22 **Abstract**

23 The main topic of this research was to evaluate the effect in the performance of stochastic landslide  
24 susceptibility models, produced by differences between the triggering events responsible for the  
25 calibration and validation datasets. In the Caldera Ilopango area (El Salvador), MARS (Multivariate  
26 Adaptive Regression Splines)-based susceptibility modeling was applied using a set of physical-  
27 environmental predictors and two remotely recognized landslide inventories: one dated at 2003 (1503  
28 landslides), which was the result of a normal rainfall season, and one which was produced by the  
29 combined effect of the Ida hurricane and the 96E tropical depression in 2009 (2237 landslides). Both  
30 the two event inventories included shallow debris- flow or slide landslides, which involved the  
31 weathered mantle of the pyroclastic rocks that largely outcrop in the study area. To this aim, different  
32 model building and validation strategies were applied (self-validation, forward and backward chrono-  
33 validations), and their performances evaluated both through cut-off dependent and independent metrics.  
34 All of the tested models produced largely acceptable *AUC* (Area Under Curve) values, albeit a loss in  
35 the predictive performance from self-validation to chrono-validation was observed. Besides, in terms of  
36 positive/negative predictions, some critical differences arose: using the 2009 extreme landslide  
37 inventory for calibration resulted in higher sensitivity but lower specificity; conversely, using the 2003  
38 inventory for validation resulted in higher specificity but lower sensitivity.

## 18 19 20 **1. Introduction**

21  
22 Landslides are among the most important causes of natural hazard in El Salvador (Rose et al. 2004),  
23  
24 being triggered either by earthquakes or tropical storms. In particular, storms which frequently hit the  
25  
26 country are responsible for the multiple activation of a large number of shallow and fast moving flow-  
27  
28 like landslides, which cause life losses and severe damages disaster scenarios (e.g., CEPAL 2010;  
29  
30 MARN 2011) either directly impacting along the slopes against inhabited areas or feeding debris floods  
31  
32 phenomena along the streams. Predicting storm triggered multiple occurring landslides is of great  
33  
34 importance in these areas where very steep slopes mantled by weathered pyroclastic rocks are exposed  
35  
36 to such recurrent storm inputs, as in large part of Central America. In fact, landslide susceptibility  
37  
38 models and their derived maps are among those tools that allow for cost/effectively mitigating the  
39  
40 natural risk associated to storm events.  
41  
42  
43  
44

45  
46 The territory of El Salvador is largely characterized by a young deeply incised tephra dominated  
47  
48 landscape, so that a history of recurrent debris flow disaster events is already known. However, in El  
49  
50 Salvador few studies have dealt with this topic. A logistic regression model for earthquake-induced  
51  
52 landslides in the whole country has been assessed, using an inventory of 2001 seismically-induced  
53  
54 landslides for calibration, but not being supported by any validation procedure (García-Rodríguez et al.  
55  
56 2008). García-Rodríguez and Malpica (2010) applied then to the same landslide inventory artificial  
57

2  
3  
4 neural networks method and validated the obtained model by means of Receiver Operating  
5  
6 Characteristic (ROC) curves, albeit without *n*-folds precision and reliability analysis. For the extreme  
7  
8 north-western sector of the country, principal component analysis was also applied (Kopačková and  
9  
10 Šebesta 2007), obtaining a landslide susceptibility map which was calibrated with post-Mitch hurricane  
11  
12 (1998) and post-2001 earthquake inventories for a study area of around 3.500 km<sup>2</sup>, but again without a  
13  
14 complete validation procedures.  
15  
16

17  
18 On a national basis, MARN (Ministerio de Medio Ambiente y Recursos Naturales) produced in 2004 a  
19  
20 landslide susceptibility map for the whole country at a 1:50.000 scale (MARN 2004) by applying a  
21  
22 heuristic approach (Mora and Vahrson 1991, 1994) and using five controlling factors. Recently, the El  
23  
24 Salvador territory was included in a regional landslide susceptibility scenario, obtained by applying a  
25  
26 fuzzy based heuristic approach, with a low spatial resolution of 30 arcseconds (Kirschbaum et al.  
27  
28 2016).  
29  
30  
31

32  
33 In this paper, a stochastic approach to landslide susceptibility modeling for storm-triggered multiple  
34  
35 debris flows events in El Salvador is proposed, exploiting the Multivariate Adaptive Regression Spline  
36  
37 (MARS) technique (Friedman 1991; Conoscenti et al. 2015) and a complete validation scheme  
38  
39 (Guzzetti et al. 2006; Frattini et al. 2010; Conoscenti et al. 2015, 2016; Lombardo et al. 2015, 2016;  
40  
41 Cama et al. 2016). In particular, we focused on the assessment of a landslide susceptibility model for  
42  
43 storm triggered landslides in the north-western inner slopes of the Ilopango Caldera in El Salvador  
44  
45 (Figs. 1), where at the end of the first decade of November 2009 a multiple landslides event occurred,  
46  
47 due to the combined effect of the Ida Hurricane and the 96E tropical depression (CEPAL 2010, 2011;  
48  
49 MARN 2010, 2011).  
50  
51  
52  
53

