also reported symptoms of chronic sleepiness, tiredness, brain fog, occasional palpitations, orthostatic intolerance, exercise intolerance and easy fatiguability.

Clinical signs included facial lower face acne, mild hirsutism, no androgenetic alopecia, no central obesity or signs of insulin resistance, no striae or other skin manifestation.

Examination revealed joint hypermobility, skin laxity, widespread joint pain, no joint swelling, she exhibited unexplained, non-traumatic easy bruising.

The patient denies any symptoms of depression or anxiety.

2. Clinical and Laboratory Findings: Examination revealed a lean phenotype with no signs of insulin resistance. Evaluation using the Beighton score confirmed a diagnosis of hypermobile Ehlers-Danlos Syndrome (hEDS) as described by Rhumatologist.

C REACTIVE PROTEIN	Normal
ACTH	26
Stimulated Cortisol	550 nmol/L
Hemoglobin (Hb)	12 g/dL
Blood Pressure (BP)	110/70 mmHg
Total Testosterone	0.9 ng/mL
DHEAS	1000 i.u.
Prolactin	19 ng/mL
TSH	2.5 mIU/L
Stimulated 17(OH) Progesterone	1300 ng/dl
HbA1C	5.0%
LH	6.5 mIU/mL
FSH	4.5 mIU/mL

Genetic confirmation chromosome 6: ***CYP21A2*** and ***TNXB***. confirmed the diagnosis of Non-Classical Congenital Adrenal Hyperplasia CAH×. Additionally, symptoms of hypovolemia and palpitations led to the diagnosis of Postural Orthostatic Tachycardia Syndrome (POTS) as it is closely related to EDS .

4. Clinical Outcome: The patient reported significant improvements in quality of life, including enhanced focus, attention, and the ability to maintain her academic performance and daily activities.

This case demonstrates that POTS is often underdiagnosed in young females and can severely impact quality of life. Furthermore, NCCAH should be considered as a differential diagnosis for hyperandrogenism in lean patients, especially when symptoms overlap with connective tissue and autonomic disorders.

Abstract citation ID: lvag096.1790

EP1728 - LBA_ECE_1445 - Takotsubo cardiomyopathy revealing pheochromocytoma: a case of severe catecholamine-induced cardiomyopathy with dramatic recovery after adrenalectomy

Aye Aye Khine, Elfreda Baker, Khurram Qayyum and Shiva Mongolu
Hull University Teaching Hospital NHS Trust, Hull, United Kingdom

Background: Pheochromocytoma is a rare catecholamine-secreting tumor with diverse cardiovascular presentations. Excess catecholamines may induce stress cardiomyopathy with severe but potentially reversible myocardial dysfunction. Early recognition is essential to enable appropriate alpha-blockade and curative surgery.

Case Presentation: A 61-year-old woman with type 2 diabetes, hypertension, and active smoking presented with persistent vomiting following metformin up-titration. She was found

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

to have stage 3 acute kidney injury and markedly elevated troponin (1484-1624 ng/L). ECG showed widespread T-wave inversion.

Echocardiography demonstrated severe left ventricular (LV) systolic dysfunction. Cardiac MRI confirmed severe LV impairment (LVEF 21%) and LV thrombus with features consistent with stress-induced cardiomyopathy and normal coronary angiography. An incidental 7 cm right adrenal mass was identified in initial cardiac MRI.

Biochemical evaluation showed markedly elevated plasma metanephrines (>25 000 pmol/L) and urinary metanephrines (metanephrine 124.4 µmol/24 h; normetanephrine 86.5 µmol/24 h). Initial adrenal CT scan revealed thick-walled centrally necrotic right adrenal lesion of 7 × 6.2 cm suspicious for pheochromocytoma. Subsequent MIBG imaging confirmed a catecholamine-secreting tumor. Genetic testing for pheochromocytoma/ paraganglioma (11-genes panel) was negative.

The patient had highly labile blood pressure with episodes of severe hypertension (180/136 mmHg) alternating with hypotension (77/56 mmHg). Alpha-blockade (doxazosin) was cautiously introduced with close hemodynamic monitoring. Fluid therapy was administered cautiously due to severe LV dysfunction. Following clinical stabilization with alfa and beta blockage, she underwent elective laparoscopic adrenalectomy after three months of diagnosis. Histology confirmed pheochromocytoma (PASS 1, Ki-67 <1%).

Post-operatively, cardiac function improved significantly, with LVEF recovering from 21% to 54% at three months, alongside resolution of myocardial oedema and LV thrombus.

Discussion: Pheochromocytoma-related cardiomyopathy is mediated by catecholamine excess causing myocardial stunning via microvascular spasm and direct toxicity. Management is challenging when severe cardiac dysfunction coexists with haemodynamic instability. Careful initiation and titration of alpha-blockade remain essential even in patients with hypotension, requiring multidisciplinary management involving endocrinology, cardiology, anaesthesia, and surgery. Definitive tumour removal often results in marked cardiac recovery.

Conclusion: Pheochromocytoma can present as severe reversible Takotsubo-like cardiomyopathy. Early diagnosis and coordinated management, including alpha-blockade and surgical resection, can lead to substantial cardiac recovery.

EP1729 - LBA_ECE_1452 - When PCOS is not PCOS: a diagnostic pitfall of non-classical congenital adrenal hyperplasia

Aye Aye Khine, Elfreda Baker, Khurram Qayyum and Najeeb Shah
Hull University Teaching Hospital NHS Trust, Hull, United Kingdom

Background: Non-classical congenital adrenal hyperplasia (NCCAH) due to partial 21-hydroxylase deficiency is an important differential diagnosis of polycystic ovary syndrome (PCOS). Both conditions may present with hyperandrogenic features including hirsutism, acne, and menstrual irregularities. Failure to recognize NCCAH may delay appropriate endocrine counselling and reproductive planning. Measurement of basal and ACTH-stimulated 17-hydroxyprogesterone (17-OHP) is recommended when adrenal androgen excess is suspected.

Clinical Case: A 24-year-old woman was referred to a PCOS clinic with hirsutism and oligomenorrhoea. She reported facial and periareolar hair growth and had a prior history of acne. She was using a levonorgestrel intrauterine system for contraception and had no current fertility concerns. Her BMI was 22.5 kg/m^2 and blood pressure was 110/70 mmHg. Secondary sexual characteristics were normal and there was no history of salt-wasting.

Initial biochemical evaluation demonstrated elevated adrenal androgens with androstenedione 11.1 nmol/L and DHEAS 19.5 µmol/L. Total testosterone was 2.2 nmol/L with a free androgen index of 6.1. Basal 17-hydroxyprogesterone was elevated at 50.8 nmol/L. A short synacthen test initially demonstrated adequate adrenal reserve (cortisol 337-485 nmol/L), but stimulated 17-OHP was not measured. Repeat testing showed baseline 17-OHP 19.6 nmol/L rising to 180.8 nmol/L following ACTH stimulation, confirming NCCAH. Cortisol response remained appropriate (264-455 nmol/L).

The patient had initially been treated for presumed PCOS with anti-androgen therapy including spironolactone and later topical eflornithine and finasteride for persistent hirsutism. Glucocorticoid therapy was not initiated following diagnosis due to preserved cortisol reserve and absence of fertility concerns.

Conclusion: This case highlights NCCAH as an important PCOS mimic. Elevated basal 17-OHP should prompt ACTH-stimulated testing to avoid misdiagnosis. Early recognition allows appropriate counselling regarding long-term endocrine follow-up and reproductive implications. This case emphasises the importance of screening for non-classical congenital adrenal hyperplasia in women presenting with hyperandrogenic features suggestive of PCOS, particularly when basal 17-hydroxyprogesterone is elevated.

EP1730 - LBA_ECE_1107 - Impact of pharmacological therapeutic transition in obesity: analysis of anthropometric variations and metabolic profile

Ignacio Nocete Aragón[1,2], Leopoldo Garcia-Valdecasas Vazquez[1], Alejandro Tomás Pérez[1], Alejandra Salomé Criollo Posso[1], Natalia Díez Fernández[1] and Vanessa Capristán Díaz[1]
[1]*Endocrinology, Hospital Universitario General de Villalba, Collado Villalba, Spain;* [2]*Endocrinología y Nutrición, Hospital Universitario General de Villalba, Collado Villalba, Spain*

Background: The sequential use of GLP-1 and GLP-1/GIP receptor agonists is increasingly common in clinical practice to manage obesity and metabolic disorders. However, real-world data evaluating the efficacy of transitioning between these therapies remains limited. This study aimed to assess the anthropometric and metabolic outcomes of switching incretin-based treatments in a real-world clinical setting.

Methods: A retrospective cohort study was conducted on 64 patients (71.9% female; mean age 54.4 ± 12.5 years). Clinical parameters, including weight, body mass index (BMI), fasting glucose, LDL cholesterol, and gamma-glutamyl transferase (GGT), were evaluated at three specific time points: baseline, time of medication switch, and final follow-up. The primary transitions involved Liraglutide, Semaglutide, and Tirzepatide.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Statistical analyses included paired t-tests and multivariable linear regression adjusted for age, sex, treatment duration, and specific drug type.

Results: The primary clinical reason for switching therapies was insufficient efficacy (64.0%). During the initial treatment phase (mean duration 283 days), patients achieved highly significant reductions in weight (−8.29 kg; $P < .001$), BMI (−2.93; $P < .001$), and fasting glucose (−7.84 mg/dL; $P < .001$). Following the medication switch, patients experienced further significant clinical improvements. Transitioning from Liraglutide to Tirzepatide resulted in the most substantial additional weight loss (−11.97 kg; $P = .004$). Alternatively, switching from Semaglutide to Tirzepatide yielded a significant secondary reduction in fasting glucose (−7.68 mg/dL; $P = .022$). Multivariable analysis demonstrated that female sex was a significant independent predictor of greater BMI reduction during the post-switch phase ($P = .027$). LDL cholesterol levels remained stable throughout the study without significant variations.

Conclusions: Switching between incretin-based therapies is a highly effective clinical strategy to overcome weight-loss plateaus and enhance metabolic control. Escalating treatment to a dual agonist (Tirzepatide) provides profound rescue efficacy, particularly in glycemic control and absolute weight loss. Furthermore, female patients appear to derive a significantly greater anthropometric benefit from this sequential treatment strategy compared to males.

EP1731 - LBA_ECE_1116 - An unusual case of hypogonadotrophic hypogonadism due to Erdheim Chester disease related pituitary hypophysitis

Kalyani Nagarajah[1,2] and Emmanuel Kofi Obuobie[1,2]
[1]Endocrinology, Aneurin Bevan Health Board, Newport, United Kingdom; [2]Endocrinology and Diabetes, Aneurin Bevan Health Board, Newport, United Kingdom

Background: Erdheim–Chester disease (ECD), is a rare cause of non-Langerhans histiocytosis. These cells may infiltrate the hypothalamic-pituitary tissues and retroperitoneum, leading to central diabetes insipidus, progressive anterior pituitary failure, and ureteral obstruction with hydronephrosis.[1-3] Male hypogonadism may also be a feature of this condition.

Case: A 52-year-old man with histologically confirmed ECD/Langerhans cell histiocytosis overlap presented for routine endocrine evaluation. He had been diagnosed with Hypopituitarism including arginine vasopressin deficiency, bilateral hydronephrosis and chronic kidney disease stage 3 due to persistent retroperitoneal fibrosis, diverticular disease, and depression. Treatment regimen consisted of cobimetinib for systemic disease, desmopressin 100 μg nocte for polyuria management, and transdermal testosterone gel for established central hypogonadism. Pituitary MRI identified characteristic stalk infundibular thickening without discrete lesion. He was Clinically stable with controlled polydipsia, testicular atrophy, and preserved visual fields, biochemical assessment revealed low-normal IGF-1, normal prolactin/TSH, therapeutic testosterone concentration (13.6 nmol/L), and indeterminate 9 am cortisol (190 nmol/L).[5] Guideline-directed 250 μg Short Synacthen testing was arranged to assess corticotroph function, which was reported as within normal range.[5] Adrenal insufficiency was then ruled out.

Discussion: hypogonadotropic hypogonadism c with diabetes insipidus and stalk thickening, is a recognised feature of ECD and gonadal histiocytosis has been noted in some patients.[1,2] Our patient had a pattern of results consistent with central hypogonadism due to Pituitary hypophysistis. Endocrinology guidelines advocate testosterone replacement and monitoring pituitary, haematologic, prostatic, and cardiovascular profiles.[8]

Conclusion: ECD constitutes an uncommon but well recognised of secondary male hypogonadism due to hypophysitis, and it is important that clinicians are made aware of this association. Testosterone therapy, adrenal stimulation assessment, and planned neuroimaging provide comprehensive endocrine management for this multisystem disorder.[1-9]

EP1732 - LBA_ECE_1444 - Grave's–Hashimoto overlap with suspicious thyroid nodules: navigating diagnostic timing and thionamides therapy in the setting of baseline neutropenia on anakinra

Azmi Mohammed, Rawan Alghawi and Zainab Alabdurubalnabi

Graves' disease and Hashimoto thyroiditis lie on a spectrum of autoimmune thyroid disease and may coexist in the same patient. Overlapping stimulatory and destructive autoimmune mechanisms may produce a fluctuating biochemical profile, complicating monitoring and therapeutic decision-making. Thionamides, such as carbimazole, remain first-line therapy in patients who defer definitive treatment; however, their use is challenging in the presence of pre-existing leukopenia and neutropenia due to the risk of agranulocytosis.

We report a 44-year-old female with Familial Mediterranean fever (FMF) on anakinra, presenting with hair loss, weight loss and overt thyrotoxicosis. Thyroid function test demonstrated: (TSH < 0.008 μIU/mL, FT4 1.97 ng/dL [0.7-1.48], FT3 12.6 pg/mL [1.58-3.91]). Thyroid peroxidase antibodies were elevated at 197.69 IU/mL (<5.3), and thyroid-stimulating immunoglobulin (TSI) was positive at 3.4 (<1.3), supporting the diagnosis of overlapping autoimmune thyroid disease.

Ultrasound demonstrated bilateral nodules, including a 3.2 cm left-sided mixed solid–cystic nodule with microcalcifications (TI-RADS 4) and a smaller right-sided 1 cm TI-RADS 3 nodule. The suspicious nodule required fine-needle aspiration; however, this was deferred until she was rendered euthyroid and her thyroiditis had settled. Cytology during inflammatory phases may be non-diagnostic due to lymphocytic infiltration. Serial ultrasound surveillance at 6-month intervals was therefore undertaken to exclude interval progression while allowing time to achieve euthyroidism.

Management was complicated by anakinra-associated chronic leukopenia and neutropenia (baseline absolute neutrophil count 0.6-1.5 × 10^9/L). Carbimazole was initiated at 5 mg on alternate days (neutrophil count 0.7 × 10^9/L at initiation) and cautiously up-titrated to a maximum required dose of 15 mg daily, with close haematological monitoring. Euthyroidism was achieved without infectious complications, and neutrophil counts during treatment ranged between 0.7-2.2 × 10^9/L.

FNA of the dominant nodule, performed after restoration of euthyroidism, confirmed a benign follicular lesion (Bethesda II). At her last follow-up, the patient remained clinically stable

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

on low-dose therapy, with normal thyroid function tests and declining TSI (2.1 after 14 months). A total treatment duration of 18 months is planned.

This case highlights four key challenges: autoimmune overlap with fluctuating thyroid function, limitations of cytology during thyroiditis, the need to delay invasive investigation until biochemical control is achieved, and the safe use of thionamides in baseline cytopenia. It underscores the importance of individualised management, careful haematological surveillance, and multidisciplinary coordination.

EP1733 - LBA_ECE_1473 - The role of pembrolizumab immunotherapy in metastatic adrenocortical carcinoma: a case series study

Kyriaki Gkoufa[1], Ariadni Spyroglou[1], Maria Theochari[1], Odysseas Violetis[2], Panagiota Konstantakou[1], Dionysia Kolomodi[1], Georgios Kyriakopoulos[1], Konstantinos Iliakopoulos[1], Konstantinos Bramis[1], Pantelis Antonakis[1], Georgios Sotiropoulos[1], Christos Papadimitriou[1], Manousos Konstadoulakis[1], George Mastorakos[1], Dimitra Argyro Vassiliadi[1] and Krystallenia Alexandraki[1]

[1]Aretaieion Hospital, National & Kapodistrian University of Athens, Athens, Greece; [2]Maroussi, Greece

Background: Adrenocortical carcinoma (ACC) is a rare endocrine malignancy with a poor prognosis in advanced stages. Standard first-line treatment for metastatic disease involves mitotane and cytotoxic chemotherapy (EDP-M); however, therapeutic options following progression are limited. Immunotherapy with immune checkpoint inhibitors, such as the anti-PD-1 agent pembrolizumab, has shown potential in solid tumors, particularly those with high microsatellite instability (MSI-H) or deficient mismatch repair (dMMR). This study presents the clinical experience, safety, and outcomes of patients treated with pembrolizumab at a specialized Endocrine Unit of a University Hospital.

Methods: This retrospective observational case series study analyzed a cohort of seven adult patients with metastatic ACC followed between 2020 and 2026. Among them, three patients receiving pembrolizumab as salvage therapy for advanced disease were evaluated. Data collection included demographic profiles, clinical and histopathological characteristics, progression-free survival (PFS), overall survival (OS), and treatment-related toxicity.

Results: Case 1: A 30-year-old female with functional, symptomatic ENSAT stage IV ACC (pulmonary, hepatic, bone metastases) and Ki-67 35%-40% (Weiss score 8). Following surgery, adrenolytic therapy, and chemotherapy, pembrolizumab was initiated three years post-diagnosis. Treatment was discontinued after a single administration due to severe drug-induced hepatitis. Although a partial reduction in pulmonary metastases occurred, the brief treatment duration precluded a definitive attribution of this response to immunotherapy.

Case 2: An 89-year-old female with functional ENSAT stage IV ACC (pulmonary, diaphragmatic, nodal, perirenal involvement) and a Ki-67 index of 50% (Weiss score 8), received pembrolizumab postoperatively alongside mitotane as salvage therapy. Efficacy could not be assessed as the patient succumbed shortly after initiation; death was attributed to rapid disease progression.

Case 3: A 56-year-old female with symptomatic ENSAT stage IV oncocytic ACC (renal, hepatic, IVC involvement) with low grade malignancy (Weiss score 4, Ki-67 15%). Following surgery and standard therapies, she received pembrolizumab for two years. She achieved a sustained initial response with disease progression occurring 2 years later.

Conclusion: Pembrolizumab demonstrates heterogeneous outcomes in metastatic ACC. While it may provide prolonged disease control in selected patients. The risk of severe immune-related adverse events, should be considered. Immunotherapy remains a viable second/third line option, though, optimal patient selection and predictive biomarker identification are essential.

EP1735 - LBA_ECE_1201 - CYP11B2 immunohistochemistry-defined subtypes and clinical outcomes after adrenalectomy in primary aldosteronism

Anna Casteràs Roman[1,2], Veronica Engracia Rodríguez[1], Sheila Bermejo[3], Andres Cardona-Arias[1], Betina Biagetti[1], Juzzy Tatiana Zuñiga[4] and Carmela Iglesias[4]

[1]Endocrinology Department, Vall d'Hebron University Hospital, Barcelona, Spain; [2]Endocrinology, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [3]Nephrology Department, Vall d'Hebron University Hospital, Barcelona, Spain; [4]Pathology Department, Vall d'Hebron University Hospital, Barcelona, Spain

Background: CYP11B2 (aldosterone synthase) immunohistochemistry has enabled a more precise histopathological subtyping of primary aldosteronism (PA) after adrenalectomy. However, the relationship between CYP11B2-defined subtypes and clinical presentation or postoperative outcomes remains unclear.

Objectives: To assess the association between CYP11B2-based histopathological findings and preoperative characteristics, as well as clinical and biochemical outcomes after unilateral adrenalectomy according to PASO criteria.

Methods: Retrospective study including 21 patients who underwent adrenalectomy for PA over the last 10 years. Clinical, biochemical and hormonal variables were analyzed alongside CYP11B2 immunohistochemistry findings according to HISTALDO criteria: solitary aldosterone-producing (AP) adenoma (>1 cm), AP-nodule <1 cm (HE+ CYP11B2+), AP-micronodule <1 cm (HE-, CYP11B2+), micronodular hyperplasia (multiple nodules/micronodules), AP-diffuse hyperplasia. Statistical analysis was further based on the presence of solitary adenoma with or without associated hyperplasia. Outcomes at 1 year were assessed using PASO criteria.

Results: A total of 21 patients were included (52.4% male), with a median age at surgery of 53 years [IQR 48-59.5]. Median duration of hypertension was 10 years [IQR 5.5-23.5]. Hypokalemia was present in 20/21 patients (2.8 mmol/L[IQR 2.5-3.1]). Median aldosterone was 36.6 ng/dL[IQR 30.7-87.7], plasma renin activity (PRA) 0.3 ng/mL/h [IQR 0.3-0.48]) and ARR 143.1 [IQR 89.6-239.5]. CT identified an adrenal adenoma in all cases (median size 1.7 cm [IQR 1.1-2]).

CYP11B2 immunohistochemistry revealed adenoma alone in 23.8%, adenoma plus micronodular hyperplasia in 42.9%,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

micronodular hyperplasia in 23.8%, and other patterns in 9.6%. No association was observed between histopathological subtype and preopertative variables such as age, gender or HTA grade or duration. In 6 cases, the adrenal adenoma identified on CT was either not confirmed on histopathology or lacked CYP11B2 expression.

All patients normalized potassium levels after surgery. Complete biochemical remission (including PRA >1) was achieved in 31.3% and complete clinical remission (BP normalization) in 38.1%. Antihypertensive treatment decreased significantly (median 3 to 1 drugs, $P < .001$), and mineralocorticoid receptor antagonist use decreased from 20 to 2 patients. CYP11B1-subtype did not predict clinical or biochemical outcomes. Female sex was associated with higher rates of hypertension remission (87.5% vs 12.5%) P .008.

Conclusions: Mixed CYP11B2-defined patterns are common in PA and are not adequately captured by current classifications. Histopathological subtype did not predict postoperative outcomes in our study. While hypokalemia is consistently corrected, blood pressure response remains variable, with female sex emerging as the only predictor of clinical remission.

EP1736 - LBA_ECE_1259 - Four-year BMI trajectories and weight regain after bariatric surgery using prespecified regain definitions: a procedure-comparative analysis

Elamin Abdelgadir[1,2], Fatheya Alawadi[1,2], Alaaeldin Bashier[1,2] and Fauiza Rashid[1,2]
[1]*Mohammed Bin Rashid University for Medicine and Health Sciences, Dubai, United Arab Emirates;* [2]*Dubai Hospital, Dubai, United Arab Emirates*

Background: Long-term bariatric outcomes are often complicated by heterogeneous weight-regain definitions and incomplete follow-up. We characterised BMI trajectories and regain prevalence through year 4 using three operational definitions.

Methods: BMI was evaluated at baseline, 6 months, and 1-4 years after index primary SG, MGB/OAGB, or RYGB. Missing values were imputed. Nadir BMI was defined as the minimum postoperative BMI across 6 months to 4 years, and last BMI was standardised as year-4 BMI. Weight regain was defined as: (A) ≥25% regain of lost BMI relative to nadir; (B) ≥5 BMI units increase from nadir; (C) ≥2 BMI units increase from 1-year BMI. Regain prevalence was summarised by procedure; a multivariable logistic regression evaluated procedure associations with Definition A.

Results: Median time-to-nadir was 24 months. At year 4, regain prevalence (Definition A) was 22.2% (SG), 17.2% (MGB/OAGB), and 25.9% (RYGB). Using Definition B, prevalences were 7.5%, 6.7%, and 8.2%, respectively. In adjusted modelling, MGB/OAGB had lower odds of regain vs SG (OR 0.57; 95% CI 0.46-0.72; $P = .0000$).

Conclusion: Regain prevalence at year 4 depended materially on the operational definition used, yet MGB/OAGB demonstrated more favourable durability across definitions. Harmonised regain definitions and risk-stratified long-term follow-up are warranted.

Table 1 Weight regain prevalence at 4 years by definition (imputed; standardised year-4 BMI).

Procedure	*n*	Median time-to-nadir (months)	Def A (%)	Def B (%)	Def C (%)
SG	1447	24	22.2	7.5	23.0
MGB/OAGB	899	24	17.2	6.7	19.0
RYGB	632	24	25.9	8.2	21.2

Background and Objective: Prediabetes is a serious public health concern worldwide. Acarbose, an α-glucosidase inhibitor, has been shown to prevent type 2 diabetes (T2DM) and

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

reduce blood pressure, incident hypertension, and cardiovascular risk in subjects with prediabetes (STOP-NIDDM trial). White mulberry (*Morus alba*) contains 1-deoxynojirimycin, a potent competitive α-glucosidase inhibitor. A nutraceutical combining standardized white mulberry leaf extract, fenugreek (*Trigonella foenum-graecum*, an AMPK activator), inulin (soluble fiber), *Lactiplantibacillus plantarum* A7 (probiotic), niacin (vitamin B3), chromium and zinc (trace elements) has been developed for patients with prediabetes.

This study evaluated the tolerability and efficacy of this formulation on metabolic profile, blood pressure, and cardiovascular risk (SCORE2) in subjects with prediabetes, with change in insulin resistance (HOMA2-IR) as the primary endpoint.

Methods: In this open-label study, adults with prediabetes received the nutraceutical once daily for 6 months, with an interim visit at 3 months. Body mass index (BMI), blood pressure, fasting glucose, insulin, lipid profile, and HOMA2-IR were assessed at each visit.

Results: Of 144 recruited patients, 113 (78.5%) completed the study (71 women; mean age 56.4 ± 6.7 years). HOMA2-IR decreased from 1.659 ± 0.721 to 1.269 ± 0.581 (−23.5%, $P < .001$). Fasting glucose decreased by 7.6 mg/dL ($P < .001$) and HbA1c by 0.22% ($P < .001$). Normoglycemia was achieved in 33 patients (29.2%, $P < .001$), while 3 (2.65%, p NS) developed T2DM. Body weight and BMI remained unchanged.

Significant improvements were observed in lipid profile: total cholesterol (−5.3%, $P = .002$), non-HDL cholesterol (−9.94%, $P < .001$), LDL cholesterol (−10.5%, $P < .001$), triglycerides (−19.3%, $P < .001$), and HDL cholesterol (+11.83%, $P < .001$). Systolic and diastolic blood pressure decreased by 5.7 (4.11%, $P < .001$) and 4.2 mmHg (4.92%, $P = .005$), respectively.

The SCORE2-estimated cardiovascular risk decreased from 4.23 ± 1.98% to 3.58 ± 1.76% (−15.4%, $P < .001$). The proportion of patients classified as low cardiovascular risk increased from 56% to 72% ($P = .005$).

Mild gastrointestinal adverse effects were reported in some patients; however, no discontinuations or serious tolerability issues occurred.

Conclusions: This white mulberry leaf-based nutraceutical was well tolerated and significantly improved glycemic control, lipid profile and blood pressure in patients with prediabetes. The reduction of the SCORE-2 cardiovascular risk index was significant, with one out of six patients progressing from the moderate/high to the low risk category. In the absence of approved pharmacological treatments for prediabetes in the European Community, it may represent a useful adjunct to lifestyle modification.

[1]Kocaeli City Hospital, Kocaeli, Turkey; [2]Ankara Guven Hospital, Ankara, Turkey; [3]Gulhane Training and Research Hospital, Ankara, Turkey; [4]Faculty of Medicine, Istanbul University, Istanbul, Turkey; [5]Fırat University, Elazig, Turkey; [6]Gazi University, Ankara, Turkey; [7]Akdeniz University, Antalya, Turkey; [8]Ufuk University, Ankara, Turkey; [9]Department of Internal Medicine, Faculty of Medicine, Istanbul Health and Technology University, Istanbul, Turkey; [10]Uludag University, Bursa, Turkey; [11]Private Practice, Kayseri, Turkey; [12]VKV American Hospital, Istanbul, Turkey; [13]Various Hospitals, Ankara, Turkey

Background: Type 2 diabetes mellitus (T2DM) substantially increases the risk of coronary artery disease (CAD) through insulin resistance, inflammation, and related complications. In this large, nationally representative multicenter study, we investigated behavioral and metabolic risk factors associated with CAD in T2DM.

Materials and Methods: This cross-sectional study was conducted across Türkiye, including 70 endocrine clinics in 36 cities. Adults with T2DM followed at the same center for at least one year were included. Sociodemographic, anthropometric, clinical, laboratory, and lifestyle data were recorded using a standardized web-based system.

Results: A total of 5707 patients with diabetes were recruited, of whom 4956 (86.8%) had T2DM (mean age 58.9 ± 10.0 years; 59.8% women). CAD status was available in 4750 patients, among whom 1061 (22.3%) had CAD.

CAD was more frequent in men than women (30.4% vs 16.9%, $P < .001$). Patients with CAD were older (62.8 ± 8.6 vs 57.8 ± 10.2 years, $P < .001$) and had longer diabetes duration (16.1 ± 8.8 vs 12.2 ± 7.7 years, $P < .001$). Body mass index was lower (31.2 ± 5.8 vs 31.8 ± 6.8 kg/m^2, $P = .005$), whereas waist circumference was higher (106.7 ± 13.7 vs 105.1 ± 14.1 cm, $P = .004$).

Lower income was associated with CAD (23.4% vs 19.5%, $P = .003$), whereas smoking and exercise were not ($P = .219$ and $P = .977$). Hypertension was associated with CAD (28.2% vs 14.5%, $P < .001$). Systolic blood pressure was higher (126.1 ± 13.6 vs 124.3 ± 13.6 mmHg, $P = .004$), while diastolic pressure did not differ ($P = .603$). HbA1c was higher in the CAD group (8.27 ± 1.94 vs 7.84 ± 1.89%, $P < .001$), and hypoglycemia was more frequent (24.6% vs 20.8%, $P = .002$).

In multivariable logistic regression, independent predictors of CAD were older age (OR 1.04, 95% CI 1.03-1.05, $P < .001$), male sex (OR 0.39, 95% CI 0.33-0.46, $P < .001$), current smoking (OR 1.37, 95% CI 1.12-1.66, $P = .002$), hypertension (OR 2.00, 95% CI 1.68-2.38, $P < .001$), microvascular complications (OR 1.48, 95% CI 1.26-1.74, $P < .001$), higher HbA1c (OR 1.12 per %, 95% CI 1.07-1.17, $P < .001$), longer diabetes duration (OR 1.04 per year, 95% CI 1.02-1.05, $P < .001$), and lower income (OR 0.74, 95% CI 0.62-0.88, $P = .001$). Exercise, diet, hypoglycemia, education, and body mass index were not independently associated with CAD (all $P > .05$).

Conclusion: In this large national cohort of T2DM patients, CAD was independently associated with classical cardiometabolic risk factors, microvascular complications, and lower income, whereas lifestyle factors were not independently associated after adjustment. These findings highlight dominant role of cumulative metabolic burden and vascular damage in determining CAD risk and emphasize the importance of early, sustained, risk factor–targeted management.

EP1744 - LBA_ECE_1037 - Adrenocortical carcinoma: a case series highlighting diagnostic challenges, hormonal heterogeneity and therapeutic complexity

Mara Patricia Rotaru-Wagner[1,2], Oana Stanoiu-Pinzariu[1,2] and Carmen Emanuela Georgescu[1,2]
[1]*Department of Endocrinology, Iuliu Haţieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania;* [2]*Department of Endocrinology, Clinical County Emergency Clinical Hospital, Cluj-Napoca, Romania*

Introduction: Adrenocortical carcinoma (ACC) is a rare malignancy (0.5-2 cases/million/year), characterised by heterogeneous clinical presentation, variable hormonal secretion and poor prognosis in advanced stages. Multidisciplinary management combining surgery, mitotane and cytotoxic chemotherapy remains the gold standard of treatment. We report three cases illustrating distinct clinical phenotypes of ACC managed at a tertiary endocrine centre.

Case Presentations: Case 1: A 39-year-old woman presented with hypertension, hirsutism and generalised oedema. Hormonal evaluation demonstrated cortisol and androgen secretion (suppressed adrenocorticotropic hormone, elevated dehydroepiandrosterone sulfate, testosterone, urinary free cortisol and no suppression of cortisol with 1 mg dexamethasone). Computed tomography (CT) identified a right retroperitoneal mass of 98 × 94 × 98 mm. Laparoscopic right adrenalectomy confirmed high-grade ACC (pT2NxMxL1V1, Ki67 15%-20%). Post-operative corticotropic insufficiency required glucocorticoid substitution. Adjuvant mitotane was initiated and therapeutic levels were achieved slowly. Serial imaging showed no recurrence, though mitotane side effects required dose adjustments.

Case 2: A 52-year-old man presented with left lumbar pain. CT identified a left retroperitoneal mass of 133 × 90 × 136 mm, bilateral pulmonary nodules, locoregional adenopathy and a right adrenal nodule. Extended surgery included tumour resection with left nephrectomy, splenectomy, body and tail pancreatectomy and periaortic lymph node dissection. Histopathology confirmed non-functioning high-grade ACC (Ki67~60%). Post-operative staging revealed multiple hepatic metastases and therapy with mitotane combined with EDP (etoposide, doxorubicin, cisplatin) chemotherapy was initiated.

Case 3: A 50-year-old male patient was incidentally diagnosed with a left adrenal mass of 12 × 7 × 8 cm on a CT performed for suspected disc herniation. Partial left adrenalectomy with splenectomy and distal pancreatectomy confirmed a low-grade oncocytic ACC (pT2L0V0R0M0, Ki67 10%). Subsequent imaging revealed local recurrence and hepatic metastases, requiring reoperation with resection of the pancreatic body and tail, residual left adrenal, atypical hepatic resection (segments II and V), partial gastrectomy and omentectomy. Adjuvant mitotane and EDP chemotherapy were initiated.

Discussion: The present case series illustrates the clinical, hormonal and histological heterogeneity of ACC: a functioning localised tumour with slow mitotane titration, a non-functioning metastatic high-grade ACC requiring systemic chemotherapy and a low-grade oncocytic ACC with metastatic relapse requiring repeated surgical interventions. These cases highlight the challenges of achieving therapeutic mitotane levels, managing adrenocortical insufficiency and coordinating multidisciplinary oncological care.

Conclusion: The cases presented confirm that no two ACC presentations are alike. Histological subtype, functional status and disease stage at diagnosis influence therapeutic strategy and long-term outcomes in this aggressive malignancy.

EP1745 - LBA_ECE_1299 - An unusual presentation: panhypopituitarism and central diabetes insipidus revealing small cell lung cancer

Neslihan Koray Fedai, Nagihan Uzun, Revah Cankaya, Murat Calapkulu, Bekir Ucan, Mustafa Ozbek and Erman Cakal
Endocrinology and Metabolism, University of Health Sciences, Ankara Etlik City Hospital, Ankara, Turkey

Pituitary metastasis (PM) is rare, accounting for approximately 1% of surgically resected sellar lesions, and is typically observed in patients with extensive disease. Breast and lung cancers represent the most common primary malignancies. Although PM is often asymptomatic, when present, the most frequent clinical manifestations include panhypopituitarism and central diabetes insipidus (CDI). CDI is uncommon in pituitary adenomas and should raise suspicion for an alternative etiology. The presence of CDI or cranial neuropathy, particularly in patients over 50 years of age, should prompt consideration of pituitary metastasis.

