

Charge-dependent spectral softenings of primary cosmic-rays below the knee

DAMPE Collaboration*

Abstract

In most particle acceleration or propagation theories, the characteristic features of the cosmic ray spectra due to acceleration limits or propagation phase changes are charge dependent[1–4]. Alternatively, the interaction scenario would expect mass dependent spectral features in general. The observational verification of which relation takes effect in nature is still lack due to the difficulty of measuring the spectra of individual particles up to very high energies. Here we report direct measurements of the carbon, oxygen, and iron spectra from ~ 20 gigavolts to ~ 100 teravolts (~ 60 teravolts for iron) with 9 years of on-orbit data collected by the Dark Matter Particle Explorer. Distinct spectral softenings have been directly detected in these spectra for the first time. Combined with the updated proton and helium spectra, the spectral softening appears universally at a rigidity of ~ 15 teravolts. A nuclei mass dependent softening is rejected at a confidence level of $> 99.999\%$. Possible interpretations of these results, including a nearby cosmic ray source[5–7] and other models such as the propagation effect[8], are discussed.

Cosmic rays (CRs) are energetic particles travelling through the Universe as high-energy beams. They are predominantly made up of nuclei, such as protons, heavier ions up to iron and beyond[2]. Depending on the production processes, CRs are typically divided into two classes, the primary species accelerated by sources and secondary species produced due to fragmentation of primary CRs via collisions with the interstellar medium (ISM). High abundance particles such as protons, helium, carbon, oxygen, and iron nuclei are believed to be dominated by primary origin, while lithium, beryllium, boron, and sub-iron nuclei belong to the secondary family[9]. Spectral structures of CRs are very important probes to understanding the physics of CRs such as the acceleration, propagation, and interactions. In the general picture of particle acceleration and propagation, charge-dependent spectral features are expected due to gyration of particles in the magnetic fields. On the other hand, in case of particle interactions with characteristic thresholds, the break off energy of particles would be mass dependent. Obtaining observational evidence to verify which factor shapes the CR spectra is highly challenging and remains elusive. To convincingly test this, precise spectra of individual CR species covering a wide range of charge numbers need to be measured up to very high energies, which requires sensitive detectors with large acceptance and good charge/energy resolution.

Important progresses on precise measurements of energy spectra of different mass compositions have been achieved in recent years. Direct measurements of the spectra of individual CR species by space-borne and balloon-borne experiments have revealed unexpected hardening features around a few hundred GV rigidity[10–19], deviating from the power-law (PL) expectation from the conventional theories of the acceleration and propagation of CRs. In addition, spectral softenings around $\sim 10–30$ TeV have also been revealed in the proton and helium spectra[14, 15, 18–21] (there were also hints from earlier experiments[11, 22, 23], but with relatively large statistical and systematic uncertainties). These new findings challenge the standard CR paradigm that a single source population with PL spectra accounts for the measured CR spectra below the so-called knee[24], giving new insights on the understanding of CR physics. Though also being among the most abundant species in CRs, the measurements of carbon, oxygen, and iron nuclei spectra in CRs are rather challenging, and the current precise measurements are limited to a rigidity of a few TV. Similar hardening features as lighter nuclei have been detected for carbon and oxygen nuclei[12, 25], while the iron spectrum is found to be consistent with a single PL above 100 GV[26, 27]. The high-

energy spectral behaviors of these medium and heavy nuclei are unclear yet, which hinders a critical understanding of the acceleration and propagation physics of CRs.

In this work, we report the direct measurements of the carbon, oxygen, and iron spectra up to PeV energies with the Dark Matter Particle Explorer (DAMPE)[28, 29]. DAMPE is a space-borne, calorimeter-type detector for high-energy particles and photons. With the plastic scintillator detector (PSD[30]), the silicon tungsten tracker-converter (STK[31]), the bismuth germanium oxide calorimeter (BGO[32]), and the neutron detector (NUD[33]), DAMPE is able to measure precisely the charge, direction, energy and particle identity of high-energy CRs. Particularly, the thick calorimeter (with ~ 32 radiation lengths) is designed for observing CR electrons/positrons and γ rays to energies beyond 10 TeV with a very high energy resolution[29]. The relatively large geometric factor ($\sim 0.3 \text{ m}^2 \text{ sr}$) and nuclear interaction depth ($\sim 1.6\lambda_0$) make it also a powerful detector of CR nuclei to hundreds of TeV energies[14, 15].

The analysis presented in this work is based on the data recorded in the first 9 years of DAMPE's on-orbit operation, from January 1, 2016 to December 31, 2024. The live time fraction is about 76.2% after excluding the instrument dead time, the time for on-orbit calibration, the time in the South Atlantic Anomaly (SAA) region, and the period between September 9, 2017 and September 13, 2017 during which a big solar flare occurred and affected the status of the detector[34]. The carbon, oxygen, and iron nuclei are efficiently identified based on the PSD charge measurements. The residual backgrounds for selected candidates are evaluated based on the template fitting for the Monte Carlo (MC) simulated charge distributions (see the Methods for details). The selection efficiency and the energy response are also obtained with MC simulations, and are validated based on the flight data and the test beam data. An unfolding procedure[35] is applied to the observed count spectrum to correct the bin-by-bin migration of events due to the limited energy resolution of the detector. The obtained energy spectra of carbon, oxygen, and iron nuclei, together with the updated proton and helium spectra, in the rigidity range from $\sim 20 \text{ GV}$ to $\sim 100 \text{ TV}$ (60 TV for iron) are shown in Figure 1. Compared with previous measurements of carbon, oxygen, and iron nuclei by the Alpha Magnetic Spectrometer (AMS-02[12, 26]) and the Calorimetric Electron Telescope (CALET[25, 27]), the DAMPE results improve the precision considerably at high energies and provide the first precise measurements of these spectra above several TV.