54  
55 Susceptibility models were prepared by applying MARS to regress a binary landslide-derived outcome  
56  
57 (stable/unstable status) on a set of geo-environmental explanatory variables, which were derived from  
58  
59  
60  
61

1  
2  
3  
4 two available thematic (geology and soil use) maps and a 10m-cell digital elevation model (DEM). The  
5  
6 model building and validation scheme exploited two original pre- and post-event landslide inventories  
7  
8 (2003 and 2009, respectively), which were recognized by means of the Google Earth™ (GE) image  
9  
10 databank and 3D-view integrated system (e.g., Costanzo et al. 2012a).  
11  
12  
13

14 The main topic of this research was to evaluate the effect in the temporal prediction performance of a  
15  
16 susceptibility models, produced by differences in the magnitude of the triggering events which caused  
17  
18 the landslides forming the calibration and validation datasets.  
19  
20

21 The present research exploited free open data and software resources: Google Earth™, SAGA GIS  
22  
23 (Conrad et al. 2015) and R software (R Core Team 2015).

## 29 **2. Materials**

### 30 **2.1 Study area**

31 El Salvador (Fig. 1) stretches SE-NW along the Central American Volcanic Front for about 250km in  
32  
33 the Pacific side of Central America, near 150km inboard of the Middle American Trench, where the  
34  
35 Cocos plate is subducted beneath the Caribbean plate (Agostini et al. 2006; Lexa et al. 2011). In  
36  
37 particular, the Ilopango Caldera is located in the central graben system of El Salvador (Fig. 2a),  
38  
39 between the coastal and the inner volcanic cordilleras, being one of the most dangerous calderas of  
40  
41 Central America, with an area of around 200km<sup>2</sup>, less than 20 kilometers east of the city of San  
42  
43 Salvador (Rose et al. 2004). At least four exceptional eruptions in the last 100kys, the last of which  
44  
45 near 2500 years ago, produced tephra layers and ignimbrites deposits which covered wide sectors of the  
46  
47 central part of the country (Stoiber and Carr 1973). The caldera presently hosts a typical volcanic lake  
48  
49 (Lake Ilopango), whose inner delimiting steep slopes are characterized by the outcropping of the  
50  
51 weathered tephra layers. Such a geomorphologic setting is responsible for a large number of landslides  
52

4 which activate in the occasion of the tropical storm events associated with the recurrent either Atlantic  
5 and Pacific cyclones.  
6  
7

8  
9 The study area (Fig. 2b) corresponds to an oblate catchment (about 5km long and 8km large) given by  
10 the convergence of several short highly steep streams into an alluvial plain named “Arenal de  
11 Cujuapa”, which progradates into the Ilopango lake with a marked delta-like head (“Punta El Pinar”).  
12  
13 Actually, two main channels can be recognized in the alluvial plain, the southernmost of which  
14 corresponds to the ending branch of the Rio El Borbollón. The whole catchment drains the inner slopes  
15 of the northeastern sector of the Ilopango Caldera, which are characterized by the outcropping of  
16 Holocenic acid pyroclastic sequences, locally named “Tierra Blanca” (TB), belonging to the San  
17 Salvador formation (Quaternary). The latter covers the underlying pyroclastic deposits of the Cuscatlan  
18 formation, which are unburied by erosion along the valley bottom of the streams. Finally, in the upper  
19 sectors of the catchment, near the town of Cojutepeque, pyroclastites of the Bálsamo formation  
20 outcrop.

## 37 **2.2 The Ida/96E event and related landslides**

38  
39 The Hurricane Ida developed on the 4<sup>th</sup> of November as a tropical depression in the south-western  
40 sector of the Caribbean Sea, increasing its strength up to tropical storm grade on the 7<sup>th</sup> of November,  
41 when it crossed the shoreline of Nicaragua, and to a second level hurricane at the midday of the 8<sup>th</sup>  
42 (Avila and Cangialosi 2010). The hurricane then moved northward crossing the Caribbean Sea and the  
43 Mexico Gulf, weakening back to tropical storm and to depression on the 9<sup>th</sup> and completely dissipating  
44 on the 12<sup>th</sup>. During these same days, the low-pressure system 96E moved from the eastern Pacific  
45 Ocean causing intense rainfall between November 7<sup>th</sup> and 8<sup>th</sup> (CEPAL 2000, 2011). In these two days,  
46 Ida and 96E simultaneously struck an area of around 400 km<sup>2</sup> centered between Ilopango Lake and San  
47 Vicente Volcano, producing more than 300mm/24hrs at the Ilopango and San Vicente villages (Fig. 3).  
48