A 65-year-old man with a history of traumatic paraplegia following a fall from height two years earlier was referred to our endocrinology clinic with a two-month history of progressive fatigue, generalized weakness, hypotension, and polydipsia. At initial evaluation, his symptoms were attributed to his underlying neurological condition. However, further laboratory assessment revealed panhypopituitarism, as shown in Table 1. Additionally, hypernatremia, elevated serum osmolality, and inappropriately low urine osmolality were consistent with CDI.

MRI of the pituitary gland revealed a 16 × 25 mm heterogeneously enhancing dumbbell-shaped sellar mass with suprasellar extension and optic chiasm indentation (Figure 1), with imaging features raising strong suspicion for metastatic disease rather than a primary pituitary adenoma. The patient had a 20 pack-year smoking history. Thoracic computed tomography was performed to identify a potential primary malignancy, revealing a 23 × 35 mm pleura-based, irregularly marginated mass lesion in the posterior segment of the right lower lobe, highly suspicious for primary lung malignancy. Endobronchial ultrasound-guided biopsy confirmed small cell lung carcinoma, with tumor cells positive for INSM1 and TTF1. FDG PET-CT demonstrated increased metabolic activity in the pituitary lesion (SUVmax 7.17), supporting metastatic involvement. Additional findings included bilateral adrenal, hepatic, skeletal, and mediastinal lymph node metastases, as well as right-sided pleural effusion.

Hormone replacement therapy was initiated, resulting in rapid clinical improvement. The patient was referred to oncology for systemic treatment.

This case highlights that panhypopituitarism and CDI may represent the initial manifestation of extensive-stage cancer. Pre-existing neurological comorbidities may mask classic

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

endocrine symptoms, leading to diagnostic delay. In any patient presenting with combined anterior and posterior pituitary failure of unclear etiology, sellar MRI and systematic screening for underlying malignancy are warranted.

Table 1

ACTH (ng/L)	5.5
Cortisol (μg/dl)	2.7
TSH (mIU/L)	0.2
T4 (ng/dl)	0.5
Prolactin (μg/L)	14.7
FSH (IU/L)	1.1
LH (IU/L)	0.3
Total testosterone (ng/dL)	<2.5
IGF-1 (ng/mL)	44

EP1746 - LBA_ECE_1378 - When a sellar mass is not what it seems: hypopituitarism caused by a suprasellar tuberculoma

Paulo Perez Damasco, Liseth Gabriela Delgado Castro and Jose Edmond Esquivel Vargas
Caja Costarricense de Seguro Social, San José, Costa Rica

Background: Although pituitary adenomas account for the majority of sellar region lesions, a small proportion correspond to less common entities such as infections, cysts, or malignancies. Involvement of the hypothalamus-pituitary axis by tuberculosis is exceedingly rare, and isolated sellar tuberculoma represents an exceptional presentation. Its clinical, radiological, and endocrine features are often indistinguishable from more frequent sellar pathologies, making diagnosis challenging. Recognizing this entity is crucial, as therapeutic strategies and outcomes differ significantly from those of neoplastic lesions.

Case Presentation: A 43-year-old woman with a history of diabetes mellitus presented with a one-year history of progressive headaches, nausea, vomiting, and dizziness, accompanied by decreased visual acuity, generalized weakness, and malaise. Cranial CT revealed a well-delimited, homogeneous, isodense solid mass in the suprasellar region with sellar extension, associated vasogenic edema, and marked contrast enhancement (>90%), measuring approximately 28 × 27 × 29 mm. MRI demonstrated a well-defined lesion located at the floor of the third ventricle, isointense on T1- and T2-weighted sequences, with intense and homogeneous contrast enhancement.

Given the radiologic appearance, germinoma or meningioma was initially suspected. Hormonal evaluation revealed hypopituitarism, including central adrenal insufficiency (low morning cortisol with inappropriately low ACTH), hypogonadotropic hypogonadism, central hypothyroidism, hyperprolactinemia, and low IGF-1. Hydrocortisone and levothyroxine replacement therapy was initiated.

The patient underwent transcranial biopsy, which revealed a midline suprasellar mass infiltrating both optic nerves without a clear surgical plane. Frozen sections suggested inflammatory tissue. Definitive histopathology showed fibroconnective tissue with mononuclear inflammatory infiltrates composed of lymphocytes and macrophages, poorly formed granulomas, CD3+ and CD20+ lymphocytes, and isolated acid-fast bacilli on special staining, with no fungal organisms identified. A diagnosis of sellar tuberculosis was made, and antifimic therapy was administered for one year.

Despite completion of treatment, the patient discontinued endocrine follow-up and hormone replacement. One year later, she presented with progressive neuropsychiatric deterioration, polydipsia, polyuria, weight loss, and persistent gastrointestinal symptoms. Evaluation revealed persistent panhypopituitarism and new central diabetes insipidus with hypernatremia and low urine osmolality. Hormone replacement with hydrocortisone, levothyroxine and desmopressin was restarted.

Conclusions: This case underscores the importance of including sellar tuberculoma in the differential diagnosis of sellar masses associated with hypopituitarism. Definitive diagnosis relies on histopathological evaluation. Early surgical sampling, prompt initiation of antitubercular therapy, and adequate hormonal replacement are key to optimizing clinical outcomes. Greater awareness of this rare condition may help reduce diagnostic delays and improve long-term prognosis.

EP1747 - LBA_ECE_1003 - TMC from *Glycyrrhiza uralensis* suppresses hypoxic tumor microenvironment by co-targeting the HIF-1α–neuroendocrine axis and angiogenic signaling in colorectal cancer

Su Jung Hwang[1], Hye Jung Bang[1], Se Yun Jeong[1], Hye In An[1], Bowon Jung[2], Eon Chung Park[1], Seulah Lee[2], Ki Hyun Kim[1] and Hyo-Jong Lee[1]
[1]*School of Pharmacy, Sungkyunkwan University, Suwon, South Korea;* [2]*College of Life Science, Kyung Hee University, Yongin, South Korea*

Hypoxia is a key feature of the tumor microenvironment that activates hypoxia-inducible factor-1α (HIF-1α), leading to enhanced angiogenesis and dysregulation of neuroendocrine signaling pathways. In this study, we investigated the effects of 3,3′,4,4′-tetrahydroxy-2-methoxychalcone (TMC), a bioactive chalcone isolated from *Glycyrrhiza uralensis*, on hypoxia-induced

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

angiogenic signaling and neuroendocrine mediator expression.

In human colorectal cancer HCT-116 cells, hypoxic exposure markedly increased HIF-1α protein expression, accompanied by elevated vascular endothelial growth factor (VEGF) levels. TMC treatment significantly suppressed hypoxia-induced HIF-1α protein accumulation through a post-translational mechanism and consequently reduced VEGF expression.

Notably, hypoxia also significantly increased the mRNA expression of neuroendocrine-related mediators, including tyrosine hydroxylase (TH), corticotropin-releasing hormone (CRH), and endothelin-1 (ET-1). Treatment with TMC significantly reduced these hypoxia-induced increases at higher concentrations, suggesting that TMC may modulate neuroendocrine stress responses under hypoxic conditions.

The anti-angiogenic activity of TMC was further evaluated in human umbilical vein endothelial cells (HUVECs), where TMC significantly inhibited VEGF-induced tube formation, wound healing, and invasion. In addition, treatment with TMC in a zebrafish model reduced HIF-1α protein levels without observable developmental or cardiac toxicity.

Collectively, these findings demonstrate that TMC acts as a multitarget inhibitor that suppresses hypoxia-driven angiogenic signaling while simultaneously modulating the neuroendocrine stress axis involving TH, CRH, and ET-1. These results suggest that TMC may serve as a potential therapeutic candidate for targeting hypoxia-associated neuroendocrine signaling and angiogenesis.

EP1748 - LBA_ECE_1446 - Association between urinary bisphenol levels and breast cancer: insights from a case–control study and lifestyle assessment

Miodrag Milošević[1], Jelena Tomašević[1], Đurđica Marić[1], Biljana Antonijević[1], Vera Lukić[2], Zoran Mihailovic[2], Mina Hagen[3], Darko Zdravković[4], Simona Petričević[4], Connor Powell[5], Michael Antoniou[5] and Aleksandra Buha[1]

[1]Department of Toxicology, University of Belgrade-Faculty of Pharmacy, Belgrade, Serbia; [2]Faculty of Medicine, University of Belgrade, Institute of Forensic Medicine, Belgrade, Serbia; [3]Department of Psychology, Faculty of Media and Communications, Belgrade, Serbia; [4]University Hospital Medical Center Bezanijska Kosa, Belgrade, Serbia; [5]Department of Medical and Molecular Genetics, Faculty of Life Sciences and Medicine King's College London, London, United Kingdom

Bisphenols are widely distributed endocrine disruptors used in the production of clear plastics such as polycarbonates and resins that are extensively used as food packaging materials. The primary route of human exposure to bisphenols is through leakage into food from packaging, while certain lifestyle habits may contribute to increased internal exposure. Bisphenol exposure has been associated with various pathological conditions. As xenoestrogens, they bind to estrogen receptors and activate signaling pathways that promote cell proliferation and inhibit apoptosis. Their potential to stimulate the proliferation of hormone-dependent breast cancers has been demonstrated. This study aimed to evaluate the correlation between urinary levels of three selected bisphenols (BPA, BPAF, BPS) and breast cancer diagnosis in women in Serbia, by comparing concentrations in urine samples of patients and healthy subjects. Additionally, the influence of lifestyle habits (frequency of canned food consumption, use of plastic packaging, and number of white dental fillings) on urinary bisphenol levels was evaluated.

The study included 72 participants, of which 40 were breast cancer patients, and 32 were healthy subjects who formed the control group. Urine samples were collected at the University Hospital Medical Center "Bežanijska Kosa" in Belgrade, Serbia. Concentrations of BPAF and BPS were measured using GC-MS/MS, while BPA was measured using an ELISA. Lifestyle habits were assessed using a questionnaire developed based on known exposure pathways, obtained from data from the European Chemicals Agency (ECHA) and in accordance with REACH guidelines, as well as relevant scientific literature.

Urinary BPA levels were statistically significantly higher in the patient group compared to the control group, while no statistically significant differences were observed for BPAF and BPS. No statistically significant association was found between self-reported lifestyle habits and urinary bisphenol concentrations. In some cases, higher bisphenol levels were observed in participants reporting fewer risk-related habits.

The results suggest a possible correlation between elevated urinary BPA levels as a marker of BPA exposure and breast cancer development. Based on the current data, no association can be established between BPAF and BPS and breast cancer. The presence of bisphenols in the urine of both study groups indicates their widespread distribution and significant exposure among women in Serbia. The results of the assessment of the impact of lifestyle habits highlight the complexity of bisphenol exposure assessment and the limited reliability of self-reported data as indicators of internal exposure.

Keywords bisphenols, breast cancer, questionnaire, lifestyle habits, urine

Objective: The gut microbiome is a source of potential non-invasive biomarkers, so we investigated the relationship

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

between serum levels of microbiome-derived short-chain fatty acids (SCFAs) and sensory diabetic polyneuropathy (DPN) in patients with comorbid type 2 diabetes mellitus (T2DM) and non-alcoholic fatty liver disease (NAFLD).

Methods: We prospectively enrolled 167 patients with T2DM and NAFLD (2023-2025). A matched cohort of 55 patients (37 T2DM +steatosis (ST), 18 T2DM+steatohepatitis (SH)) underwent detailed assessment. SH was diagnosed by transient elastography with elevated ALT and AST (patients with other reasons of high level of this enzymes excluded). Serum SCFAs were quantified by gas chromatography-mass spectrometry (GC-MS) (Agilent Technologies, USA). Sensory neuropathy was evaluated via standardized tests: vibration (128 Hz tuning fork), thermal (TipTherm, at 23 °C), and tactile (10-g monofilament) sensitivity. Statistical analyses used Fisher's exact test and binary logistic regression.

Results: The prevalence of DPN was high (89.2% T2DM+ST vs 88.9% T2DM+SH) and comparable. No significant differences were found in vibration ($P = .382$), tactile or temperature ($P = .713$) impairment. Distinct SCFA profiles predicted each sensory modality: thermal impairment (Nagelkerke $R^2 = 0.582$, 78% sensitivity (Se) and 73.5% specificity (Sp), $P = .039$) was associated with C2, C4, C5; tactile impairment ($R^2 = 0.507$, Se – 78.3% and Sp – 67.9%, $P = .039$) with C3, C5, iC5, C6; and vibration impairment ($R^2 = 0.641$, Se – 70.6% and Sp – 82.6%, $P = .044$) with C2, C3, iC4, C6.

Discussion/Conclusion: This pilot study confirms a high burden of sensory DPN in T2DM-NAFLD patients. The finding that distinct SCFA profiles are associated with thermal, tactile, and vibratory deficits suggests divergent pathophysiological mechanisms and highlights the relevance of branched-chain isomers (iC4, iC5). While these preliminary results indicate a link between SCFAs and specific nerve fiber damage, the cross-sectional design limits causal inference. Further longitudinal and mechanistic studies are needed to validate these associations and explore therapeutic implications.

EP1750 - LBA_ECE_1239 - The impact of glycated hemoglobin on rehospitalizations in patients with peripheral arterial disease undergoing surgical intervention

Jennifer Romani, Izabella Zgoda, Beatriz Santos, Julia Ventura Niclewicz, Amanda Araújo MacHado and Giovanna Voigt Pisconti MacHado
Hospital Universitário Cajuru, Curitiba, Brazil

Introduction: Peripheral Arterial Disease (PAD) is a serious manifestation of atherosclerosis, frequently associated with diabetes mellitus (DM). Chronic glycemic control, measured by glycated hemoglobin (HbA1c), is a key parameter for identifying perioperative risks and optimizing clinical outcomes in patients undergoing vascular surgical procedures.

Objective: To investigate the association between HbA1c levels at admission and the 30-day readmission rate in patients with PAD undergoing vascular procedures at a tertiary care hospital.

Methods: A retrospective, analytical study was conducted involving a review of the medical records of 136 patients who underwent vascular surgical procedures between January 2023 and October 2025. The sample was divided into controlled HbA1c (≤7%) and elevated HbA1c (>7%) groups. Chi-square tests, Fisher's exact test, and Student's t-test were used for statistical analysis.

Results: Most patients were male (70.6%) and underwent emergency surgery (66.9%). Prior DM was identified in 67.6% of the sample. There was no statistically significant difference in the readmission rates between the two groups (33.3% for the controlled group and 27.8% for the elevated group, $P = .571$). The mean length of stay also showed no significant difference between the groups ($P = .216$).

Conclusion: HbA1c levels at admission did not act as isolated predictors of readmission within 30 days. In high-severity and critical ischemia scenarios, where emergency interventions predominate, acute clinical status and the extent of vascular disease have a greater impact on short-term outcomes than chronic metabolic control.

Keywords diabetes mellitus, peripheral arterial disease, glycated hemoglobin, hospital rehospitalization, vascular surgery

EP1751 - LBA_ECE_1411 - Rare presentation of down syndrome without congenital heart defect complicated by hypothyroidism, dyslipidemia, and ischemic heart disease in a 10-year-old girl—marked improvement after treatment

Uttam Kumar Dey
Birdem Hospital, Dhaka, Bangladesh

Background: Down syndrome (DS, trisomy 21) is frequently associated with congenital heart defects (40%-60% prevalence), hypothyroidism (up to 25% in children), intellectual disability, and dyslipidemia. Acquired ischemic heart disease (IHD) is exceptionally rare in pediatric DS, especially in the absence of septal defects. Untreated hypothyroidism can exacerbate cardiac strain, cognitive impairment, and delayed puberty. We present a rare case of late-diagnosed DS without congenital septal defect, complicated by hypothyroidism-induced features of IHD and dyslipidemia, with remarkable recovery after targeted therapy.

Case Presentation: A 10-year-old girl presented with low IQ and developmental delay. Karyotyping confirmed DS (47,XX,+21). Echocardiography revealed no septal defect or major congenital heart anomaly. Laboratory evaluation showed overt hypothyroidism (elevated TSH, low free T4), dyslipidemia (elevated total cholesterol and LDL), and clinical/electrocardiographic features consistent with myocardial ischemia (ST-segment changes, exertional symptoms). No coronary anomalies were identified. Multidisciplinary management included levothyroxine replacement (titrated to normalize thyroid function), statin therapy for dyslipidemia, anti-ischemic measures, nutritional support, and developmental interventions.

Results: After 12-18 months of consistent treatment, the patient showed significant improvement: thyroid function normalized, lipid profile improved markedly, ischemic symptoms resolved completely, and repeat cardiac evaluation demonstrated stable ventricular function. Cognitive and memory functions enhanced noticeably (improved school performance and recall). Menarche occurred at age 11, indicating restored pubertal progression. Overall quality of life improved with better daily functioning and reduced fatigue.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Conclusion: This case highlights that late diagnosis of DS can present with reversible multimorbidity, including hypothyroidism-driven IHD and dyslipidemia even without structural heart defects. Early thyroid screening and aggressive multidisciplinary management in DS can reverse cardiac, metabolic, cognitive, and pubertal complications. Routine thyroid function testing and cardiac vigilance are essential in all DS patients, regardless of age or absence of congenital heart disease. Larger prospective studies in resource-limited settings are warranted to optimize protocols.

EP1752 - LBA_ECE_1438 - Case study—pseudohypoparathyroidism: albright hereditary osteodystrophy (AHO)

Nazi Tchelidze[1] and Natia Vashakmadze[2]
[1]Endocrinology, LTD"Aversi Clinic"; University of Georgia, Aversi Clinic, Tbilisi, Georgia; [2]Endocrinology, Israeli-Georgian Medical Research Clinic "Healthycore"; Ilia State University, Israeli-Georgian Medical Research Clinic "Healthycore", Tbilisi, Georgia

A patient, 24 y/o female, presented with weakness, fatigue, brittle nails, frequent cramping around her mouth. She had been diagnosed with epilepsy from 10 years of age. The main trigger for the seizures—increased physical activity. She was being treated with carbamazepine and levetiracetam. The June 2024 brain CT scan showed multiple areas of calcification (especially in cerebellar area and basal ganglia), that led to her neurologist checking the levels of PTH which was markedly elevated – 322 ng/l (normal range 11-43). Additional tests: total Ca^{2+} – 1.23 mmol/l (2.15-2.5); albumin – 28 g/l (35-52); corrected Ca^{2+} – 1.02 mmol/l; ionized Ca^{2+} – 0.67 mmol/l (1.12-1.32); Mg^{2+} – 0.64 mmol/l (0.66-1.07); Pi – 2.22 mmol/l (0.81-1.45); 25(OH)D3 – 6.71 ng/mL (30-100). Clinical signs: short stature, short fingers (especially the 4^{th} and 5^{th}), obesity, round face, apparent physical and mental developmental delay.

Based on the patient's history, lab results and physical evaluation the diagnosis of pseudohypoparathyroidism type 1a was made. At the same time she was diagnosed with chronic hypothyroidism (TSH – 7.7 mIU/mL) due to the thyroid gland hypoplasia. The patient was prescribed calcitriol, cholecalciferol, calcium carbonate, magnesium carbonate/oxide, levothyroxine. Within the month PTH levels normalized – 16 ng/l (11-43), total and corrected calcium levels increased – 2.45 mmol/l (2.15-2.5).

After 5 months of treatment, on the patient's next clinic visit all the initial laboratory results had been normalized: PTH – 19 ng/l, 25(OH)D – 29.4 ng/mL, TSH – 6.26 mIU/l, corrected Ca – 2.28 mmol/l, ionized Ca^{2+} – 1.22 mmol/l, Pi – 1.3 mmol/l, Mg^{2+} – 0.79 mmol/l.

Due to continuous treatment and surveillance, the patient's symptoms and overall quality of life has improved. The complete withdrawal of the antiepileptic medications is planned, the doses are being titrated down by the neurologist. The patient has not had any more cramps or seizures.

Abstract citation ID: lvag096.1809

EP1754 - LBA_ECE_1086 - The value of PTH fine needle aspiration washout in the preoperative diagnostic work-up of primary hyperparathyroidism: a retrospective real-life study

Antonino Russo[1], Davide Donner[2], Fabio Magnani[2], Marco Erini[2], Silvia Fasanella[3], Carlo Cosimo Quattrocchi[4] and Vito Racanelli[1]
[1]Internal Medicine Division, Azienda Sanitaria Universitaria Integrata del Trentino (ASUIT), Santa Chiara Hospital, Trento, Italy; [2]Nuclear Medicine Unit, Azienda Sanitaria Universitaria Integrata del Trentino (ASUIT), Santa Chiara Hospital, Trento, Italy; [3]Clinical Pathology Unit, Azienda Sanitaria Universitaria Integrata del Trentino (ASUIT), Santa Chiara Hospital, Trento, Italy; [4]Multizonal Unit of Rovere to and Arco, Radiology, Azienda Sanitaria Universitaria Integrata del Trentino (ASUIT), Rovereto, Italy

Introduction: The success of Minimally Invasive Parathyroidectomy (MIP) is dependent upon the precision of imaging modalities necessary for Parathyroid Adenoma (PA) localization.[1] Parathyroid hormone assay on fine needle aspiration ultrasound-guided biopsy (FNA-US) washout is a promising, simple and safe localization's diagnostic method.[2]

Aim: Evaluate if PTH FNA-US washout, due to its safety and the possibility of combining it with ultrasound examination, could be characterised as a first-level investigation in the diagnostic work-up of primary hyperparathyroidism, and the role of nuclear medicine diagnostic tools to identify PA.

Methods: A single-center retrospective study on 32 patients undergoing parathyroidectomy for primary hyperparathyroidism. Histological data and PTH levels in FNA washout were available for all patients. Biochemical assessment together with nuclear imaging (99mTc-MIBI-SCAN, PET-CT 18F-Choline) were evaluated.

Results: In 20/32 patients (21.8%), PTH FNA-US washout was positive: 7/20 (35%) were referred for surgery based only on PTH FNA-washout, and in all cases, histological examination confirmed the preoperative diagnosis of localization; 13/20 (65%) were referred to surgery based on the results of PTH FNA washout + MIBI; however, only in 7/13 (53.8%) MIBI was diagnostic, while in the remaining 6/13 (46.2%) it was not diagnostic. In 12/32 patients (37%), the PTH FNA-US washout value was negative. In this group, the sensitivity of MIBI was 6/12, or 50%. In the remaining patients, where both PTH FNA washout and MIBI were negative, 18F-Choline PET-CT was performed and allowed parathyroid adenoma to be located in 100% of cases.

Conclusions: Although the limited data and its retrospective nature, this study emphasises the usefulness of the PTH FNA-US washout method in the preoperative diagnosis of primary hyperparathyroidism. This method could be characterised as a first-level investigation in a large proportion of patients and could be a filter for selecting those patients to be sent for a single second-level examination such as 18F-Choline PET-CT for preoperative localization of the incriminated parathyroid gland. In this context, the use of MIBI could be avoided, which would reduce costs, diagnosis times and the degree of radiation exposure for patients.

EP1755 - LBA_ECE_1325 - Altered myokine profile and reduced muscle strength in primary hyperparathyroidism: reversal after parathyroidectomy

Seren Aksun[1], Banu Ertürk[1], Incilay Lay[2], Ahmet Bülent Doğrul[3], Ömer Cennet[3], Didem Karaduman[4], Murat Pehlivan[4], Meltem Gülhan Halil[4] and Alper Gurlek[1]
[1]Division of Endocrinology and Metabolism, Department of Internal Medicine, Hacettepe University Faculty of Medicine, Ankara, Turkey; [2]Department of Biochemistry, Hacettepe University Faculty of Medicine, Ankara, Turkey; [3]Department of General Surgery, Hacettepe University Faculty of Medicine, Ankara, Turkey; [4]Division of Geriatrics, Department of Internal Medicine, Hacettepe University Faculty of Medicine, Ankara, Turkey

Background and Aim: Primary hyperparathyroidism (PHPT) is associated with skeletal and neuromuscular manifestations; however, the potential role of myokines in PHPT-related muscle dysfunction remains poorly understood. We aimed to evaluate circulating myokine levels and muscle strength in patients with PHPT and to assess their changes after parathyroidectomy.

Methods: Fifty-seven patients with primary hyperparathyroidism (PHPT) and 50 age-, sex-, and body mass index (BMI)-matched healthy controls were included. Circulating levels of myostatin, follistatin, decorin, irisin, adiponectin, rantes, and resistin were measured. Muscle strength was assessed using handgrip dynamometry. A subgroup of 30 patients were reassessed after parathyroidectomy with a median follow-up of 134 days. Correlation analyses and adjusted group comparisons were performed.

Results: Patients with PHPT exhibited significantly higher circulating myostatin levels (30.3 ± 7.2 vs 23.7 ± 8.0 ng/mL, $P < .001$) and decorin levels (1081.3 vs 852.0 pg/mL, $P = .003$), **accompanied by lower circulating follistatin levels** ($P = .048$). Handgrip strength was also reduced in the PHPT group (24.1 vs 26.6 kgf, $P = .03$). Circulating myostatin levels showed positive correlations with both PTH ($r = 0.346$, $P < .001$) and serum calcium levels ($r = 0.373$, $P < .001$). After adjustment for age, sex, and BMI, PHPT status remained a significant determinant of circulating myostatin levels (ANCOVA $F = 9.57$, $P = .003$).

Parathyroidectomy was associated with significant changes in circulating myokines and muscle strength, marked by a reduction in myostatin levels (30.7 ± 7.7 to 22.7 ± 9.9 ng/mL, $P < .001$) and concomitant increases in follistatin ($P < .001$), irisin ($P = .003$), and handgrip strength ($P = .007$).

Conclusion: PHPT is characterized by a distinct circulating myokine profile marked by increased myostatin and reduced follistatin levels, accompanied by impaired muscle strength. The reversal of these alterations after parathyroidectomy suggests a potentially reversible myokine-mediated mechanism underlying muscle dysfunction in PHPT and supports a role for the myostatin–follistatin axis in the neuromuscular manifestations of this disease.

Background: Adult-onset growth hormone deficiency (AO-GHD), most commonly secondary to pituitary or hypothalamic pathology, is associated with impaired quality of life (QoL) and adverse metabolic outcomes. NICE TA64 recommends GH therapy only in severe cases with documented QoL impairment and continuation only if benefit is demonstrated. Contemporary UK real-world data on AO-GHD remain limited.

Methods: We retrospectively analysed adults diagnosed with GHD at ≥18 years and currently receiving GH therapy at a tertiary endocrine centre. Extracted variables included demographics, aetiology, diagnostic modality, pituitary hormone deficits, IGF-1 values, and Adult Hypopituitarism and Growth Hormone Deficiency Assessment (AGHDA) scores. Pre- and post-treatment AGHDA scores were compared.

Results: Of the 50 patients receiving GH therapy, 29 met criteria for AO-GHD. The mean age at diagnosis was 51.0 ± 15.7 years (range 24-75), with most patients aged 60-75 years. The current mean age is 62.1 ± 12.7 years (range 44-84). The cohort was predominantly Caucasian (93%) and female (18/29).

Non-functioning pituitary adenoma (NFPA) was the leading aetiology (52%), followed by craniopharyngioma (10%), prolactinoma (7%), acromegaly (7%), and rarer causes including autoimmune hypophysitis, Sheehan's syndrome, and chemotherapy-associated GHD.

Diagnosis was confirmed by GH stimulation testing in 25/29 (86%), predominantly via Glucagon stimulation test. Four patients were diagnosed based on low IGF-1 with ≥3 additional pituitary deficits (2/29) or historical documentation (2/29).

Multi-axis pituitary failure was common: central hypothyroidism (97%), ACTH deficiency (69%), ADH deficiency (28%), and hypogonadism in all males. Six patients had four additional hormonal deficits and eleven had three.

AGHDA scores improved significantly from baseline (median 17, range 12-22) to follow-up (median 10, range 7-15). Current GH doses ranged from 0.2-0.5 mg/day.

Limitations included missing baseline AGHDA scores in long-standing patients and incomplete diagnostic documentation in transferred cases.

Conclusion: AO-GHD in this UK cohort was predominantly secondary to NFPA and characterised by a high burden of multi-axis pituitary hormone deficiency. GH therapy was associated with clinically meaningful improvement in QoL scores. These findings emphasise the importance of systematic pituitary assessment, adherence to NICE TA64, and structured long-term follow-up in adults with suspected GHD.

EP1759 - LBA_ECE_1376 - Higher order serum–adipose coordination defines functional markers of glucocorticoid action

Kate Bennett[1], Dimitrios Chantzichristos[2], Anja Meyer[1], Eleanor Doman[1], Terence Garner[1], Per-Anders Jansson[2], Gudmundur Johannsson[2] and Adam Stevens[1]
[1]Developmental Biology and Medicine, University of Manchester, Manchester, United Kingdom; [2]Sahlgrenska University Hospital, Gothenburg, Sweden

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: Glucocorticoids (GCs) regulate metabolism across tissues, yet systems-level mechanisms linking adipose and circulating metabolites remain unclear. Analyses often track pathways or pairwise correlations and miss *higher-order interactions*—coordinated relationships among ≥3 molecular features that reveal emergent organisation. We asked how GCs reorganise this higher-order, adipose–serum multi-omic structure in humans.

Methods: In a randomised, cross-over trial ($n = 10$) with near-physiological hydrocortisone exposure versus withdrawal (26 h), we profiled transcriptomics and microdialysis metabolomics in adipose tissue, and serum metabolomics. We quantified:

transcriptomic entropy (pathway-level specialisation);

) hypergraph modelling of higher-order associations (hyperedges linking multiple nodes);

topological data analysis (TDA) to characterise global omic architecture (connected components H0, loops H1, voids H2).

Group differences (GC exposure vs withdrawal) were assessed using Δ total co-degree and Wasserstein distance, with bootstrapping and permutation testing to confirm that differences reflected genuine GC-driven network reorganisation.

Results: GC exposure in adipose tissue increased lipid mobilisation and amino-acid catabolism. Entropy analysis revealed consistent pathway-level reorganisation across nine metabolic pathways, distinct from random controls. Adipose entropy was generally lower during GC exposure—indicating more specialised networks—while amino-acid, carbohydrate and lipid catabolism showed the strongest changes.

Cross-tissue hypergraphs revealed that serum metabolites formed more higher-order connections to both adipose transcripts and adipose metabolites during exposure. This produced a right-shift in Δ total co-degree (mean $\Delta = 0.167$ exposure vs −0.003 withdrawal), demonstrating increased serum–adipose higher-order coordination beyond pairwise relationships.

TDA confirmed robust topological separation between GC states: inter-state Wasserstein distances exceeded intra-state across dimensions ($H1 = 1.36$, $H0 = 1.22$, $H2 = 0.74$; permutation $P = .0005$). GC exposure also generated longer-persistence H1 features, indicating a more ordered integrated serum–adipose network structure. Independent TDA testing across homology dimensions yielded $P < .05$.

Conclusion/Clinical Application: GCs remodel not only adipose-intrinsic pathways but also the higher-order architecture linking adipose molecular networks to circulating metabolites. This distinguishes changes arising in adipose tissue (lipid and amino-acid metabolism, pathway specialisation) from those detected in serum (cross-tissue higher-order coordination and topological restructuring). Circulating metabolites embedded in these multi-molecule features represent mechanistically anchored serum markers of adipose GC action. Such markers could support personalised glucocorticoid dosing in adrenal insufficiency by more accurately capturing tissue-level GC effects.

EP1760 - LBA_ECE_1404 - Enhanced selectivity and reduced off-target effects of seviteronel as a CYP17A1 inhibitor targeting castration-resistant prostate cancer

Jibira Yakubu, Therina Du Toit and Amit Pandey
University of Bern, Bern, Switzerland

Background: Androgen Receptor (AR) signaling remains a key driver in castration-resistant prostate cancer (CRPC), necessitating agents that effectively suppress it. While abiraterone is a foundational therapy that inhibits the CYP17A1 enzyme, its lack of selectivity leads to off-target endocrine effects requiring concomitant corticosteroid administration. Recent studies also connect AR signaling to ferroptosis, a form of programmed cell death, suggesting that AR inhibition may sensitize cells to this pathway.

Aims: To compare the next-generation CYP17A1 inhibitor seviteronel against abiraterone. The analysis aims to delineate seviteronel's mechanistic and selectivity profiles and to explore its potential to induce ferroptosis by targeting the AR axis.

Methods: We synthesized preclinical data from in vitro and in vivo studies. In vitro assays included proliferation studies in prostate cancer cell lines (LNCaP) and steroidogenic cell lines (NCI-H295R), as well as radioactive substrate and LC-MS analyses to measure androgen biosynthesis inhibition and selectivity. An AR ligand binding assay was used to characterize direct AR antagonism.

Results: Seviteronel demonstrated potent and highly selective inhibition of the CYP17A1 17,20-lyase activity (IC_{50} 69 nM), with a 10-fold selectivity over its 17α-hydroxylase activity (IC_{50} 670 nM). In contrast, abiraterone was found to be hydroxylase-selective, with an IC_{50}

of 2.5 nM for hydroxylase activity versus 15 nM for lyase activity. Seviteronel also showed no significant inhibition of the CYP21A2 enzyme, a key enzyme in cortisol synthesis, preventing the mineralocorticoid excess syndrome associated with abiraterone and allowing for a prednisone-free regimen. Though mechanistic studies on AR modulation and ferroptosis induction are ongoing, existing evidence suggests that AR axis disruption may enhance sensitivity to ferroptosis cell death. This dual mechanism may confer efficacy against mutated AR forms that drive resistance to abiraterone and other antiandrogens.

Conclusions: Seviteronel's superior selectivity and unique dual-action mechanism, combining potent androgen synthesis inhibition with direct AR antagonism, positions it as a promising next-generation therapeutic for CRPC. This profile not only addresses abiraterone's primary clinical limitations but also presents a novel strategy to overcome treatment resistance by potentially sensitizing tumors to ferroptosis. Further studies are warranted to fully explore this synergistic effect.

EP1764 - LBA_ECE_1033 - A decade-long diagnostic journey: central diabetes insipidus as the first manifestation of multisystem langerhans cell histiocytosis

Melinda Kolcsar[1] and Krisztina Lázár[2]
[1]*Pharmacy, Sciences and Technology of Targu Mures, Pharmacology and Clinical Pharmacy, George Emil Palade University of Medicine, Tg Mures, Romania;* [2]*Endocrinology, Mures County Clinical Hospital, Tg Mures, Romania*

Introduction: Langerhans cell histiocytosis (LCH) is a rare disorder characterized by clonal proliferation and tissue infiltration of CD1a/CD207-positive dendritic cells. Although bone and skin are the most commonly affected sites, the hypothalamic–pituitary axis may also be involved. Arginine vasopressin (AVP)

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

deficiency, presenting as central diabetes insipidus, may represent the first manifestation of the disease, often preceding the diagnosis of LCH.