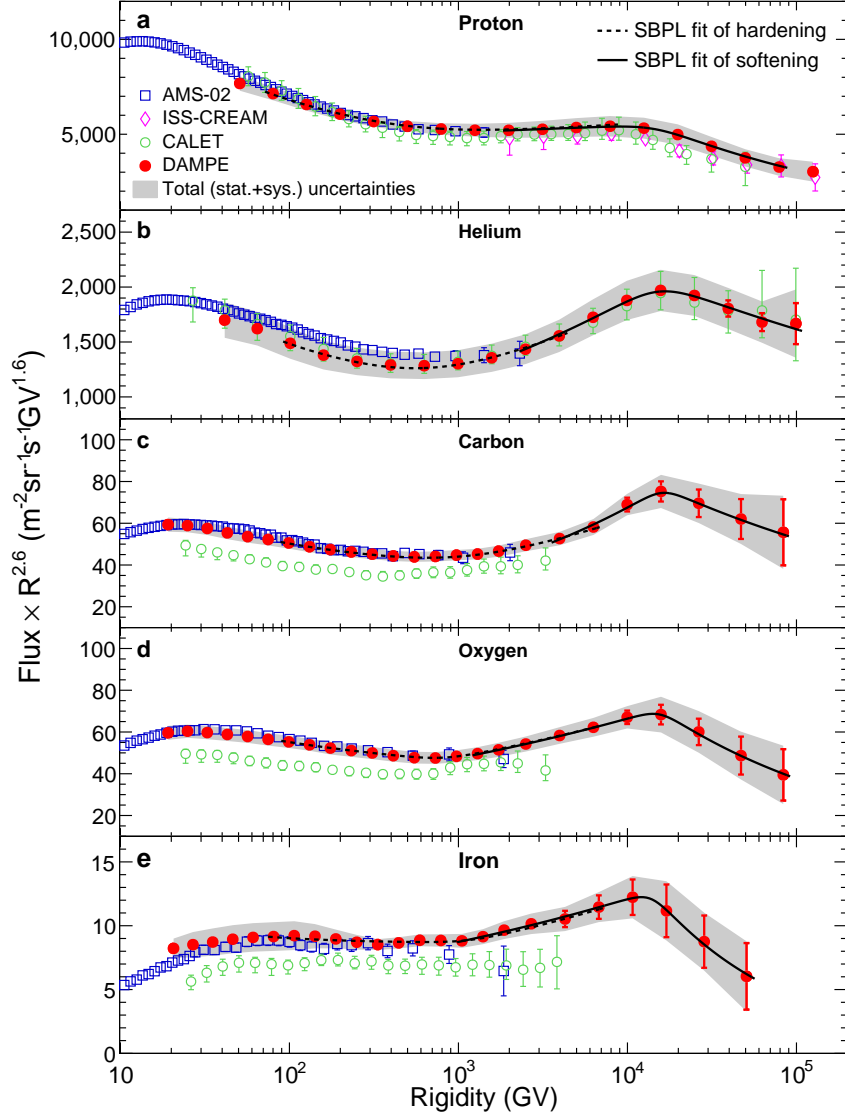

FIG. 1: **Rigidity spectra.** Panels a - e show the spectra of protons, helium, carbon, oxygen, and iron, weighted by $R^{2.6}$. Red dots are the DAMPE measurements, with $\pm 1\sigma$ statistical uncertainties (errorbars) and the total statistical and systematic uncertainties added in quadrature (shaded bands). Dashed and solid lines show the best-fitting results of the SBPL function. The fluxes are converted from the total kinetic energy bins to rigidity bins assuming a mass number of 12, 16, and 56 for carbon, oxygen, and iron. For proton and helium, the average mass number is calculated assuming $D/p = 0.027$ and ${}^3\text{He}/{}^4\text{He} = 0.142 \times (R/4.5 \text{ GV})^{-0.289}$ based on the AMS-02 measurements[45]. Also shown are the measurements from other experiments: AMS-02[12, 13, 26], CALET[18, 19, 25, 27], and the Cosmic Ray Energetics And Mass on the International Space Station (ISS-CREAM)[21].

It can be clearly found that similar spectral structures, i.e. a hardening at $\sim 500 - 1000$ GV rigidity followed by a softening at ~ 15 TV, are observed among all the five species of CRs. The spectral fitting with a smoothly broken power-law (SBPL) model (see the Methods) provides significance of the hardening of 29σ , 23σ , 11σ , 10σ , and 2.7σ with hardening rigidity at 590 ± 40 , 595 ± 40 , 892 ± 210 , 799 ± 76 , and 1104 ± 435 GV for proton, helium, carbon, oxygen, and iron, respectively. The smoothness parameter of the break can also be obtained (except for iron), as given in Table S6. The results show that in general a smooth hardening is favored by the data. Although the spectra of all these CR species show similar hardening features, their detailed spectral shapes and break rigidities (energies) differ from each other. Fitting to the AMS-02[13] and CALET measurements give also diverse results of the hardening rigidities[18, 19, 25, 36]. Measurements of the secondary-to-primary ratios of CRs such as B/C and B/O show hardenings around 200 GV[13, 16, 37], which is different from the break rigidities found here for primary CRs. This may suggest that the hardenings of primary and secondary CRs are not solely due to the same origin such as a unified propagation effect[38].

What is more interesting is the spectral softening which is for the first time clearly identified in the spectra of carbon, oxygen, and iron. The significance of the softening is 3.2σ , 4.1σ and 2.4σ with the break rigidity of 16.1 ± 5.6 , 15.4 ± 4.8 , and 13.8 ± 6.0 TV for carbon, oxygen, and iron, respectively. The updated proton and helium spectra yield softening rigidity at 14.6 ± 1.3 and 15.3 ± 2.3 TV, respectively. It has been clearly established that the softenings occur at the same rigidity for all the five species, as shown in Figure 2. The proportional relation between the particle charge Z (for the four species with $Z \geq 2$) and the softening energy E_{br} is best fitted as $\bar{E}_{\text{br}}/\text{TeV} = (15.3 \pm 1.6) \times Z$, which is well consistent with the E_{br} of proton, i.e. 14.6 ± 1.3 TeV. Assuming a general power-law scaling of the break energy and the charge, we get the fitting power-law index of 1.01 ± 0.09 , which shows a good consistency with the linear correlation. On the other hand, the mass number (A) dependence of the softening energies can be excluded at a confidence level of $> 99.999\%$ (4.4σ) by comparing the $E_{\text{br}}/\text{TeV} = 14.6 \pm 1.3$ for proton and the $\bar{E}_{\text{br}}/\text{TeV} = (7.6 \pm 0.9) \times A$ for other four species with $Z \geq 2$. The universal softening feature in the spectra of primary CRs from protons ($Z = 1$) to iron nuclei ($Z = 26$) and the charge-dependence of the softening energy indicate a common origin of the break due to acceleration or propagation effect.