61  
62  
63  
64  
65

1  
2  
3  
4 In this area, large damages were recorded caused by floods and landslides with around two-hundreds  
5  
6 deaths and a quarter of a billion dollars of economic losses (MARN 2010), the larger part of which in  
7  
8 the north-western flank of San Vicente Volcano, where huge debris flow phenomena severely struck  
9  
10 the villages of Verapaz and Guadalupe. At the same time, in the Ilopango Caldera area, hundreds of  
11  
12 landslides triggered from steep slopes causing damages to cropland, rural houses and roads, as well as  
13  
14 strongly affecting and modifying the connected fluvial system.  
15  
16

17  
18 In order to prepare the required two (ante- and post-event) landslide inventories, a remote recognition  
19  
20 was carried out through a systematic GE-based analysis, which was performed on two different epochs:  
21  
22 one dated at 9/10/2003 (DigitalGlobe Catalog ID: 1010010002459C02) and one dated at 11/21/2009  
23  
24 (DigitalGlobe Catalog ID: 101001000AA5D801), the latter being taken just two weeks after the  
25  
26 Ida/96E combined event. Unfortunately, the 2003 GE images were affected by a partial cloud coverage,  
27  
28 so that the study area had to be subdivided into a 2003 cloud-free (CF) and a cloudy blind (CB) sector.  
29  
30

31  
32 By comparing 2003 to 2009 rainfall data, it is clearly evident (Fig. 4) that 2003 can be considered as a  
33  
34 “normal” rainfall year, during which the maximum 24h, 48h and 72h rainfall resulted far below the  
35  
36 Ida/96E records. In the following, as a consequence, the 2003 and the 2009 landslide inventories were  
37  
38 relatively considered as a “normal” and an “extreme” one, respectively.  
39  
40

41  
42 It is worth to mention that, in the time span of some years, a large part of the 2009 landslide areas  
43  
44 resulted as almost completely covered by vegetation and hardly recognizable on the field. At the time  
45  
46 of our field survey (May 2015), the study area resulted as generally affected by dormant and active  
47  
48 landslides, which were mainly classifiable as debris slides or debris flows. The warm-humid climate is  
49  
50 in fact responsible for the fast growing of the vegetation, so that, with the exception of few cases of  
51  
52 very recent landslides, the large part of the study area showed only smoothed forms of the previous  
53  
54 slope failures (Fig. 5). Each landslide area was mapped as a polygon and represented by means of a

landslide identification point (LIP; Costanzo et al. 2014), which was positioned on the highest point along the crown line. In light of the type of slope movement, LIPs were assumed as potentially suitable for detecting the site conditions responsible for the previous failures that, as such, can be used as diagnostic landforms (Rotigliano et al. 2011; Lombardo et al. 2014; Cama et al. 2015) for calibrating the predictive models. It is worth to note that, as a consequence, using a LIP inventory for calibrating the susceptibility models obviously led to estimating the probability for a pixel to be an initiating area, to be then integrated with propagation and/or runout stages modeling.

The two landslide inventories (Fig. 6) included 1503 and 2237 landslides, for 2003 and 2009 respectively. It is worth to note that 253 2009-cases corresponded to reactivation of 2003 landslides.

### 3. Methods

Landslide susceptibility modeling through stochastic approaches requires the definition of a set of independent variables or covariates, which are expected to play the role of predictors, and of a dependent variable, representing the outcome to be predicted. Differently from deterministic approaches, through the adoption of statistical methods proxy variables can be included as predictors, which potentially play an indirect role into the physics of slope failures; however, in basin scale studies, these proxy variables are the only available at reasonable costs. The predictors are selected among those geo-environmental variables that are supposed to have controlled the slope failure mechanisms responsible for the observed past landslide scenarios (Costanzo et al. 2012b); the latter directly expresses the spatial distribution of the outcome, in terms of stable/unstable status of each mapping unit and constitutes the calibration dataset. At the same time, statistical methods allow for verifying if and to what extent a single predictor does control the estimated susceptibility, as well as potential multi-collinearity between predictors.