Case Presentation: A previously healthy 31-year-old woman presented in December 2009 with severe polyuria and polydipsia, consuming approximately 16 liters of fluid daily. A positive water deprivation test confirmed central diabetes insipidus, while other pituitary hormones were initially within the normal range. Sellar MRI demonstrated the absence of the posterior pituitary bright spot, a thickened pituitary stalk (4.5 mm), and a small suprasellar lesion, initially interpreted as lymphocytic hypophysitis. Desmopressin therapy successfully controlled symptoms. During follow-up, the patient developed central hypogonadism and central hypothyroidism requiring hormone replacement. Serial MRI examinations showed progressive enlargement of the pituitary stalk lesion, which grew until 2021 (measuring $10 \times 7 \times 8$ mm), after which it stabilized. In 2022, a fracture of the left eighth rib prompted further investigation, revealing an osteolytic lesion. Histopathological examination following partial rib resection confirmed Langerhans cell histiocytosis (positive for CD1a, CD68, and S100). Retrospective evaluation also identified a previously excised vulvar lesion as LCH. Genetic analysis revealed the presence of wild-type BRAF-V600E. Follow-up PET-CT scans demonstrated decreasing metabolic activity of residual lesions under bisphosphonate therapy.

Discussion and Conclusion: The multisystem nature of the disease suggests that AVP deficiency and progressive multiple pituitary hormone deficiencies result from hypothalamic–pituitary infiltration by LCH. This case highlights AVP deficiency as a potential sentinel manifestation of infiltrative disorders, particularly when associated with thickening of the pituitary stalk.

EP1766 - LBA_ECE_1328 - Thoracic paraganglioma with SDHB germline mutation

Constantina Philippidou, Chrysanthi Balodimou, Georgios Christantoniou, Charalampos Papadopoulos, Eleana Zisimopoulou, Maria Boudina and Alexandra Chrisoulidou
Department of Endocrinology, Theagenio Cancer Hospital, National Center of Oncology, Thessaloniki, Greece

Thoracic paragnagliomas (PPGLs) are rare neuroendocrine tumors arising from extra-adrenal chromaffin tissue and are frequently associated with hereditary syndromes, such as mutations in the succinate dehydrogenase subunit B (SDHB) gene. These tumors often present diagnostic and therapeutic challenges due to their location and potential for multifocal and progressive disease.**Objective:** To present a case of intrathoracic paraganglioma located behind the inferior vena cava in a young patient harboring an SDHB germline mutation.

Methods: A 21-year-old woman presented with long-standing hypertension, palpitations, vomiting and intermittent febrile episodes, for approximately two years. Cardiac magnetic resonance imaging identified a 35×35 mm mass posterior to vena cave without evidence of vascular invasion. Biochemical assessment demonstrated elevated 24-hour urinary metanephrines and normetaphrines. Histopathological evaluation following unsuccessful surgical intervention due to extensive hemorrhage, confirmed paraganglioma, with Ki-67 index 2%, 10 mitotic figures, absence of necrosis, and positive synaptophysin immunostaining and CgA. Fuctional imaging included MIBG scintigraphy, Ga-PET, FDG-PET.

Results: Ga-PET demonstrated uptake in the main lesion (SUVmax 4,6), while FDG-PET revealed intense metabolic activity (SUVmax 44,6) and two additional nodular lesions, suggestive of multifocal disease involvement. The patient underwent embolization followed by three therapeutic doses of 131-MIBG, confirming uptake in the known lesions. Follow-up computed tomography scans indicated further progressive enlargement of the lesion to 5 cm despite medical treatment with alpha-adrenergic blockade, beta-blockers, and calcium channel antagonists.

Conclusion: Thoracic paragangliomas associated with SDBH mutations represent rare but clinically significant entities with potential for multifocal progression. Management often requires a multimodal approach, including embolization, radionuclide therapy and systemic or targeted treatments such as peptide receptor radionuclide therapy (PRRTs), chemotherapy, tyrosine kinase inhibitors and local therapies. Multidsciplinary evaluation is essential for optimizing patient outcomes.

EP1767 - LBA_ECE_1133 - Self-management education in type 2 diabetes: a path to better glycemic control and patient outcomes

Daria Lahoda, Valentyna Velychko and Yelyzaveta Tuliantseva
Odessa National Medical University, Odesa, Ukraine

Background: Type 2 diabetes remains a major global health challenge, particularly in patients with obesity, where glycemic control is often suboptimal. Patient education and self-management are ключові components of effective care. However, real-world evidence on their clinical impact is limited, highlighting the need to evaluate their role in improving metabolic outcomes and quality of life.

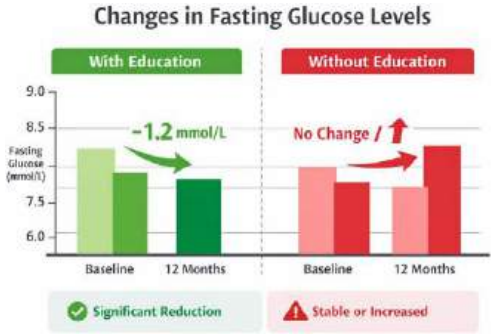
Materials and methods: A prospective observational study included patients with type 2 diabetes and obesity or overweight, divided into groups with and without self-management education. Clinical, metabolic, and behavioral parameters were assessed at baseline and after 3, 6, and 12 months. Statistical analysis was performed to evaluate changes and between-group differences.

Aim: To evaluate the impact of self-management education on glycemic control and clinical outcomes in patients with type 2 diabetes, with a focus on metabolic parameters, behavioral changes, and overall patient-related outcomes.

Results: Self-management education significantly improved glycemic control, with a sustained reduction in HbA1c over 12 months.

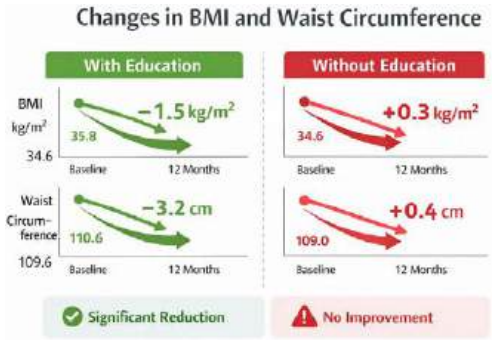
Fasting glucose levels decreased significantly in trained patients, while remaining stable or worsening without education.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

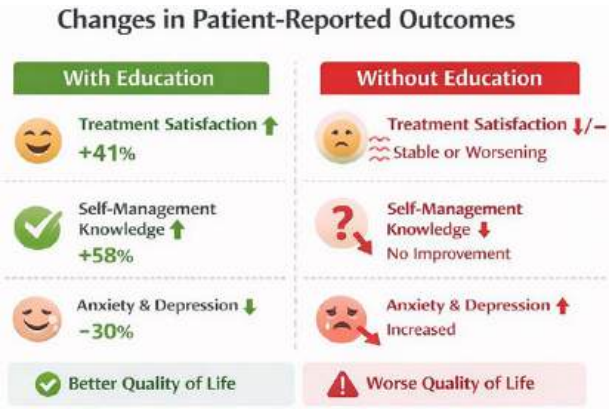


Timepoint	With Education	Without Education
Baseline	~7.6%-7.9%	~7.3%-7.5%
3 months	↓ significant	~no change
6 months	↓ further	slight increase
12 months	~6.8%-7.0%	~7.6%-7.9%

Patients who received education showed significant reductions in BMI and waist circumference, indicating improved metabolic status.



Education was associated with improved treatment satisfaction, reduced anxiety and depressive symptoms, and better self-management knowledge.



Conclusions:

1. Self-management education is a key driver of improved glycemic control in type 2 diabetes.
2. Educational interventions positively influence metabolic, behavioral, and psychological outcomes.
3. Integrating patient education into routine care can significantly enhance long-term diabetes management.

Abstract citation ID: lvag096.1817

EP1769 - LBA_ECE_1076 - Severe hyponatremia (104 mmol/L) and SIADH-like syndrome associated with tirzepatide: a novel safety signal

Nithin Tumkur Prasad[1,2]
[1]Bengaluru, India; [2]Department of Internal Medicine, Apollo Speciality Hospital | Best Hospital in Jayanagar, Bengaluru, India

Introduction: Tirzepatide, a dual glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) receptor agonist, is increasingly used for the management of type 2 diabetes and obesity. While gastrointestinal adverse effects are well recognised, its impact on water homeostasis remains poorly characterised.

Aim: To report a case of severe symptomatic hyponatremia with syndrome of inappropriate antidiuretic hormone secretion (SIADH)-compatible biochemical features temporally associated with tirzepatide therapy.

Case Report: In early February 2026, a 46-year-old woman with type 2 diabetes and obesity (BMI 45.4 kg/m^2) developed severe symptomatic hyponatremia two weeks after initiation of tirzepatide. At presentation, serum sodium was 104 mmol/L (baseline within normal limits) with a calculated serum osmolality of 224 mOsm/kg. Clinical examination was consistent with euvolemia.

Investigations: Biochemical evaluation demonstrated hypoosmolar hyponatremia with inappropriately elevated urine osmolality and urine sodium (assessed following appropriate diuretic washout), consistent with SIADH physiology. Adrenal insufficiency and hypothyroidism were excluded with normal morning cortisol and thyroid function tests. No alternative etiology was identified.

Management: The patient was managed in the intensive care unit with hypertonic saline and fluid restriction. Sodium correction was carefully controlled (<10 mmol/L per 24 h) to minimise the risk of osmotic demyelination syndrome. Tirzepatide was discontinued. Serum sodium normalised gradually with complete clinical recovery and no neurological sequelae.

Conclusion: The case suggests a probable association between tirzepatide and SIADH-compatible hyponatremia. Potential mechanisms include non-osmotic vasopressin release due to gastrointestinal symptoms or direct pharmacological effects on water regulation. The profound hyponatremia (Na 104 mmol/L) may reflect a synergistic 'triple-hit' mechanism: GLP-1/GIP-mediated inhibition of the renal sodium-hydrogen exchanger 3 (NHE3), increased atrial natriuretic peptide (ANP) release, and reduced oral solute intake. This is consistent with emerging pharmacovigilance signals suggesting dual-incretin agonists may contribute to SIADH-like presentations.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Impact: This case highlights a clinically significant and potentially under-recognised association between tirzepatide and severe hyponatremia. Given the frequency of gastrointestinal adverse effects during treatment initiation, heightened clinical vigilance may facilitate early identification and management of drug-associated hyponatremia. A low threshold for serum sodium monitoring should be considered in patients with significant gastrointestinal symptoms or concomitant diuretic use. Given its direct clinical implications, this case may inform practice and stimulate discussion in a broad cardiometabolic audience.

Abstract citation ID: lvag096.1818

EP1772 - LBA_ECE_1314 - Not All SIADH Is SIADH": chronic hyponatraemia revealing radiation-induced isolated secondary adrenal insufficiency despite preserved pituitary function

Paul Chatee, Muhammad Waqar Khan, Nur Fatin Aqilah Binti Suharinizam and Paul Pravin
Endocrinology, Univeristy Hospital Limerick, Limerick, Ireland

Background: Hyponatraemia is frequently attributed to Syndrome of Inappropriate Antidiuretic Hormone Secretion, particularly in patients with intracranial pathology. However, SIADH remains a diagnosis of exclusion, and adrenal insufficiency must be excluded prior to confirmation.[1] Secondary adrenal insufficiency is an important mimic, particularly following cranial radiotherapy.[2]

Case Presentation: We report a patient with a history of astrocytoma treated with cranial radiotherapy, presenting with chronic hypotonic hyponatraemia. Initial evaluation demonstrated low serum osmolality with inappropriately elevated urine osmolality and sodium, consistent with euvolaemic hyponatraemia, leading to a presumptive diagnosis of SIADH. Fluid restriction resulted in minimal improvement.

Further evaluation revealed a low morning cortisol. Plasma ACTH was within the reference range but inappropriately normal in the context of cortisol deficiency. A Synacthen test demonstrated a borderline cortisol response. Given persistent clinical suspicion, and as insulin tolerance testing was contraindicated due to intracranial pathology and seizure risk, a Glucagon stimulation test was performed, demonstrating an inadequate cortisol response and confirming secondary adrenal insufficiency.

Other pituitary axes were preserved, consistent with isolated corticotroph deficiency. In the context of prior cranial radiotherapy, this was attributed to hypothalamic–pituitary dysfunction. Glucocorticoid replacement resulted in rapid normalisation of serum sodium.

Discussion: Secondary adrenal insufficiency can mimic SIADH both clinically and biochemically. Cortisol deficiency increases vasopressin secretion and impairs free water clearance, producing an indistinguishable biochemical profile. In early disease, adrenal responsiveness to exogenous ACTH may be preserved, resulting in a borderline Synacthen response, while dynamic testing reveals impaired ACTH reserve. This highlights the importance of interpreting results in clinical context and pursuing further testing where suspicion persists.[3]

Conclusion: Adrenal insufficiency must be excluded in all cases of hyponatraemia prior to diagnosing SIADH. This case highlights the limitations of the Synacthen test and the importance of second-line dynamic testing, as failure to recognise this may delay treatment and worsen outcomes.

EP1773 - LBA_ECE_1350 - Coital cramps as a highly specific sentinel manifestation of subclinical hypokalemia in primary hyperaldosteronism: a striking case of refractory hypertension in a young woman

Claudia Arnas-Leon[1,2], Asuncion Acosta-Merida[3], Inmaculada Molinero-Marcos[1], Borja Santana-Ojeda[1], Ricardo Jose de Leon-Durango[1], Alba Hernandez-Lazaro[4], Carmen Acosta-Calero[5], Agnieszka Kuzior[2], Fabianna Genesi[6] and Francisco Javier Martinez-Martin[1,2]
[1]Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain; [3]Digestive and General Surgery, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [4]Servei d'Endocrinologia i Nutricio, Parc Taulí Hospital Universitari, Sabadell, Barcelona, Spain; [5]Cardiology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [6]Centro de Salud de Arucas, Arucas, Las Palmas, Spain

Background: Primary aldosteronism (PA) is the most common cause of secondary hypertension. However, it remains substantially underdiagnosed, often with prolonged diagnostic delay. Although classically characterized by hypertension and hypokalemia, fewer than one-third of patients present with overt hypokalemia, limiting clinical recognition.

In young, lean women, PA may present predominantly with hypokalemia-related neuromuscular symptoms, even in the absence of overt hypertension. Atypical presentations may further obscure diagnosis. We report a case of PA presenting with a previously undescribed symptom.

Case Presentation: A 30-year-old lean woman was referred to Endocrinology for refractory hypertension, maintained for the last three years. She did not use oral contraceptives. Over approximately the same timeframe she was experiencing recurrent intense bilateral lower limb cramps which were triggered only during sexual intercourse, resolving promptly with rest. She had undergone a thorough dyspareunia workup in a Gynecology Clinic with negative results. Serum potassium was borderline low (3.64 mEq/L) in multiple determinations, without overt hypokalemia. The renal angio-MRI showed normal renal arteries but also revealed a 1.2 cm left adrenal adenoma with signal drop on opposed-phase T1 imaging, suggestive of lipid-rich adenoma. After washout of the antihypertensive treatment, adrenal function testing was performed in the follicular phase, showing adequate cortisol suppression and normal plasma metanephrines, but borderline results for primary aldosteronism (aldosterone 151 pg/mL, renin 5.63 mIU/L, aldosterone-to-renin ratio 2.68). Confirmatory testing with captopril challenge showed

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

non-suppressible aldosterone (227-214 pg/mL) and persistently suppressed renin (1.61-1.57 mIU/) confirming PA (Litinsky-Conn syndrome). Adrenal venous sampling was not performed due to the patient's age. Laparoscopic left adrenalectomy was successfully performed. Postoperatively, serum potassium normalized rapidly, hypertension improved allowing drug withdrawal, and coital cramps resolved completely.

Discussion: This case illustrates a remarkably specific "stress test" unmasking relative hypokalemia: the autonomic activation, sustained isometric muscle contraction, and metabolic demand during coitus lowered the threshold for neuromuscular irritability due to aldosterone-driven potassium wasting. Literature on situation-specific neuromuscular symptoms in PA is virtually absent; generalized cramps or weakness predominate when hypokalemia is overt. The rapid and complete resolution of this sentinel symptom post-adrenalectomy underscores the causal link and highlights the value of detailed, unbiased history-taking in young patients with resistant hypertension.

Conclusions: Coital cramps can serve as a unique sign of underlying PA-associated hypokalemia. Systematic screening for PA should be pursued in refractory hypertension irrespective of potassium levels or classic features, as subtle or unexpected symptoms may hold the diagnostic key.

Abstract citation ID: lvag096.1820

EP1774 - LBA_ECE_1371 - Arginine vasopressin deficiency as the initial presentation of suspected multisystem Langerhans cell histiocytosis

Nisa Babacanlar, Kadircan Karatoprak, Can Özgü, Alper Batu, Rümeysa Kantar, Ozen Oz Gul, Soner Cander, Canan Ersoy and Erdinc Erturk
Department of Endocrinology and Metabolism, Bursa Uludag University, Bursa, Turkey

Background: Arginine vasopressin deficiency (AVP-D) is a rare disorder characterized by impaired vasopressin secretion, resulting in polyuria and polydipsia. Although many cases are idiopathic, infiltrative and neoplastic disorders should be considered, particularly in patients with pituitary stalk abnormalities. Langerhans cell histiocytosis (LCH) is a rare inflammatory myeloid neoplasm that may involve multiple organs, including the lungs and hypothalamic-pituitary axis. AVP-D may rarely be the first manifestation of multisystem disease.

Case Presentation: A 24-year-old man presented with progressive polydipsia and polyuria. His daily fluid intake had increased from 5-6 L to approximately 15 L. He had no history of head trauma, malignancy, cranial surgery, or medication use, and reported smoking one pack every three days. Initial evaluation revealed a urine density of 1.004 and serum sodium of 147 mmol/L. The patient was diagnosed with AVP-D and started on desmopressin therapy. Following treatment, urine osmolality increased and urine output decreased, supporting the diagnosis. Pituitary magnetic resonance imaging demonstrated loss of the posterior pituitary bright spot and thickening of the infundibular stalk (3.5 mm), suggesting an infiltrative process. Seven months after the diagnosis of AVP-D, thoracic computed tomography performed for an unrelated indication revealed bilateral upper lobe–predominant cystic changes and multiple centrilobular ground-glass nodules, raising suspicion for pulmonary Langerhans cell histiocytosis; miliary tuberculosis was also considered in the differential diagnosis but was subsequently excluded based on clinical and microbiological evaluation. Positron emission tomography showed diffuse reticulonodular changes with mild heterogeneous hypermetabolic activity, consistent with interstitial lung involvement. Bronchoalveolar lavage cytology was benign, immunohistochemical staining was negative for CD1a and Langerin, and BRAF V600 mutation analysis was negative. Given the characteristic radiological findings and clinical context, thoracic imaging was considered highly compatible with pulmonary LCH, and invasive biopsy was not pursued. Considering the coexistence of AVP-D, pituitary stalk thickening, pulmonary involvement, and smoking history, multisystem LCH was considered the most likely diagnosis.

Conclusion: AVP-D may be the initial manifestation of multisystem LCH. In patients presenting with AVP-D and pituitary stalk thickening, LCH should be considered in the differential diagnosis even in the absence of histopathological confirmation, particularly when characteristic pulmonary findings emerge during follow-up. Although BRAF mutations are detected in more than half of cases, their absence does not exclude the diagnosis. Early recognition of this association is important for timely evaluation of systemic involvement and long-term endocrine follow-up.

EP1776 - LBA_ECE_1240 - Targeting prediabetes and MASLD: effects of a nutraceutical based on white mulberry, fenugreek, inulin, niacin, chromium and zinc on FIB-4 score and C-reactive protein in subjects with prediabetes

Inmaculada Molinero-Marcos[1], Sara Andrada-Diaz[2], Agnieszka Kuzior[3], Ana Maria Sanchez Garcia[3], Juan Fernandez-Jimenez[3], Irene Hernandez-Hernandez[1,3], Facundo Marcelo Guerrero-Kesselman[3], Borja Santana-Ojeda[1], Claudia Arnas-Leon[1,3] and Francisco Javier Martinez-Martin[1,3]
[1]Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Medical Advisory, Bioksan Naturalmente Juntos, Las Palmas de Gran Canaria, Spain; [3]Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain

Background and Objectives: Prediabetes is frequently associated with overweight or obesity, low-grade chronic inflammation, and metabolic dysfunction-associated steatotic liver disease (MASLD). We conducted a trial in patients with prediabetes to evaluate a novel nutraceutical. This formulation includes several key components:

- White mulberry (*Morus alba*) leaf extract, containing the α-glucosidase inhibitor 1-deoxynojirimycin;
- Fenugreek (*Trigonella foenum-graecum*) extract, an AMPK activator;
- Inulin (a soluble fiber) and *Lactiplantibacillus plantarum* A7 (a probiotic);
- Niacin (vitamin B_3), chromium, and zinc.

The primary endpoint was the change in insulin resistance, estimated by HOMA2-IR index, a predictor for the development of type 2 diabetes (T2DM).

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

In this substudy, we aimed to assess changes in liver enzymes and the FIB-4 score. We also examined related changes in body mass index (BMI) and C-reactive protein (CRP), while monitoring the overall tolerability.

Methods: Adult participants with prediabetes were enrolled in this open-label trial to receive a daily dose of the nutraceutical over a 6-month period, including a 3-month interim assessment.

The clinical evaluations at each visit included BMI, HOMA2-IR index, FIB-4 score, liver enzymes (ALT, AST, GGT) and CRP. Additionally, a questionnaire was used to record adverse effects.

Results: Out of the 144 individuals enrolled, 113 finished the trial (71 female, age 56.4 ± 6.7 years).

The HOMA2-IR index decreased from 1.659 ± 0.721 to 1.269 ± 0.581, (−23.5%, $P < .001$). 33 participants (29.2%, $P < .001$) achieved normoglycemia, whereas 3 (2.65%, p NS) progressed to T2DM. Notably, there were no significant alterations in body weight during the study period.

The FIB-4 score decreased from 1.42 ± 0.25 to 1.22 ± 0.24 ($P = .003$). The number of patients with FIB-4 <1.45 (cutoff point for low risk of liver fibrosis) increased significantly ($P = .028$) from 61 (54%) to 78 (69%). Plasma CRP decreased from 3.66 ± 1.97 to 2.89 ± 1.27 (−21%; $P < .001$).

Although a few patients (9, 8%) reported mild gastrointestinal side effects, the treatment was well-tolerated overall, with no serious issues or related study withdrawals.

Conclusions: The nutraceutical was well-tolerated and yielded significant improvements in insulin resistance among patients with prediabetes, occurring independently of alterations in body mass index.

Treatment was further associated with a marked attenuation of systemic inflammation and a reduction in liver fibrosis risk, as characterized by significant decreases in CRP levels and FIB-4 scores, alongside an increased proportion of patients achieving low-risk status. These findings suggest a potential therapeutic role in mitigating the metabolic and hepatic dysfunctions associated with prediabetes, warranting further validation in controlled clinical trials.

Background and Objective: Globally, diabetic nephropathy represents a major concern for public health. Prediabetes is associated with insulin resistance, low-grade inflammation, endothelial dysfunction, and activation of the renin–angiotensin system. These mechanisms can lead to subtle glomerular damage and increased urinary albumin excretion even before the onset of overt hyperglycemia.

We investigated the effects of a novel nutraceutical in individuals with prediabetes. This formulation combined white mulberry leaves (containing the potent competitive α-glucosidase inhibitor 1-deoxynojirimycin), fenugreek (an AMPK activator), inulin (soluble fiber), the probiotic *Lactiplantibacillus plantarum* A7, niacin, chromium, and zinc. While the primary endpoint focused on changes in the HOMA2-IR insulin resistance index (a key indicator for the risk of developing T2DM) this specific substudy evaluates alterations in renal function.

The objective was to examine changes in the albumin/creatinine ratio (ACR) and estimated glomerular filtration rate (eGFR), and to determine how these relate to changes in HOMA2-IR.

Methods: This open-label study enrolled adults with prediabetes who were administered the nutraceutical once daily over a 6-month period. Assessments for eGFR, ACR, and HOMA2-IR were conducted at baseline, at a 3-month interim visit, and at the 6-month conclusion. Furthermore, any issues regarding tolerability were documented using a participant questionnaire.

Results: The study was completed by 113 of the 144 enrolled patients (78.5%), including 71 women, with a mean age of 56.4 ± 6.7 years. A significant reduction in HOMA2-IR was observed, falling from 1.659 ± 0.721 to 1.269 ± 0.581 (−23.5%, $P < .001$). While 3 patients (2.65%, p NS) progressed to T2DM, 33 individuals (29.2%, $P < .001$) successfully reached normoglycemia.

Regarding renal markers, eGFR showed no significant variation, moving from 86.5 ± 11.9 to 88.3 ± 11.6 ($P = .251$, paired t-test). However, albuminuria experienced a significant decline from 28.4 ± 15.2 to 21.5 ± 14.3 mL/min/1.73 m^2 (−24.3%, $P = .036$, Mann-Whitney´s U).

A backwards stepwise multiple regression analysis identified the change in HOMA2-IR as a significant independent predictor of eGFR alterations (p-value 0.012). In contrast, changes in HbA1C, body weight, or mean blood pressure did not function as independent predictors.

Conclusions: This study shows that the nutraceutical significantly improves insulin resistance in prediabetes, with nearly 30% of participants reverting to normoglycemia. Kidney filtration (eGFR) remained stable, while albuminuria decreased significantly, indicating reduced early renal damage. Changes in insulin resistance independently predicted renal function changes, unlike HbA1c, weight, or blood pressure. These findings suggest that improving insulin sensitivity may play a key role in protecting renal health, supporting this nutraceutical as a promising strategy for early metabolic and renal risk reduction.

EP1778 - LBA_ECE_1292 - GLP-1 receptor agonist therapy in "double diabetes": a case demonstrating arked improvement in glycaemic control and insulin requirements in type 1 diabetes

Tabinda Dugal

Endocrinology Unit, Lusail, Qatar

Background: "Double diabetes" describes individuals with type 1 diabetes (T1D) who develop insulin resistance, often associated with overweight or obesity, leading to increased insulin requirements and glycaemic variability. While GLP-1 receptor agonists

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

(GLP-1RA) are established in type 2 diabetes, their use in T1D remains off-label. Randomised trials (ADJUNCT ONE and TWO) and recent meta-analyses demonstrate modest HbA1c reductions (~0.2%-0.4%), weight loss (~3-5 kg), and reductions in insulin dose (10%-20%), albeit with an increased risk of ketosis and hyperglycaemia with reduced insulin dosing.[1-4]

Case Presentation: A 38-year-old Danish male with a 12-year history of T1D and 10-year history of hypertension was reviewed in October 2025. He was treated with basal-bolus insulin (faster aspart 10-15 units per meal; insulin degludec 46 units daily) and atorvastatin. BMI was 28 kg/m^2 (102 kg, 191 cm). There was no evidence of microvascular or macrovascular complications.

Continuous glucose monitoring (Libre) showed suboptimal control:

- Time in range (3.9-10 mmol/L): 55%
- Time >13 mmol/L: 16%
- Recurrent nocturnal hypoglycaemia

GLP-1RA therapy was initiated off-label in January 2026 following structured counselling regarding risks, ketone monitoring, and conservative insulin dose adjustment.

At 2-month follow-up:

- Mealtime insulin reduced to ~6 units/meal
- Basal insulin reduced from 46 to 38 units
- Time in range improved to 80% (HbA1c improved from 7.2% to 6.5%
- Marked reduction in hypoglycaemia
- Significant improvement in patient-reported quality of life

Discussion: This case demonstrates clinically meaningful improvements exceeding those typically reported in trials. GLP-1RA effects include delayed gastric emptying, appetite suppression, and reduced postprandial glycaemic excursions. However, safety is critical; trials report increased risk of ketosis, particularly with rapid insulin reduction.[1,2]

Contraindications include prior pancreatitis, medullary thyroid carcinoma or MEN2, severe gastroparesis, and high risk of insulin omission.

Conclusion: GLP-1RA therapy may offer substantial benefit in selected patients with T1D and insulin resistance. Careful patient selection, education, and monitoring are essential. This case supports a personalised adjunctive role of GLP-1RA in “double diabetes.”

EP1779 - LBA_ECE_1459 - Beyond idiopathic diabetes insipidus: dynamic pituitary stalk changes and progressive hormonal deficits in children—case series

Diandra Carmen Cosma[1], Bianca Andreea Balint[1], Radomir Lidia[1], Aura Madalina Boboc[1,2], Andreea Cristiana Brehar[1], Elena Braha[1] and Iuliana Gherlan[1,2]

[1]Pediatric Endocrinology, CI Parhon National Institute of Endocrinology, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania

Introduction: Pituitary stalk lesions are rare hypothalamic–pituitary disorders, most often identified during the diagnostic work-up of patients presenting with diabetes insipidus.

Aim: To describe the clinical and imaging findings in a series of pediatric patients presenting with diabetes insipidus evaluated in a pediatric endocrinology department between 2011 and 2025.

Results: We included 10 patients (6 boys, 4 girls), aged 3.1-13.3 years at diagnosis; 9 presented with complete and 1 with partial diabetes insipidus. Eight patients were diagnosed in our department, while 2 were already under treatment.

Anterior pituitary function. At diagnosis, one patient had associated pituitary deficiency—central hypothyroidism (case_9). During a median follow-up of 3.9 years, 5 patients (50%) developed growth hormone (GH) deficiency; 3 received somatropin for short stature, while 2 maintained normal height. Three patients developed central adrenal insufficiency during follow-up (at 10.2 and 13.8 years in two cases; missing data in one case). One patient presented panhypopituitarism and hyperprolactinemia (case_10) during follow-up.

Imaging findings. At diagnosis, 8 patients had a normal anterior pituitary on MRI, one had a non-functioning microadenoma and one had an infundibular tumor. The posterior pituitary bright spot was absent in 9 patients. Pituitary stalk thickening was identified in 5 patients at diagnosis (4 by MRI, 1 by CT) and in 2 additional patients during follow-up. Five patients had an undulating evolution of the stalk thickening, but eventually showed partial regression.

Pituitary stalk and hormonal deficiencies. Among the 7 patients with stalk thickening, 3 developed pituitary deficiencies during follow-up (GH deficiency in 3, adrenal insufficiency in 1). Notably, one of the two patients with initially normal stalk developed both GH deficiency and central adrenal insufficiency.

Etiological screening. Serum β-human chorionic gonadotropin and alpha-fetoprotein were normal in all patients, making germinoma unlikely. In one patient (case_7) the suspicion was high, so cerebrospinal fluid evaluation was proposed. Langerhans cell histiocytosis was excluded in 3 cases (case_3, case_6, case_9). One patient is under evaluation for hypophysitis (case_4). One patient (case_6) had a cranial trauma before the onset of polyuria and polydipsia. Syndromic diabetes insipidus was suspected in one case (case_10), with negative array-CGH and NGS; whole exome sequencing is ongoing.

Conclusion: Idiopathic diabetes insipidus in children may mask a dynamic hypothalamic–pituitary process, characterized by evolving pituitary stalk abnormalities and progressive hormonal deficiencies. In our series, imaging changes did not consistently predict endocrine outcome. Larger registries are needed to better define long-term outcomes.

EP1780 - LBA_ECE_1440 - Virilization in a female child: taking clues from antenatal history

Sai Subrahmanyam Pappu, Bhanu Nalluri, Neelaveni Kudugunti and Rakesh Sahay

Osmania General Hospital, Hyderabad, India

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: Virilization in a female child is due to androgen exposure during 10-12 weeks of gestation. The most common cause is CAH due to 21 OH deficiency. Placental Aromatase deficiency is a rare disorder that leads to defective conversion of androgens into estrogens by the placenta, thus causing maternal and fetal virilization. The effected infants present with atypical genitalia and no features of CAH like salt wasting crisis or hyperpigmentation and the virilization is characteristically non progressive in the immediate postnatal period.

Case Presentation: A 2 months old child, reared as a female was brought with history of enlarged phallic structure noted at birth. There was no history of pigmentation or crisis.

Antenatally, mother had a severe form of cystic acne.

On examination, Genitalia were female looking with an enlarged phallic structure of 15 mm in length.

There were no palpable gonads, labioscrotal swellings or inguinal hernias.

There was a single urogenital opening, Prader stage 3, with evidence of posterior fusion of labioscrotal folds.

No hyperpigmentation or rugosity was seen.

EGS was 2.5 with an anogenital ratio of 0.7.

Serum potassium- 4.9 meq/l.

Stimulated 17 OHP-75 ng/dl, Cortisol-41.8 microgram/dl-Normal.

Androstenedione was elevated at 392 ng/dl and testosterone was also elevated, 70 ng/dl.

FSH was elevated at 25.34 mIU/mL.

MRI pelvis identified the presence of Uterus and Ovaries.

In view of elevated androgens, no biochemical features of CAH and history of maternal virilization, Aromatase deficiency was suspected and whole exome sequencing was sent A Homozygous mutation in CYP19A1 gene with a novel c.[1369C>T] variant on exon 10 was identified.

The latest follow up was at 12 months of age where the child was well and maternal acne was spontaneously resolving.

Treatment: The proposed management is usually estrogen supplementation at puberty for development of secondary sexual characters and preserving bone mineral density. Monitoring for Rupture of ovarian cysts. The child was not started on any estrogen.

Follow-up: The child was last seen at 12 months of age, was thriving well.

Acne almost completely resolved in the mother.

The child is planned for feminizing genitoplasty.

Conslusion: We hereby present a case of virilization in mother and neonate due to placental aromatase deficiency. This is a rare disorder can be suspected when there is history of antenatal maternal virilization. The genetic variant in our case is a novel mutation. The identification of this disease has important therapeutic implications for treatment and followup.

EP1782 - LBA_ECE_1381 - Short- and long-term effects of hormonal replacement on body composition and metabolism in congenital hypogonadotropic hypogonadism—a study combining longitudinal and cross-sectional cohorts

Rui Zhang[1], Wenzhen Hao[2], Songbai Lin[2] and Xueyan Wu[2]

[1]Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; [2]Peking Union Medical College Hospital, Beijing, China

Background & Aim: Congenital hypogonadotropic hypogonadism (CHH) is characterized by testosterone deficiency and is associated with adverse body composition and metabolic abnormalities. However, the temporal dynamics of treatment-induced changes and the extent of metabolic normalization remain unclear. This study aimed to evaluate both short- and long-term effects of hormonal replacement on body composition, adipokines, and metabolic parameters in male CHH patients.