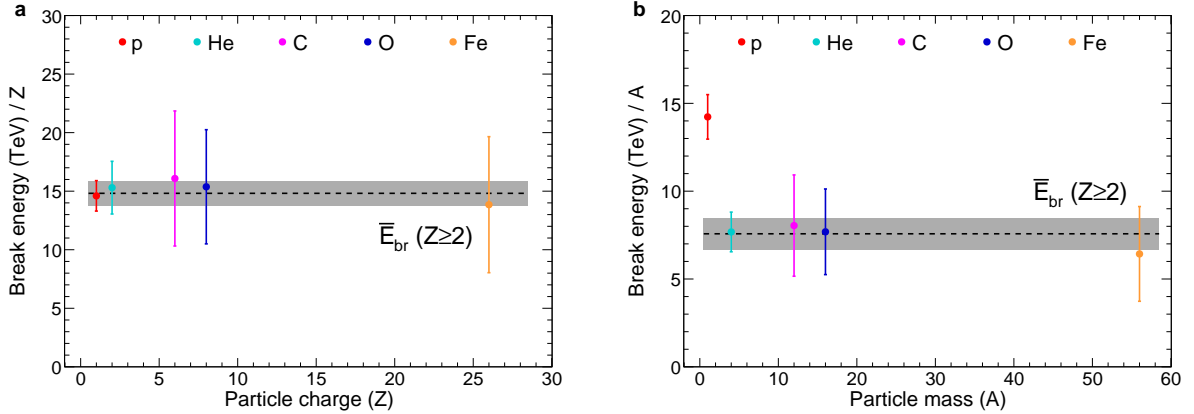

FIG. 2: **The break energy for different species.** Panel **a** shows the break energy divided by Z as a function of particle charge Z , and panel **b** is that divided by A as a function of mass number A . The average mass number A is assumed to be 1.026, 3.985, 12, 16, and 56 for proton, helium, carbon, oxygen, and iron, respectively. The shaded bands represent the average softening energies of the particles heavier than proton.

The spectra can be decomposed into two components, a soft component which dominates the CR fluxes in the low-energy band, and a hard component with a spectral cutoff which contributes mainly to the bump feature. A simple idea to account for the spectral structures is the superposition of a nearby source on top of the background source population[5–7], as shown by solid lines in Figure 3. The addition of the nearby source component with proper distance and age can simultaneously reproduce the observed energy evolution of the amplitudes and phases of the dipole anisotropies (see Figure S4). See the Methods for details of the model setting. In this scenario, the spectrum from the nearby source shows both low-energy suppression due to the inefficient propagation of these particles within the age of the source and high-energy suppression due to the acceleration limit, and hence produces naturally a bump structure. Assuming an exponential form of the spectral cutoff, we obtain a cutoff rigidity of about 30 TV for the nearby source, which is consistent with the estimation of acceleration by supernova remnants[39]. Supposing the spectral features are indeed imprints from a nearby source, we propose that the supernova explosion associated with the Geminga pulsar could be a good candidate for this source, given its proper age, distance, and location in the sky[7, 40]. The energetics needed to account for the data is

about 3.3×10^{50} erg, which is consistent with that can be produced for a typical core collapse supernova. Via comparing the relative abundances of nuclei at $R = 0.1$ TV and $R = 10$ TV, we can infer that the metallicity of the nearby source may be slightly higher than the average value of the background source population, as shown in Figure S5.

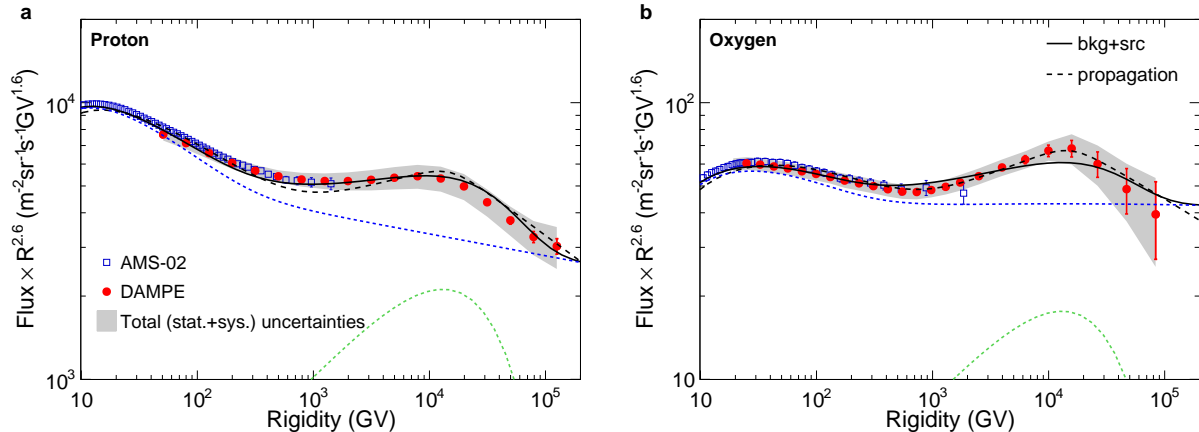

FIG. 3: **Comparison of the spectra with model expectations.** Panel **a** is for protons, and panel **b** is for oxygen nuclei. Solid lines show the model expectations of the background plus nearby source scenario, with individual contributions from the two components being shown by dotted lines (blue for the background and green for the nearby source), and dashed lines show the results of the propagation scenario.

Alternatively, the spectral breaks could be due to a propagation effect, especially that universal spectral hardenings have been found in the secondary-to-primary ratios[13, 16, 37]. The physical modeling of the effect of self-generated turbulence with nonlinear Landau and ion-neutral damping of magnetohydrodynamic waves by CRs can properly account for both the hardening and softening of the proton spectrum[8]. As an effective approach, we introduce two breaks of the diffusion coefficient to mimic the change of propagation properties, and calculate the propagated spectra. The results are shown by dashed lines in Figure 3. The detailed parameter setting can be found in the Methods. The spectral structures observed by DAMPE and AMS-02 can also be properly reproduced by this model.

Additional theoretical models to account for the bump structures include multiple source populations[41, 42], and the re-acceleration of CRs by a local star[43]. All these models can properly explain the features of the spectra. To explain the large-scale anisotropies in

these scenarios, additional assumptions about the source distribution and/or magnetic field configuration are necessary[44]. The DAMPE results reported in this work demonstrate a clear presence of rigidity-dependent softening features in the spectra of primary CR nuclei, indicating a common origin due to acceleration and/or propagation processes.

Acknowledgments: The DAMPE mission was funded by the strategic priority science and technology projects in space science of Chinese Academy of Sciences (CAS). Supplemental Materials

DAMPE experiment

The DAMPE satellite was launched into a 500-km Sun-synchronous orbit on December 17, 2015, and has operated stably in space since then. The on-orbit calibration of each detector shows that the payload has maintained a good long-term performance over the past years[46]. Also, the detector performance was validated with test beams of protons, electrons and fragmented ions with $A/Z = 2$ from helium to argon. The linearity of the energy measurement of DAMPE is validated with the electron beams up to 243 GeV[32]. At higher energies, the laser test suggested that the measurement of the deposited energy in a single BGO crystal retains a good linearity up to a few TeV[47]. The absolute energy scale of DAMPE is determined with the geomagnetic cutoff of the electron plus positron spectrum, which results in a small bias of $\sim 1.3\%$ [48] and is not corrected.