1  
2  
3  
4 Once a set of predictors is defined, a value for all of the variables is assigned to each of the mapping  
5  
6 units (Rotigliano et al. 2012) in which the study area is partitioned. The application of statistical  
7  
8 methods allows then for optimizing and testing for significance the quantitative relationships which  
9  
10 link the probability of the observed outcome status (stable/unstable) and the site multivariate  
11  
12 geomorphological conditions of each mapped pixel. The predictive capability of the calibrated  
13  
14 susceptibility model is then submitted to quantitative validation tests, which must be based on the  
15  
16 evaluation of the accuracy, precision and general reliability of the derived predictive images (i.e., the  
17  
18 susceptibility maps) in matching the spatial distribution of one or more unknown validation landslide  
19  
20 inventories.  
21

23  
24  
25  
26

### 27 **3.1 The MARS method**

28 Recently, the adoption of Multivariate Adaptive Regression Spline (MARS; Friedman 1991) has  
29  
30 proved to strengthen the predictive skill of generalized linear modeling techniques. MARS is a non-  
31  
32 parametric regression technique that aims at fitting un-linear relationships between predictors and  
33  
34 outcome, by fragmenting their range into an optimized number of linear branches. Each branch defines  
35  
36 into the covariate axis a basis function (BF) that is structured as hinge function delimited by knots.  
37  
38 More complex BFs can be defined as the product of one or more hinge functions associated to different  
39  
40 covariates. A particular case is the BF that corresponds to the model intercept, set to a constant value of  
41  
42 1.  
43  
44  
45  
46  
47

48 The application of the MARS algorithm is based on a two stages procedure. In a first stage (forward  
49  
50 pass) a model is generated by stepwise adding (starting from a constant only model) pairs of terms  
51  
52 corresponding to the mirrored hinge functions generated by a knot. At each step, the added pair of  
53  
54 terms that results in the regression giving the maximum reduction of the residual sum-of-squares error  
55  
56 (RSS) is added. In light of the simple structure and fast computing, the searching of the best pair is run  
57  
58  
59  
60  
61

1  
2  
3  
4 systematically (in a “brute force” fashion). This stage can be run up either a minimum RSS gain is  
5  
6 obtained or the whole set of possible BFs are added. In the second stage (backward pass) MARS  
7  
8 stepwise prunes the best fitting but typically overfitted model, by dropping out of the model at each  
9  
10 step the single term whose removal results in the lowest Generalized Cross-Validation parameter  
11  
12 (GCV; Craven and Wahba 1979). The criterion expressed by the GCV parameter is in fact the best  
13  
14 compromise between fitting (low RSS) and model complexity, the latter depending on the number of  
15  
16 terms. At each pruning step, a best model subset is then obtained.  
17  
18  
19

20  
21 MARS regression function is so given by:

$$f(x) = \alpha + \sum_{i=1}^N \beta_i h_i(x),$$

22  
23  
24  
25  
26  
27  
28  
29 where  $\alpha$  is the model intercept and the  $\beta_i$  the coefficients of the  $h_i$  basis functions obtained by knots-  
30  
31 splitting the range of the  $x$  covariates.  
32  
33

34  
35 In this research, MARS modeling was performed using the “earth” package (Milborrow et al. 2011) of  
36  
37 R software. In order to reduce the complexity of the models, the maximum degree of interaction was  
38  
39 set equal to 1, thus avoiding terms given by combinations of two or more BFs. The software semi-  
40  
41 automatically determined the maximum number of terms entering the MARS models. The “evimp”  
42  
43 function of “earth” was employed to estimate the variable importance, as a function of the number of  
44  
45 entered model subsets. Only subsets equal to or smaller than the final model are considered to evaluate  
46  
47 predictor importance (Milborrow 2015).  
48  
49

50  
51 In light of its flexibility and fast/easy to apply software/hardware structure the MARS algorithm has  
52  
53 been recently adopted in stochastic modeling of geomorphological phenomena, including soil erosion  
54  
55 and landslides (e.g., Conoscenti et al. 2016, 2017). In this paper a first application to debris flow  
56  
57 phenomena prediction through a time-partition based validation scheme is presented.  
58  
59  
60

### 3.2 Predictors

The following covariates were assumed at the initial stage as potential predictors for slope failures in the study area: outcropping lithology (LIT), land use (USE), landform classification (LCL), elevation (ELE), steepness (STP), aspect (ASP), plan (PLN) and profile (PRF) curvatures, topographic wetness index (TWI) and terrain ruggedness index (TRI). The 10m pixel structure of the source DEM was adopted for partitioning the study area into mapping units (Cama et al. 2016). Table 1 details the DEM-derived covariates in the area and their related references, while the classes for each of the categorical predictors are listed in Table 2.