Methods: For the short-term analysis, a **longitudinal cohort** of 15 untreated CHH patients was prospectively followed for 3-10 months during testosterone-based therapy. For the long-term analysis, a **cross-sectional study** was conducted, comparing 33 treated CHH patients (mean therapy duration 4.8 ± 2.3 years) with 33 untreated patients and 21 age-matched healthy controls. Body composition was assessed by dual-energy X-ray absorptiometry (DXA). Serum biochemical parameters, adipokines (leptin, adiponectin), and insulin sensitivity indices were measured.

Results: After short-term treatment (median 6 months), serum testosterone increased significantly (0.36-2.80 ng/mL, $P < .001$). Total fat percentage decreased (0.40-0.39, $P = .008$), lean mass (39.3-45.0 kg, $P < .001$) and basal metabolic rate increased, with parallel improvements in ALT, fasting glucose, and total cholesterol. After long-term treatment, treated patients showed significantly lower body fat percentage (32.0% vs 39.4%, $P < .001$) and visceral adipose tissue volume (741 vs 1015 cm^3, $P = .036$) compared with untreated patients, reaching healthy control levels for visceral fat, lean mass, bone mineral content, and insulin sensitivity indices. Serum leptin decreased significantly (9.62-1.81 ng/mL, $P < .001$), and testosterone was identified as an independent negative predictor of leptin ($\beta = -0.277$, $P = .004$) after adjusting for fat mass.

Conclusion: Hormonal replacement in CHH induces early favorable changes in body composition and metabolism within months. Long-term treatment achieves normalization of visceral fat, lean mass, and insulin sensitivity, though total adiposity remains incompletely reversed. DXA sensitively captures these treatment responses, and testosterone is independently associated with lower leptin levels, independent of fat mass.

EP1787 - LBA_ECE_1348 - Real-world treatment persistence and metabolic outcomes with a GLP-1 receptor agonist (tirzepatide) in adults with obesity: an observational cohort study

Mirjeta Guni, Juliana Karanxha, Monika Dede and Florian Toti

Spitali Amerikan 3—American Hospital 3, Tirana, Albania

Background: Obesity is a chronic, relapsing disease associated with increased cardiovascular and metabolic risk. Tirzepatide, a dual glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) receptor agonist, has demonstrated substantial weight reduction in randomized trials. However, real-world data on treatment persistence and early metabolic outcomes remain limited.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Objective: To evaluate treatment persistence, dose escalation, and changes in weight and metabolic parameters over six months following tirzepatide initiation in routine clinical practice.

Methods: This single-center observational cohort study included 50 adults with obesity (BMI ≥30 kg/m^2) who initiated tirzepatide between March and September 2025. All patients started at 2.5 mg weekly, with dose escalation every ~4 weeks based on tolerability and clinical response. Patients were followed for six months under standard care.

Primary outcomes were treatment persistence and changes in weight and BMI. Secondary outcomes included changes in HbA1c, systolic blood pressure (SBP), LDL cholesterol, dose achieved, and gastrointestinal adverse events. Analyses were descriptive.

Results: Treatment persistence at six months was 100%. Most patients (98%) reached ≥10 mg weekly. Final doses were 5 mg (2%), 10 mg (60%), 12.5 mg (12%), and 15 mg (26%).

Mean weight decreased from 111.4 ± 19.1 kg to 95.3 ± 19.3 kg (−16.1 ± 6.2 kg), corresponding to −14.7 ± 6.0%. BMI decreased from 38.6 ± 5.3 to 32.9 ± 5.8 kg/m^2 (−5.8 ± 1.8). Weight-loss thresholds achieved were ≥5% (94%), ≥10% (82%), ≥15% (50%), and ≥20% (16%).

HbA1c improved from 9.48 ± 1.10% to 6.52 ± 0.88% (−2.96 ± 0.73%). SBP decreased by −7.2 ± 4.9 mmHg, and LDL cholesterol by −12.1 ± 14.8 mg/dL.

Gastrointestinal adverse events were common but manageable: loss of appetite (80%), nausea (76%), vomiting (28%), diarrhea (24%), and constipation (20%). No treatment discontinuations due to adverse events were reported.

Conclusions: In this real-world cohort, tirzepatide was associated with high treatment persistence, substantial weight loss, and significant improvements in glycemic and cardiometabolic parameters over six months. These findings support its effectiveness in routine clinical practice when appropriate titration and follow-up are implemented. Longer-term studies are needed to assess sustainability and cardiovascular outcomes.

EP1789 - LBA_ECE_1152 - Short stature in a Tall syndrome: a rare Xq isochromosome Klinefelter variant in monozygotic twins

Leire Perez Garcia
Hospital Universitario Araba, Vitoria-Gasteiz, Spain

Background: Klinefelter syndrome (KS) is the most common sex chromosome aneuploidy in males (1:500-1000), typically characterized by tall stature. However, the isochromosome Xq variant is exceptionally rare, representing less than 0.3% of cases. Unlike classic 47,XXY KS, this specific variant lacks an extra copy of the *SHOX* gene (located on the short arm of the X chromosome, Xp), which often results in normal or short stature due to *SHOX* gene haploinsufficiency. We report a unique case of monozygotic twins with this rare variant and discordant growth patterns.

Case Presentation: A 14-year-old male was referred for evaluation of short stature (150 cm, −2.33 SDS, 1st percentile), with a mid-parental height of 179 ± 5 cm. The patient and his monozygotic twin were born preterm (30 weeks), appropriate for gestational age. Physical examination revealed prepubertal testes (<3 mL) and a 1-year bone age delay. Laboratory tests showed borderline low IGF-1; while a clonidine stimulation test ruled out GH deficiency, an IGF-1 generation test showed a 62% increase, suggesting bioinactive GH. Karyotype analysis identified the rare 47,XY,i(X)(q10) variant.

Subsequent evaluation of the monozygotic twin revealed the same karyotype despite less severe growth impairment (5th percentile). The second twin failed the clonidine test but passed an insulin tolerance test (ITT), with a 112% IGF-1 increase in the generation test. Both twins developed progressive hypergonadotropic hypogonadism. Semen analysis confirmed azoospermia, and no spermatozoa were identified via testicular biopsy for cryopreservation. Both siblings commenced testosterone replacement at age 17. Growth hormone therapy was denied by the advisory committee due to advanced bone maturity at the time of the request.

Conclusion: This case highlights the remarkable clinical heterogeneity of Klinefelter variants, even in monozygotic twins. The 47,XY,i(X)(q10) variant represents a significant diagnostic pitfall because it lacks the “tall stature” hallmark of classic KS. Clinicians should maintain a high index of suspicion for rare cytogenetic KS variants in adolescents presenting with unexplained short stature and microorchidism to ensure timely management of the GH-IGF-1 axis and appropriate fertility counseling.

(PGLs) are rare neural crest–derived tumors characterized by considerable morphological heterogeneity and variable clinical behavior. Some PGLs exhibit cystic or necrotic alterations, which may influence the clinical presentation and disease course; however, their prevalence and clinical relevance remain insufficiently defined. In this retrospective single-center study (2011-2021), 103 patients with confirmed PGLs were evaluated for cystic and

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

necrotic alterations based on imaging findings, pathological reports, and pathological re-evaluation. Cystic alterations, including microscopic, macroscopic, and pseudocystic changes, were identified in 61.8% of tumors. Regardless of their morphological subtype, cystic alterations were not associated with differences in clinical presentation. In contrast, necrotic alterations were observed in 3.9% of PGLs and were associated with a significantly higher rate of metastasis (75% vs 10%, $P = .0124$), larger tumor volume (53.6 cm^3 vs 6.6 cm^3, $P = .0339$), and more pronounced clinical symptoms, including hypertension, palpitations, and weakness, compared with patients without cystic or necrotic lesions. Both cystic and necrotic alterations were more frequently observed in adrenal than in extra-adrenal PGLs. A complementary meta-analysis including 235 patients with PGLs confirmed the higher metastatic rate in necrotic tumors (16% vs 4.5%, $P = .0369$), which were also significantly more often associated with cardiovascular complications ($P < .0001$) compared with cystic PGLs. These findings suggest that pathological alterations, particularly necrosis, may have important implications for the clinical management of PGLs. Incorporating these features into preoperative assessment and follow-up strategies may improve risk stratification, given the increased metastatic potential and cardiovascular risk associated with necrotic PGLs.

Abstract citation ID: lvag096.1830

EP1791 - LBA_ECE_1162 - Relentless recurrence: multimodal treatment-refractory Cushing's disease with aggressive tumour progression, cranial nerve palsy, and neurovascular encasement

Mohammed Mohammed[1], Fresht Naomi[2], Anouk Borg[2], Ahmed Yousseif[1], Efthimia Karra[1], Eleni Armeni[1,2,3], Peirre Bouloux[2], Gayathri Bhaskaran[1], Nasreldin Gifoon[1] and Quazi Tamjidul Islam[1]

[1]*Endocrinology and Diabetes, Royal Free Hospital, London, United Kingdom;* [2]*University College Hospital, London, United Kingdom;* [3]*National and Kapodistrian University of Athens, Aretaieio Hospital, Athens, Greece*

Introduction: Aggressive ACTH-secreting pituitary adenomas causing refractory Cushing's disease is a formidable management challenge on its' own. We present a 50-year-old male with a three-decade history of recurrent disease resistant to successive surgical, radiotherapeutic, and pharmacological interventions, ultimately developing complex neurovascular involvement.

Case History: The patient underwent Le Fort maxillotomy with hypophysectomy (1995) and frontal craniotomy with external beam radiotherapy (1996) in Iran. Following relocation to the UK, transsphenoidal hypophysectomy in 2002 (NHNN) achieved remission until 2016. Relapse prompted metyrapone 500 mg TDS, repeat transsphenoidal surgery (November 2016), and Gamma Knife radiosurgery (2017). Histology confirmed an ACTH-expressing adenoma without atypical features. Block-and-replace therapy was commenced post-radiosurgery, and temozolomide was administered from 2021 to 2022. He has a background of hypertension and a right-sided ischaemic stroke in 2019 without residual deficit. Current treatment includes dexamethasone 0.5 mg, metyrapone (escalated to 500 mg three times daily), levothyroxine, desmopressin, testosterone, and atorvastatin.

Clinical Presentation and Investigations: Recurrence presented with new left sixth cranial nerve palsy causing diplopia, requiring strabismus surgery in 2025. Plasma ACTH increased progressively from 141 pmol/L (1280 pg/mL) in October 2024 to 387 pmol/L (3513 pg/mL) by December 2025 despite escalating blockade with Metyrapone and Dexamethasone as replacement, with variable serum cortisol (81-462 nmol/L; 2.9-16.7 µg/dL) indicating inadequate biochemical control. Panhypopituitarism was confirmed: suppressed TSH (<0.01 mU/L), low FSH/LH (<0.3 IU/L), low testosterone (<4.6 nmol/L; <1.3 ng/mL), undetectable prolactin and low IGF-1 (11.9 nmol/L).

Radiology: Pituitary MRI (February 2023) showed stable residual enhancing tissue in the right sella. Repeat MRI (March 2025) confirmed significant tumour growth with retroclival extension, partial effacement of the pre-pontine cistern, new contact with the basilar artery and right pons, and progressive right cavernous sinus invasion with encasement of the right internal carotid artery. The vessel remained patent. This was flagged as a significant finding likely to alter clinical management.

Management and Conclusion: Pituitary MDT deemed the tumour unsuitable for repeat Gamma Knife or surgery given prior irradiation and neurovascular encasement. Temozolomide rechallenge was recommended. This case highlights the relentless natural history of treatment-refractory Cushing's disease and the role of temozolomide rechallenge in aggressive pituitary tumours when surgical and radiosurgical options are exhausted.

Keywords Cushing's disease, ACTH-secreting adenoma, pituitary tumour, temozolomide, cavernous sinus invasion, cranial nerve palsy, refractory hypercortisolism

EP1793 - LBA_ECE_1203 - The TENIS syndrome challenge: empiric RAI may be considered when chronic TSH suppression harms quality of life

Tatia Kutchava[1] and Natalia Jojua[2]

[1]*LTD Diacor, Tbilisi, Georgia;* [2]*Medison Holding, Tbilisi, Georgia*

Background: TENIS syndrome (TG positive, scan negative) can be a challenge for DTC, which mostly has an excellent long-term prognosis. Guidelines recommend avoiding RAI overtreatment, and dynamic risk stratification is used, but TENIS syndrome raises a clinical question whether empiric RAI may still be considered, especially when the TSH target cannot be relaxed.

Aim: To demonstrate that empiric RAI might still be relevant in managing TENIS syndrome and can be an option.

Method: Observational clinical case study: we followed a patient with confirmed TENIS syndrome for 3 years.

Clinical Case: A 17-year-old girl was diagnosed with DTC in 2023, when she underwent total thyroidectomy and RAI therapy (50 mCi). The histopathology result confirmed PTC, with 3 out of 8 lymph nodes showing metastasis (TNM: pT1bN1aMx, pN1a >2 mm). It was considered to have a low-intermediate risk (10%-15%) of recurrence, but pre-RAI TG (151.8 ng/mL) was a significant factor in deciding to perform RAI therapy, and the RAI scan showed pathological uptake in the neck. During LT4 suppression, TG tests remained above 6 ng/mL. A follow-up diagnostic RAI scan (10 mCi) with stimulated TG (139 ng/mL) was performed 6 months later and showed no pathological uptake.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Ultrasounds, neck and chest CT with and without contrast and FDG PET-CT revealed no structural pathology. Therefore, TENIS syndrome was confirmed. The TSH goal was set below the normal reference range because non-stimulated TG consistently remained above 4 ng/mL (>1 ng/mL indicates an incomplete biochemical response), and stimulated TG was over 100 ng/mL (>10 ng/mL indicates an incomplete response). The patient experiences weight loss and heart palpitations. Bone health is also a concern, as the patient already has confirmed permanent hypoparathyroidism. TG levels are highly TSH-dependent, with even a 12.5 mcg change in LT4 raising TG levels. Because of a low quality of life, we began to wonder whether the potential health risks and further decline in QoL might outweigh the benefits of avoiding additional RAI.

Results: Empiric RAI may have an advantage compared to prolonged TSH suppression in individualized cases when QoL is a concern.

Conclusion: When deciding between empiric RAI and ongoing TSH suppression, personalized management should be prioritized and empiric RAI may still be an option for patients.

EP1795 - LBA_ECE_1156 - What beyond height? Quality of life in adults with growth hormone deficiency treated with recombinant human growth hormone

Magdalena Goralska[1,2], Marek Roslon[1], Agnieszka Stanczyk[1] and Urszula Ambroziak[1]

[1]Endocrinology and Internal Medicine Department, Warsaw Medical University, Warsaw, Poland; [2]Endokrynology, Medical University of Warsaw, Warszawa, Poland

Growth hormone (GH), beyond influencing growth processes in childhood, plays a crucial role in regulating metabolic processes throughout all stages of life. Its deficiency leads not only to metabolic consequences but also to reductions in muscle and bone mass, significantly increasing mortality from cardiovascular complications and osteoporotic fractures, while markedly impairing quality of life.

Decreased quality of life (QoL) is a common feature in adults with GH deficiency (GHD) and serves as a key measure of treatment efficacy. Various tools have been used to assess QoL in GHD studies, including the Adult Growth Hormone Deficiency Assessment (AGHDA).

Materials and Methods: In a single-center, observational, retrospective study, we evaluated 72 patients with growth hormone deficiency over 24 months of observations (2023-2025), all qualified for recombinant human growth hormone (rhGH) therapy. Patients with GHD requiring GH therapy were classified into two groups: childhood-onset GHD (CO-GHD) which also included patients with Prader-Willi syndrome and adult-onset GHD (AO-GHD).

The Quality of Life questionnaire (QoL-AGHDA) was administered. Biochemical and hormonal assessments were performed, including IGF-1 levels.

Results: Assessment of quality of life (QoL) using the Adult Growth Hormone Deficiency Assessment (AGHDA) scale demonstrated that pre-treatment QoL in adults with GHD is significantly lower than in the general population. However, rhGH replacement therapy leads to QoL improvements that can persist long-term for several years. In patients with multiple pituitary hormone deficiencies, adequate replacement of other pituitary axes was also critical.

Conclusions: Growth hormone deficiency in adults requires precise diagnostics and appropriately managed substitution therapy. Effective GH treatment positively impacts both the quality and longevity of life in patients with somatotropic pituitary insufficiency

EP1796 - LBA_ECE_1318 - Two cases of familial partial lipodystrophy associated with a novel LMNA variant

Artemis Kyriakidou[1], Eirini Melidou[1], Georgios Karaliolios[1], Charilaos Kostoulas[2], Ioanna Bouba[2], Hlianna Korosidou[1], Maria Resta[3], Maria Zikopoulou[1], Anastasia Gkounta[1], Litsa Rakitzi[1], Maria Grammatiki[1], Ioannis Georgiou[2], Camille Vatier[4,5,6] and Kalliopi Kotsa[1]

[1]Division of Endocrinology and Metabolism—Diabetes Center, 1st Department of Internal Medicine, Medical School, Aristotle University of Thessaloniki, AHEPA University Hospital, Thessaloniki, Greece; [2]Department of Medical Genetics in Clinical Practice, School of Health Sciences, University of Ioannina, Ioannina, Greece; [3]Department of Paediatric Endocrinology, University Hospital of Nice, Nice, France[4]Department of Endocrinology, National Reference Center for Rare Diseases of Insulin Secretion and Insulin Sensitivity (PRISIS), Sorbonne University, Inserm U938, AP-HP, Saint-Antoine University Hospital, Paris, France; [5]Department of Diabetology and Reproductive Endocrinology, National Reference Center for Rare Diseases of Insulin Secretion and Insulin Sensitivity (PRISIS), Sorbonne University, Inserm U938, AP-HP, Saint-Antoine University Hospital, Paris, France; [6]Department of Molecular Biology and Genetics, National Reference Center for Rare Diseases of Insulin Secretion and Insulin Sensitivity (PRISIS), Sorbonne University, Inserm U938, AP-HP, Saint-Antoine University Hospital, Paris, France

Background: Lipodystrophies comprise a rare and heterogeneous group of congenital or acquired disorders, classified as generalized or partial based on the pattern of adipose tissue loss. Fat atrophy and redistribution are associated with metabolic complications, including insulin resistance, hypertriglyceridaemia, hepatic steatosis, and albuminuria, as well as increased cardiovascular risk. Familial partial lipodystrophy type 2 (FPLD2) is the most common form of congenital partial lipodystrophy and is caused by variants in the *LMNA* gene, encoding nuclear lamins A/C, with autosomal dominant inheritance.

Methods: Two unrelated female patients of Greek origin with clinical features suggestive of partial lipodystrophy were evaluated. Whole exome sequencing (WES) was performed using next-generation sequencing technology.

Results: The first case concerns an 87-year-old woman with a body mass index (BMI) of 19.6 kg/m^2, without metabolic comorbidities, presenting with loss of adipose tissue in both upper and lower limbs and central fat distribution.

The second case concerns a 66-year-old woman with a BMI of 28 kg/m^2, characterized by absence of adipose tissue in the lower limbs, prominent musculature in the thighs and gluteal region, central fat accumulation, and preserved facial fat. She also had

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

hypertriglyceridaemia, insulin-treated type 2 diabetes mellitus, arterial hypertension, hypothyroidism, and hepatic steatosis.

In both patients, a heterozygous nucleotide substitution c.571G>T in the *LMNA* gene was identified. This is a missense variant resulting in a valine-to-leucine substitution at position 191 of the protein. The variant has not been previously reported in the literature and is currently classified as a variant of uncertain significance (VUS).

Conclusions: The identification of the same novel *LMNA* variant in two unrelated individuals with different phenotypes underscores the clinical heterogeneity of the disease and supports a potential pathogenic role of this variant. These findings raise the possibility of a population-specific variant and highlight the importance of integrating genetic testing into the diagnostic evaluation of lipodystrophy.

EP1797 - LBA_ECE_1017 - The diagnostic dyssey of Cushing syndrome: unmasking an ectopic ACTH source after multiple pituitary surgeries

Sabri Engin Altıntop[1], Yagmur Eken[2], Irem Sonmezoglu Kutuk[1], Altinova Alev[1], Ali Celik[3], Emetullah Cindil[4], Ethem Turgay Cerit[1], Mujde Akturk[1], Ayhan Karakoc[1] and Fusun Toruner[1]

[1]*Department of Internal Medicine, Division of Endocrinology and Metabolism, Gazi University Faculty of Medicine, Ankara, Turkey;* [2]*Department of Internal Medicine, Gazi University Faculty of Medicine, Ankara, Turkey;* [3]*Ankara, Turkey;* [4]*Department of Radiology, Gazi University Faculty of Medicine, Ankara, Turkey*

Introduction: ACTH-dependent Cushing's syndrome most commonly originates from a pituitary adenoma but can also result from an ectopic source. This case illustrates a prolonged diagnostic course in a patient who underwent three pituitary surgeries before the ectopic source was identified.

Clinical Case: A 48-year-old woman was referred to our center with persistent ACTH-dependent Cushing's syndrome despite three prior transsphenoidal pituitary surgeries performed at different institutions over four years. Initial MRI revealed a 14 × 5 mm nodular lesion in the sellar cavity. Baseline ACTH levels ranged between 20 and 40 pg/mL. Histopathology revealed necrosis with pituitary tissue in the first surgery, normal pituitary tissue in the second, and active chronic inflammation in the third. Ga-68 DOTATATE PET/CT after second surgery revealed no evidence of a neuroendocrine tumor. No inferior petrosal sinus sampling had been performed prior to referral. Her symptoms persisted throughout this period.

At presentation, she had typical cushingoid features with a history of pathological fractures, osteoporosis, hypertension, and type 2 diabetes. Baseline hormonal evaluation in our center showed markedly elevated cortisol in serum, urine, and saliva, absence of suppression after low-dose dexamethasone, and elevated ACTH. Histopathology specimens obtained from her earlier pituitary surgeries were re-evaluated at our center, which demonstrated active chronic inflammation and normal pituitary tissue without evidence of an ACTH-positive adenoma. Pituitary MRI at our center demonstrated no adenoma. Given ongoing hypercortisolism and the absence of MRI findings, inferior petrosal sinus sampling (IPSS) was performed, demonstrating results consistent with ectopic ACTH secretion. Subsequent Ga-68 DOTATATE PET/CT identified a 1 cm left lower lobe lung nodule with mild uptake (SUVmax 6.5).

Following multidisciplinary team meeting, the patient underwent wedge resection of the pulmonary lesion. On postoperative day 1, serum cortisol dropped to 2.2 µg/dL, and glucocorticoid replacement was initiated. Histopathology confirmed a typical grade 1 carcinoid tumor (Ki-67 index <%2, ACTH immunostaining diffusely positive). She required glucocorticoid replacement for approximately six months. At one-year follow-up, she remained in biochemical remission with improved blood pressure, glucose control, and a 4 kg weight loss.

Conclusion: Diagnosing ectopic ACTH syndrome and determining its origin can be highly challenging, especially when initial findings suggest a pituitary source. Persistent hypercortisolism after multiple non-diagnostic pituitary surgeries should prompt strong consideration of an ectopic origin. This case underscores the role of the IPSS in differential diagnosis, and the value of functional imaging at regular intervals in identifying small ectopic neuroendocrine tumors.

Abstract citation ID: lvag096.1835

EP1798 - LBA_ECE_1467 - Thyroglossal duct cyst carcinoma

Blertina Dyrmishi

Hygea Hospital, Tirana, Albania

Introduction: Thyroglossal duct cyst has an incidence around 7% of neck masses in adults and around 70% of midline neck masses in children, but incidence of cancer is rare.

Case Presentation: A 33-year-old woman with a midline neck mass was initially diagnosed with thyroglossal duct cyst and underwent surgery. The histopathologic examination was papillary thyroid carcinoma with extra capsular infiltration and metastasis to the regional lymph node pT1N1Mx. A total thyroidectomy and regional lymph node dissection follow by a treatment with radioactive iodine was performed. After thyroidectomy: TSH (off) 60.9 IU/mL; Thyroglobulin <0.2 ng/mL; Anti Thyroglobulin Ab 114.3 U/mL (Normal values <70). Ablation with radioactive iodine 131 was performed. One year after the surgery, the patient was stable, on levothyroxine therapy and free of disease.

Discussion: Thyroglossal duct carcinoma has a rare incidence. Sistrunk procedure and total thyroidectomy are surgical options for patients who need ablation with 131 radioactive iodine.

Comments and Conclusions: We should consider possible malignancy in the thyroglossal duct cyst before a surgery, if we find suspicions data on ultrasound, although the incidence of thyroglossal duct cyst is rare. In some cases, deferential diagnosis between papillary micro carcinoma with distant metastasis is not easy.

Keywords papillary thyroid carcinoma, thyroglossal duct cyst

EP1799 - LBA_ECE_1466 - Pituitary plurihormonality in MEN1: a case of concurrent ACTH, prolactin and IGF-1 excess

Gayathri Bhaskaran[1], Beenish Masood[2], Suhail Abdul-Wahab[3], Rishi Iyer[1], Mohammed Mohammed[1], Eleni Armeni[1] and Bernard Khoo[1]

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

[1]Endocrinology, Royal Free London NHS Foundation Trust, London, United Kingdom; [2]University College London Hospitals NHS Trust, London, United Kingdom; [3]Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, United Kingdom

Introduction: Multiple Endocrine Neoplasia Type 1 (MEN1) is a rare autosomal dominant syndrome characterised by primary hyperparathyroidism (PHPT), pituitary adenomas, and pancreatic neuroendocrine tumours (pNETs), with a prevalence of 1 in 10 000 in the UK.[1] The coexistence of acromegaly, hyperprolactinaemia, and Cushing's disease within a single MEN1-associated pituitary complex is exceptionally rare. We present a rare case of MEN1-associated silent triple pituitary hormonal hypersecretion.

Case Presentation: A 48-year-old Caucasian man presented with asymptomatic hypercalcaemia (adjusted calcium 2.8 mmol/L) and elevated PTH (8.3 pmol/L) with severe osteoporosis (Z-scores: −3.2 lumbar spine, −1.6 right total hip, −4.3 right forearm), bilateral nephrolithiasis. Parathyroid ultrasound and 99mTc-sestamibi SPECT-CT identified bilateral superior parathyroid adenomas. He was listed for 3.5-gland parathyroidectomy.

Genetic testing confirmed a pathogenic heterozygous MEN1 frameshift variant (c.1517_1530del; p.Thr506Serfs*20).

MRI pituitary revealed showed equivocal areas of reduced enhancement, raising suspicions of microadenomas. He had raised monomeric prolactin (2974 mIU/L), elevated IGF-1 (41.7 nmol/L) unsuppressed GH on OGTT (nadir 2.2 mcg/L), and a low free testosterone of 0.201 nmol/L, LH: 4.4 U/L and FSH:1.9 U/L He was started on cabergoline 1500 mcg weekly.

CT Chest Abdomen Pelvis showed multiple stable p-NETs (largest 11 mm) and a stable non-functioning left adrenal adenoma (3.7 cm). Metanephrines and Aldosterone Renin Ratio were normal. He failed an ONDST (cortisol 301 nmol/L), and subsequent LDDST confirmed ACTH-dependent Cushing's syndrome. Inferior petrosal sinus sampling further confirmed a pituitary source.

He underwent trans-sphenoidal surgery, however post-operative cortisol remained elevated (300-500 nmol/L), suggesting non-remission. Prolactin nadir was 43 mIU/L and IGF-1 of 48.2 nmol/L.

Histology suggested PIT-1 lineage but co-expression of SF-1 and PIT-1 transcription factors suggested native anterior pituitary tissue.

This patient had no symptoms of acromegaly or Cushing's syndrome. The only tell-tale signs were severe osteoporosis (disproportional to mild hypercalcemia) and intermittent hyperglycaemia (HbA1c 38 mmol/mol).

Discussion and Conclusion: This case highlights an exceptionally rare MEN1 presentation with silent triple pituitary hormonal hypersecretion (prolactin, GH and ACTH) detected only through biochemical surveillance. The patient's severe osteoporosis and PTH dependent hypercalcaemia were the only indicators of endocrine dysfunction, emphasising the importance of comprehensive hormonal assessment in MEN1 even when asymptomatic.

Persistent post-operative hypercortisolaemia reflects the challenges of treating MEN1-related Cushing's disease and reinforces the importance of multidisciplinary, iterative evaluation. As pituitary surgery did not likely cure the Cushing's disease, he is planned for further dynamic function tests, functional imaging and re-discussion with neurosurgeons.

EP1803 - LBA_ECE_1461 - Management of carbimazole-induced neutropenia in Graves' disease: a case report of alternative therapeutic strategies

Helena Fahmi, Dilini Abeyratne, Hyma Rachabattula and Nilukshana Yogendranathan

King's College Hospital NHS Foundation Trust, London, United Kingdom

Introduction: Antithyroid drug-induced neutropenia occurs in less than 0.5% of patients with Graves' disease, typically within 90 days of therapy. Carbimazole can cause minor adverse effects including pruritus and major complications such as agranulocytosis requiring immediate discontinuation. When antithyroid drugs are contraindicated, alternative approaches are needed to achieve biochemical control prior to definitive treatment. This case demonstrates successful management using cholestyramine and lithium carbonate as bridging therapy to radioactive iodine ablation.

Case Presentation: A 55-year-old female presented with palpitations, bone pain, and weakness. Examination revealed tachycardia, fine tremor, and palpable goiter. Laboratory investigations confirmed severe thyrotoxicosis (TSH <0.01 mIU/L, FT4 48.5 pmol/L, FT3 >30.7 pmol/L) with elevated TRAb (16.75 U/L), confirming Graves' disease. Carbimazole 30 mg daily and propranolol 40 mg three times daily were initiated. At 3-week follow-up, thyroid function partially improved (FT4 27.6 pmol/L, FT3 14.1 pmol/L), but the patient developed pruritus and neutropenia (neutrophil count 0.97×10^9/L, WBC 3.1×10^9/L). Carbimazole was discontinued immediately. Three weeks later, her repeat blood tests showed that her White cell and neutrophil counts had normalized, but thyroid function was worsened (FT4 >64.3 pmol/L, FT3 >30.7 pmol/L, TRAb 34.93 U/L). Cholestyramine 4 g every 6 hours was initiated but required dose reduction to 4 g three times daily following the symptoms of diarrhea. Lithium carbonate 200 mg twice daily was introduced. Persistent fluctuating neutropenia ($0.62\text{-}1.46 \times 10^9$/L) despite 4 months off carbimazole prompted hematology consultation, suggesting benign ethnic neutropenia. Technetium-99m uptake scan showed diffuse uptake of 25%. 2-week follow-up following lithium initiation demonstrated clinical improvement on combination therapy with improving thyroid function (FT4 36.7 pmol/L, FT3 18.4 pmol/L, TSH < 0.01). The patient opted for radioactive iodine ablation as a definitive treatment.

Conclusion: This case illustrates effective management of Graves' disease when antithyroid drugs are contraindicated. Cholestyramine interrupts enterohepatic circulation of thyroid hormones, producing significant reductions in hormone levels at 4 weeks. Lithium carbonate inhibits thyroid hormone release and serves as effective bridging therapy, with studies demonstrating significant reductions in free T4 and T3 after median exposure of 37 days. Persistent neutropenia after carbimazole

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

discontinuation highlights the importance of distinguishing drug-induced neutropenia from ethnic neutropenia, a benign condition affecting individuals of African, Middle Eastern, and West Indian descent. Combination therapy with cholestyramine and lithium provided effective biochemical control as a bridge to definitive radioactive iodine treatment, demonstrating the value of individualized approaches and multidisciplinary collaboration in managing Graves' disease complications.

EP1804 - LBA_ECE_1058 - Genetic distribution of FCS in 6 countries of Latin America

Alejandro Roman-Gonzalez[1], Alejandro Castellanos[2], Claudia Monsalve[3], Johnayro Gutierrez Restrepo[1], Juliana Lores[4], Cristina Armijos[5], Maria Sanchez[6], Virgilio Melgar Manzanilla[7], Sonia Chavez[8], Laura Olate[9], Melissa Chacon[9], Alejandro Cob[10], Karla Garay[11], Juan Pozo[12], Natalia Agudelo[13], Diana Sanchez[13], Josefina Gonzalez[13] and Heidi Mateus[13]

[1]Endocrinology, Universidad de Antioquia, Medellín, Colombia; [2]Centro Médico Santa Clara, Monteria, Colombia; [3]Universidad Pontificia Bolivariana, Medellín, Colombia; [4]Clínica Imbanaco, Cali, Colombia; [5]Hospital San Rafael, Pereira, Colombia; [6]Hospital Roosevelt, Bogota, Colombia; [7]Hospital Faro del Mayab, Mexico, Mexico; [8]Hospital Juarez, Mexico, Mexico; [9]Hospital Clinica Biblica, Costa Rica; [10]Clinica Los Yoses, Costa Rica; [11]Hospital Eugenio Espejo, Quito, Ecuador; [12]Universidad de Cuenca, Cuenca, Ecuador; [13]PTC Therapeutics, Bogota, Colombia

Background and Aims: Familial chylomicronemia syndrome (FCS) is an ultra-rare genetic disorder caused by pathogenic variants in fivegenes (LPL, APOA5, APOC2, LMF1, and GPIHBP1), characterized by severe hypertriglyceridemia and a high risk ofacute pancreatitis. The available evidence, derived mainly from European and North American cohorts, identifiesLPL as the most frequently implicated gene (Hegele et al.), with limited representation of Latin Americanpopulations. The aim of this study was to characterize the genetic and demographic profile of patients with FCSacross six Latin American countries and to compare these findings with those reported in the literature.

Methods: This was a retrospective study of 83 patients with genetically confirmed FCS. Anonymized data from the PTCTherapeutics Diagnostic Program, collected between 2020 and 2025, were analyzed.

Results: A total of 83 cases from Colombia, Costa Rica, Ecuador, Guatemala, Mexico, and Panama were included, with amean age of 33.2 ± 20.5 years and a female predominance (63.0%). LPL was the most frequently affected gene (55.4%), followed by APOA5 (15.7%), GPIHBP1 (12.0%), LMF1 (12.0%), and APOC2 (3.6%). Differences wereobserved across countries, with greater genetic heterogeneity in Ecuador. Compared with the literature, the LatinAmerican cohort showed a lower proportion of LPL-associated cases and a greater relative contribution of non-LPLgenes.

Conclusions: FCS in Latin America appears to exhibit greater genetic heterogeneity than that described in European and NorthAmerican cohorts, underscoring the need for further characterization.