Monte Carlo simulation

Extensive MC simulations are carried out to obtain the instrument response to incident particles in the DAMPE detector. The GEometry ANd Tracking (GEANT) toolkit v4.10.05[49] with the FTFP_BERT physics list is adopted for the simulations of nuclei up to 100 TeV/n. For higher energies, we use the EPOS_LHC model from the the Cosmic Ray Monte Carlo (CRMC; <https://web.ikp.kit.edu/rulrich/crmc.html>) linked to GEANT through a custom interface[50]. The energy response of MC simulations is corrected by including the Birks' quenching effect when calculating the ionization energy deposits in the calorimeter[51]. Such a correction is important for high Z and low energy particles.

The simulated events are generated assuming an isotropic source with an E^{-1} spectrum. The simulation data are re-weighted to $E^{-2.6}$ and $E^{-3.0}$ spectra, for primary (e.g. carbon, oxygen, and iron) and secondary (e.g. boron) nuclei, respectively. To evaluate the uncertainties from the hadronic interaction model, another simulation program is developed with the FLUKA[52] 2011.2x package, which uses DPMJET3 for nucleus-nucleus interaction above 5 GeV/n.

Event selections

Given that the analysis procedures for protons and helium nuclei closely follow those established in refs.[14] and [15], the present work focuses primarily on the analysis of carbon, oxygen, and iron nuclei. Nine years of on-orbit data are used with a total exposure time of

$\sim 2.17 \times 10^8$ s, corresponding to $\sim 76.2\%$ of the operation time. A general pre-selection is applied to select events with good quality of reconstruction. The selection logic for different nuclei is broadly consistent, although the specific parameters are adjusted accordingly.

- (I) **Pre-selection.** The pre-selection is to ensure good shower development and proper event reconstruction in the calorimeter, including:
 - (i) the total deposited energy (E_{dep}) must exceed 50 GeV, 63 GeV, and 150 GeV for carbon, oxygen, and iron nuclei, respectively, to minimize the geomagnetic cutoff effect[53];
 - (ii) the energy deposited in any single BGO layer must not exceed 35% of the total deposited energy to exclude events incident from the sides.
- (II) **Trigger condition.** Events satisfying the High Energy Trigger (HET) condition[28] are selected. The HET is optimized to select well-contained events. For carbon, oxygen, and iron nuclei, the HET efficiency exceeds 95%.
- (III) **Track selection.** A deep learning based tracking approach[54] is employed, which achieves a better performance especially at high energies than the Kalman filter track reconstruction. The reconstructed track is further required to align with the maximum number of hits in both the PSD- x and PSD- y layers and to penetrate the calorimeter from top to bottom. This ensures that the event is fully contained within the detector and the key characteristics can be accurately measured.
- (IV) **Charge selection.** The particle charge Z is measured by both the PSD and the STK. For carbon and oxygen, the first STK layer charge is required to satisfy $Q_{\text{STK1}} > 2.8$ to suppress contamination from protons and helium nuclei. For PSD charge measurement, the signals from the four sub-layers are employed to build a global PSD charge, with proper corrections due to strip alignments, light attenuation, fluorescence quenching, and equalization of different channels[55, 56]. The candidate events are selected using energy-dependent charge intervals as:

$$\begin{aligned}
 5.7 < Q_{\text{PSD}} < 6.3 + 0.015 \cdot \log^2(E_{\text{dep}}/\text{GeV}), & \quad (\text{for carbon}), \\
 7.7 < Q_{\text{PSD}} < 8.35 + 0.015 \cdot \log^2(E_{\text{dep}}/\text{GeV}), & \quad (\text{for oxygen}), \\
 25.5 < Q_{\text{PSD}} < 27.2 & \quad (\text{for iron}).
 \end{aligned}$$

The charge selection criteria maintain an efficiency of approximately 90% over the full analysis energy range. The same procedure and selections are applied to the MC simulations, and the MC charge distributions are shrunk to match the flight data for different particles. For proton and helium analysis, a combination of the PSD and STK charge measurements is employed to keep a stable selection efficiency at high energies (> 10 TeV).

Background subtraction

An MC-based template fit is performed on the charge distribution to estimate the background contamination within the selected charge windows for each species, as shown in as shown in Figure S1. In these figures, the hatched regions show the GEANT4 simulated charge distributions of given particle species, and the red solid lines show the total contribution of relevant species. Good match between the data and the simulation can be obtained.

The contamination for target nuclei are estimated through computing the fractions of adjacent nuclei in the specified charge window according to the MC templates. For proton and helium, their cross-contamination dominate the backgrounds, which are estimated to be less than 4% and 5%, respectively, in the whole energy range. For carbon, in the lower-energy region, the dominant background arises from the fragmentation of heavier nuclei (particularly oxygen). At high energies, above the TeV scale, high-abundance helium nuclei can produce showers in the calorimeter that spawn back-scattered secondaries penetrating the PSD strips. This leads to an overestimation of the reconstructed charge and introduces a non-negligible contamination in both carbon and oxygen samples. Consequently, the total contamination ratios for carbon and oxygen increase from 0.5% and 0.4% at 100 GeV to 2.4% and 1.8% at 50 TeV, respectively. For iron, both lighter nuclei (chromium, manganese) and heavier ones (e.g., cobalt and nickel) are far less abundant than iron itself. Moreover, the iron signal is sufficiently large that the impact of back-scattered shower particles on charge reconstruction is negligible. Therefore, the contamination ratio of the iron sample remains within 3% in the whole energy range.

CR flux measurements

The total deposited energy in the calorimeter (E_{dep}) is measured by summing up the energies of all BGO bars together. When the energy deposited in a single BGO bar exceeds ~ 4 TeV, some readout channels may saturate[57], leading to non-linearity in the energy response. A