The selection of the predictors was based on largely adopted geomorphological criteria (Costanzo et al. 2012b) and was here also supported by a multi-collinearity analysis based on classic *VIF* (Variance Inflation Factor) estimation which exploited the “usdm” package (Naimi 2015). A *VIF* value of 10 was set to exclude collinear variables from the models (Heckmann et al. 2014; Jebur et al. 2014; Bui et al. 2016). All the variables resulted as not collinear and were so included into the final models.

### 3.3 Model building and validation strategy

According to the adopted research design, two validation schemes were applied (Tab. 3): chrono-validation, based on the 2003/2009 time partition, and self-validation, based on the spatial random partition of each of the two inventories (Chung and Fabbri 2003; Guzzetti et al. 2006; Cama et al. 2015, 2017; Lombardo et al. 2015). In particular, forward chrono-validation scheme was applied, by calibrating with 2003 and validating on 2009, whilst the opposite scheme was applied for backward chrono-validation. Moreover, due to the presence of the cloudy area in the 2003 GE coverage, chrono-validation schemes were adopted for predicting either the whole 2009 landslide inventory (2009<sub>ALL</sub>) or the CF (2009<sub>CF</sub>) subset. For the same reason, the backward chrono-validation procedure was performed

1  
2  
3  
4 only in the CF sector, by calibrating with 2009 landslides and validating in predicting the 2003s. By  
5  
6 applying either time and random partition schemes, starting from the three available calibration dataset  
7  
8 (2003CF, 2009CF and 2009ALL), the six models of Table 3 were obtained.  
9

10  
11 Comparing model A to model D, or model B to model E, allows investigating the role of the calibration  
12  
13 inventory in the prediction skill of the derived susceptibility models. In fact, in both the two cases the  
14  
15 same landslide scenario (2003 and 2009, respectively) was predicted by calibrating the susceptibility  
16  
17 models either on a randomly partitioned of the same coeval landslides or on the whole dataset of the  
18  
19 landslides recognized in the other epoch. The different model performances were then more clearly  
20  
21 highlighted by directly comparing the model B to the model D. At the same time, in order to have  
22  
23 reference levels for evaluating the performance of the temporal (chrono-validated) predictions, the  
24  
25 2003<sub>CF</sub>, 2009<sub>ALL</sub> and 2009<sub>CF</sub> datasets were also submitted to random splitting based self-validation.  
26  
27  
28  
29

30  
31 To estimate the potential role of the blind area in hampering the research strategy, B to C and E to F  
32  
33 models were also compared.  
34

35  
36 Each dataset was balanced by adding to the positives (i.e. pixels hosting a LIP) an equal number of  
37  
38 randomly selected negatives, corresponding to LIP-free pixels (Conoscenti et al. 2016). For temporal  
39  
40 partition based validations, one hundred replicates were obtained by randomly multi-extracting a  
41  
42 different subset of negatives both in the calibration and validation datasets. Self-validations were based  
43  
44 on 10-folds with 10 repetitions cross-validation schemes, obtaining one hundred estimates of model  
45  
46 parameters and performance metrics (Tab. 3).  
47

48  
49 The performances of the models were evaluated by adopting both cut-off dependent and independent  
50  
51 metrics. In particular, the prediction skill of the model was evaluated by computing the *AUC* (Area  
52  
53 Under Curve) in the ROC (Receiver Operating Characteristics) sensitivity Vs. fall out (1-specificity)  
54  
55

#### 17 **4. Results**

18  
19 In order to explore the structure of the models in terms of selected variables, the nsubsets criterion was  
20  
21 adopted (Conoscenti et al. 2016), by counting the number of model subsets including each selected  
22  
23 variable throughout the pruning pass, which is assumed as expressing the variable importance. Table 4  
24  
25 summarizes the results for the three calibrated models. With a threshold of variable importance of 1 or  
26  
27 more, only 27 variables were extracted at least for one model, out of the 44 included at the first step of  
28  
29 the modelling procedures, with larger set of variables included in the 2009CF and 2009ALL models.  
30  
31  
32

33  
34 Based on the comparison between the results of the three models, five main groups of variables can be  
35  
36 defined: I, variables selected for all the three models; II, variables selected only for the 2009CF and  
37  
38 2009ALL models; III, variable selected only for the models calibrated in the CF area; IV, variables  
39  
40 selected for the 2003CF and 2009ALL models; V, variables selected only for one single model. TRI  
41  
42 and ELE are the most important variables, with very similar and high mean values. The Ia subgroup is  
43  
44 completed by quite important and homogeneous variables. The high importance of North-eastern  
45  
46 facing observed for the 2003CF model resulted as very lowered for both the 2009. The Ic subgroup  
47  
48 includes variables which are very important for the two 2009 models, whilst a lowering of one order of  
49  
50 magnitude is observed for 2003CF. The II group includes a large set of variables which are important  
51  
52 for the two 2009 models (ASP\_South and ASP\_SouthEast, in particular), but not extracted throughout  
53  
54 the pruning pass in the 2003CF calibration. SLO is selected as a quite important variable only for  
55  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4 models calibrated in the CF sector, whilst group IV variables were extracted with varying importance,  
5  
6 only for 2003CF and 2009ALL models. Finally, group V variables were extracted only for one of the  
7  
8 calibrated models.  
9