EP1805 - LBA_ECE_1177 - A pilot trial of a nutraceutical based on bergamot (*Citrus bergamia*), berberin (*Berberis aristata*), fenugreek (*Trigonella foenum-graecum*) and probiotic (*Lactobacillus plantarum*), for mild dyslipidemia

Claudia Arnas-Leon[1,2], Rosa María Sanchez-Hernandez[3], Sara Andrada-Diaz[4], Agnieszka Kuzior[2], Evigeni Fierro-Milla[2], Lucia Belen Zele-Alvarez[2], Ana Martinez-Martinez[2], Inmaculada Molinero-Marcos[1], Borja Santana-Ojeda[1] and Francisco Javier Martinez-Martin[1,2]

[1]Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain; [3]Complejo Hospitalario Universitario Insular Materno-Infantil, Las Palmas de Gran Canaria, Spain; [4]Bioksan Naturalmente Juntos, Medical Advisory, Las Palmas de Gran Canaria, Spain

Introduction: Monacolins from red yeast rice are a safety concern, with potential adverse effects even at low intakes. Bergamot extracts contain flavonoids that may help improve lipid profiles in patients with statin intolerance or unwillingness to initiate statin therapy. We conducted an open-label pilot trial to evaluate the LDL-cholesterol lowering efficacy of a novel nutraceutical based on bergamot, berberin and fenugreek extract plus a probiotic.

Methods: We recruited patients with low-to-moderate cardiovascular risk, LDL cholesterol <190 mg/dL who rejected statins. Participants received one daily capsule containing 375 mg of standardized bergamot extract (40% flavonoids, including naringin, neoeriocitrin, and neohesperidin), 250 mg of berberine and fenugreek extract, and 30 mg of the probiotic *Lactobacillus plantarum*.

All patients provided written informed consent and underwent baseline anthropometric and laboratory assessments before starting treatment. These measurements were repeated after 3-4 months. Health-related quality of life was assessed using the EuroQoL-5D-3L questionnaire at baseline and follow-up. Adverse effects and treatment satisfaction (Likert scale) were also recorded.

Results: A total of 29 patients (86% female; mean age 53.7 years) completed both visits. LDL cholesterol showed a non-significant reduction of 3.22% (139.4 ± 26.6-134.9 ± 25.4 mg/dL; $P = .291$, paired t-test).

Changes in body mass index (−0.26%), waist circumference (−2.05%), systolic (−0.50%) and diastolic (−0.80%) blood pressure, heart rate (−2.76%), triglycerides (−2.15%), total cholesterol (−1.72%), HDL cholesterol (+1.21%), non-HDL cholesterol (−2.85%), apolipoprotein B (−5.30%), lipoprotein(a) (+1.64%), and SCORE2 cardiovascular risk (−2.49%) were also not statistically significant.

Similarly, no significant changes were observed in glucose metabolism (glucose −1.88%, insulin +8.09%, HOMA-IR +5.25%, HbA1c +0.31%), liver enzymes (AST −4.38%, ALT 0.00%, GGT +9.77%, alkaline phosphatase −2.59%, LDH +2.28%, total bilirubin +4.11%), FIB-4 score (−9.88%), renal function (eGFR −0.71%, albumin/creatinine ratio −8.65%), vitamins B_9 (−0.37%) and B_{12} (+0.96%), calcium (−0.21%), phosphate (−0.81%), C-reactive protein (−1.16%), and creatine-kinase (+0.30%).

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Quality of life remained unchanged (+4.3% index score; +6.11% health status). No serious adverse effects were reported, and 79.2% of patients reported high/very high satisfaction with the treatment.

Conclusions: The supplement demonstrated excellent tolerability, with high patient satisfaction. However, it showed no significant effect on LDL cholesterol or on cardiovascular, hepatic, or renal risk markers. These findings suggest that more effective therapeutic alternatives are needed for this patient population.

EP1806 - LBA_ECE_1372 - Hidden cardiovascular risk in obese adults with normal routine parameters: association of waist-to-height ratio with carotid IMT and hepatic steatosis

Juliana Karanxha[1] and Mirjeta Guni[2]
[1]Cardiology, America Hospital, Tirane, Albania; [2]Endocrinology, America Hospital, Tirane, Albania

Background: Obesity is a major driver of cardiometabolic disease; however, individuals with normal routine laboratory parameters may still harbor significant subclinical organ damage. Anthropometric indices such as waist-to-height ratio (WHtR) may better reflect visceral adiposity and associated metabolic risk compared to traditional measures.

Objective: To evaluate the association between WHtR and early markers of subclinical cardiovascular and metabolic damage, including carotid intima-media thickness (cIMT) and hepatic steatosis, in obese adults with otherwise normal routine parameters.

Methods: This single-center observational study included adult patients with obesity (BMI $\geq$30 kg/m^2) and normal routine laboratory parameters (lipid profile and fasting glucose). Anthropometric measurements, including WHtR, were recorded. Carotid ultrasound was performed to assess cIMT, and hepatic ultrasound was used to evaluate the presence of steatosis. Associations between WHtR and markers of subclinical organ damage were analyzed using descriptive and correlation methods.

Results: Despite normal routine laboratory findings, a considerable proportion of patients demonstrated increased cIMT and evidence of hepatic steatosis. Higher WHtR values were associated with increased cIMT and a higher prevalence of hepatic steatosis. Patients with elevated WHtR showed clustering of subclinical cardiovascular and metabolic abnormalities, suggesting the presence of hidden cardiometabolic risk.

Conclusions: WHtR appears to be a simple and effective marker for identifying hidden cardiovascular and metabolic risk in obese individuals with otherwise normal routine parameters. These findings support the need for broader screening strategies incorporating anthropometric indices to detect early organ damage and improve risk stratification in obesity.

Keywords obesity, WHtR, carotid IMT, hepatic steatosis, visceral adiposity, cardio metabolic risk

EP1808 - LBA_ECE_1094 - Familial 11β-hydroxylase deficiency associated with a CYP11B1 mutation: phenotypic variability across two generations, including a severe form with salt-wasting syndrome

Meryem Eladla[1], Sanae El Moudden[2] and Sanae Abourazak[3]
[1]Endocrinology, University Hospital Center, Fez, Morocco; [2]Pediatric Endocrinology, University Hospital, Fez, Morocco; [3]Endocrinology, Pediatric Endocrinology, University Hospital, Fes, Morocco

Introduction: 11β-hydroxylase deficiency is an autosomal form of congenital adrenal hyperplasia, accounting for 5%-8% of cases. It results in impaired cortisol synthesis, leading to an accumulation of precursors that causes hyperandrogenism and, in some cases, hypertension. This study describes the clinical, biological, and progressive characteristics of a familial deficiency observed in three sisters born to an affected mother.

Materials and Methods: A retrospective descriptive study conducted in the pediatric endocrinology department at Hassan II University Hospital in Fez. Clinical, laboratory, genetic, therapeutic, and follow-up data for the patients were collected from their medical records.

Results: Patient 1 (14 years old): neonatal sexual differentiation disorder with testosterone 2.5 ng/mL, 17-OHprogesterone 12 ng/mL, Δ4-androstenedione 17 ng/mL, 11-deoxycortisol 24 ng/mL, cortisol 2.8 µg/dl, ACTH 95 pg/mL, hyponatremia, normal serum potassium. CYP11B1 mutation confirmed. Started on hydrocortisone at birth, vaginoplasty at age 3. Course marked by poor compliance, melanoderma, and episodes of hyponatremia, with advanced bone age.

Patient 2 (10 years old): similar neonatal presentation, identical CYP11B1 mutation. Early replacement therapy and corrective surgery. Favorable outcome without melanoderma, initial short stature and low weight with gradual catch-up.

Patient 3: comparable neonatal presentation but with hyponatremia and hyperkalemia; identical mutation. Death at age 1 due to salt-wasting syndrome.

All three patients are daughters of an asymptomatic mother who was diagnosed secondarily after her daughters were diagnosed with 11β-hydroxylase deficiency and placed on hydrocortisone. Two other daughters, treated with antenatal dexamethasone (SRY-negative), had a favorable outcome.

Conclusion: This case illustrates the phenotypic variability of a CYP11B1 mutation within the same family, ranging from a compensated form to severe salt-wasting disease. It underscores the importance of family screening, genetic counseling, and strict adherence to treatment to prevent progressive complications.

EP1810 - LBA_ECE_1361 - A rare case of ectopic adrenal found in liver

Bhavna Sharma[1], Smita Singh[2], Kiran Agarwal[2] and Shivali Sehgal[2]
[1]Endocrinology, Queen Mary University of London, London, United Kingdom; [2]Lady Hardinge Medical College, New Delhi, India

Background: Ectopic adrenal tissue or adrenal rests refer to adrenal gland tissue located in abnormal regions. Adrenal ectopia has a reported incidence of less than 1% in adults, with a predominance in males.[1]

Common locations include along the path of embryological descent (especially near reproductive tissues), tests or spermatic cord, the ovaries or the broad ligament or in the retroperitoneum. Ectopic adrenal tissue is often a remnant due to faulty migration during embryonic development.[2]

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

These, even though mostly are asymptomatic, may become significant when they enlarge, produce hormones, or be misdiagnosed as another tumour.[1]

Rarely, these may be involved in endocrine conditions, including congenital adrenal hyperplasia.

In this clinical case, we highlight its potential for misdiagnosis, as this was found in the liver.

Case Summary: A 31-year-old female of Indian origin with no past medical history presented with abdominal pain. She was asymptomatic with no signs or symptoms to suggest adrenal axis pathology.

She had no hormonal profiles done pre-op due to no clinical suspicion.

Ultrasound abdomen revealed a well-defined cystic lesion at segments VI and VII of the liver of size $7.2 \times 7.5 \times 7.8$ cm with an ill-defined hyperechoic mural nodule. CT abdomen found a hypodense lesion in the liver with a calcific nodule. Both radiological investigations were suggestive of a complex Hydatid cyst.

Excision was performed.

Gross examination of the excised tissue was described as multiple flap-like tissue pieces varying in colour from grey-white to yellow. On microscopic examination, strips of fibrocollagenous tissue with numerous congested blood vessels and focal chronic inflammatory infiltrate were described. Encapsulated adrenal tissue was identified, adjacent to which a few cystic spaces lined by flattened cells (CK Negative and CD34 Positive) were present. A diagnosis of Adrenal ectopia with endothelial cyst was made.

Discussion: This case highlights the importance of careful preoperative evaluation and emphasises the need to consider adrenal ectopia when encountering unusual hepatic lesions. Consideration of possible secretion is cautioned; however would be extremely challenging.

EP1811 - LBA_ECE_1252 - Silent hyperandrogenism: a functioning gonadotroph adenoma presenting as pituitary apoplexy without clinical features of androgen excess

Helena Fahmi, Dilini Abeyratne, Nilukshana Yogendranathan, Charmaine Ilangaratne and Eleni Maratos
King's College Hospital NHS Foundation Trust, London, United Kingdom

Introduction: Functioning gonadotroph adenomas (FGAs) are rare pituitary neuroendocrine tumors (PitNETs) that secrete biologically active gonadotropins. While gonadotroph-lineage tumors are the most common subtype among clinically non-functioning pituitary adenomas, functioning cases with elevated sex steroids are exceedingly rare in males. In adult men, FGAs with secondary testosterone elevation do not produce a recognizable clinical syndrome, making preoperative diagnosis challenging. We report a functioning gonadotroph PitNET presenting with features of pituitary apoplexy and biochemically elevated androgens without clinical signs of androgen excess.

Case Presentation: A 57-year-old male with no prior medical history presented with acute severe frontal headache and right-sided diplopia. Examination revealed hypertension, right ptosis, and a right visual field defect. CT demonstrated a large pituitary mass with suprasellar extension compressing the optic chiasm. Empirical intravenous hydrocortisone was administered. MRI confirmed a $21 \times 26 \times 32$ mm macroadenoma extending into the suprasellar cistern, sphenoid sinus, and bilateral cavernous sinuses with possible carotid encasement, though no definitive hemorrhage was identified. Hormonal evaluation revealed elevated testosterone (35.5 nmol/L), free androgen index (101.7%), FSH (24.9 IU/L), LH (10.6 IU/L), and mildly elevated prolactin (1086 mIU/L) consistent with stalk effect. Secondary hypothyroidism was present. The patient denied symptoms of androgen excess, and examination revealed no hyperandrogenic features.

Ophthalmological assessment demonstrated progressive compressive visual field changes, prompting urgent transsphenoidal surgery. Histopathology confirmed a gonadotroph PitNET with widespread LH, FSH, and pan-α-subunit positivity, diffuse SF-1 expression, and bone and sinonasal mucosal invasion with a low Ki-67 index (2%-3%). Postoperatively, visual fields normalized. Hormonal reassessment revealed low testosterone (0.5 nmol/L) with normalized gonadotropins and suboptimal cortisol and growth hormone responses on insulin stress testing. The patient was commenced on testosterone replacement and hydrocortisone with good response.

Conclusion: This case highlights a rare functioning gonadotroph PitNET presenting with features of pituitary apoplexy. Despite biochemically elevated androgens and gonadotropins, no clinical features of androgen excess were observed, consistent with reports that elevated sex steroids in male FGAs lack a recognizable clinical syndrome. The 2022 WHO classification, emphasizing SF-1-based lineage identification, has improved recognition of gonadotroph PitNETs. Transsphenoidal resection resolved visual deficits and hormonal hypersecretion while providing tissue for definitive classification. This case underscores the importance of comprehensive hormonal evaluation in pituitary macroadenomas, as functioning gonadotroph tumors may be underdiagnosed due to the absence of a distinct clinical phenotype in males.

EP1812 - LBA_ECE_1462 - Pachydermoperiostosis mimicking acromegaly: a case report

Doha Dahmani, Aziouaz Fatima and Benkacem Mariem
Endocrinology and Metabolic Diseases Department, Mohammed VI University Hospital, Tangier, Morocco

Introduction: Pachydermoperiostosis is a rare disorder characterized by skin thickening and periosteal bone formation, often mimicking acromegaly and complicating the differential diagnosis. We report a case illustrating this diagnostic challenge.

Observation: A 70-year-old woman with a history of poorly differentiated thyroid carcinoma was referred for suspected

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

acromegaly. She reported a more than 20-year history of progressive enlargement of the hands and feet, increased shoe size, skin thickening, and facial dysmorphism. Clinical examination showed coarse facial features with a broadened nasal base, mandibular prognathism, and spade-like hands and feet. Serum IGF-1 levels were normal. Radiographs revealed periosteal apposition involving the metacarpals, metatarsals, and long bones. Extensive evaluation excluded secondary hypertrophic osteoarthropathy, including pulmonary, cardiac, neoplastic, hepatic, and inflammatory causes. The diagnosis of incomplete pachydermoperiostosis was retained.

Discussion: Pachydermoperiostosis is a rare genetic disease, usually autosomal dominant with variable penetrance, typically beginning in adolescence and predominantly affecting males.

It classically associates acromegaloid features, periostosis, and pachydermia, with possible hyperhidrosis and seborrhea. Osteoarticular manifestations include bone pain, mechanical arthralgia, and recurrent joint effusions, with bilateral symmetrical periosteal new bone formation without erosions.

Diagnosis relies on clinical criteria such as those proposed by Borochowitz, and requires exclusion of secondary hypertrophic osteoarthropathy, particularly paraneoplastic pulmonary causes, as well as cardiac, hepatic, gastrointestinal, hematologic, and endocrine disorders.

Management is mainly symptomatic, including nonsteroidal anti-inflammatory drugs, corticosteroids, colchicine, retinoids for cutaneous involvement, and bisphosphonates or tamoxifen in severe cases.

Conclusion: Although rare, pachydermoperiostosis is an important differential diagnosis of acromegaly. The association of periostosis, digital clubbing, and pachydermia in the absence of systemic disease strongly supports this diagnosis and should alert endocrinologists.

EP1813 - LBA_ECE_1418 - A sight-threatening form of TED in an elderly woman—case presentation

Porcereanu Natalia[1], Ina Dusa[1], Lorina Vudu[2] and Tatiana Magla[1]
[1]IMSP SCR, "Timofei Moșneaga", Chișinău, Moldova; [2]USMF, "Nicolae Testemițanu", Chișinău, Moldova

Introduction: Thyroid eye disease (TED) is the major extrathyroidal manifestation of Graves' disease (GD). Although in only 1% of patients TED presents a sight-threatening form, requiring an urgent medical intervention, the elderly represent a specific group at risk, due to the physiologic changes and the disease's particularities.

Case Presentation: A 72 years old woman was first referred to an endocrinologist with a 2 months history of thyrotoxic symptoms (palpitations, tremor, weight loss). Blood tests show primary thyrotoxicosis (TSH - 0.01 mIU/mL, fT4 - 2.54 ng/dl, fT3 - 7.06 ng/dl) with positive TRAb (50 IU/l). TED was appreciated as Moderate-severe, Clinical Activity Score (CAS) 6 points OD, 6 points OS.

Patient was started on Thiamazole 30 mg/day, Propranolol 30 mg/day and 500 mg methylprednisolone (MP) pulse therapy was started. After the discharge, the patient continued the pulse scheme with 500 mg MP for 2 weeks (total dose of MP 2g), then she missed 1 dose. Three days after withdrawal, TED symptoms evolved rapidly to marked redness, severe chemosis and the vision loss, and the patient was admitted to the hospital. An improvement in thyroid hormones was found: TSH from 0.01 to 0.1 (N 0.27-4.20 mlU/mL); T4f from 20.2 to 13.7 pmol/l (N 12-22 pmol/l). The ophthalmologic exam showed OD lagophthalmos, protrusion, diffuse conjunctival injection, chemosis and corneal ulceration. The CAS score was: OD - 10 points, OS - 5 points. The severe, sight-threatening form of TED with corneal ulceration requiredprompted intervention and three ivMP pulses (1000 g) given alternate days was administrated. Topical treatment with NSAIDs, antibiotic, lubrication was started and a protective contact lense was applied. After 2 weeks, an improvement of the CAS was noted (5p OD, 4p OS), and the recovery of gross vision and of the color vision was noticed.

Discussion: Old age is one of the known risk factors for TED worsening and poor response to treatment. The ocular surface disease in elderly patients precipitates the TED occurring in this category of patients. Corneal breakdown demands expeditious and intensive multimodal management—topical and systemic medications and orbital decompression surgery in particular cases.

Conclusion: Early identification of the progression of TED to more severe forms has a profound impact on the quality of life of the patients. Elderly patients with TED must be counseled to avoid the progression lubrication, nighttime protection and bandage lenses.

EP1814 - LBA_ECE_1433 - Multimodal management of silent corticotroph tumors with Crooke's cell features transforming into severe Cushing's disease—the ERCUSYN Kraków cohort

Aleksandra Gilis-Januszewska[1], Aleksandra Gamrat-Żmuda[1,2], Anna Bogusławska[1], Ewelina Rzepka[1], Mari Minasyan[1], Wiktoria Suchy[1] and Alicja Hubalewska-Dydejczyk[1]
[1]Department of Endocrinology, Jagiellonian University Medical College, Krakow, Poland; [2]Doctoral School of Medical and Health Sciences, Jagiellonian University Medical College, Krakow, Poland

Background: Silent corticotroph tumors (SCTs) are pituitary neuroendocrine tumors of corticotroph lineage characterized by T-PIT positivity without clinical or biochemical hypercortisolism at diagnosis. Transforming into overt ACTH-dependent Cushing's disease (CD) has been reported in approximately 4% of cases, representing a rare but clinically significant phenomenon.

Methods: We report three patients from the ERCUSYN Kraków cohort with initially silent corticotroph PitNETs with Crooke's cell features who subsequently developed overt CD during long-term follow-up.

Results: A 53-year-old woman underwent resection of a non-functioning pituitary macroadenoma measuring up to 40 mm. Histopathology demonstrated a densely granulated corticotroph tumor with scattered Crooke's cells (Ki-67 approximately 3%). Proton radiotherapy was subsequently performed. Six years later, rapid tumor progression involving the sella and left cavernous sinus was observed together with biochemical

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

ACTH-dependent hypercortisolism (loss of circadian rhythm, late-night cortisol 19.3 µg/dL, urinary free cortisol 308-445 µg/24 h, ACTH 97.7 pg/mL), despite only mild clinical manifestations. The progression was accompanied by severe mass-effect symptoms, including visual field impairment, ptosis, and convergent strabismus. Combination therapy with pasireotide LAR and temozolomide was initiated. Temozolomide was discontinued after the first cycle due to bone marrow aplasia, while continued pasireotide therapy resulted in radiological stabilization and normalization of cortisol levels.

An 80-year-old man underwent incomplete transsphenoidal resection of a 35 mm nonfunctioning macroadenoma (Knosp grade 2). Histopathology confirmed a corticotroph PitNET with Crooke's cell features, followed by adjuvant radiotherapy. Approximately nine years later, the patient developed clinically overt ACTH-dependent CS without significant radiological tumor progression. Initial treatment with pasireotide was insufficient. Due to severe hypercortisolism, osilodrostat was initiated directly in a block-and-replace regimen (up to 30 mg/d) with hydrocortisone supplementation, resulting in biochemical remission and clinical improvement.

A 71-year-old woman underwent four transsphenoidal resections of a corticotroph macroadenoma within two years followed by radiotherapy. Five years later, marked tumor progression (Knosp grade 4) occurred with severe mass-effect symptoms including convergent strabismus and impaired ocular motility. Treatment with pasireotide and temozolomide was initiated; however, overt CD developed during therapy. Osilodrostat was introduced and administered for six months, achieving biochemical control of hypercortisolism. Subsequently, temozolomide therapy was continued, and after seven cycles the patient remains clinically stable with radiological tumor regression.

Conclusions: SCTs with Crooke's cell features may transform into severe CD many years after the initial diagnosis, sometimes even without marked radiological progression. These observations highlight the importance of long-term endocrine surveillance and often necessitate multimodal therapeutic strategies including surgery, radiotherapy, and targeted medical therapy.

EP1815 - LBA_ECE_1182 - The impact of Semaglutide and Tirzepatide intervention on the metrics of metabolic function, bioimpedance analysis, and dietary behaviors in individuals receiving treatment

Gamze Akkus[1], Irem Kolsuz Türker[1], Erdem Ince[1], Ali Örs[1,2] and Gulsah Seydaoğlu[2]
[1]Endocrinology, Cukurova University, Adana, Turkey; [2]Cukurova University, Adana, Turkey

Introduction: In the present investigation, our objective is to conduct a comparative analysis of the biochemical, metabolic, bioimpedance, and dietary habitus subcriteria among patients receiving treatment with either semaglutide or tirzepatide.

Methods: We enrolled a cohort of 57 individuals diagnosed with obesity (comparing Tirzepatide and Semaglutide; 39 vs 18), utilizing a prospective study design. We meticulously documented various parameters, including weight, body mass index, fasting plasma glucose, liver function tests, and lipid profiles of the participants both prior to and following the therapeutic intervention. All subjects underwent bioelectrical impedance analyses, which encompassed measurements of fat percentage (fat%), fat mass, free fat mass (FFM), and total body water (TBW) both before and after treatment, approximately 12 weeks post-initiation). Additionally, we solicited information from the patients regarding their alimentary practices, encompassing three factors, namely: uncontrolled eating, emotional eating, and restrictive eating.

Results: Both cohorts demonstrated a statistically significant reduction in body weight and body mass index (BMI) ($P < .001$).Within the semaglutide cohort, BMI exhibited a reduction from 36.03 to 32.94 kg, while body weight diminished from 98.25 to 89.89 kg. Conversely, in the tirzepatide cohort, BMI declined from 35.52 to 31.57 kg, accompanied by a weight reduction from 94.87 to 84.12 kg. The average change in Body Mass Index (BMI) was −1.97 kg/m^2 within the semaglutide cohort and −3.17 kg/m^2 within the tirzepatide cohort. The percentage of body fat exhibited a decline of −1.86% and −3.96%, correspondingly, while the total fat mass demonstrated reductions of −4.59 kg and −7.12 kg. Both cohorts demonstrated enhancements in nutritional habits prior to and subsequent to the intervention ($P < .001$). In the intergroup comparison, the decrease in uncontrolled and emotional eating scores was more pronounced and statistically significant in the tirzepatide group ($P = .004$ and $P = .006$, respectively). The increase in restrictive and mindful eating scores was also found to be stronger in favor of tirzepatide ($P = .021$ and $P = .028$).

Conclusion: Although glucagon-like peptide-1 (GLP-1) receptor agonists yield considerable reductions in body weight, enhancements in glycemic control, and favorable modifications in body composition, Tirzepatide demonstrated a greater efficacy in ameliorating the parameters related to adipose tissue mass and dietary behaviors, notably resulting in a diminished score pertaining to emotional and uncontrolled eating while simultaneously fostering an increase in mindful and restrictive eating practices.

EP1816 - LBA_ECE_1394 - A rare cause of male infertility: SRY-negative 46,XX testicular DSD associated with SOX3 duplication

Filipa Sales[1], Maria Luís Mazeda[1], Bruna Silva[1], Catarina Chaves[1], Ana Saavedra[1], Catarina Cidade Rodrigues[1,2], Alexandra Araujo[3], Ana Morgado[4], Mário Laço[5] and Margarida Almeida[1]
[1]Endocrinology, ULS Tâmega e Sousa, Penafiel, Portugal; [2]Endocrinology Department of the Centro Hospitalar do Tâmega e Sousa, Porto, Portugal; [3]Endocrinology, ULS Matosinhos, Matosinhos, Portugal; [4]Obstetrics and Gynecology, ULS Tâmega e Sousa, Penafiel, Portugal; [5]Genetics, ULS Tâmega e Sousa, Penafiel, Portugal

Introduction: 46,XX testicular disorders of sex development (DSD) are rare and most cases result from translocation of *SRY* to an X chromosome, producing SRY-positive 46,XX males. In contrast, *SRY*-negative 46,XX testicular DSD is much less frequent and has been associated with gain-of-function or increased dosage of alternative testis-determining genes, including *SOX3*, and shows a variable clinical phenotype ranging from nearly typical male development to overt DSD.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Case Report: A 40-year-old phenotypic male was referred to endocrinology for primary infertility. His history included epilepsy, Hashimoto thyroiditis with hypothyroidism, prediabetes, and dyslipidemia. He reported more than 10 years of infertility, decreased libido, and anejaculation, and described normal, spontaneous pubertal development. There was no family history of DSD, infertility, or other relevant endocrine or genetic disorders. Physical examination showed bilateral gynecomastia, reduced facial and truncal hair, and bilaterally small testes, with otherwise normal male external genitalia. Baseline biochemistry revealed normal renal and hepatic function, with prediabetes and dyslipidemia, controlled hypothyroidism and hypogonadism with total testosterone 0.6 ng/mL, free testosterone 1.57 pg/mL, SHBG 84.6 nmol/L, and DHEA-S 0.49 mg/mL. Gonodatrophins were slightly elevated (LH 9.4 mUI/mL (1.2-8.6) and FSH 21.1 mUI/mL (1.3-19.3)) and prolactin was normal. Scrotal ultrasound documented markedly reduced testicular volume (2 mL bilaterally), mildly heterogeneous echotexture, reduced vascularization, and a moderate left varicocele, without focal lesions; pituitary MRI was unremarkable. Conventional karyotyping revealed 46,XX; one chromosome X with an abnormal long arm. Chromosomal microarray showed an approximately 6.5 Mb duplication at Xq27.1q27.3 consistent with a female genomic profile and including *SOX3*, compatible with 46,XX testicular DSD. Subsequent testing for *SRY* was negative, and multiplex ligation-dependent probe amplification *for NROB1, NR5A1, SOX9*, and *WNT4* disclosed no clinically relevant alterations. The patient declined gonadotropin therapy and started intramuscular testosterone 250 mg every 4 weeks, with improved libido, normalization of total testosterone, and modest improvement of the lipid profile. He was referred for assisted reproductive techniques and genetic counseling.

Discussion: This *SRY*-negative 46,XX testicular DSD due to a large Xq27.1q27.3 duplication including *SOX3* broadens the clinical spectrum of *SOX3*-associated sex development disorders, demonstrating that normal pubertal development and a fully male external phenotype may coexist with severe primary testicular failure and infertility. It reinforces the need to incorporate high-resolution genomic analysis with specific evaluation of *SOX3* dosage into the work-up of *SRY*-negative 46,XX males with hypergonadotropic hypogonadism, and underlines the importance of multidisciplinary long-term management with endocrine, reproductive, and genetic counseling.

EP1818 - LBA_ECE_1407 - Rapid visual recovery and decreasing prolactin levels in a giant prolactinoma with extreme hyperprolactinemia under low-dose dopamine agonist therapy

Jacob Ritter[1,2], Leonard Kozarzewski[1,2], Cinzia Tarallo[1,2], Linus Hesse[1,2], Christian J. Strasburger[1,2], Linus Haberbosch[1,2], Knut Mai[1,2,3] and Dominik Soll[1,2]
[1]*Department of Endocrinology and Metabolism, Humboldt-Universität zu Berlin, and Berlin Institute of Health, Charité—Universitätsmedizin Berlin, Berlin, Germany;* [2]*Humboldt-Universität zu Berlin, and Berlin Institute of Health, Pituitary Tumor Center of Excellence at Charité—Universitätsmedizin Berlin, Berlin, Germany;* [3]*Department of Human Nutrition, German Institute of Human Nutrition Potsdam-Rehbrücke, Potsdam, Germany*

Background: Giant prolactinomas are rare pituitary adenomas, accounting for approximately 2%-5% of all prolactin-secreting pituitary tumors, characterized by extreme hyperprolactinemia and significant mass effects (>4 cm), often including optic chiasm compression. Dopamine agonist treatment as first-line therapy can achieve rapid tumor shrinkage and biochemical remission, thereby avoiding acute neurosurgical intervention to improve visual impairment. However, the optimal initial dosing strategy remains undefined, particularly in patients with acute visual compromise, and is currently being addressed in ongoing prospective research.

Case Presentation: We report a 41-year-old male patient presenting with a 2-month history of progressive diplopia, blurred vision, and increasing visual fatigue, culminating in bitemporal hemianopsia, which was confirmed by medical examination. Cranial MRI demonstrated a large 4×4×3 cm sellar and suprasellar mass, consistent with a giant pituitary adenoma. Initial prolactin was markedly elevated at 17 300 µg/L (normal range: 4.00-15.20 µg/L), confirming the diagnosis of a giant prolactinoma. Macroprolactinemia was excluded by PEG precipitation. Endocrine workup revealed mild hypogonadotropic hypogonadism without other pituitary deficiencies. Cabergoline 0.25 mg every other day was started immediately.

Results: Visual symptoms improved within 5 days of treatment initiation (MD values: 20 -> 15.2). Serial computer-assisted perimetry performed at each follow-up demonstrated consistent and objective improvement in visual field defects. In addition, a rapid and profound decline of prolactin was observed within 48 hours to 12 800 µg/L and 5 days to 1659 µg/L. Continued decline was documented after 46 days (534 µg/L).

Conclusion: This case illustrates the dramatic and rapid reversibility of severe neuro-ophthalmologic deficits in giant prolactinoma with extreme hyperprolactinemia. Despite presentation with impending blindness, dopamine agonist therapy resulted in rapid biochemical reduction and early visual recover. As part of ongoing research, this case supports the hypothesis that even low-dose dopamine agonist therapy may induce rapid and clinically meaningful recovery in high-risk giant prolactinoma.

Abstract citation ID: lvag096.1850

EP1820 - LBA_ECE_1225 - A case of co-existence of prediabetes and insulinoma and the advantages of EUS-RFA

Maria Pandelieva[1], Nevena Chakarova[2], Tsvetalina Tankova[2] and Petko Karagyozov[3]
[1]*University Specialized Hospital for Active Treatment in Endocrinology 'Acad. Ivan Penchev', Sofia, Bulgaria;* [2]*Clinic of Diabetology, University Specialized Hospital for Active Treatment in Endocrinology 'Acad. Ivan Penchev', Sofia, Bulgaria;* [3]*Acibadem City Clinic University Hospital Tokuda, Sofia, Bulgaria*

Insulinomas are functional neuroendocrine tumors (NETs) of the pancreatic β-cells characterized by inappropriate insulin secretion, resulting in recurrent episodes of hypoglycemia. Endoscopic ultrasound-guided radiofrequency ablation (EUS-RFA) is an innovative, minimally invasive technique for treatment of small (≤2 cm) pancreatic NETs, especially for comorbid patients with high surgical risk. EUS-RFA enables localized thermal destruction, under real-time endoscopic ultrasound guidance, leading to coagulative necrosis of tumor mass, preserving surrounding pancreatic tissue.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

We present the case of a 61-year-old man with obesity—BMI 40.1 kg/m^2, and confirmed episodes of severe hypoglycemia over the last 2 years. Initially, based on OGTT results consistent with prediabetes and severe insulin resistance—HOMA IR 12.2, a diagnosis of functional hypoglycemia was assumed. Treatment with a GLP-1 receptor agonist and insulin sensitizers was initiated, and because of the persistence of episodes of severe hypoglycemia further diagnostic evaluation was performed. MRI was negative while PET/CT 68Ga DOTA-TATE revealed a linear parenchymal structure with increased accumulation in the head of the pancreas, without the typical characteristics of insulinoma. A supervised fasting test lasting for 12 hours confirmed the presence of endogenous hyperinsulinism—a serum glucose of 2.3 mmol/l and unsuppressed insulin secretion with an extremely high insulin level—126.8 mIU/l (2-25 mIU/l) and C-peptide level—10.2 ng/mL (1.1-3.5 ng/mL). Endoscopic ultrasound showed a 18 mm hypoechoic mass and the immunostaining of the biopsy material confirmed NET G1. The patient refused surgery and EUS-RFA was performed without complications with immediate resolution of hypoglycemia. At the first follow-up 1 month after the intervention, the OGTT revealed persistence of prediabetes and severe insulin resistance—HOMA-IR 15.5, with stimulated insulin secretion reaching over 350 mIU/l during the test. The fasting test was performed in full 72 hours without registering a hypoglycemia. The test was terminated at a serum glucose of 4.5 mmol/l, low beta-hydroxybutirate level of 0.4 mmol/l, insulin 21.36 mIU/l and C-peptide 4.51 mmol/l. At this early stage, it was assumed that there is no evidence on the persistence of endogenous hyperinsulinism.

This case underscores the possibility of coexistence of prediabetes and insulinoma and the difficulty in the interpretation of hyperinsulinemia in this setting. The case also underlines the importance of follow-up after EUS-RFA as the complete effect of the procedure takes several months. On the other hand another advantage of this treatment modality is the possibility to repeat in case of persistence of the endogenous hyperinsulinism.

EP1821 - LBA_ECE_1120 - Obesity in wartime Ukraine: evidence from 10 years of real-world data

Daria Lahoda[1,2], Valentyna Velychko[3] and Veronika Neporada[4]

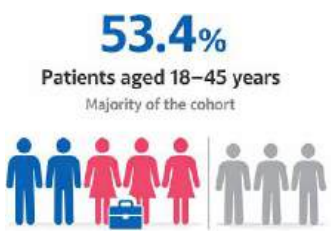
[1]Odesa National Medicine Univercity, Odesa, Ukraine; [2]Medical House Odrex, Odesa, Ukraine; [3]Odesa National Medicine University, Odesa, Ukraine; [4]Medical Hub Odrex, Odesa, Ukraine

Background: Obesity is a major global public health challenge with rapidly increasing prevalence and significant cardiometabolic risks. In Ukraine, epidemiological data remain limited, particularly in the context of ongoing war. Real-world clinical evidence is essential to understand current trends, identify high-risk groups, and improve early detection and multidisciplinary management strategies.