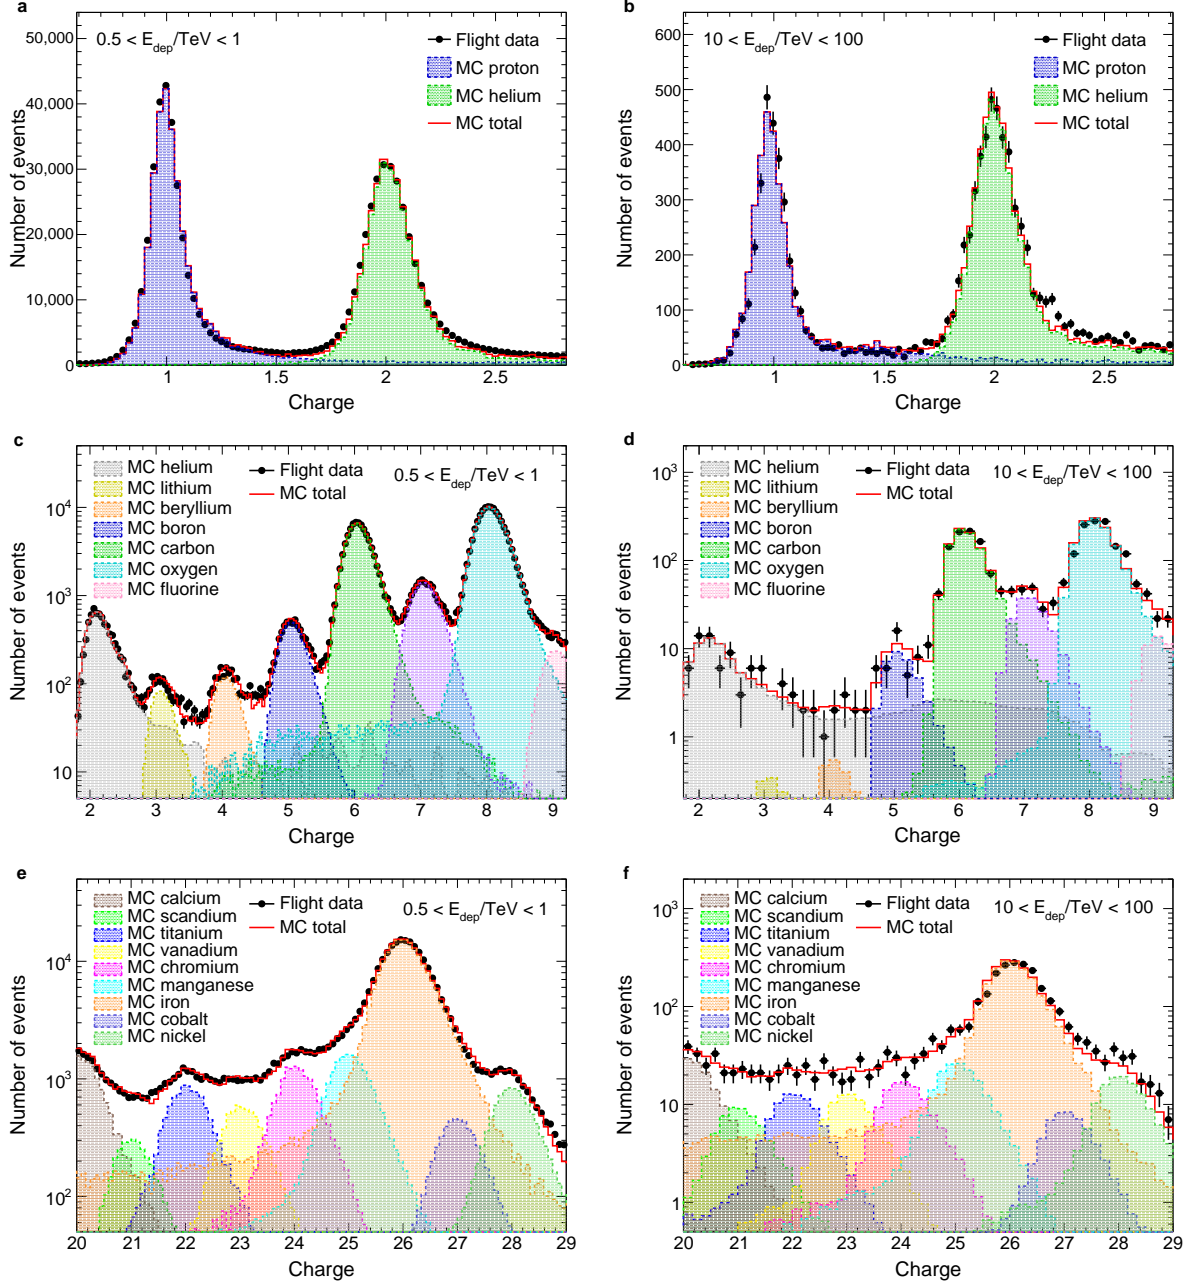

FIG. S1: **Charge distributions of events.** The left panels (a, c, e) are for deposited energy bin of $0.5 < E_{\text{dep}} < 1$ TeV, and the right panels (b, d, f) are for deposited energy bin of $10 < E_{\text{dep}} < 100$ TeV. From top to bottom, three charge ranges relevant to protons and helium, carbon and oxygen, and iron nuclei are shown. Black dots depict the flight data. Dashed lines with different colors show the best-fit MC simulated samples. The red solid lines show the sum of MC samples.

deep learning approach[58] based on MC simulation was developed to correct the energy

deposit(s) of those saturated bar(s) for nuclei up to PeV. Due to the relatively large spread of the calorimeter's energy response to the nuclei, an unfolding procedure[35] is employed to derive the primary fluxes of CRs. The differential flux in a given incident energy bin $[E_i, E_i + \Delta E_i]$ is then calculated as

$$\Phi(E_i, E_i + \Delta E_i) = \frac{N_{\text{inc},i}}{\Delta E_i A_{\text{eff},i} \Delta t}, \quad (1)$$

where ΔE_i is the energy bin width, $A_{\text{eff},i}$ is the effective acceptance, and Δt is the live time. The unfolded number of events, $N_{\text{inc},i}$, is given by

$$N_{\text{inc},i} = \sum_{j=1}^n P(E_i|W_j) N_{\text{dep},j}, \quad (2)$$

where $N_{\text{dep},j}$ is the number of events in the j -th deposit energy bin $[W_j, W_j + \Delta W_j]$, and $P(E_i|W_j)$ is the transfer probability from the j -th deposit energy bin to the i -th incident energy bin.

The effective acceptance in the i -th kinetic energy bin is estimated from MC samples as

$$A_{\text{eff},i} = G_{\text{gen}} \times \frac{N_i^{\text{sel}}}{N_i^{\text{gen}}}, \quad (3)$$

where G_{gen} is the geometric factor corresponding to the generation surface in the MC simulation, N_i^{gen} is the number of generated events in the i -th energy bin, and N_i^{sel} is the number of events that pass all of the selection criteria.

Uncertainties

The statistical uncertainties are associated with Poisson fluctuations of the number of detected events $N(E_{\text{dep},j})$. To properly determine the error propagation in the unfolding procedure, a toy-MC approach is applied, via sampling the event numbers in each deposited energy bin with Poisson fluctuations. The variations of the unfolded numbers of events in each kinetic energy bin are then obtained and the standard deviations are assigned as the 1σ statistical uncertainty.