10  
11 As regards the predictive performances, Figure 7 shows the averaged ROC curves that were obtained  
12  
13 for the six models through their replicates, while, to ease the comparison of the global accuracy, a  
14  
15 boxplot displaying each of the corresponding mean *AUCs* was prepared (Fig. 8).  
16  
17

18  
19 The whisker symbols along the ROC curves (Fig. 7) attest for highly stable results through the  
20  
21 replicates, with higher dispersion gradually shifting from true to false positives, in the direction of the  
22  
23 lower scores. For the calibrated subsets, the frequency distribution of the scores shows a different shape  
24  
25 in the intermediate range (0.7-0.3), with a more picked bi-modal trend for the 2003 model (Figs. 7a-c),  
26  
27 resulting in a flat zone, where a wide range of scores is equally represented in terms of mapped pixels.  
28  
29

30  
31 As regards the *AUCs* (Fig. 8), the 2003CF, 2009CF and 2009ALL self-validated models obtained  
32  
33 similar excellent performances, with *AUC* values above the 0.8 threshold (Hosmer and Lemeshow  
34  
35 2000). At the same time, in the CF sector, the forward and the backward chrono-validations produced  
36  
37 almost the same results in terms of *AUCs*, with largely acceptable values of 0.76 and 0.78, respectively.  
38  
39 For the forward chrono-validations, only a slight performance decreasing was observed from the CF  
40  
41 sector to the whole catchment ( $AUC=0.74$ ); the same small difference was observed for the 2009 self-  
42  
43 calibrated model, from 2009CF ( $AUC=0.83$ ) to 2009ALL ( $AUC=0.81$ ).  
44  
45  
46  
47

48  
49 If cutoff-dependent performance metrics are taken into consideration (Tab. 5), it is evident that the loss  
50  
51 in prediction skill from 2003 and 2009 self-validation (model A and model E) to forward and backward  
52  
53 chrono-validation (model B and model D), respectively, depends on a sensitivity decreasing, which is  
54  
55 more marked for the 2003 model, with no coupled loss of specificity. Furthermore, by directly  
56  
57 comparing the backward (model E) to the forward (model B) chrono-validated models in the CF sector,  
58  
59  
60  
61

1  
2  
3  
4 in spite of the similar *AUC* performance (0.71 and 0.70, respectively), a marked higher sensitivity and  
5  
6 lower specificity of the former arises. In both cases, the specificity does not change from self- to  
7  
8 chrono-validation. It is worth to note that the two opposite behaviors of specificity and sensitivity  
9  
10 compensated each other, so that the two models result in a similar accuracy.  
11  
12

13  
14 Figure 9a,b shows the two susceptibility maps prepared by calibrating the models in the CF sector  
15  
16 exploiting the 2003 and 2009 landslide inventory, respectively. The maps were obtained by averaging,  
17  
18 for each pixel, the one hundred estimates of probability values. A map of the residuals is also shown  
19  
20 (Fig. 9c), where the difference in the estimated score of the two models ( $\text{score}_{2003} - \text{score}_{2009}$ ) was  
21  
22 depicted. In spite of the similar general spatial pattern of the two prediction images, the 2009 model  
23  
24 produced higher scores on average, whilst positive and negative residuals stretch along the north-  
25  
26 westward and south-eastward slopes of the main SW-NE running pyroclastic ranges, respectively.  
27  
28

29  
30 However, in terms of positive and negative predictions, if applying Youden index cut-offs, few pixels  
31  
32 resulted as differently classified in the two maps (Fig. 10): less than 5% of the pixels with scores  
33  
34 diverging for more than one susceptibility class; a larger percentage (13%) of pixels classified with a  
35  
36 one class shift and crossing the cut-off score value.  
37  
38