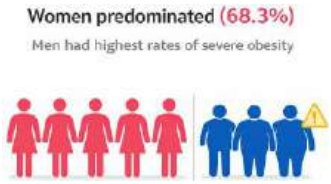
Materials and Methods: A retrospective single-center study analyzed 8760 electronic medical records of patients aged 18-75 years (2016-2025). Demographics, BMI categories, and referral patterns were assessed. Descriptive and comparative statistical methods were applied to evaluate trends, age- and sex-related differences, and associations between BMI and specialist referrals.

Aim: To analyze obesity trends in Ukraine during wartime using 10 years of real-world clinical data, focusing on BMI categories, age and sex differences, and patient referral pathways.

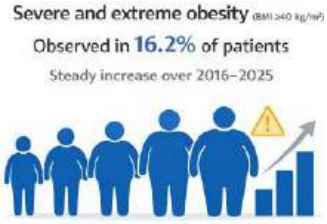
Results: The majority of patients were of working age (18-45 years), accounting for 55.0% of the cohort



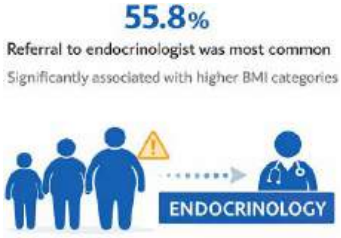
Women predominated (67.9%), while men more frequently presented with severe obesity



Severe and extreme obesity (BMI ≥40 kg/m^2) was observed in 15.3% of patients, with a steady increase over 2016-2025



Referral to endocrinologists was most common (56.1%) and was significantly associated with higher BMI categories



Conclusions:

1. Obesity increasingly affects individuals of working age, highlighting a growing impact on the active population and healthcare systems.
2. Gender differences suggest distinct clinical patterns, with women more likely to seek care, while men present with more advanced disease.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

3. The rising burden of severe obesity and its link to specialist referral emphasizes the need for earlier detection and structured care pathways.

EP1825 - LBA_ECE_1464 - Elevated serum selenium as a potential marker for destructive thyroiditis: insights from a clinical case series

Natia Vashakmadze[1,2]

[1]*Department of Endocrinology, Ilia State University, Tbilisi, Georgia;* [2]*Department of Endocrinology, Israeli-Georgian Medical Research Clinic "Healthycore", Tbilisi, Georgia*

Selenium is a part of selenoproteins in thyrocytes, aiding thyroid hormone production and protecting the thyroid gland.

This case series investigates how serum selenium correlates with different types of thyroid dysfunction. Despite a small sample size, significant pathophysiologic patterns emerged. Patients with destructive thyroiditis and thyrotoxicosis showed high serum selenium, while those with non-destructive conditions had normal levels.

Case	Age	Sex	Disease	TSH	FT4	FT3	Thyroid US	TRAB	Anti-TPO	Serum selenium

#8	66	F	Recurrent thyrotoxicosis due to exacerbation of subacute thyroiditis after steroid withdrawal *(After 2 weeks from steroid* withdrawal)	0.011 mIU/mL	40.10 (12.00-22.00) pmol/l	9.18 (3.10-6.80) pmol/l;	Thyroid painful, volume – 25.3 cm^3, markedly nonhomogeneous + multinodular goiter;	<1.1 mIU/mL (<1.5)		78 µg/l 50-120
#9	49	M	Amiodarone induced thyrotoxicosis mixed type	0.01 mIU/mL	3.21 ng/mL (0.9-1.75)	7.47 (2-4.2 pg/mL)	Thyroid volume 37 cm^3. Multinodular Goiter;	0.51 IU/L (<1.5)		132 µg/l (50-120)
#10	54	M	Amiodarone induced thyrotoxicosis type 2	0.01 mIU/mL	2.45 µg/mL (0.9-1.75)	6.46 pg/mL (2-4.2)	Volume – 14.5 cm^3; Non-Homogenous	0.25 IU/L (<1.5)		160 µg/l (50-120)

Consulsion: We hypothesize that follicular cell destruction releases selenium into the bloodstream. Therefore, elevated serum selenium could potentially serve as a diagnostic marker for thyrotoxicosis induced by various types of destructive thyroiditis.

EP1829 - LBA_ECE_1443 - Dramatic response to cabergoline in a non-operable macroprolactinoma presenting with atypical tremor

Ezgi Yılmaz, Gulsah Elbuken and Sayid Zuhur

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Endocrinology and Metabolism, Tekirdağ Namık Kemal University, Tekirdağ, Turkey

Background: Invasive giant prolactinomas are rare subtypes of prolactin (PRL)–secreting pituitary neuroendocrine tumors (PİT-NETS), measuring >40 mm accounting for only 4.4% of all prolactinomas. Neurological manifestations such as tremor are highly uncommon and may obscure the diagnosis. We report a case of giant invasive macroprolactinoma presenting primarily with head tremor,without prominent classical endocrine symptoms.

Case Presentation: A 61-year-old male patient with no known disease presented to the neurology department with tremor in his head while looking at his phone for 3-5 years. A contrast-enhanced cranial magnetic resonance imaging (MRI) revealed a macroadenoma measuring 43*33*31 mm extending into the supracellar cistern,significantly compressing the optic chiasm and showing invasion of the right cavernous sinus. He was referred to the endocrinology outpatient clinic .The patient didn't present with typical symptoms of prolactinoma such as galactorrhea, erectile dysfunction,headache or visual field loss.His initial PRL level was 2259 ng/mL (4.04-15.2). Hooke's effect was ruled out .There were no abnormalities in the anterior pituitary panel except for hypogonadism. Visual field examination was normal . The patient was started on cabergoline 0.25 mg. The PRL level measured after 1 month was 148 ng/mL, and after 2 months it was 32.2 ng/mL. A pituitary MRI performed 1 month later after cabergoline showed the lesion regressed to 33 * 23 mm . Since the patient refused surgery, he kept under close observation with medical therapy. Patient's symptoms completely resolved.

Conclusion: This case is notable for its atyp,cal presentaton, as tremor was leading and only symptom of macroprolactinoma. The rapid biochemical and clinical response further supports the effectiveness of dopamin agonists, even in cases with very high prolactin levels and huge adenoma sizes.

Keywords prolactinoma, macroprolactinoma, giant

EP1833 - LBA_ECE_1128 - Effect of a nutraceutical based on white mulberry leaves, fenugreek, niacin, chrome, zinc and a probiotic in a female patient with prediabetes, obesity and polycystic ovary syndrome: a case report

Borja Santana-Ojeda[1], Inmaculada Molinero-Marcos[1], Sara Andrada-Diaz[2], Claudia Arnas-Leon[1,3], Ricardo Jose de Leon-Durango[1], Agnieszka Kuzior[3], Carmen Acosta-Calero[4], Estefani Alcantara-Manzueta[1], Lisette Ojeda-Sanchez[1] and Francisco Javier Martinez-Martin[1,3]

[1]*Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain;* [2]*Medical Advisory, Bioksan Naturalmente Juntos, Las Palmas de Gran Canaria, Spain;* [3]*Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain;* [4]*Cardiology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain*

Introduction: Polycystic ovary syndrome (PCOS) is closely linked to insulin resistance, a key driver of its metabolic and reproductive manifestations. This report describes a woman with obesity and prediabetes treated with a nutraceutical targeting insulin resistance, highlighting the causal role of metabolic dysfunction in PCOS and its therapeutic implications.

Methods: Review of the patient's clinical records and the relevant scientific literature.

Results: A 40-year-old administrative worker with overweight was referred for endocrine evaluation. She was reluctant to adopt dietary and exercise interventions.

She initially presented to Gynecology with irregular menses and hirsutism and was diagnosed with PCOS and prediabetes. She was subsequently referred to Endocrinology for metabolic control and weight management.

On physical examination, body mass index (BMI) was 29.7 kg/m^2, blood pressure 137/86 mmHg, heart rate 67 bpm. She had Ferriman–Gallwey grade II/IV hirsutism on the lower back (other areas depilated), waist circumference of 104 cm, and hepatomegaly (2 fingerbreadths). Acrochordons and acanthosis nigricans were present on the neck and axillae.

Baseline laboratory results showed: fasting glucose 102 mg/dL, HbA1c 6.2%, insulin 13.2 µIU/mL, total cholesterol 238 mg/dL, HDL-C 41 mg/dL, LDL-C 158 mg/dL, triglycerides 195 mg/dL, AST 68 U/L, ALT 43 U/L, GGT 83 U/L, and testosterone 0.98 ng/mL.

In addition to lifestyle advice, the patient was prescribed a nutraceutical based on white mulberry leaf, with demonstrated beneficial effects on insulin sensitivity.

After 6 months, the patient reported good tolerability and 94% adherence. She did not significantly modify diet or physical activity and experienced minimal weight loss (0.5 kg). However, she was very satisfied, reporting regular menstrual cycles over the previous 4 months.

On follow-up, BMI was 29.5 kg/m^2, blood pressure 126/78 mmHg, heart rate 64 bpm, with reduced acanthosis nigricans. Laboratory tests showed: fasting glucose 94 mg/dL, HbA1c 5.5%, insulin 6.4 µIU/mL, total cholesterol 233 mg/dL, HDL-C 49 mg/dL, LDL-C 152 mg/dL, triglycerides 160 mg/dL, AST 39 U/L, ALT 35 U/L, GGT 71 U/L, and testosterone 0.68 ng/mL.

HOMA2-IR improved from 1.75 to 0.84, FIB-4 from 1.52 to 0.92, and SCORE2 cardiovascular risk from 1.4% to 1.0%. Prediabetes resolved to normoglycemia.

Conclusion: This case illustrates that targeting insulin resistance can lead to meaningful metabolic and reproductive improvements in PCOS, including normalization of glycemia and menstrual cycles, even in the absence of significant weight loss. It supports a causal role of insulin resistance in PCOS and highlights the potential utility of nutraceutical-based interventions.

Carmen Acosta-Calero[5] and Francisco Javier Martinez-Martin[1,3]
[1]Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [2]Ophthalmology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain; [3]Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain; [4]Servei d'Endocrinologia i Nutricio, Parc Taulí Hospital Universitari, Sabadell, Barcelona, Spain; [5]Cardiology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain

Background: In malabsorptive bariatric procedures such as biliopancreatic diversion (Scopinaro), late weight regain remains a frequent post-surgery challenge. These procedures also carry substantial long-term risk of fat-soluble vitamin deficiencies, particularly vitamin A, which can manifest as nyctalopia (night blindness), a potentially sight-threatening complication, yet reversible if addressed promptly.

We describe a paradigmatic case in which targeted micronutrient repletion reversed severe nyctalopia despite prior parenteral failure, while GLP-1 receptor agonist therapy effectively countered weight regain.

Methods: Review of the patient's clinical records and of the relevant scientific literature.

Results (Case Presentation): A 51-year-old woman with laparoscopic Scopinaro biliopancreatic diversion (2015; preoperative weight 149.5 kg, nadir 99 kg) presented in 2024 with progressive weight regain to 116 kg (waist circumference 124 cm) and refractory nyctalopia unresponsive to previous intramuscular vitamin A.

Biochemistry revealed profound deficiencies: vitamin A 0.09 µg/mL (lower normal limit 0.3 µg/mL), 25-OH vitamin D_3 7.8 ng/mL (lower normal limit 30 ng/mL), secondary hyperparathyroidism (PTH 119 pg/mL), and lumbar osteopenia (T-score −2.3).

Ophthalmologic evaluation confirmed preserved acuity (0.8/1), normal fundoscopy/Optical Coherence Tomography (OCT), consistent with functional nyctalopia.

Dual intervention included: (1) high-dose oral vitamin A (50 000 IU thrice daily) plus 25-OH vitamin D_3 loading/maintenance; and (2) weekly parenteral semaglutide titration for weight control. At six months: weight decreased to 106 kg (waist circumference 117 cm), vitamin A was almost normalized (0.29 µg/mL) with near complete nyctalopia resolution, vitamin D reached 88 ng/mL, PTH declined, and glycemic stability persisted (fasting glucose 96-100 mg/dL).

Conclusions: This case delivers two pivotal messages:

1. Severe vitamin A deficiency-induced nyctalopia after malabsorptive bariatric surgery remains reversible with sustained high-dose oral repletion, even after parenteral inadequacy, emphasizing the primacy of aggressive enteral strategies in compliant patients
2. GLP-1 receptor agonists like high-dose parenteral semaglutide offer a powerful, evidence-supported tool to reverse late weight regain, achieving substantial body weight reduction in a challenging post-bariatric cohort.

Lifelong multidisciplinary surveillance and multimodal therapy are essential to mitigate late complications such as these.

EP1836 - LBA_ECE_1421 - Challenges and successful management of amiodarone-induced thyrotoxicosis: a report of two cases

Dilini Abeyratne, Helena Fahmi and Nilukshana Yogendranathan
Diabetes and Endocrinology, Princess Royal University Hopsital, King's College NHS Foundation Trust, Orpington, Kent, United Kingdom

Introduction: Amiodarone, an iodine-containing antiarrhythmic, is associated thyroid dysfunction ranging from subclinical biochemical abnormalities to overt disease. Amiodarone-induced thyrotoxicosis (AIT) may arise from increased thyroid hormone synthesis (AIT-1) or from destructive thyroiditis with the release of preformed hormones (AIT-2). Accurate differentiation is essential for guiding management; however, overlapping/ mixed forms are common, posing diagnostic and therapeutic challenges.

Case Presentations: Case 1: A 67-year-old man with prior ablation for atrial tachycardia (September 2023) presented with recurrence in October 2024 and new thyrotoxicosis (FT4 39.8 pmol/L, FT3 8.5 pmol/L, TSH <0.01 mIU/L), with previously normal thyroid function tests (TFTs). He had received amiodarone 200 mg daily for 3 months (November 2023–January 2024). He reported weight loss and intermittent diarrhoea, with no autoimmune family history. He was started on daily doses of carbimazole 20 mg, prednisolone 30 mg, and sotalol. Thyroid Stimulating Receptor Antibodies (TRAb) were negative; Thyroid ultrasound demonstrated normal dimensions, echotexture and vascularity. A nuclear medicine (NM) thyroid scan showed diffusely increased uptake, consistent with AIT-1.

Prednisolone was rapidly tapered and discontinued. Carbimazole was down titrated and was stopped by February 2026 following biochemical improvement. He remained euthyroid and discharged to primary care after one year of monitoring. Annual TFTs was recommended due to risk of late-onset hypothyroidism.

Case 2: A 55-year-old man presented to endocrinology in May 2025 with palpitations and weight loss following prolonged amiodarone use (200 mg daily, April 2023–January 2025). He had no goitre, ophthalmopathy or family history of thyroid disease. TRAb were negative. Ultrasound demonstrated bilateral hypoechoic micronodularity with normal vascularity, suggestive of thyroiditis.

NM scan demonstrated markedly reduced uptake of 0.09% (normal range = 1%-3%) consistent with AIT-2. He was treated with prednisolone 30 mg daily and short-term carbimazole, subsequently discontinued. Prednisolone was tapered and stopped by January 2026 following normalized TFTs. He remains euthyroid off treatment undergoing follow-up.

Conclusion: These two cases highlight the spectrum of AIT and the importance of distinguishing AIT-1 and AIT-2. Despite similar clinical presentations, differing underlying mechanisms necessitate tailored management, guided by biochemical, imaging, and antibody testing. Mixed/overlapping features, variable latency following amiodarone exposure and non-specific clinical findings pose diagnostic challenges. Therapeutically, balancing antithyroids and corticosteroids, while monitoring response and

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

avoiding overtreatment can be complex. These cases underscore the importance of close follow-up to optimize outcomes and detect potential late-onset hypothyroidism.

EP1838 - LBA_ECE_1326 - Functional transformation of metastatic neuroendocrine carcinoma presenting with refractory hyperinsulinemic hypoglycemia in type 2 diabetes: a bi-directional dynamic glycemic phenotype

Rawan Alghawi, AlAnood AlQahtani and Azmi Mohammed
Department of Endocrinology and Metabolism, Johns Hopkins Aramco Healthcare, Dhahran, Saudi Arabia

Functional transformation of poorly differentiated, non-functioning neuroendocrine neoplasms is rare and often clinically under-recognised. We report a 78-year-old man with metastatic high-grade poorly differentiated pancreatic neuroendocrine carcinoma and hepatic metastases. He had long-standing type 2 diabetes mellitus, previously stable on oral therapy. After receiving systemic palliative chemotherapy, he developed recurrent hypoglycaemia, marking a transition from chronic hyperglycaemia to unexplained hypoglycaemia. Continuous glucose monitoring and serial laboratory glucose measurements confirmed frequent episodes with plasma glucose levels reaching 47 mg/dL. Biochemical evaluation during spontaneous hypoglycaemia showed inappropriately elevated insulin (77.3 µU/mL; reference 2-25 µU/mL) and C-peptide (9.15 ng/mL; reference 0.78-5.19 ng/mL), confirming endogenous hyperinsulinaemic hypoglycaemia. Insulin autoantibodies were negative. Adrenal insufficiency was excluded. There was no exposure to exogenous insulin or insulin secretagogues. Repeat histopathological evaluation was not feasible.

Subsequently, Diazoxide was started and effectively suppressed hypoglycaemia. However, after receiving lanreotide for oncologic management, the patient developed progressive hyperglycaemia. This necessitated the discontinuation of Diazoxide. He was transitioned to basal insulin, then to basal-bolus insulin therapy. Serial measurements over three months demonstrated a declining trend in C-peptide despite continued hyperglycaemia (5.87 ng/mL at glucose 337 mg/dL, then 1.89 ng/mL at glucose 156 mg/dL).

This case illustrates a bi-directional glycaemic phenotype driven by tumour-associated insulin secretion under therapeutic modulation. Notably, such functional transformation, although described in isolated reports, is exceptionally uncommon in poorly differentiated neuroendocrine carcinomas, in which hormone secretion is typically absent. These sequential changes reflect tumour plasticity and highlight the need for vigilant metabolic surveillance and adaptive multidisciplinary management.

EP1841 - LBA_ECE_1249 - Does testosterone therapy resolve endometriosis symptoms in young transgender men? A retrospective study

Francisco Javier Martinez-Martin[1,2], Borja Santana-Ojeda[1], Inmaculada Molinero-Marcos[1], Estefani Alcantara-Manzueta[1], Lisette Ojeda-Sanchez[1], Alba Hernandez-Lazaro[1,3], Ricardo Jose de Leon-Durango[1], Claudia Arnas-Leon[1,2], Agnieszka Kuzior[1,2] and Carmen Acosta-Calero[1,4]
[1]*Endocrinology & Nutrition, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain;* [2]*Endocrinology & Nutrition, Hospitales Universitarios San Roque, Las Palmas de Gran Canaria, Spain;* [3]*Servei d'Endocrinologia i Nutricio, Parc Taulí Hospital Universitari, Sabadell, Barcelona, Spain;* [4]*Cardiology, Hospital Universitario de Gran Canaria Doctor Negrin, Las Palmas de Gran Canaria, Spain*

Background and Objectives: Approximately half of transgender men receiving gender-affirming hormonal therapy (GAHT) with testosterone report nonmenstrual pelvic pain, and around one in eleven are diagnosed with endometriosis, according to a recent systematic review (doi: 10.1016/j.jmig.2025.08.009). Given that endometriosis is an estrogen-dependent condition, it has been hypothesized that testosterone therapy may improve symptoms by suppressing ovarian estrogen production, ovulation, and menstruation, and by inducing endometrial atrophy. However, evidence supporting this effect remains limited, heterogeneous, and largely observational. Furthermore, some individuals may retain hormonally active endometrial tissue. Potential mechanisms for persistent disease include peripheral aromatization of testosterone to estrogens, local estrogen production within endometriotic lesions, and progesterone resistance.

This study aimed to retrospectively assess the clinical course of symptomatic endometriosis in transgender men undergoing GAHT with testosterone in a real-world clinical setting.

Methods: We conducted a retrospective review of clinical records from transgender men aged <45 years who initiated testosterone therapy in our Transgender Clinic from January 2015 and had at least one year of follow-up. Patients with a prior diagnosis of endometriosis or diagnosed after presenting with chronic nonmenstrual pelvic pain at the initial visit were included. Data collected included persistence, improvement, or resolution of pelvic pain, as well as referral for total hysterectomy with bilateral adnexectomy (THBA).

Results: A total of 258 transgender men met inclusion criteria. Seventeen (6.6%) had endometriosis: 12 with a prior diagnosis and 5 diagnosed after their initial evaluation. All reported chronic nonmenstrual pelvic pain at baseline. Median follow-up after initiation of GAHT was 4.3 years.

During follow-up, six patients (35%) reported complete resolution of symptoms, and three (18%) experienced clear and sustained improvement. However, eight patients (47%) continued to report persistent pelvic pain, although none described consistent worsening. Among these, five reported occasional spotting, but none resumed regular menses.

Four patients (23.5%) were referred for THBA due to persistent symptoms. Surgical intervention resulted in symptom resolution or significant improvement in four patients (80%), while one (20%) continued to report chronic pelvic pain.

Conclusions: Testosterone therapy was associated with symptom improvement or resolution in approximately half of transgender men with endometriosis; however, a substantial proportion experienced persistent symptoms. THBA appears to be more resolutive, although not universally. These findings indicate that GAHT alone does not reliably resolve endometriosis and that additional interventions, including surgery, may

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

be required. Further prospective studies are needed to better define optimal management strategies in this population.

Abstract citation ID: lvag096.1859

EP1842 - LBA_ECE_1005 - Homozygous familial hypobetalipoproteinemia with abetalipoproteinemia-like phenotype: a rare multisystemic substrate crisis with negative MTTP sequencing

Beren Ayşe Altunsaray[1], Hanne Beyza Ayalan[1], Mina Gulfem Temizturk[2] and Muge Kuzu Kumcu[1,2]
[1]Faculty of Medicine, Atilim University, Ankara, Turkey; [2]Ankara, Turkey

Introduction: Abetalipoproteinemia (ABL) and Homozygous Familial Hypobetalipoproteinemia (HHBL) are ultra-rare lipid metabolism disorders. While ABL is typically caused by MTTP mutations, HHBL results from codominant APOB mutations. Both lead to a near-complete absence of apolipoprotein B-containing lipoproteins, creating a critical substrate crisis for fat-soluble vitamins and cholesterol, which precipitates hepatic, hematologic, and neuro-ophthalmological dysfunction.

Case Presentation: A 28-year-old female presented with menstrual irregularities, fatigue, and persistent steatorrhea. Laboratory screening revealed severe hypolipidemia (LDL-C <5 mg/dL). Diagnosis was confirmed by ApoB <20 mg/dL, Vitamin E 2.36 µg/mL (critical deficiency), and Vitamin A 520 ng/mL. Hormonal evaluation showed suppressed Estradiol (26 pg/mL). Peripheral smear demonstrated pathognomonic acanthocytosis.

Multidisciplinary screening revealed no irreversible pathologies. Hepatobiliary USG showed hepatomegaly (15.5 cm) with Grade 2 steatosis. Family screening confirmed a familial pattern: the 52-year-old father and 50-year-old mother exhibited significant asymptomatic hypolipoproteinemia (LDL-C: 27.8 and 61 mg/dL, respectively). Although there is no known consanguinity, both parents originate from the same small geographical region (approximately ≤250 000 inhabitants), suggesting a potential founder effect. This profile directs the diagnosis toward HHBL despite the severe phenotype.

Genetic Evaluation: Targeted MTTP sequencing detected no pathogenic mutations. Since MTTP defects are a regulatory prerequisite for official orphan drug access (eg, Lomitapide), the patient was ineligible for such targeted therapies. To explore the underlying pathology explaining this favorable clinical course, an expanded genetic panel is currently pending.

Management & Conclusion: Management involved a strict Low-LCT diet supplemented with Medium-Chain Triglyceride (MCT) oil. Initially, high-dose oral Vitamin E (400 IU 2 × 3) and Vitamin A (30 000 IU 1 × 3) were administered. The high cost of orphan drugs and the non-orphan status of MCT oil posed significant therapeutic barriers. Due to clinical stabilization and financial constraints, treatment was optimized to daily maintenance doses (1 × 1), aligning with state-covered insurance limits. This case underscores the challenges in drug access when canonical markers are absent. Aggressive ADEK supplementation remains the gold standard for stabilizing this phenotype, even when advanced pharmacological options are inaccessible.

Abstract citation ID: lvag096.1860

EP1843 - LBA_ECE_1388 - Resistant hypertriglyceridaemia associated with low-molecular-weight heparin in heterozygous LPL variant carriers

Murat Tozman[1], Adam D. McIntyre[2], Robert Hegele[2], Ilgin Simsir[1] and Gökçen Ünal Kocabaş[1]
[1]School of Medicine, Ege University, Izmir, Turkey; [2]University of Western Ontario, Ontario, Canada

Introduction and Objective: Biallelic pathogenic variants in the apolipoprotein (APO) C2, APOA5l, glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1 (GPIHBP1), lipase maturation factor 1 (LMF1), and lipoprotein lipase (LPL) genes cause familial chylomicronemia syndrome (FCS). Although heterozygous carriers typically exhibit a milder phenotype, severe hypertriglyceridemia (HTG) may develop in the presence of secondary triggers. Low-molecular-weight heparin (LMWH) can increase the release of LPL from the endothelium, potentially leading to an initial transient reduction in triglyceride (TG) levels; however, with continued use, rapid clearance of circulating LPL and limited resynthesis capacity may result in depletion of the functional LPL pool. In this report, we present a possible association between enoxaparin use and resistant HTG in a patient carrying a heterozygous pathogenic LPL variant.

Case Presentation: A 49-year-old man presented with a TG level of 5502 mg/dL (63.3 mmol/L), without a history of alcohol consumption. His medical history was notable for myocardial infarction 14 years earlier, 11 episodes of pancreatitis, and portal and splenic vein thrombosis following a severe pancreatitis episode six months prior, as well as pancreatitis-related secondary diabetes mellitus. Glycemic control was stable, with a hemoglobin A1c level of 6.4% at presentation.

Genetic analysis identified a heterozygous pathogenic variant in the LPL gene, c.347G>C (p.Arg116Pro). Although the patient's sister carried the same heterozygous variant, her TG levels had been reported to be no higher than 500 mg/dL (5.6 mmol/L).

Despite treatment with fenofibrate, rosuvastatin, nicotinic acid, orlistat, and intravenous insulin infusion, the TG level remained elevated at 4770 mg/dL (53.9 mmol/L), without a meaningful reduction. After treatment reassessment, LMWH was discontinued due to its potential contributory role, and rivaroxaban was initiated. Following this modification, the TG level decreased to 1516 mg/dL (17.1 mmol/L).

Discussion and Conclusion: The marked interindividual variability in phenotypic severity among heterozygous LPL variant carriers suggests a substantial contribution of secondary modifiers. In our patient, persistently elevated TG levels despite intensive lipid-lowering therapy and adequate glycemic control suggested an ongoing precipitating factor. The substantial decline in TG levels following discontinuation of LMWH suggests that anticoagulant therapy may have had a clinically relevant impact in the setting of genetically limited LPL activity.

This observation underscores the importance of carefully reviewing not only metabolic determinants but also concomitant pharmacologic treatments in patients with severe and refractory HTG. In individuals with an underlying genetic predisposition, LMWH use should be assessed on an individual basis for its potential contributory role.

EP1848 - LBA_ECE_1170 - Dual-mechanism life-threatening hyponatraemia: NSAID-induced hyporeninemic hypoaldosteronism unmasking Sheehan's syndrome latent for four decades

Zain Komal[1,2], Haroon Arshad[3], Asif Mehmood[1], Ma Pyeh Kyithar[1] and Jayant Sharma[1]
[1]Endocrinology, Midland Regional Hospital, Portlaoise, Ireland; [2]Endocrinology, Internal Medicine, Midland Regional Hospital, Portlaoise, Ireland; [3]Midland Regional Hospital, Portlaoise, Ireland

Introduction: Severe hyponatraemia refractory to saline resuscitation typically prompts investigation of a single cause. We report the first characterisation of concurrent NSAID-induced hyporeninemic hypoaldosteronism and panhypopituitarism from Sheehan's syndrome, two pathologies that synergised to produce refractory salt-wasting hyponatraemia through dual peripheral and central mechanisms, identifiable through parallel mineralocorticoid and pituitary axis evaluation. Given widespread NSAID use and increasing migrant populations with undiagnosed peripartum pituitary injury across Europe, this combination may be under-recognised.

Case Description: A 64-year-old woman presented with bilateral lower limb pain, proximal myopathy, weight loss (>7 kg), fatigue and polyuria after three months of NSAID use and recent radiocontrast exposure. She had a prior episode of severe hyponatraemia (Na 112 mmol/L) four years earlier without aetiological workup. Sodium was 121 mmol/L on admission, dropping to 110.8 mmol/L despite 0.9% normal saline 1 litre TDS–QDS and repeated 2.7% hypertonic saline boluses throughout a 32-day admission with 30 days in ICU. Urinary sodium was 160 mmol/L with output peaking at 7185 mL/24 h, representing daily renal sodium losses exceeding 500 mmol. Serum osmolality was 231 mOsmol/kg against inappropriately concentrated urine (656 mOsm/kg) with flat IVC on ultrasound. A desmopressin challenge worsened hyponatraemia (133-123 mmol/L), excluding SIADH and confirming salt-wasting physiology.

Results: Parallel axis evaluation identified two mechanistically distinct pathologies. Mineralocorticoid axis: aldosterone 39 pg/mL (ref 68-249), renin 3.4 pg/mL (suppressed), ARR 11.47, with hypokalaemia and low bicarbonate at normal anion gap, confirming hyporeninemic hypoaldosteronism. Pituitary axis: fasting cortisol 96 nmol/L, ACTH 12.4 pg/mL (inappropriately low, confirming central aetiology), FT4 4.1 pmol/L (ref 9.8-23), FT3 2.1 pmol/L (ref 4.7-7.2), TSH 0.38 mIU/L (inappropriately low), prolactin 64 mIU/L (low), IGF-1 12 µg/L (ref 36-244). MRI revealed empty sella with tiny residual pituitary. Autoimmune screen was negative. Collateral history uncovered prolonged labour, lactation failure and premature menopause, consistent with Sheehan's syndrome undiagnosed for four decades. This coexistence has not been previously described.

Conclusions: Fludrocortisone, hydrocortisone and levothyroxine normalised sodium to 136-140 mmol/L. At three-month follow-up, aldosterone normalised (39-158 pg/mL) and fludrocortisone was discontinued, establishing the NSAID-induced component as transient, while permanent pituitary deficiency required ongoing replacement, with complete resolution of myopathy confirming the diagnosis. This case establishes that refractory salt-wasting hyponatraemia can arise from simultaneous peripheral and central endocrine failure, distinguishable only through systematic parallel evaluation of mineralocorticoid and pituitary axis. We propose this approach for any patient with NSAID exposure presenting with unexplained, refractory or recurrent hyponatraemia.

EP1851 - LBA_ECE_1409 - Primary amenorrhea revealing idiopathic premature ovarian insufficiency with early bone compromise: a missed opportunity for early diagnosis

Dilini Abeyratne, Helena Fahmi and Nilukshana Yogendranathan
Diabetes and Endocrinology, Princess Royal University Hopsital, King's College NHS Foundation Trust, Orpington, Kent, United Kingdom

Introduction: Primary amenorrhea is an important clinical presentation in adolescence. Evaluation is guided by hormonal assessment, with progestin or combined estrogen–progestin challenge tests helping differentiate central, ovarian, and outflow tract causes.

Premature ovarian insufficiency (POI) is a rare cause of primary amenorrhea, and may present diagnostic challenges. We report a 16-year-old girl who presented with primary amenorrhea and was ultimately diagnosed with idiopathic POI following a thorough evaluation, with negative genetic and autoimmune workup. In this case, a delay in diagnosis following initial presentation to primary care, contributed to compromised bone health at the time of diagnosis. This report underscores the importance of early recognition and prompt evaluation of primary amenorrhea to reduce the risk of long-term complications.

Case Presentation: A 16-year-old female presented with primary amenorrhea despite normal secondary sexual characteristics. She denied anosmia, galactorrhea, hirsutism, headaches, visual disturbances, weight changes, or cyclical abdominal pain. Past medical, drug, and family histories were unremarkable.

On examination, BMI was 15.5 kg/m^2 with normal blood pressure. She had Tanner stage IV breast development and stage II-III pubic hair, with no dysmorphic features or clitoromegaly.

Initial investigations demonstrated elevated gonadotropins (FSH 85.7 U/L, LH 25.3 U/L) with low estradiol (<92 pmol/L), consistent on repeat testing. Anti-Müllerian hormone (AMH) was markedly reduced (<0.2 pmol/L). Prolactin, thyroid function, Dihydroepiandrostendione, 17 hydroxy-progesterone, and androgen profiles were normal. Ovarian and adrenal antibodies were negative. Autoimmune screening, including, anti-thyroid peroxidase, anti-intrinsic factor, anti-diabetic antibodies and celiac screen were negative.

Pelvic ultrasound revealed small ovaries without follicles and a normal-sized uterus. No outflow tract abnormalities were identified. Progesterone challenge produced withdrawal bleeding. Genetic testing confirmed a normal 46,XX karyotype. Full genetic panel testing for POI including FMR1 premutation were negative. Very low AMH favoured against possible FSH/LH resistance

Conclusion: A diagnosis of idiopathic POI was made. Initial bone densitometry showed osteopenia. The patient was commenced on oestrogen–progesterone replacement therapy, resulting in regular withdrawal bleeds, with ongoing management focused on bone health preservation.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Early evaluation of primary amenorrhea is essential, as prompt diagnosis of conditions such as idiopathic POI allows timely initiation of hormone replacement therapy, which is critical to preserve bone health and reduce long-term metabolic and reproductive complications. Delayed diagnosis may result in preventable morbidity, underscoring the need for early and thorough assessment at first presentation.

EP1854 - LBA_ECE_1118 - Discordant growth hormone dynamics and hyperprolactinaemia associated with migraine-related hypothalamic dysfunction

Ciaran Walsh, Uroosa Moqeem and Aneliya Sirkova
London, United Kingdom

A woman in her 30s was referred to Endocrine clinic for persistent galactorrhoea and intermittent mild hyperprolactinaemia. She had a history of migraine with aura. Insulin-like growth factor-1 concentrations were mildly elevated but consistently remained below recognised diagnostic thresholds for acromegaly, with normal insulin-like growth factor binding protein-3. Pituitary magnetic resonance imaging was normal. Oral glucose tolerance testing demonstrated elevated basal growth hormone concentrations with failure of suppression. Despite these biochemical findings, there was no clinical or radiological evidence of acromegaly. The constellation of discordant growth hormone dynamics, mild hyperprolactinaemia, and migraine supports hypothalamic inhibitory dysfunction affecting multiple pituitary axes rather than autonomous endocrine disease. This case highlights the importance of recognising functional hypothalamic–pituitary dysregulation as a cause of abnormal dynamic endocrine testing and avoiding misdiagnosis of pituitary tumours.