The systematic uncertainties due to different sources are investigated extensively. The selection efficiencies derived from the MC simulation, e.g. HET and track, are compared with the efficiencies estimated from the flight data for different particles and the deviations are taken as the associated systematic uncertainties. The uncertainty of charge selection is estimated by varying the charge selection window and checking the flux variations. The uncertainty due to background subtraction is estimated by considering the errors of the

contamination fractions from the template fit procedure. The uncertainty from the BGO saturation correction is obtained by artificially modifying the energy correction for the saturated events by ± 1 standard deviation of the corrected ratio variation.

For proton and helium, the related uncertainties are found to be significantly below 1% up to 200 TeV and thus negligible in the current flux measurements. Finally, the systematic uncertainty associated with the hadronic interaction model used in the MC simulation is obtained through comparing simulation results with the test beam data or two different simulation tools, i.e. GEANT4 and FLUKA. Specifically, for proton, helium, carbon and oxygen, the uncertainty of the hadronic interaction model in lower energy region (< 400 GeV for proton and < 75 GeV/n for others) is estimated according to the comparison of the energy response between the test beam data and the GEANT4 simulation. At higher energies, the uncertainty is assigned as the difference between the fluxes measured using the GEANT4 and the FLUKA simulations. For iron, no beam test data is available and hence the uncertainty is evaluated as the difference between the two simulations.

The total uncertainty budgets for proton, helium, carbon, oxygen and iron are shown in Figure S2. The measured fluxes and the associated uncertainties, including the statistical uncertainties and systematic ones from the analysis procedure and the hadronic interaction models, are presented in Tables S1, S2, S3, S4, and S5.

Spectral fitting

The significance of the spectral hardening or softening feature is estimated by comparing the fittings with two different models. One is a power-law (PL) function

$$\Phi_{\text{PL}}(E) = \Phi_0 \cdot \left(\frac{E}{10^3 \text{ GeV}} \right)^{-\gamma}, \quad (4)$$

and the other is a Smoothly Broken Power Law (SBPL) function

$$\Phi_{\text{SBPL}}(E) = \Phi_0 \cdot \left(\frac{E}{10^3 \text{ GeV}} \right)^{-\gamma} \left[1 + \left(\frac{E}{E_{\text{br}}} \right)^s \right]^{\frac{\Delta\gamma}{s}}, \quad (5)$$

where γ is the spectral index below the break energy E_{br} , $\Delta\gamma$ is the change of the spectral index and s is the smoothness parameter.

The same fit method as refs.[14] and [15] is applied to account for the systematic uncertainties by multiplying a set of independent nuisance parameters w_j on the input model[59].

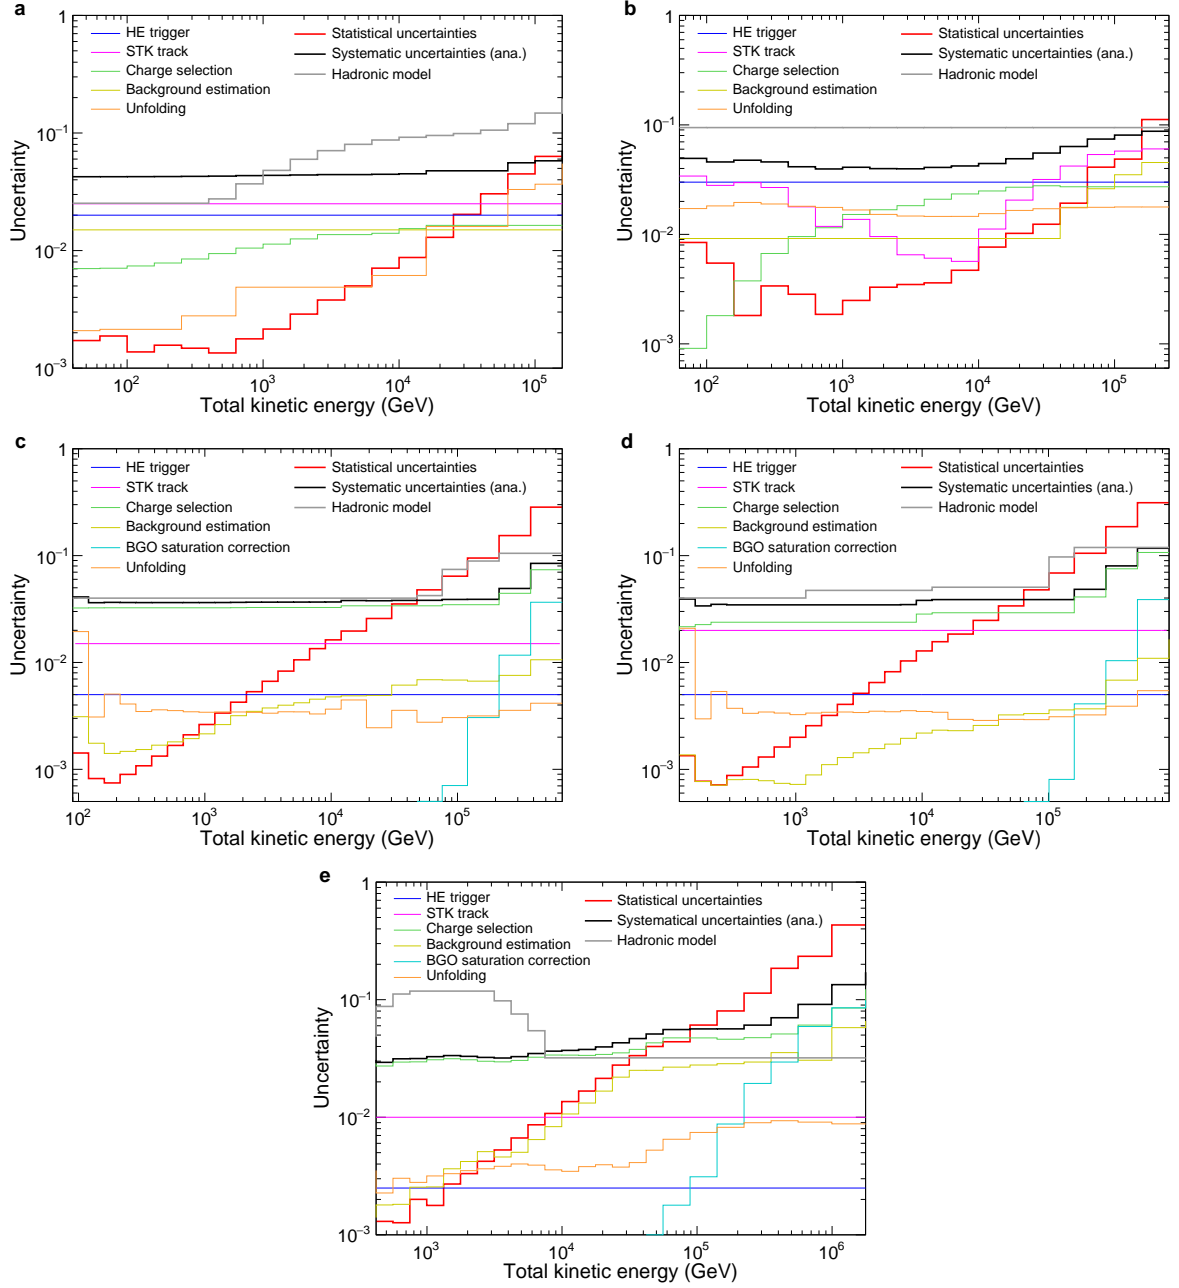

FIG. S2: **Relative uncertainties versus energy.** Panels a - e correspond to those of proton, helium, carbon, oxygen, and iron, respectively. The systematic uncertainties in analysis, shown in black, are the quadratic sum of all systematic contributions except for those from the hadronic models.