## 39 40 41 **5. Discussion**

42  
43 The analysis of the variable importance of the three calibrated models highlights that more variables  
44  
45 are involved in the definition of the susceptibility for the extreme event datasets. At the same time,  
46  
47 some variables play a role in the predictive models, no matter the intensity of the trigger, with two  
48  
49 topographic factors showing the maximum importance: elevation (ELE) and Topographic Ruggedness  
50  
51 Index (TRI). On the other hand, some variables (Topographic Wetness Index, Pasture and Crop  
52  
53 Cultivation soil use) resulted as much more important (one order of magnitude) under extreme  
54  
55 scenario, with the case of South and South-East facing, which are among the most important variables  
56  
57  
58  
59  
60  
61

1  
2  
3  
4 for the two 2009 models, but never extracted for 2003CF. Conversely, North-eastern facing has an  
5  
6 importance index of more than 10 only for normal event condition. The SLO variable was selected only  
7  
8 for the models calibrated in the CF sector, probably due to the geomorphologic conditions.  
9

10  
11 Figure 11 puts the main results of the validation tests inside the framework of the investigation strategy  
12  
13 adopted in this research. The results attested that the 2003 landslide inventory allowed to calibrate a  
14  
15 predictive model, whose *AUC* performance was estimated as very high and reliable, after a self-  
16  
17 validation procedure was applied (model A); that was the only test we could have performed in 2003,  
18  
19 before the 2009 the 2009 Ida/96E event. However, if trying to predict the sites where then debris flow  
20  
21 and debris slide phenomena triggered (model B), a small *AUC* decreasing (from above to below the 0.8  
22  
23 threshold), but coupled with a relevant number of false negative occurrences (low sensitivity), arose:  
24  
25 relying on a map prepared on 2003 would have resulted in 32% of missing positives (against the 22%  
26  
27 expected on the basis of the 2003 self-validation test). An analogous *AUC* decreasing resulted for the  
28  
29 backward chrono-validation (model D) with respect to the 2009CF self-validated model (model E), but  
30  
31 caused by a moderate false negative prediction (miss rate) increasing, with only 21% of missing  
32  
33 positives (against the 17% obtained from self-validation). It is worth to highlight that the model E  
34  
35 showed the same accuracy of the self-validated model B in predicting the 2003 positives, suggesting  
36  
37 the model calibrated with an extreme event landslide scenario of a different epoch (2009) as being able  
38  
39 to reach the same performance in recognizing the sites of activation for a normal season landslide  
40  
41 scenario of a self-validated one. Conversely, the model calibrated with this lower trigger landslide  
42  
43 scenario resulted in a markedly lower sensitivity than the one calibrated under the extreme event  
44  
45 (sensitivity = 0.68, against 0.83). In particular, the 2009-calibrated model resulted capable to detect as  
46  
47 nearly as the 80% of the 2003 landslides, but expecting a higher number of positives, actually  
48  
49 corresponding to 2003 stable sites (type-I errors), with low specificity and high number of false  
50  
51  
52

3  
4 positives. The same model calibrated in 2003 recognized the negative locations in the 2009 landslide  
5 scenario with a higher performance than the 2009 self-validated itself (specificity = 0.72, against 0.63).  
6  
7

8  
9 The results of this research seem to confirm non-linear stochastic relationships between predictors and  
10 outcome under different driving conditions, as the crossing with a more severe landslide scenario does  
11 not only correspond to a false-to-true conversion of the predicted positives (actually, a small decreasing  
12 of PPV is recorded for the 2003 forward chrono-validation), but also to positive occurrences for a  
13 number of predicted negatives. However, a similar but slighter effect is observed when models are  
14 calibrated with the extreme landslide scenario, which means the larger scenario does not fully include  
15 the smaller one.  
16  
17

18  
19 In terms of geomorphological model, a more intense triggering of the slopes is responsible for the  
20 activation of large part of those site conditions which typically activate under normal triggering but  
21 together with other regions of the multivariate parameter hyperspace, having stable status under normal  
22 triggering, as attested by the 2009 models, which are controlled by more variables. This means that, if  
23 we focus on the applicative relevance of the prediction, exploiting landslide scenarios caused by more  
24 intense triggering events allows to fit large part of the normal-trigger caused landslides as well as the  
25 same extreme-trigger ones. At the same time, a source of errors in terms of successful positive  
26 predictions is introduced by extreme events, so that a moderate lowering of the sensitivity is to be  
27 expected. This could be due to the activation on 2009 of a secondary triggering mechanisms, caused by  
28 landslide coupling, which add a non-stochastic component to the spatial relationships between  
29 predictors and outcome, being rather controlled by morphodynamic slope connectivity. In fact, in a  
30 relevant number of cases, landslides in that extreme event scenario were triggered by the impact or the  
31 erosion (either laterally or at the foot of the slopes) of the moving mass detached from the primary  
32

2  
3  
4 slope failures. In Figure 12 a field example is given, highlighting a number of coupled landslides, in the  
5  
6 2009 landslide scenario. The same setting can be observed in Figure 5.  
7