EP1855 - LBA_ECE_1309 - Parathyromatosis presenting as severe hypercalcemia after multiple parathyroid surgeries: a diagnostic challenge

Eirini Melidou[1], Artemis Kyriakidou[1], Xanthippi Tsekmekidou[1], Maria Zikopoulou[1], Konstantinos Sapalidis[2], Maria Grammatiki[1], Litsa Rakitzi[1], Kyriakos Chatzopoulos[3] and Kalliopi Kotsa[1]
[1]*Division of Endocrinology and Metabolism—Diabetes Center, 1st Department of Internal Medicine, Medical School, Aristotle University of Thessaloniki, AHEPA University Hospital, Thessalonki, Greece;* [2]*3rd Surgical Department, Aristotle University of Thessaloniki, AHEPA University Hospital, Thessaloniki, Greece;* [3]*Laboratory of General Pathology and Pathological Anatomy, Aristotle University of Thessaloniki, Thessaloniki, Greece*

Objective: Parathyromatosis is a rare cause of persistent or recurrent primary hyperparathyroidism, typically occurring after parathyroid surgery. We present a case of severe hypercalcemia caused by parathyromatosis in a patient with multiple previous cervical surgeries for primary hyperparathyroidism.

Case Presentation: A 65-year-old woman presented with nausea, dizziness and generalized weakness. Her medical history included hemithyroidectomy with postoperative hypothyroidism, type 2 diabetes mellitus and surgically treated primary hyperparathyroidism. The patient had recently discontinued cinacalcet therapy. Clinical examination revealed a palpable painless mass near the angle of the left mandible. Laboratory evaluation showed severe hypercalcemia (Ca: 16 mg/dL), elevated parathyroid hormone levels (PTH: 188 pg/mL; reference range 14.9-56.9 pg/mL), hypomagnesemia (Mg: 1.38 mg/dL) and hypophosphatemia (P: 1.6 mg/dL). The patient was treated with intravenous hydration, diuresis, reintroduction of cinacalcet and magnesium supplementation, resulting in gradual improvement of calcium levels and symptoms. Review of the patient's medical history revealed five previous cervical surgeries for primary hyperparathyroidism and the presence of a 3-cm left adrenal lesion compatible with an adenoma that had not been previously investigated. Neck ultrasound demonstrated a 1.3-cm hypoechoic lesion posterior to the left thyroid lobe compatible with an enlarged parathyroid gland, as well as suspicious lymph nodes. Parathyroid scintigraphy revealed hyperfunctioning parathyroid tissue in two locations adjacent to the upper and lower poles of the left thyroid lobe. Based on imaging findings and surgical history, parathyromatosis was suspected, with parathyroid carcinoma considered in the differential diagnosis. Additional imaging with 4D CT revealed multiple nodular lesions in the left lateral cervical region, the esophageal wall and along the sternocleidomastoid muscle, suggestive of disseminated parathyroid tissue. Due to persistent hypercalcemia despite maximal cinacalcet therapy (360 mg/day), surgical treatment was recommended by the multidisciplinary tumor board.

Follow-up: Histopathological examination confirmed parathyromatosis. Seven months after surgery, the patient remains asymptomatic without medical therapy and maintains normal calcium and parathyroid hormone levels.

Conclusion: Parathyromatosis is a rare but important cause of persistent or recurrent hyperparathyroidism following parathyroid surgery. It may present with severe hypercalcemia and can mimic parathyroid carcinoma. Diagnosis requires careful correlation of clinical history, imaging findings and histopathological confirmation. Early recognition is essential to guide appropriate surgical management and prevent complications related to prolonged hypercalcemia.

EP1856 - LBA_ECE_1316 - Kallmann syndrome mimicking as Müllerian agenesis: a diagnostic challenge

Selma Jusufovic, Enra Desevic, Anisa Sahbaz, Ilma Sirbegovic and Lamija Mlaco
Department of Reproductiv Endocrinology, Clinical Center University of Sarajevo, Clinic for Endocrinology, Sarajevo, Bosnia and Herzegovina

Introduction: Hypogonadotropic hypogonadism is a rare but important cause of primary amenorrhea. Kallmann syndrome, characterized by gonadotropin-releasing hormone deficiency and anosmia, may be misdiagnosed when prolonged estrogen deficiency results in non-visualization of reproductive organs.

Case Presentation: A 26-year-old woman with primary amenorrhea and absent pubertal development had previously been diagnosed with uterine and ovarian agenesis. Hormone replacement therapy had been recommended but not initiated. At presentation, she had poor breast development (Tanner stage II), normal external genitalia, and pubic hair consistent

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

with Tanner stage III/IV. Her history revealed progressive hyposmia evolving into anosmia. Hormonal evaluation confirmed hypogonadotropic hypogonadism, and the karyotype was 46, XX. Initial imaging again failed to visualize the uterus and ovaries, raising suspicion of Müllerian agenesis. Pituitary MRI showed hypoplasia, and bone densitometry revealed osteopenia. Estrogen therapy was initiated. Follow-up ultrasound demonstrated uterine development with appropriate endometrial thickness and visualization of adnexal structures. After five months, transvaginal ultrasound confirmed a normal uterus with a trilaminar endometrium and both ovaries, excluding Mayer-Rokitansky-Küster-Hauser syndrome. MRI of the olfactory region showed hypoplastic olfactory structures, confirming Kallmann syndrome. Progesterone was added, resulting in regular withdrawal bleeding.

Conclusion: This case highlights that prolonged estrogen deficiency can lead to misdiagnosis as Müllerian agenesis on imaging. Timely recognition and hormone therapy are essential for accurate diagnosis, restoration of reproductive anatomy, and preservation of bone and reproductive health.

Keywords Kallmann syndrome, hypogonadotropic hypogonadism

EP1859 - LBA_ECE_1300 - Patient with anaplastic thyroid carcinoma evolving from papillary thyroid carcinoma ten years after initial diagnosis

Chrysanthi Balodimou, Georgios Christantoniou, Constantina Philippidou, Charalampos Papadopoulos, Eleana Zisimopoulou, Maria Boudina and Alexandra Chrisoulidou

Department of Endocrinology, Theagenio Cancer Hospital, National Center of Endocrine Oncology, Thessaloniki, Greece

Background: The majority of anaplastic thyroid carcinomas (ATC) derives from preexisting papillary thyroid carcinomas (PTC). Although ATC is a rare entity, when it occurs, it is more often detected at the site of the primary tumor or at cervical lymph nodes and less often at distant metastases, such as lungs, breast and retroperitoneum.

Case Presentation: A 61-year-old female underwent total thyroidectomy and right lateral lymph node dissection ten years ago. The histology revealed a papillary thyroid carcinoma sized 2 cm, with foci of solid nests, no evidence of extrathyroidal extension, but metastases in 8 out of 36 cervical lymph nodes. The patient underwent RAI ablation and active surveillance thereafter, due to persistent high thyroglobulin levels. During her close follow-up, ultrasound findings were consistent with remnant pathological right lateral lymph nodes and she developed pulmonary nodules. She was then subjected to RF ablation of right lateral lymph nodes, followed by a second dose of radioiodine treatment. Due to deterioration of secondary pulmonary lesions (progressive disease according to RECIST criteria), initiation of treatment with Lenvatinib was decided. Three years after treatment with TKIs, she presented a sudden right-sided neck swelling. The ultrasound revealed enlargement of right lateral cervical lymph nodes. The patient underwent central and right lateral neck lymph node dissection and histopathology revealed that 19 lymph nodes and 2 lymph blocks out of 31 excised lymph nodes were infiltrated by ATC.

Conclusions: Increased vigilance and close follow-up are required for patients with differentiated thyroid carcinoma, whose histopathology subtypes and characteristics imply aggressive behavior.

Abstract citation ID: lvag096.1867

EP1860 - LBA_ECE_1034 - Metachronous hormonal syndromes in digestive neuroendocrine tumors: a case of sequential gastrin and ACTH secretion

Solène Eon[1], Marine Briand[1], Morgane Mauger[1], Nina Kissel[2], Florence Pihan-Le Bars[2], Daniela Hurjui-Jarnet[2], Anne-Laure Coulon[2], Oana Ionesco[2], Mélanie Priou[2] and Patricia Vaduva[1]

[1]Rennes University Hospital, Rennes, France; [2]Saint-Brieuc Hospital, Saint-Brieuc, France

Background: Metachronous hormonal syndromes (MHS) occur in 3.4%-6.8% of digestive neuroendocrine tumors (NETs), predominantly in pancreatic locations. This report examines the rare metachronous association of gastrinoma and paraneoplastic ACTH secretion, a combination characterized by high clinical severity.

Case Presentation: We report the case of a 75-year-old patient with hepatic lesions discovered during follow-up of a previously treated sarcoma. Liver biopsy revealed a well-differentiated grade 2 NET (Ki-67 8%), initially non-functional. Six months later, the patient presented with hematemesis, and duodenal biopsies confirmed a grade 2 NET with gastrinoma. Clinical and radiological stability was initially achieved with proton pump inhibitors and somatostatin analogues. One year later, new-onset diabetes associated with severe hypokalemia led to the diagnosis of ACTH-dependent Cushing's syndrome, with markedly elevated urinary free cortisol (58 times upper limit of normal), suggesting paraneoplastic secretion. Osilodrostat was initiated. Due to tumor progression, repeat liver biopsy demonstrated focal ACTH expression and an increased Ki-67 index (15%), supporting tumor evolution. In the context of severe hypercortisolism and hypergastrinemia, the biopsy was complicated by duodenal perforation, requiring high-dose proton pump inhibitors and temporary intravenous etomidate. Despite biochemical control of hypercortisolism and systemic chemotherapy (temozolomide–capecitabine), the disease progressed with hepatic and bone metastases, leading to death three years after diagnosis.

Discussion: Pathophysiologically, MHS likely stems from clonal evolution or the emergence of distinct cell subpopulations, often correlating with an increased Ki-67 index and tumor grade progression. Diagnostic confirmation is frequently hindered by heterogeneous hormone expression, underscoring the necessity for repeated biopsies during clinical progression. Management remains complex and multimodal, requiring urgent hormonal stabilization alongside systemic therapy. Ultimately, MHS illustrates the biological plasticity of NETs; recognizing these transitions is vital, as secondary hormonal functionalization significantly alters therapeutic priorities and patient prognosis, necessitating lifelong clinical vigilance.

Conclusion: Metachronous hormonal syndromes (MHS) in digestive neuroendocrine tumors are rare but pose significant clinical challenges. This case highlights the sequential emergence of

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

gastrinoma and paraneoplastic ACTH secretion and its major clinical impact. Early recognition of new endocrine symptoms is essential, as secondary hormonal secretions profoundly alter therapeutic priorities and patient survival.

EP1862 - LBA_ECE_1040 - Type 1 diabetes mellitus (T1DM) in real-world clinical practice in Odessa, Ukraine: a six-year retrospective analysis of prevalence, age, and gender of patients for the period 2019-2025

Veronika Neporada
Дім Медицини, MH "Odrex", Clinic, Одеська міська громада, Ukraine

Materials and Methods of the Study: According to the design of the study, it was a retrospective single-center observational study. The study material was the medical records of patients who were treated at MH "ODREX" in the period from January 1, 2019. to December 31, 2025.

The study included 121 electronic medical records of patients aged 14-90 years. The inclusion criteria were: consent to the processing of personal data, the presence of a confirmed diagnosis of T1DM according to the protocol, initial treatment or hospitalization within the specified period (to avoid duplication of patients).

The study was conducted in compliance with the ethical standards of biomedical research and the principles of the Declaration of Helsinki. All patient data were depersonalized and used exclusively for scientific purposes.

Table 1 Age characteristics of patients with T1DM by 2019 year.

Age	*n*	%
14-18 years	0	**0%**
18-44 years	7	**22.6%**
45-59 years	5	**16.1%**
60-74 years	13	**41.9%**
75-90 years	6	**19.4%**
31 patients		

Table 2 Gender characteristics of patients with T1DM by 2019 year.

Gender	*n*	%
Women	24	77
Men	7	31
Total	31	**100**

Table 3 Age characteristics of patients with T1DM by 2025 year.

Age	*n*	%
14-18 years	7	**7.7%**
18-44 years	28	**31.1%**
45-59 years	26	**28.9%**
60-74 years	23	**25.6%**
75-90 years	6	**6.7%**
90 patients		

Table 4 Gender characteristics of patients with T1DM by 2025 year.

Gender	*n*	%
Women	57	63
Men	33	37
Total	90	**100**

Conclusions: The proportion of patients increased by 190% (2.9 times or 59 people)—this indicates a steady trend towards an increase in the proportion of patients with T1DM during the period 2019-2025.

In the total sample of patients, there was a predominance of women compared to men

Abstract citation ID: lvag096.1869

EP1863 - LBA_ECE_1163 - Semaglutide and contraceptive efficacy: insights from FAERS and patient experiences

Nithin Tumkur Prasad
Bengaluru, India

Introduction: Semaglutide delays gastric emptying and may alter absorption of oral medications, including combined oral contraceptives. The real-world implications of this interaction remain uncertain, representing a potentially important patient safety concern in women of reproductive age.

Aim: To evaluate whether semaglutide is associated with disproportionate reporting of contraceptive-related pregnancy outcomes in women of reproductive age and to explore patient-reported experiences to identify potential signals from real-world data.

Methods: A retrospective pharmacovigilance study was conducted using the U.S. Food and Drug Administration (FDA) Adverse Event Reporting System (FAERS) from January 2018 to January 2026. Female reports involving semaglutide were identified. Disproportionality was assessed using reporting odds ratio (ROR) and proportional reporting ratio (PRR) with predefined signal detection thresholds (ROR 95% CI >1, PRR ≥2, χ^2 ≥4). Complementary thematic analysis of 635 publicly available posts from X and Reddit was performed, including posts clearly discussing semaglutide use and contraceptive experiences, with duplicates removed to ensure unique patient perspectives.

Results: Among 37 733 female semaglutide reports, 16 involved pregnancy while on oral contraception. Disproportionality analysis revealed a significant signal (ROR 5.15, 95% CI 3.15-8.42; PRR 5.15), with the lower confidence interval exceeding the predefined threshold. Signal strength was highest for obesity-indicated formulations. Social media analysis identified users reporting unintended pregnancies and concerns regarding contraceptive efficacy, frequently alongside gastrointestinal adverse effects.

Conclusion: A pharmacovigilance signal for contraceptive-related pregnancy was identified with semaglutide. While causality cannot be established, these findings highlight a potential real-world safety concern not fully captured in pharmacokinetic studies.

Impact: Endocrinologists and obesity specialists should discuss potential contraceptive efficacy concerns with women starting

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

semaglutide, especially during dose escalation, and review alternative or additional contraceptive options.

Abstract citation ID: lvag096.1870

EP1864 - LBA_ECE_1317 - SGLT2 inhibitor–associated euglycemic diabetic ketoacidosis: the importance of early acid–base assessment

Nikolaos Davanellos, Rafail Giannas, Nikolaos Kouris, Dimitrios Argiropoulos and Mixalis Apergis
Ermoupoli, Greece

Background: SGLT2 inhibitors increase the risk of euglycemic diabetic ketoacidosis (EDKA), a potentially life-threatening condition that may be overlooked due to near-normal glucose levels.

Case Presentation: A 43-year-old man with type 2 diabetes treated with empagliflozin–linagliptin–metformin presented with vomiting and diffuse abdominal pain for 16 hours following reduced oral intake and a urinary tract infection. On admission, he was mildly dehydrated and tachycardic (HR 111 bpm), with plasma glucose of 173 mg/dL. Despite the absence of marked hyperglycemia, early arterial blood gas analysis revealed severe metabolic acidosis (pH 7.15, HCO_3^- 8.7 mEq/L) with low lactate (0.8 mmol/L). Serum ketones were markedly elevated (7.1 mmol/L), confirming EDKA precipitated by infection and fasting. The SGLT2 inhibitor was discontinued, and the patient was treated with intravenous fluids, insulin infusion, dextrose, and potassium replacement. Metabolic parameters normalized within 24 hours, and he was discharged on basal–bolus insulin with appropriate education.

Conclusion: EDKA should be suspected in SGLT2-treated patients presenting with gastrointestinal symptoms even in the absence of hyperglycemia. Early arterial blood gas analysis is critical for prompt diagnosis and timely management. Delay in recognition may lead to severe metabolic deterioration and increased morbidity.

Abstract citation ID: lvag096.1871

EP1865 - LBA_ECE_1230 - Rare case of phaeochromocytoma presenting with pancreatitis, complicated by duodenal fistulation and massive upper gastrointestinal haemorrhage from a splenic artery pseudoaneurysm

Neha Fatima[1,2], Aiyappa Biddanda[1], Emily Goodchild[3], Scott Akker[3], William Martyn Drake[3], Sulmaaz Qamar[1] and Ravi Menon[1]
[1]*North Middlesex University Hospital, Royal Free London NHS Foundation Trust, London, United Kingdom;* [2]*North Middlesex University Hospital, London, United Kingdom;* [3]*Barts Health NHS Trust, London, United Kingdom*

Background: Phaeochromocytoma typically presents with catecholamine excess, while pancreatitis, diabetic ketoacidosis (DKA) and delayed catastrophic gastrointestinal haemorrhage are distinctly uncommon manifestations. We report a complex case of residual biochemically active left phaeochromocytoma complicated by duodenal fistulation and massive upper gastrointestinal bleeding from a splenic artery pseudoaneurysm, highlighting the importance of coordinated multi-centre stabilisation and intervention.

Case Presentation: A 35-year-old man initially presented in 2022 with acute pancreatitis, severe hypertriglyceridemia (triglycerides 140 mmol/L) and DKA. Cross-sectional imaging revealed a 63 mm necrotic left adrenal mass. Biochemistry showed plasma normetanephrine >10 000 pmol/L and elevated 3-methoxytyramine, consistent with a noradrenergic/dopaminergic-secreting phaeochromocytoma. Germline testing using an 11-gene susceptibility panel was negative. Following staging and alpha-blockade, he underwent left adrenalectomy in January 2024. Resection was difficult because of extensive pancreatitis-related adhesions involving the pancreatic tail, splenic flexure and tumour bed. Histology confirmed a 7.5 cm phaeochromocytoma with central necrosis, retained SDHB staining and Ki-67 up to 10% in hotspot areas, without vascular invasion. Despite surgery, post-operative imaging and biochemistry remained concerning for persistent locoregional disease, including an FDG-avid 26 mm lesion in the adrenalectomy bed, ongoing normetanephrine elevation and a suspicious 10 mm retroperitoneal node at the coeliac axis. Stereotactic ablative radiotherapy was administered to the tumour bed. In October 2025, he presented to a district general hospital with severe abdominal pain, diarrhoea, haematochezia and haemodynamic instability. Haemoglobin fell from 122 to 75 g/L, requiring transfusion of 3 units of packed red cells. Urgent upper gastrointestinal endoscopy identified clot and a suspected bleeding source beyond the distal duodenum. After initial stabilisation with blood products, he was transferred to a tertiary centre. Triple-phase CT demonstrated a gas-containing cavity at the adrenalectomy bed with direct communication to D4, consistent with potential fistulation, and a splenic artery pseudoaneurysm causing haemorrhage. He underwent urgent splenic artery embolisation, which resolved the bleeding, and was discharged with endocrine follow-up for repeat plasma metanephrines, interval imaging and ongoing multidisciplinary discussion regarding management of persistent disease. During admission, no additional alpha-blockade was given because of ongoing hypotension and low catecholamine burden, which was considered inconsequential to his haemodynamic status.

Conclusion: This case illustrates an exceptionally rare and clinically important trajectory of phaeochromocytoma, from presentation with pancreatitis and DKA to persistent locoregional disease and delayed massive upper gastrointestinal haemorrhage due to duodenal fistulation and splenic artery pseudoaneurysm. It emphasises the need for coordinated endocrine, radiological, surgical and interventional management in complex residual phaeochromocytoma.

EP1869 - LBA_ECE_1302 - A case report of a 17 year old male patient presenting with tetany and secondary hyperparathyroidism. A diagnostic revision

Eirini Biliou[1,2], Maria Tzoraki[2], Sofia Leka-Emiri[2], Stefanos Fakiolas[3], Evanthia Kassi[1] and Elpis Vlachopapadopoulou[2]
[1]*Endocrine Unit, First Department of Propaedeutic and Internal Medicine, Medical School, National and Kapodistrian University of Athens, C.E.R.E.D, Laiko General Hospital of Athens, Athens, Greece;* [2]*Department of Endocrinology, Growth and Development, Children's Hospital P. & A. Kyriakou, Athens, Greece, Athens, Greece;*

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

[3]Biochemical Department, 'P. & A. Kyriakou' Children's Hospital of Athens, Athens, Greece

Background: Pseudohypoparathyroidism (PHP) is a group of heterogeneous genetic disorders, characterized by kidney and bone unresponsiveness to PTH, with hypocalcemia, hyperphospatemia and elevated parathormone levels. It is divided into PHP Type 1 and 2. Type 1 demonstrates diminished cAMP and phosphate excretion in urine and Type 2 shows normal cAMP response but blunted phosphate excretion. PHP type 1b is defined as resistance to PTH in the kidney and normal PTH response in bone. Unlike patients with PHP type 1a and 1c patients with type 1b do not have phenotypic expression of Albright hereditary osteodystrophy (AHO). The differential diagnosis of hypocalcemia includes hypoparathyroidism, Vitamin D deficiency and chronic kidney disease.

Clinical Case: A 17-year-old boy presented with tetany. He had no notable prior personal of family medical history, skeletal abnormalities or intellectual impairment.

During physical examination Chvostek sign was positive and intermittent carpometacarpal spasms were present. Biochemical testing revealed Calcium: 5.7 mg/dl, PTH: 188 pg/mL (12-65), 25(OH)VitD:35 ng/mL.

Imaging studies were normal. He received intravenous calcium and alfacalcidol when normocalcemia was achieved, he was switched to oral treatment with calcium carbonate, alfacalcidol and cholecalciferol.

In his first follow up visit,patient demonstrated normal calcium levels, hyperphosphatemia, normal creatinine,high parathormone and suboptimal 25(OH)D_3(19.7 ng/mL) levels. Due to limited resources, genetic testing was not performed and the patient was treated as a suspected case of pseudohypoparathyroidism type 1.

During his follow up visits, primary hypothyroidism was diagnosed and he achieved adequate 25(OH)VitD_3 levels (>30 ng/mL) for a limited period.

On his last visit at the pediatric department, his lab exams showed normal calcium, parathormone and 25(OH)VitD_3 levels.

In view of these results, the initial diagnosis was re-considered.The patient discontinued treatment for one month, after which a repeat biochemical workup was performed revealing normal calcium,phosphorus, parathormone, suboptimal 25(OH)VitD_3 and normal 1,25$(OH)_2$VitD_3 levels (Ca: 9.9 mg/dl, P: 4.5 mg/dl Creat: 1 mg/dl, Alb: 4.2 g/dl, PTH: 44 pg/mL, 25(OH)VitD_3: 17 ng/mL, Mg: 2 mg/dl, 1,25Vit(OH)D_3 46 pg/mL). The results were evaluated, revising the diagnosis to secondary hyperparathyroidism due to Vitamin D deficiency. The patient will receive cholecalciferol monotherapy until his next follow-up appointment.

Conclusion: This case illustrates the diagnostic challenges of calcium disorders, as the initial diagnosis of pseudoparathyroidism, was re-evaluated during follow-up and the patient was managed as a case of severe and prolonged Vitamin D deficiency and secondary hyperparathyroidism.

EP1872 - LBA_ECE_1395 - Delayed diagnosis of Turner syndrome in an adolescent presenting with progressive lower limb spasticity

Maria Tzoraki[1], Ioanna Kosteria[1], Marina Kontitsi[2], Christina Karastathi[2], Anastasia Konidari[2] and Elpis Vlachopapadopoulou[1]

[1]Department of Endocrinology-Growth and Development, Children's Hospital P. & A. Kyriakou, Athens, Greece; [2]Second Department of Pediatrics, Children's Hospital P. & A. Kyriakou, Athens, Greece

Background: Turner syndrome (TS) is typically diagnosed in childhood on the basis of short stature, dysmorphic characteristics and coarctation of the aorta, or in pubertal age with delayed or absent pubertal development. However, diagnosis may be delayed, particularly in patients with atypical features.

Case Presentation: We report the case of a 15-year-old Roma adolescent referred for progressive gait disturbance and bilateral lower limb pain, short stature and primary amenorrhea. Symptoms initially affected the right lower limb and subsequently involved the left and had a 3 months duration. She reported no menarche but an episode of transient vaginal bleeding.

Clinical Evaluation: Height: 148 cm (<3rd Percentlie), weight: 36.8 kg, BP: 114/67 mmHg. Thyroid: Non-palpable. Head circumference: 54 cm. No dysmorphic features but a small triangular mandible. Tanner stage I for breast and II for pubic hair.

Neurological examination revealed hypertonia and increased deep tendon reflexes.

Laboratory Investigations: Brain and spine MRI were unremarkable, and cerebrospinal fluid analysis was normal. Metabolic and autoimmune investigations were negative. Bone age was delayed (10-11 years compared to chronological age of 15 years), and bone mineral density was significantly reduced (DEXA Z-score TBLH: −3.4, Lumbar spine: −3.5). Pelvic ultrasound failed to visualize the ovaries. Hormonal evaluation showed elevated gonadotropins and undetectable estradiol (FSH 61 IU/L, LH 31.9 IU/L, estradiol <5 pg/mL). Thyroid evaluation: TSH: 2.19 μIU/mL, FT4: 1.45 ng/dl, antiTPO: 3.97 IU/mL, antiTg: 6.08 IU/mL. IGF-1: 291.9 ng/mL.

The presence of hypergonadotropic hypogonadism and short stature alluded the possible diagnosis of Turner's syndrome. Thus, cytogenetic analysis was performed and revealed a structural X chromosome abnormality, 46,X,idic(X)(q13.1), consistent with a Turner syndrome variant.

Conclusion: This case illustrates a delayed diagnosis of Turner syndrome in an adolescent with atypical neurological presentation. Karyotype analysis should be performed in all girls with short stature, furthermore when it is associated with delayed puberty the likelihood of Turner's syndrome is very high and should prompt endocrine evaluation and karyotype analysis, even when non-endocrine symptoms predominate, in order to ensure timely diagnosis and appropriate management.

EP1875 - LBA_ECE_1447 - Severe familiar hypercholesterolemia in a patient with hypothyroidism due to Hashimoto thyroiditis

Adishah Çerma

Internal Medicine, Kukës Regional Hospital, Kukës, Albania

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Introduction: Hypothyroidism is associated with hyperlipidemia due to modifications in lipid synthesis, absorption and metabolism, mainly with increased total cholesterol and LDL-cholesterol. The case presented is that of a 40-year-old patient with primary hypothyroidism and severe hypercholesterolemia, with a positive familiar history for both.

Case Presentation: Patient A.B, 40 years old, presents to the clinic with tiredness and pain in her neck, starting after viral tonsillitis. She reported a positive family history for thyroid disorders including her mother and sisters. Her thyroid ultrasound showed diffuse goiter with heterogenous structure and small hypoechoic areas, which were slightly painful on examination. TSH was 0.023 μU/L, Anti-TPO 2000 IU/mL with a slightly elevated CRP of 0.64 mg/dl. Ibuprofen was started to treat the subacute thyroiditis and selenium 200 μg/day. After the subacute thyroiditis resolution, she was reevaluated and TSH resulted 28.648 μU/L with normal ft4 and ft3. A lipid profile was requested: Total Cholesterol was 319 mg/dl, LDL-cholesterol 248 mg/dl, Triglycerides 113 mg/dl and HDL-cholesterol 55 mg/dl. She takes no medication to affect lipid metabolism. Diabetes, hepatitis, nephrotic syndrome and other hormonal alterations were excluded. On further questioning, she recalls that both her sisters had been taking statins for hypercholesterolemia, before the age of 40. No early cardiac event was reported. On physical examination, no xanthoma or xanthelasma were present. Her peripheral doppler and heart ultrasound were normal. No genetic testing was possible.

Patient was started on Levothyroxine 75 mcg/day and Rosuvastatin 20 mg/day, with dietary restrictions. Her TSH remained high (57.524 μU/L) in a 2-month follow-up, with a decrease in Total Cholesterol 239 mg/dl and LDL-cholesterol 150 mg/dl. TSH dosage was raised again to 100 mcg/day, advising her on the medication compliance. After 5 months of follow-up, her TSH was 17.301 μU/L and total cholesterol elevated at 301 mg/dl and LDL-cholesterol 202 mg/dl, despite medication and slight dietary changes. Ezetimibe 10 mg was added and Levothyroxine 125 mcg/day. No changes were seen in the follow up (total cholesterol 319 mg/dl and LDL-cholesterol 231 mg/dl). Rosuvastatin dosage was raised to 30 mg/dl and a strict daily diet recommended. After almost a year of treatment, her TSH normalized (0.880 μU/L) and total cholesterol 135 mg/dl with LDL 76 mg/dl. She continues to be on close follow-up.

Conclusion: Severe hypercholesterolemia should be carefully evaluated in every patient, to determine primary and secondary causes, including hypothyroidism. Treatment and follow-up are necessary to avoid future cardiac complications.

EP1877 - LBA_ECE_1047 - FSH resistance syndrome in a young woman with primary amenorrhea

Evangelia Makri[1], Georgios Kostopoulos[1], Konstantinos Ravanos[2], Ioannis Papoulidis[3] and Foteini Adamidou[1]

[1]*Endocrinology, Hippokration General Hospital of Thessaloniki, Thessaloniki, Greece;* [2]*Embryolab Next Gen IVF, Thessaloniki, Greece;* [3]*Clinical Genetics Laboratory, Access To Genome—ATG, Thessaloniki, Greece*

Introduction: FSH-resistant ovary syndrome is a rare cause of primary or secondary amenorrhea. It is characterized by menopausal levels of FSH and LH, low estradiol levels, normal anti-Müllerian hormone (AMH) levels, and the presence of immature ovarian follicles with impaired maturation due to mutations in the FSH receptor (*FSHR*) gene. Patients present with anovulation and infertility and are commonly diagnosed with premature ovarian insufficiency.

Case Presentation: A 32-year-old woman with a history of primary amenorrhea presented for fertility evaluation. The patient had normal secondary sexual characteristics and had been treated with cyclic hormonal therapy with estrogen and progesterone since adolescence. Laboratory evaluation showed a normal female karyotype, elevated FSH/LH levels (101.9 mIU/mL and 41.4 mIU/mL, respectively), low estradiol levels (17.2 pg/mL), and normal AMH levels (1.7 ng/mL). Transvaginal ultrasound demonstrated normal internal genitalia, with an antral follicle count of 10. There was no known family history of infertility.

The patient underwent ovarian stimulation with follitropin alfa 300 IU, without follicular development.

Genetic testing revealed a novel homozygous missense variant in the FSHR gene, c.1412T>G p.(Ile471Ser), classified as likely pathogenic, confirming the diagnosis of FSH resistance syndrome.

The patient was referred for further specialized assisted reproductive treatment.

Conclusions: FSH resistance should be suspected in women of reproductive age presenting with primary or secondary amenorrhea, when elevated FSH and LH levels are found alongside low/normal estradiol levels, but preserved ovarian reserve. The combination of clinical evaluation, laboratory findings, and genetic testing enables early recognition and appropriate

counseling. In these cases, conventional ovarian stimulation has low likelihood of success, and recommended reproductive strategies include in vitro maturation (IVM) of oocytes and oocyte donation.

EP1879 - LBA_ECE_1137 - Adrenal hemangioma: an unusaul cause of abdominal pain

Eleftheria Kakargia[1], Danai Georgakopoulou[1], Akrivi Kostopoulou[2], Giorgos Zografos[3], Labrini Papanastasiou[1], Athanasios Fountas[1] and Athina Markou[1]

[1]*Department of Endocrinology and Diabetes Center, Center of Excellence of Rare Endocrine Adrenal Disorders, Athens, Greece;* [2]*Department of Pathology, General Hospital of Athens G.Gennimatas, Athens, Greece;* [3]*First Departmennt of Surgery, G. Gennimatas' General Hospital of Athens, Athens, Greece*

Background: Adrenal hemangioma is a rare benign vascular tumor of uncertain pathogenesis, most often identified incidentally. Fewer than 100 cases have been reported in the literature since it was first described approximately 70 years ago. Herein, we present a rare case of an adrenal hemangioma presenting with abdominal pain.

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

Case Report: A 61-year-old woman with a recent history of a transient ischemic attack secondary to a patent foramen ovale was referred to our clinic after an adrenal mass was detected on abdominal CT, performed for intermittent abdominal pain. CT demonstrated a 3.5 cm bilobed and heterogeneous right adrenal lesion with large calcifications and no contrast enhancement. The left adrenal gland was unremarkable and there was no lymph node enlargement. Further assessment with gadolinium-enhanced MRI revealed a complex right adrenal mass with heterogeneous T1 and T2 signal intensity and prominent cystic components. There were no clinical features suggestive of a secreting adrenal tumor, which was confirmed by comprehensive hormonal evaluation excluding cortisol, aldosterone, adrenal androgens and catecholamines excess. Adrenal tuberculosis was included in the differential diagnosis, given that adrenal calcifications are a characteristic imaging finding in tuberculous adrenalitis, and subsequently excluded. To further characterize the lesion a ^{18}F-FDG PET/CT was performed, which demonstrated a photopenic lesion without FDG uptake, as well as a ^{68}Ga-DOTATATE PET/CT, which showed no increased uptake in the right adrenal gland. Taking into account the suspicious imaging features of the adrenal mass and the absence of definite diagnosis the option of adrenalectomy was offered to the patient. An uneventful laparoscopic right adrenalectomy was performed followed by complete resolution of the abdominal pain. Histopathological examination was indicative of an adrenal hemangioma.

Conclusion: Our case highlights the challenges in the diagnostic evaluation of an adrenal hemangioma. Despite being benign, it may present as a radiologically suspicious adrenal mass and mimic malignant lesions including adrenocortical carcinoma, metastases or pheochromocytomas. Pre-operative diagnosis is difficult and given its rarity and non-specific imaging features surgical resection is ultimately needed to establish the diagnosis.

EP1881 - LBA_ECE_1313 - When fluid restriction makes it worse: cerebral salt wasting masquerading as SIADH after traumatic brain injury

Paul Chatee, Muhammad Waqar Khan, Nur Fatin Aqilah Binti Suharinizam and Paul Pravin
Endocrinology, Univeristy Hospital Limerick, Limerick, Ireland

Background: Hyponatraemia is a frequent complication following acute brain injury and is most commonly attributed to Syndrome of Inappropriate Antidiuretic Hormone Secretion. However, Cerebral salt wasting represents an important alternative diagnosis. Distinguishing between these entities is critical, as management strategies are opposing. Misclassification may worsen hyponatraemia and increase morbidity.[1]

Case Presentation: A 44-year-old male was admitted following a mechanical fall. CT brain demonstrated bilateral intraparenchymal haemorrhages with subarachnoid haemorrhage. Neurosurgical review advised conservative management, and antiepileptic therapy was commenced.