100000 - 158489	$(2.85 \pm 0.139 \pm 0.24 \pm 0.27) \times 10^{-10}$
158489 - 251189	$(8.52 \pm 0.954 \pm 0.78 \pm 0.81) \times 10^{-11}$

the data in such an energy range. When calculating $\Phi(E_i)$, the flux at the central energy of each bin is used, which results in negligible differences of the fitting parameters compared with the method of integrating the fluxes over the energy bin.

The fit parameters of the SBPL model for the hardening and softening features are presented in Tables S6 and S7, respectively. For the fit for the softening features, the smoothness parameter s is fixed as 5 or 10 due to a lack of good constraint on it. The significances of those spectral features are evaluated by the comparisons of the χ^2 values

Interpretations

(I) The background plus nearby source model. This model assumes that the ensemble of many sources contributes to the majority of the observed CRs (called as background), with the addition of a nearby one which gives distinct features from the background. We adopt the GALPROP propagation code[60] to calculate the fluxes from the background

component. The propagation halo is characterized by a cylinder with radius r_h and half-height z_h . We work in a two-halo propagation framework as indicated by the slow diffusion of particles in the vicinities of middle-aged pulsars[61, 62]. To reproduce the observed breaks of the secondary-to-primary ratios[16], the rigidity-dependence of the diffusion coefficient in the Milky Way halo is parameterized as a broken PL form, $D_{\text{halo}}(R) = \beta D_0 (R/\text{GV})^{\delta_1} [1 + (R/R_{\text{br}})^2]^{\delta_2 - \delta_1/2}$, where δ_1 and δ_2 are the slopes below and above R_{br} , β is the particle velocity in unit of light speed. The diffusion coefficients in the disk and halo connect with each other smoothly, via $D_{\text{disk}} = f(z) D_{\text{halo}}$, where $f(z) = \xi + (1 - \xi)[1 - \exp(-z^2/2h^2)]$. The propagation parameters are summarized in Table S8.

The injection spectrum is assumed to be a PL in rigidity, $q_{\text{bkg}}(R) \propto (R/\text{GV})^{-\alpha}$. In the energy range we are interested in, the single PL injection is adequate, although more complicated injection form is required to reproduce the data in a wider energy range[63]. The spectral indices for different species differ slightly from each other, as given in Table S8. The spatial distribution is assumed to follow the Galactic SNR distribution[64], but with parameters slightly tuned based on γ -ray data[65]. The predicted secondary flux from the background CRs is consistent with the data[13, 17] for rigidity below $\sim \text{TV}$, as can be seen in Figure S3. To better compare with the low-energy AMS-02 data, a force-field solar modulation with potential of 650 MV has been applied[66]. There might also be contribution from secondary interactions occurring around the sources given those particles may get trapped for some time[67, 68] (see, however, ref.[69] for a pessimistic opinion).

For the nearby source, we assume an instantaneous injection at time t and location \mathbf{r} . We assume the nearby source is Geminga-like[40], which has $r = 250$ pc and $t = 3.4 \times 10^5$ yr[70, 71]. Note that the distance and age of the nearby source are different from those of ref.[5], in which a ~ 2 Myr old nearby source with ~ 200 pc distance was assumed. The main difference is that, in ref.[5], the nearby source dominates the fluxes and anisotropies in the 1 – 100 TeV band, while in our case, the contribution to the fluxes from the nearby source is sub-dominant and the anisotropies are jointly contributed by both components. The injection spectrum is assumed to be an exponential cutoff power-law (ECPL) form, $q_{\text{src}} \propto (R/\text{GV})^{-\beta} \exp(-R/R_c)$. The propagated flux at Earth can be obtained via the Green's function as, $\psi(r, t, R) = \frac{q_{\text{src}}}{(\sqrt{2\pi\sigma})^3} \exp\left(-\frac{r^2}{2\sigma^2}\right)$, where $\sigma(R, t) = [2D_{\text{disk}}(R)t]^{1/2}$ is the effective diffusion length within time t . The slow diffusion coefficient D_{disk} is adopted. We find that for $\beta = 1.9$ and $R_c = 30$ TV, the bump features of spectra can be reproduced,

TABLE S8: Model parameters used to give the results shown in Figure 3.

Parameter	Background + nearby source		Propagation
r_h (kpc)	20.0		20.0
z_h (kpc)	5.0		5.0

FIG. S3: **Rigidity spectra of boron weighted by $R^{2.6}$.** The solid lines show the results from the background plus nearby source model, with individual contributions from the two components being shown by dotted lines (blue for the background and green for the nearby source). The dashed lines show the results from the propagation model. Thin lines correspond to the results in the local interstellar medium and thick lines are modulated fluxes with potential of 650 MV. The measurements of AMS-02[13] and DAMPE[17] are shown for comparison.

as shown in Figure 3. Here the proton and oxygen spectra are shown for illustration. The same solar modulation potential of 650 MV is adopted. The expected boron flux from CRs produced by the nearby source is calculated with the same Green's function method through an integration over the volume and time assuming a gas density of 1 hydrogen cm^{-3} , which is also shown in Figure S3. The grammage for CRs from the nearby source can be estimated as $X \sim 0.3 \text{ g cm}^{-2}$ for the assumed gas density and a propagation time of $\sim 2 \times 10^5 \text{ yr}$. We find that the contribution from the nearby source is sub-dominant in the whole energy range. Adding such a component can nevertheless better reproduce the data at the highest rigidity part.