On day 8, serum sodium declined from 139 to 123 mmol/L. The patient appeared clinically euvolaemic, although subtle hypovolaemia may have been masked. Urine sodium was 150 mmol/L and urine osmolality 639 mOsm/kg. Urine output remained elevated at >3 L/day. Thyroid function and cortisol were normal. SIADH was initially diagnosed.

Fluid restriction (1 L/day) was instituted; however, hyponatraemia worsened, with sodium approaching levels requiring escalation to high-dependency care for hypertonic saline. The lack of response, alongside ongoing natriuresis and high urine output, prompted reconsideration of the diagnosis.

Cerebral salt wasting was suspected, and isotonic fluid replacement was initiated. This resulted in stabilisation and subsequent improvement in serum sodium, confirming the diagnosis.

Discussion: SIADH and CSW share overlapping biochemical features, including hyponatraemia with elevated urine sodium and osmolality, and may appear clinically euvolaemic. However, CSW is characterised by renal sodium loss, likely mediated by natriuretic peptides, leading to hypovolaemia and high urine output.

Failure of standard therapy should prompt reconsideration of diagnosis. Early misclassification may expose patients to inappropriate fluid restriction and progression to severe hyponatraemia requiring critical care intervention. Response to fluid administration may provide a useful diagnostic distinction.[2,3]

Conclusion: Accurate differentiation between SIADH and CSW is essential following brain injury. This case highlights that worsening hyponatraemia despite guideline-directed therapy should trigger diagnostic reassessment, as incorrect classification may delay treatment and worsen outcomes.

EP1886 - LBA_ECE_1112 - Association between waist-to-height ratio as an indicator of central obesity and glucose dynamics during oral glucose tolerance test in individuals with prediabetes

Irem Sonmezoglu Kutuk[1], Fidan Yusifova[2], Ethem Turgay Cerit[1], Mehmet Muhittin Yalcin[1], Mujde Akturk[1], Fusun Toruner[1], Ayhan Karakoc[1] and Altinova Alev[1]
[1]*Department of Internal Medicine, Division of Endocrinology and Metabolism, Gazi University Faculty of Medicine, Ankara, Turkey;* [2]*Department of Internal Medicine, Gazi University Faculty of Medicine, Ankara, Turkey*

Introductıon: Central obesity plays an important role in the development of insulin resistance and type 2 diabetes. Although body mass index (BMI) is widely used, it may not adequately reflect visceral adiposity and the associated metabolic risk. In recent years, waist-to-height ratio (WHtR) has been suggested as a more sensitive marker for evaluating central obesity. In this study, it was aimed to evaluate the relationship between WHtR and glucose dynamics obtained during the oral glucose tolerance test (OGTT) in individuals without diabetes.

Methods: A total of 86 individuals who underwent OGTT, had no diagnosis of diabetes, and had prediabetes were included in this cross-sectional study. Demographic characteristics,

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

HbA1c levels and anthropometric measurements of the participants were recorded. Using plasma glucose values at 0, 30, 60, 90 and 120 minutes during OGTT, total glucose area under the curve (AUC), early AUC, late AUC, peak glucose level and glucose excursion were calculated. Central obesity was defined as WHtR ≥0.5. The relationships between WHtR and BMI with OGTT parameters were evaluated by correlation analyses and OGTT parameters were compared according to WHtR categories.

Results: The mean age of the participants was 51 ± 12 years and 70.6% were female. Mean HbA1c was 5.96 ± 0.22% and BMI was 26.46 ± 3.44 kg/m^2. WHtR showed significant correlation with 30-minute glucose level ($r = 0.222$, $P = .042$), peak glucose ($r = 0.247$, $P = .022$), early AUC ($r = 0.249$, $P = .022$) and delta glucose (peak glucose—0-minute glucose) ($r = 0.245$, $P = .023$). In contrast, no significant relationship was found between BMI and OGTT glucose dynamics.

In individuals with WHtR ≥0.5, 30-minute glucose level (150.5 ± 21.9 vs 136.2 ± 22.9 mg/dL, $P = .041$) and delta glucose (82.1 ± 27.6 vs 63.1 ± 28.9 mg/dL, $P = .031$) were found to be higher. Additionally, WHtR values were found to be significantly higher in individuals with 60-minute glucose ≥155 mg/dL ($P = .029$).

Discussion and Conclusion: Waist-to-height ratio, which indicates central obesity, was found to be associated with early glucose abnormalities occurring during OGTT before the development of diabetes, whereas this relationship was not observed with BMI. These findings suggest that WHtR may be a more sensitive anthropometric marker than BMI in determining early metabolic risk demonstrated during OGTT and may be a clinically more valuable measurement in detecting glycemic abnormalities occurring before the development of diabetes.

EP1887 - LBA_ECE_1064 - Functional adrenocortical oncocytoma with androgen excess and subclinical hypercortisolism: a rare cause of infertility

Arnautu Ana Maria[1], Catalina Petrescu[1], Claudia Nacea[1], Mirona Dinca[1,2], Beatrice Grecu[1], Dana Tilici[1,2], Adina-Ioana Onofrei[1], Ruxandra Costinescu[1] and Diana Paun[1,3]

[1]Ploiesti, Romania; [2]Doctoral School of "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania; [3]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania

Background: Oncocytic neoplasms are predominantly benign tumors most commonly identified in the kidney, thyroid, parathyroid, and salivary glands. Adrenocortical oncocytomas are exceptionally rare and are typically non-functioning. However, a subset may exhibit hormonal activity, and a proportion demonstrates features suggestive of uncertain or malignant biological potential.

Case Presentation: We report the case of a 23-year-old woman initially referred to gynecology for evaluation of infertility, where markedly elevated DHEA-S levels (approximately four times the upper limit of normal) were identified.

Subsequent endocrine assessment revealed mild chin acne on clinical examination. An extended hormonal evaluation confirmed elevated adrenal androgens, associated with lack of cortisol suppression following the 1 mg overnight dexamethasone suppression test and loss of circadian cortisol rhythm, while ACTH levels remained within the normal range.

Contrast-enhanced abdominal CT demonstrated a large (86 × 80 × 93 mm), well-circumscribed, heterogeneous right adrenal mass, with an attenuation of 40 HU and washout >50%, exerting significant mass effect on adjacent structures.

The patient underwent laparoscopic right adrenalectomy. Histopathological examination revealed an adrenocortical oncocytic neoplasm of uncertain malignant potential. According to Lin–Weiss–Bisceglia criteria, major criteria included equivocal venous invasion, while minor criteria comprised large tumor size (maximum diameter 105 mm), capsular invasion, and equivocal sinusoidal invasion. Immunohistochemistry showed a Ki-67 index of 2% and negative staining for inhibin, Melan-A, MCK, vimentin, PHH3, and MSA.

Postoperative evolution was favorable. At 3-month follow-up, the patient had a normal clinical examination and significant improvement in biochemical hyperandrogenism, with only mild persistent elevation of total testosterone and 17-hydroxyprogesterone (measured in the luteal phase). Follow-up CT imaging showed no evidence of recurrence.

Given the uncertain malignant potential, periodic follow-up with hormonal assessment and imaging at 3-month intervals was recommended.

Conclusion: Adrenocortical oncocytomas are uncommon adrenal tumors, typically non-functional, but occasionally associated with clinically relevant hormone secretion. This case underscores the need to include functional oncocytic tumors in the differential diagnosis of hyperandrogenism and infertility. Establishing their biological behavior remains challenging and relies on thorough histopathological and immunohistochemical assessment, given the limited ability of preoperative investigations to reliably distinguish them from malignant adrenal lesions.

EP1888 - LBA_ECE_1077 - Demographic profile and symptoms distribution in patients with diabetic peripheral neuropathy in Armenia

Naira Zohrabyan, Yeranuhi Khanoyan and Yelena Aghajanova

Endocrinology, Yerevan State Medical University after Mkhitar Heratsi, 'Muratsan' University Hospital, Yerevan, Armenia

Background: Diabetic peripheral neuropathy is a common complication of diabetes, that results damage to multiple peripheral nerves. It is characterized by sensory, motor, and/or autonomic nerve dysfunction, with symptoms including pain, burning, numbness and weakness in the limbs, as well as disturbances in digestion, urination, sweating and cardiovascular regulation. Understanding the demographic profile and symptom patterns of patients with DPN is essential for improving diagnosis, management, and patient outcomes. This study aims to describe key characteristics of patients diagnosed with DPN in ambulatory clinics of RA, focusing on pain status, age distribution, and possible sex differences.

Objectives: The primary objective of this study was to describe the demographic and clinical characteristics of patients with

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

diabetic peripheral neuropathy in Armenia. Specifically, the study aimed to determine the proportion of patients with painful vs painless DPN, analyze the age and sex distribution of the patient population, assess the response to benfotiamine over one month of treatment.

Methods: A cross-sectional study was conducted on patients diagnosed with 383 completing the study. Incompletely or incorrectly completed questionnaires were excluded from the analysis. Patients were classified into two groups: those experiencing painful DPN and those with painless DPN. Data on patients' year of birth (ranging 1941-1973), sex, and presence or absence of neuropathic pain were collected using standardized clinical assessment forms. All patients received benfotiamine treatment, one tablet daily, for one month. Descriptive statistics were used to analyze and summarize the demographic and clinical features.

Results: Of the 383 patients included, 328 (85.6%) reported painful symptoms associated with DPN, whereas 55 patients (14.4%), had DPN without pain. The age of the patients varied, with birth years ranging between 1941 and 1973, indicating an adult to elderly population affected by DPN. The sex distribution showed a marked predominance of female patients, with 276 females (72.1%) and 107 males (27.9%). Painful DPN was more commonly observed across both sexes, however, no further stratification by sex was performed.

Conclusion: The findings indicate that painful DPN constitutes the majority of cases among patients with diabetic peripheral neuropathy in Armenia. Daily benfotiamine for one month was consistently applied and was associated with moderate to significant improvement in neuropathic symptoms, highlighting its benefit in DPN management. These findings underscore the importance of early detection and appropriate management of neuropathic pain in diabetic patients to improve quality of life and prevent further disability.

EP1889 - LBA_ECE_1478 - PTH replacement therapy with palopegteriparatide in women with severe hypoparathyroidism—a case report

Jowita Halupczok-Żyła[1], Anna Brona[1] and Marek Bolanowski[2]

[1]Department of General and Experimental Pathology, Wroclaw Medical University, Wrocław, Poland; [2]Department and Clinic of Endocrinology and Internal Medicine, Wroclaw Medical University, Wrocław, Poland

Hypoparathyroidism is a rare disease usually characterized by a lack or deficiency of parathyroid hormone (PTH), which results in hypocalcemia and may lead to hyperphosphataemia. In most cases, hypoparathyroidism in adults is iatrogenic and caused by thyroid and parathyroid surgery or radiation to the neck. Conventional therapy consists of oral calcium and active vitamin D supplementation. However, this approach does not restore physiological PTH function. Palopegteriparatide, a PTH analogue, causes a sustained PTH effect, and therefore, it may be a promising option that will be more widely used in hypoparathyroidism.

A 52-year-old patient underwent total thyroidectomy due to retrosternal goiter. A few days after the surgery, she complained of typical symptoms of tetany. Laboratory examinations showed decreased concentrations of total calcium (7.1 mg/dl) and corrected calcium (7.28 mg/dl), and increased phosphorus (5.5 mg/dl). Postoperative hypoparathyroidism was diagnosed. She was treated with calcium carbonate (10 g/day), calcium citrate (1.2 g/day), calcitriol (1.5 μg), cholecalciferol (4000 IU/day), and hydrochlorothiazide (25 mg/day). After several months, treatment with palopegteriparatide was successfully initiated with a gradually increasing dose. The starting dose was one daily subcutaneous injection of 18 μg. During the therapy, skin redness at the injection site, nausea, diarrhea, and an increase in blood pressure occurred. After two months of treatment, the patient felt better and reported no side effects (27 μg/day). Laboratory results revealed normalization of total calcium (8.56 mg/dl) and phosphorus (3.69 mg/dl) levels. The use of palopegteriparatide allowed for a reduction in calcium doses (calcium carbonate - 2 g/day, calcium citrate - 0.8 g/day) and hydrochlorothiazide (12.5 mg/day). Calcitriol was discontinued. This case illustrates that palopegteriparatide may provide an effective therapeutic option in the management of severe postoperative hypoparathyroidism.

EP1890 - LBA_ECE_1160 - Effects of exam-period lifestyle changes, sleep patterns, and stress awarness on fasting glucose levels in medical students in Georgia

Mariam Dumbadze[1], Ketevan Dundua[2] and Teona Gogitidze[3]

[1]Medicine, BAU International University, Batumi, Georgia; [2]David Aghmashenebeli University of Georgia, Tbilisi, Georgia; [3]Medicine, BAU International University, BAU International Hospital, Batumi, Georgia

Introduction: Medical students experience significant psychological and physiological stress due to demanding training and lifestyle. Mental health issues such as depression, eating disorders, and anxiety[1] are common. Lifestyle factors—including genetic predisposition, poor sleep,[2] irregular diet,[3] and chronic stress—also play an important role. These factors may lead to metabolic changes such as altered fasting glucose, weight fluctuations and reduced well-being. Studying these patterns helps clarify their link with fasting glucose and metabolic risk, especially in genetically predisposed individuals.

Aim: To evaluate the effect of exam-period lifestyle changes (sleep, stress, diet) on fasting glucose levels and metabolic risk among medical students, and to determine whether these changes are common.

Methods: A case-control survey was conducted among 200 medical students (1st–6th year) at BAU International University, Georgia. Participants represented diverse nationalities. Data were collected via questionnaire assessing demographics, chronic and genetic diseases, sleep, study habits, stress, and physical activity. Fasting glucose was measured during the final exam period. The analysis focused on associations between lifestyle factors and glucose levels.

Results: Among 200 students (mean age 21.8 years; 59% female), 93 (46.5%) without chronic disease or family history were

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

excluded. Data from 80 students were analyzed: 20% with chronic disease and family history of diabetes, and 20% with family history, without chronic disease. Among chronic cases, insulin resistance was present in 7%, PCOS in 4.5%, and type 1 diabetes in 0.5%. Many were likely pre-diabetic. Family history included type 2 diabetes in 48 (24%), type 1 in 14 (7%). During exams, 57% slept <6 hours and 73% reported moderate–severe anxiety. Symptoms such as fatigue, dizziness, tremor and poor concentration were reported by 76%. Physical activity decreased in 32%; weight gain occurred in 20%, 60% consumed unhealthy diets. Mean glucose was 91.3 and mean BMI 25.4.

Conclusion: Higher stress and shorter sleep were linked to increased fasting glucose and BMI, especially in insulin-resistant and pre-diabetic students. These findings suggest increased risk of dysglycemia. Greater awareness, lifestyle support, and preventive strategies are needed to improve both students' well-being and future patient care.

Keywords exam stress, sleep deprivation, lifestyle habits, fasting glucose, medical students

EP1894 - LBA_ECE_1304 - X-linked hypophosphatemic rickets and ulcerative colitis: a rare association requiring multidisciplinary management

Sabina Maria Dumitrache, Luminita Cima, Roxana-Elena Busioc, Diana Puscasu and Carmen Gabriela Barbu
Endocrinology, Elias University Emergency Hospital, Bucharest, Romania

Introduction: X-linked hypophosphatemic rickets (XLH) is a rare inherited disorder caused by PHEX mutations, characterized by FGF23-mediated renal phosphate wasting and impaired bone mineralization. Ulcerative colitis is a chronic inflammatory bowel disease with immune-mediated mechanisms. The coexistence of XLH and UC is poorly described in the literature. We report a case highlighting this association and its clinical implications.

Case Report: A 25-year-old male with genetically confirmed XLH (PHEX c.1224del, p.Phe409Leufs*15), diagnosed in childhood, was referred for endocrinological evaluation due to persistent hypophosphatemia and progressive skeletal complications despite long-term conventional therapy (active vitamin D and oral phosphate supplementation). Biochemical assessment revealed hypophosphatemia (~2.0 mg/dL), elevated alkaline phosphatase, reduced tubular phosphate reabsorption (TRP 76%), and low TmP/GFR, consistent with ongoing renal phosphate wasting. Imaging studies showed characteristic skeletal abnormalities, including femoral bowing, cortical thickening, periosteal reaction and decreased bone mineralization. A pseudofracture of the left femur was identified, and the patient was evaluated by orthopedic specialists for structural complications and functional impairment. Given the coexistence of a chronic inflammatory condition and a progressive metabolic bone disease, both potentially requiring targeted biological therapies, management was coordinated within a multidisciplinary team involving endocrinology and gastroenterology. Particular attention was given to the potential interactions and safety of introducing biologic treatment in the context of an underlying inflammatory disease.

Due to insufficient response to conventional XLH therapy and ongoing skeletal deterioration, treatment with Burosumab (anti-FGF23 monoclonal antibody) was initiated at a dose of 1 mg/kg every 4 weeks, with planned biochemical and clinical follow-up.

Discussion: This case raises the question of whether the coexistence of XLH and ulcerative colitis is incidental or may reflect a link between phosphate metabolism and chronic inflammation. FGF23 may have a role beyond phosphate regulation, including involvement in inflammation, while chronic inflammatory diseases can impact bone metabolism. To our knowledge, this coexistence has not been clearly described in the current literature. The coexistence of a condition requiring targeted therapy and a chronic inflammatory disease highlights the complexity of management. Further studies are warranted to investigate this potential association.

Abstract citation ID: lvag096.1884

EP1895 - LBA_ECE_1417 - Unrecognized primary hyperparathyroidism presenting with life- threating hypercalcemia

Hristina Vlavcheska[1], Biljana Todorova[1], Iskra Bitovska[1], Sasha Jovanovska Mishevska[1], Tatjana Prosheva Bajraktarova[1], Irfan Ahmet[1], Hristijan Petreski[2] and Tatjana Milenkovic[1]
[1]*Department of Endocrinology, Univerzitet Sveti Kiril i Metodij-Rektorat, University Clinic of Endocrinology, Diabetes and Metabolic Disorders, Skopje, North Macedonia;* [2]*Department of Internal Medicine, Endocrinology Unit, Opshta bolnica-Kichevo, Kichevo, North Macedonia*

Background: Primary hyperparathyroidism (PHPT) is most commonly diagnosed in older adults and typically presents as asymptomatic hypercalcemia. However, in younger patients, PHPT may lead to significant multisystem complications. This case highlights the diagnostic and clinical challenges of PHPT in a 31-year-old female patient presenting with recurrent hypercalcemia, gastrointestinal symptoms, and nephrolithiasis.

Case Presentation: A 31-year-old female presented with intermittent vomiting and epigastric pain, progressing to fatigue and palpitations requiring hospital admission. Endoscopy showed erosive antral lesions, and renal ultrasound confirmed bilateral nephrolithiasis. Labs revealed hypercalcemia, hypophosphatemia, elevated PTH, and increased creatinine, indicating renal impairment. Bone resorption (B-CrossLaps 6000, Osteocalcin 300.0) with decreased Vitamin D3 suggested high bone turnover and risk for osteoporosis. Dual-phase SPECT/CT parathyroid scintigraphy showed a pathological focus inferior to the left thyroid lobe, consistent with a parathyroid adenoma. The patient

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

underwent surgical parathyroidectomy. Postoperatively, hungry bone syndrome was managed with intravenous and oral calcium, vitamin D, and magnesium. Follow-up showed normalized calcium and improved bone markers.

Discussion: Hypercalcemia can be subclinical yet life-threatening, often presenting with nonspecific symptoms delaying diagnosis. Timely serum calcium measurement is crucial in patients with chronic multisystem complaints. Vitamin D deficiency may induce compensatory PTH hypersecretion, worsening bone metabolism. Standard imaging like cervical ultrasound may miss ectopic or small adenomas, whereas dual-phase SPECT/CT improves localization.

Conclusion: Hypercalcemia is a potentially life-threatening condition requiring prompt recognition and management, even when symptoms are nonspecific. Early evaluation with serum calcium and PTH is crucial to distinguish PTH-dependent from PTH-independent hypercalcemia. Delayed recognition of primary hyperparathyroidism can lead to severe metabolic, cardiac, neurocognitive, and skeletal complications. Surgical excision of the affected parathyroid achieved rapid biochemical remission, while careful perioperative monitoring and supplementation managed hungry bone syndrome. This case highlights the importance of systematic assessment, combined imaging for accurate lesion localization, anticipation of postoperative complications, and multidisciplinary care to ensure patient safety and long-term bone health.

Abstract citation ID: lvag096.1885

EP1897 - LBA_ECE_1063 - A rare cause of Iatrogenic Cushing's syndrome: prolonged oral corticosteroid therapy for chronic headache

Arnautu Ana Maria[1], Catalina Petrescu[1], Claudia Nacea[1], Dana Tilici[1,2], Ruxandra Costinescu[1], Adina-Ioana Onofrei[1], Beatrice Grecu[1], Mirona Dinca[1,2] and Diana Paun[1,3]
[1]Ploiesti, Romania; [2]Doctoral School of "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania; [3]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania

Background: Iatrogenic Cushing's syndrome (ICS) is the most common form of hypercortisolism and results from prolonged exposure to exogenous glucocorticoids. Although corticosteroids are widely used in neurological conditions, ICS associated with treatment of primary headache disorders is rarely reported. We present a case of severe ICS caused by intermitent, but prolonged oral corticosteroid use in a patient with chronic headache later diagnosed as hemicrania continua, complicated by multiple metabolic, endocrine and infectious manifestations.

Case Presentation: A 39-year-old man developed iatrogenic Cushing's syndrome after intermittent treatment with oral dexamethasone for chronic headache initially considered cluster-type. The headache syndrome began at the age of 16, and since 2021 the patient had been self-administering corticosteroids intermittently in variable doses. In 2025 he was diagnosed with hypercholesterolemia and diabetes mellitus, considered complications of chronic glucocorticoid excess.

At admission, the patient presented typical cushingoid features, including moon facies, central obesity, proximal myopathy, periorbital edema, and wide violaceous striae. Ulcerative lesions over the Achilles tendon and toenail onychomycosis were also observed. Laboratory evaluation revealed hematological changes suggestive of hypercortisolism, mild hepatic cytolysis, controlled LDL cholesterol under statin therapy, and hyperglycemia. Endocrine evaluation also showed central hypothyroidism likely related to chronic glucocorticoid exposure, as well as normal gonadotropins with undetectable testosterone levels consistent with functional hypogonadism.

Hormonal evaluation performed a week after glucocorticoid withdrawal demonstrated suppression of the hypothalamic–pituitary–adrenal axis, with undetectable basal cortisol, low ACTH, and decreased DHEAS levels. A 250 μg synthetic cosyntropin stimulation test confirmed severe secondary adrenal insufficiency, and glucocorticoid replacement therapy with prednisone 5 mg/day was initiated. A 1-mg intramuscular tetracosactide test induced a rapid cortisol rise during hospitalization, declining to the lower limit of normal by discharge.

Multidisciplinary management included dermatology and infectious disease consultations, which confirmed *Staphylococcus aureus* superinfection of the ulcerative lesions requiring targeted antibiotic therapy. Hyperglycemia initially required insulin therapy but was subsequently controlled with oral antidiabetic agents. During hospitalization, recurrent headache episodes prompted neurological evaluation, and an indomethacin test supported the diagnosis of hemicrania continua. Cardiology consultation revealed a right bundle branch block-like conduction abnormality, and psychiatric evaluation confirmed depressive disorder requiring SSRI therapy.

During follow-up, laboratory abnormalities improved progressively, with normalization of hematologic and hepatic parameters and gradual recovery of hormonal axes.

Conclusion: This case highlights the severe consequences of uncontrolled glucocorticoid exposure and the need for careful monitoring when corticosteroids are used in chronic headache disorders.

EP1898 - LBA_ECE_1207 - Clinical, biochemical and tumoral characterization of adrenal hypercortisolism: a multicenter experience (2022-2026) in southwestern Colombia

Andres Garcia[1], Carlos Berrocal[1], Jhon Quintana[2], Diego Fernando Ocampo Cortes[3] and Alejandro Roman[4]
[1]Universidad del Valle, Cali, Colombia; [2]Clínica de Occidente—Universidad Santiago de Cali, Cali, Colombia; [3]Angiografia de Occidente, Cali, Colombia; [4]Facultad de Medicina U. De A, Universidad de Antioquia, Medellín, Colombia

Background and Aims: Adrenal hypercortisolism represents a clinical and biochemical spectrum ranging from mild autonomous cortisol secretion (MACS) to overt Cushing's syndrome, including rare malignant etiologies such as adrenocortical carcinoma. This study aimed to characterize the clinical presentation of patients with adrenal hypercortisolism from referral centers in southwestern Colombia.

Methods: We conducted a retrospective study of 12 patients with confirmed adrenal hypercortisolism (2022-2026). Demographics, metabolic comorbidities, biochemical profile, and imaging findings were analyzed.

Results: The cohort was predominantly female (91.7%), with ages ranging from 29 to 71 years. Most cases (75%) corresponded

Downloaded from academic.oup.com/ejendo/issue/195/Supplement_1 by guest on 05 September 2026

to MACS, **followed by overt adrenal Cushing's syndrome and adrenocortical carcinoma**, and were associated with a high burden of metabolic comorbidities: dyslipidemia (66.7%), central obesity (58.3%), hypertension (41.7%), diabetes mellitus (25%), and osteoporosis/low bone mass (25%). Thrombotic events were identified in 16.7% of patients.

Biochemically, all cases showed an ACTH-independent profile (median ACTH: 8.4 pg/mL). Lack of suppression after DST was universal (median cortisol: 6.4 µg/dL; maximum: 25.2 µg/dL), with a median UFC of 102 µg/24 h.

Imaging revealed predominantly unilateral lesions, more frequently left-sided (66.7%). Adenomas ranged from 16 to 40 mm, while one patient presented severe hypercortisolism due to a 120 mm adrenocortical carcinoma, representing the extreme end of the disease spectrum. Surgical remission was achieved in 50% of followed cases.

Conclusions: Adrenal hypercortisolism exhibits a wide clinical spectrum, from subclinical forms associated with incidentalomas and significant metabolic burden to severe presentations caused by malignant tumors. These findings highlight the importance of early recognition and comprehensive evaluation of even mild cortisol excess.

Table Baseline characteristics: adrenal hypercortisolism ($N = 12$).

Variable	Frequency (n)/ Median	Percentage (%)/Range or IQR
Demographic and Clinical Profile		
Female Sex	11	91.7%
Age (years)	57.0	Range: 29-71
Incidental Diagnosis (MACS)	9	75.0%
Central Obesity	7	58.3%
Hypertension (HTN)	4	33.3%
Osteoporosis/Low Bone Mass	3	25.0%
Metabolic Profile (HbA1c)		
HbA1c (%)	5.86	Range: 5.4-7.46
Diabetes Mellitus (HbA1c $\geq$ 6.5%)	3	25.0%
Prediabetes/At risk (HbA1c 5.7%-6.4%)	5	41.7%
Normal (<5.7%)	3	25.0%
Biochemical Profile (Cortisol & ACTH)		
Plasma ACTH (pg/mL)	**8.4**	**IQR: 7.2 (Range: 1.5-84.2)**
ACTH Classification:		
- Suppressed/ Independent	7	58.3%
- Normal	3	25.0%
Cortisol post-1mg DST (µg/dL)	**6.4**	**IQR: 10.65 (Range: 2.07-25.17)**
24-hour Urinary Free Cortisol (µg/24 h)	**102.0**	**IQR: 198.6 (Range: 13.2-2950.0)**
Hypokalemia (K+ <3.5 mEq/L)	1	8.3%

EP1899 - LBA_ECE_1457 - Steroid-replete but stress-deficient: hidden secondary adrenal insufficiency in a routine thyroid workup

Tabinda Dugal
Endocrinology Unit, Lusail, Qatar

Background: Non-specific symptoms such as fatigue and weight gain are frequently attributed to thyroid dysfunction or perimenopause. However, unrecognised glucocorticoid exposure remains an underappreciated cause of secondary adrenal insufficiency (SAI), with significant diagnostic and safety implications.[1,2]

Case: A 42-year-old woman presented with fatigue, impaired morning energy, and 3 kg weight gain. Past history included vitamin B12 and vitamin D deficiency and psoriasis. Examination was unremarkable (BMI 21 kg/m^2, BP 109/68 mmHg). Initial tests showed mildly elevated TSH (5 mIU/L), prompting broader endocrine evaluation.

Serum cortisol was profoundly suppressed at 4.4 nmol/L (reference 46-626). Targeted history revealed repeated intramuscular betamethasone injections over 3-4 years due to limited access to biologic therapy.

Interpretation: Betamethasone is a potent long-acting glucocorticoid (20-40× hydrocortisone potency; half-life 36-72 hours) that suppresses ACTH and endogenous cortisol production.[3,4] As it does not cross-react with cortisol immunoassays, measured cortisol appears extremely low despite ongoing glucocorticoid activity.[4] Patients are therefore "steroid replete" at baseline but unable to mount an adequate stress response, placing them at risk of adrenal crisis.[2,5]

Early SAI represents a key diagnostic trap: adrenal responsiveness may be preserved, leading to false-negative short Synacthen tests.[1,6] Definitive evaluation requires testing after steroid washout and, where necessary, dynamic assessment (eg, insulin tolerance or metyrapone testing). Suppression of ACTH-dependent adrenal androgens may further contribute to fatigue and reduced well-being.

Conclusion: This case highlights a critical and preventable cause of SAI in routine endocrine practice. Mild thyroid abnormalities may act as a diagnostic distraction. A careful drug history—including intermittent or depot glucocorticoid use—is essential. Patients receiving long-acting steroids must be counselled regarding adrenal suppression, issued steroid emergency cards, and managed with appropriate stress-dose precautions. Early recognition is key to avoiding unnecessary investigations and potentially life-threatening adrenal crisis.

EP1902 - LBA_ECE_1476 - The changes in the patients profile with the different types of somatotroph PitNETs in the time progression

Mariana Solovey[1,2], Olena Danevych[1] and Mykola Guk[1]
[1]Romodanov Neurosurgery Institute, Kyiv, Ukraine; [2]Komisarenko Endocrinology and Metabolism Institute, Kyiv, Ukraine

Background: Acromegaly and acrogigantism are chronic systemic diseases caused by growth hormone (GH) hypersecretion predominantly due to pituitary neuroendocrine tumors (PitNETs). Epidemiological data on somatotroph PitNETs are heterogeneous and diagnostic delays contribute to the patient's outcomes.

Objective: To investigate the immunohistochemical and clinical profile of patients with GH-positive PitNETs surgically resected in our center over the past six years.

Materials and Methods: The study included 220 cases of somatotroph PitNETs surgically resected in our center from January 1, 2020 to December 31, 2025. The median age of diagnosis and the male-to-female ratio have been analyzed separately for each year period. Immunohistochemical profile of all GH-positive tumors was analyzed in males and females accordingly to the clinical presentation.

Results: The clinical presentation varied from totally silent to classic acromegaly picture or acrogigantism. The male-to-female ratio have been changed from 0.35 in 2020 and 0.26 in 2021 to 1.05 in 2023 and 1.08 in 2024. The median age of acromegaly diagnosis in females varied from 47 years in 2020 (IQR: 37-53 years) to 50 years in 2025 (IQR: 39-59 years). The median age of acromegaly diagnosis in males has been changed from 46.5 in 2020 (IQR: 34-50 years) to 36 in 2023 (IQR: 28-48 years) and 41.5 in 2025 (IQR: 33-46 years).

Silent somatotroph PitNETs represented 12.5% from 136 consecutive cases of GH-positive PitNETs in females and 14.3% from 84 somatotroph PitNETs in males. Pure somatotroph tumors constituted 59% of 99 patients with clinical acromegaly in females and 50.8% of 65 cases of acromegaly in males.

Conclusions: The gender predominance have changed from overt female to slight male predominance as well as the median age of acromegaly diagnosis in males due to the active screening in wartime. Clinical presentation of somatotroph PitNETs depends on the the immunohistochemical characteristics.

EP1903 - LBA_ECE_1258 - Comparative effectiveness of sleeve gastrectomy, mini/one-anastomosis gastric bypass, and Roux-en-Y gastric bypass on 12-month weight and glycaemic outcomes: a real-world cohort study

Elamin Abdelgadir[1,2], Alaaeldin Bashier[1,2], Fauiza Rashid[1,2] and Fatheya Alawadi[1,2]
[1]Mohammed Bin Rashid University for Medicine and Health Sciences, Dubai, United Arab Emirates; [2]Dubai Hospital, Dubai, United Arab Emirates

Background: Comparative effectiveness evidence across bariatric procedures is heterogeneous and regionally underrepresented. We evaluated procedure-specific 12-month changes in BMI and HbA1c using robust multivariable modelling in a real-world cohort.

Methods: We analysed adults undergoing index primary sleeve gastrectomy (SG), mini/one-anastomosis gastric bypass (MGB/OAGB), or Roux-en-Y gastric bypass (RYGB). Outcomes were change in BMI at 6 and 12 months and change in HbA1c at 12 months. Multivariable linear regression adjusted for age, sex, baseline BMI, baseline HbA1c, baseline fasting insulin, and surgery year. Among participants with baseline HbA1c ≥6.5%, a biochemical remission proxy was defined as HbA1c <6.5% at 12 months.

Results: The cohort included 2978 individuals (SG $n = 1447$, MGB/OAGB $n = 899$, RYGB $n = 632$); mean age 33.9 years and 67.9% were female. At 12 months, compared with SG, MGB/OAGB achieved greater BMI reduction (adjusted beta -1.31 kg/m^2; 95% CI -1.67 to -0.96; $P = .0000$). For HbA1c, MGB/OAGB showed a greater reduction vs SG (beta -0.189%; 95% CI -0.231 to -0.147; $P = .0000$), while RYGB did not differ materially from SG (beta 0.047%; $P = .0881$). Among baseline HbA1c ≥6.5%, adjusted remission proxy probabilities were 83.4% (SG), 93.6% (MGB/OAGB), and 83.2% (RYGB). Relative to SG, MGB/OAGB increased odds of remission (OR 2.91; 95% CI 1.45-5.84; $P = .0027$), while RYGB was not different (OR 0.98; $P = .9620$).

Conclusion: In this real-world cohort, MGB/OAGB was associated with greater 12-month BMI and HbA1c improvements compared with SG and higher likelihood of biochemical remission proxy among those with diabetes-range baseline HbA1c.

EP1903 Table 1 Baseline characteristics by procedure (imputed dataset; descriptive).

Procedure	*n*	Age mean	Age SD	Pre BMI mean	Pre BMI SD	Pre HbA1c mean	Pre HbA1c SD	Pre insulin median	Pre insulin IQR
SG	1447	30.6	11.2	41.93	6.54	5.68	0.92	27.39	16.50
MGB/OAGB	899	35.8	10.0	42.55	6.61	6.09	1.45	25.30	15.41
RYGB	632	38.8	9.9	41.06	7.40	6.12	1.49	22.00	14.84