The dipole component of the large-scale anisotropies from the model can be obtained as $\Delta = 3|\nabla(D_{\text{disk}}\psi)|/(c\psi)$. Since the gradients from the background sources and the nearby source are different, a vector sum is necessary. We assume that the Galactic coordinate

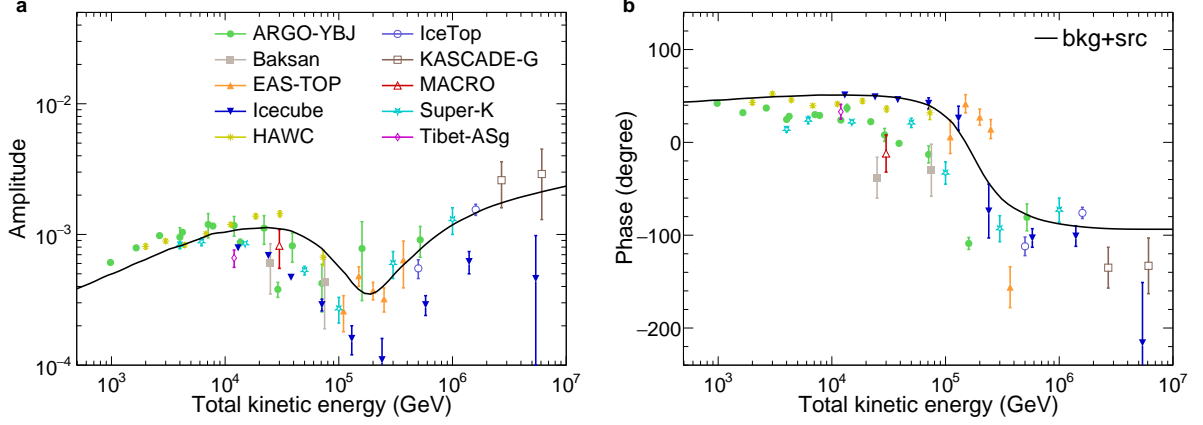

FIG. S4: **Dipole anisotropies of CRs.** Panel **a** shows the amplitudes of the dipole anisotropies, and panel **b** shows the phases. The solid lines show the predictions from the background plus nearby source model. The measurements are from: ARGO-YBJ[77], Baksan[78], EAS-TOP[79], HAWC[80], IceCube[81], IceTop[81], KASCADE-Grande[82], MACRO[83], Super-K[84], Tibet-AS γ [85].

of the nearby source is $(l, b) = (165^\circ, -17^\circ)$, which is close to but not exactly at the anti-Galactic-center direction. The location of the source in the sky is consistent with the fitting results obtained in ref.[40]. The resulting amplitude and phase (the right ascension of the maximum CR intensity) are shown in Figure S4., which reproduce properly the measurements. Particularly, at high energies (above a few hundred TeV), the anisotropy is dominated by the background which has a phase of $\sim -90^\circ$ (Galactic center). At low energies, the anisotropy is in turn dominated by the nearby source, and a phase flip exists. There is also wide discussion about the effect of regulating the propagation of CRs by the local magnetic field[44, 72, 73]. The anisotropic diffusion in the directions perpendicular or parallel to the magnetic field would result in a projection of the CR flow onto the direction of the magnetic field[6, 73, 74]. In such a case, the original direction of the CR source becomes less correlated with the observed anisotropy direction, and the constraint on the location of the source is relaxed. In addition, it has been shown by the joint observation of HAWC and IceCube that there is a sharp division between excesses and deficits of the large-scale anisotropies, and there are also high-order anisotropies beyond the dipole[75]. More detailed studies are necessary to fully understand these observational facts of Galactic CRs.

The relative abundances (normalized to $O = 1$) of the measured CR fluxes at $R = 0.1$ TV

where the background sources dominate and $R = 10$ TV where the nearby source contributes a considerable fraction are shown in S5. The solar system abundances are also shown for reference[76]. One can see that heavier nuclei become more abundant at $R = 10$ TV than those at $R = 0.1$ TV, indicating that the nearby source tends to have higher metallicity than the background sources.

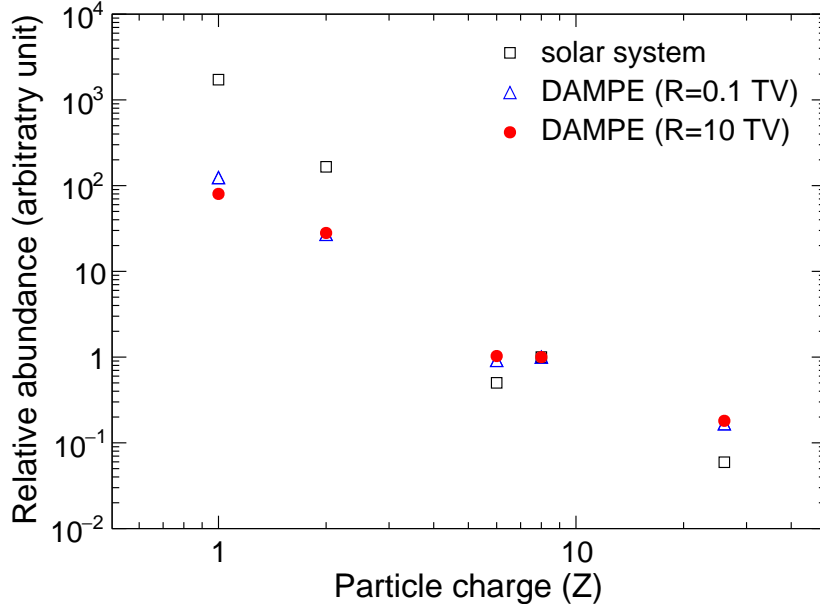

FIG. S5: **Relative abundances (normalized to oxygen) of the measurements.** Blue triangles show the results at 0.1 TV, red dots show those at 10 TV, and black squares show the solar system abundances[76].

(II) The propagation model. The other scenario is to ascribe the spectral breaks to a propagation effect. Two breaks of the diffusion coefficient are required to give the hardenings and subsequent softenings of the spectra. Physically this may be due to the self-generated turbulence with nonlinear Landau and ion-neutral damping of magnetohydrodynamic (MHD) waves by CRs, as proposed in ref.[8]. Here we empirically approximate the equivalent effect as a change of the rigidity dependence of the diffusion coefficient as

$$D(R) = \beta D_0 (R/\text{GV})^{\delta_1} [1 + (R/R_{\text{br}})^2]^{(\delta_2 - \delta_1)/2} [1 + (R/R_{\text{br},2})^5]^{(\delta_3 - \delta_2)/5}. \quad (7)$$

Since the softening features are sharper than the hardening features in general, we assume different smoothness parameters of the breaks. Note that we also assume a two-halo propagation model, with the spatial dependence of the diffusion coefficient being the same as

above. The injection spectrum is again assumed to be a single PL form. The model parameters can be found in Table S8. The results for the secondary boron spectrum and primary proton and oxygen spectra are shown in Figure S3 and Figure 3 by dashed lines. While the spectral features can also be reproduced by the propagation model, whether the observed complicated behaviors of the large-scale anisotropies can be explained need further studies.