8  
9 As regards the susceptibility maps, under an applicative perspective the 2009-calibrated models  
10 confirmed to be much more accurate in predicting positives, avoiding false negative predictions.  
11  
12 Among the pixels predicted as negatives at 2003, but as positive at 2009, 227 out of 580 (39%) resulted  
13  
14 unstable in the 2009 landslide scenario (Fig. 10); conversely, very few (0.5%) of the negative predicted  
15  
16 pixels at 2009, but as positive at 2003, actually resulted unstable in 2003. Again, if considering the  
17  
18 potential severity of a false negative prediction, the 2009 model confirmed to produce the more realistic  
19  
20 and prudential prediction image in terms of potential damages.  
21  
22

23  
24 Differences in temporal validations between models trained under normal or extreme event triggered  
25  
26 landslide scenarios have been investigated in other papers (Lombardo et al. 2014; Cama et al. 2015 and  
27  
28 references therein). However, in this research, deepening the analysis to cut-off dependent performance  
29  
30 metrics highlighted that, together with the confirmation of a *AUC* decreasing from self- to chrono-  
31  
32 validation, which could suggest using either one or the other model be the same, a clear difference  
33  
34 arises in terms of type of predictive errors.

## 44 **6. Conclusions**

45 Predicting storm triggered landslides always poses the problem of the morphodynamic coherence  
46  
47 between calibration and validation datasets. In fact, the prediction skill of a model can be hampered by  
48  
49 a large difference between the trigger intensity of the event responsible for the calibration and one for  
50  
51 the validation landslide dataset.  
52  
53

54  
55 In the present research, a test was carried out in the Caldera Ilopango, which is a representative area of  
56  
57 Central America, where recurrent extreme events occur striking landslide prone pyroclastic slopes.

65

Two different landslide inventories were exploited: one produced by normal rainfall, the other being the result of a very intense triggering storm (the Ida/96E 2009 event). The results confirmed the relevant role played by the triggering conditions both in the importance of the variable included in the susceptibility models, and in their predictive performance. As regards the predictors, it is worth to note that some variables were selected for both the two triggering scenarios, whilst some other only for the extreme event one, demonstrating that the slope failures occur under different mechanisms depending on the rainfall intensity. At the same time, in terms of predictive performances, the specificity of the predictive models resulted as not conditioned by the type of validation (chrono- or self-validation), nevertheless being higher for the model calibrated under normal event. Conversely, the sensitivity changes from self- to chrono-validation, with the models calibrated with a landslide inventory associated to normal trigger less capable to predict the sites of landslide activation under intense triggering and resulting in very critical type-II errors (high miss rate). On the contrary, models calibrated with extreme landslide scenarios resulted very efficient in self-predicting the positives as well as less critically limited in predicting the normal event triggered landslides.

It is worth to note that focusing only in an *AUC* estimation for assessing the quality of a susceptibility model could be misleading in terms of the applicative exploitation of the susceptibility maps, whose quality is critically dependent on the correctness of binary positive/negative discriminations.

This research demonstrated that validating on an extreme-event landslide inventory a susceptibility map calibrated with a normal landslide dataset does not result into a simple conversion from false to true positives (i.e., the turning of negatives but susceptible cases into positive), but that new susceptible conditions arises under intense triggering, which cannot be predicted if a normal event inventory is used for calibration. Conversely, extreme landslide inventories allow to calibrate susceptibility maps

1  
2  
3  
4 which are very effective in predicting the landslides produced by normal events but with limits in  
5  
6 discriminating stable conditions.  
7

8  
9 Summarizing what above discussed, models calibrated with normal landslide scenario result in higher  
10  
11 specificity (less Type-I error) but lower sensitivity (more Type-II error). To explain these differences,  
12  
13 two main hypotheses are here suggested: the non-linear behavior in the trigger intensity dimension of  
14  
15 regressed relationships which link predictors and outcome; the role of a non-stochastic  
16  
17 (morphodynamic), related to the multiple coupled triggering between different landslides under extreme  
18  
19 events. This point is obviously of great importance in terms of applicative consequences. In fact, it  
20  
21 means that landslide susceptibility stochastic modeling requires multi-temporal calibration inventories,  
22  
23 so to detect and estimate the effects of differences in the intensity of the trigger, optimizing positive  
24  
25 and negative predictions. Strategies for integrating low and high trigger landslide inventories are to be  
26  
27 issued and constitute the logical conclusive perspective of this research.

Fig. 11 – Graphical summary scheme of the adopted validation strategies and main performance metrics.

Fig. 12 – Field example of coupled multiple landslides in 2009.

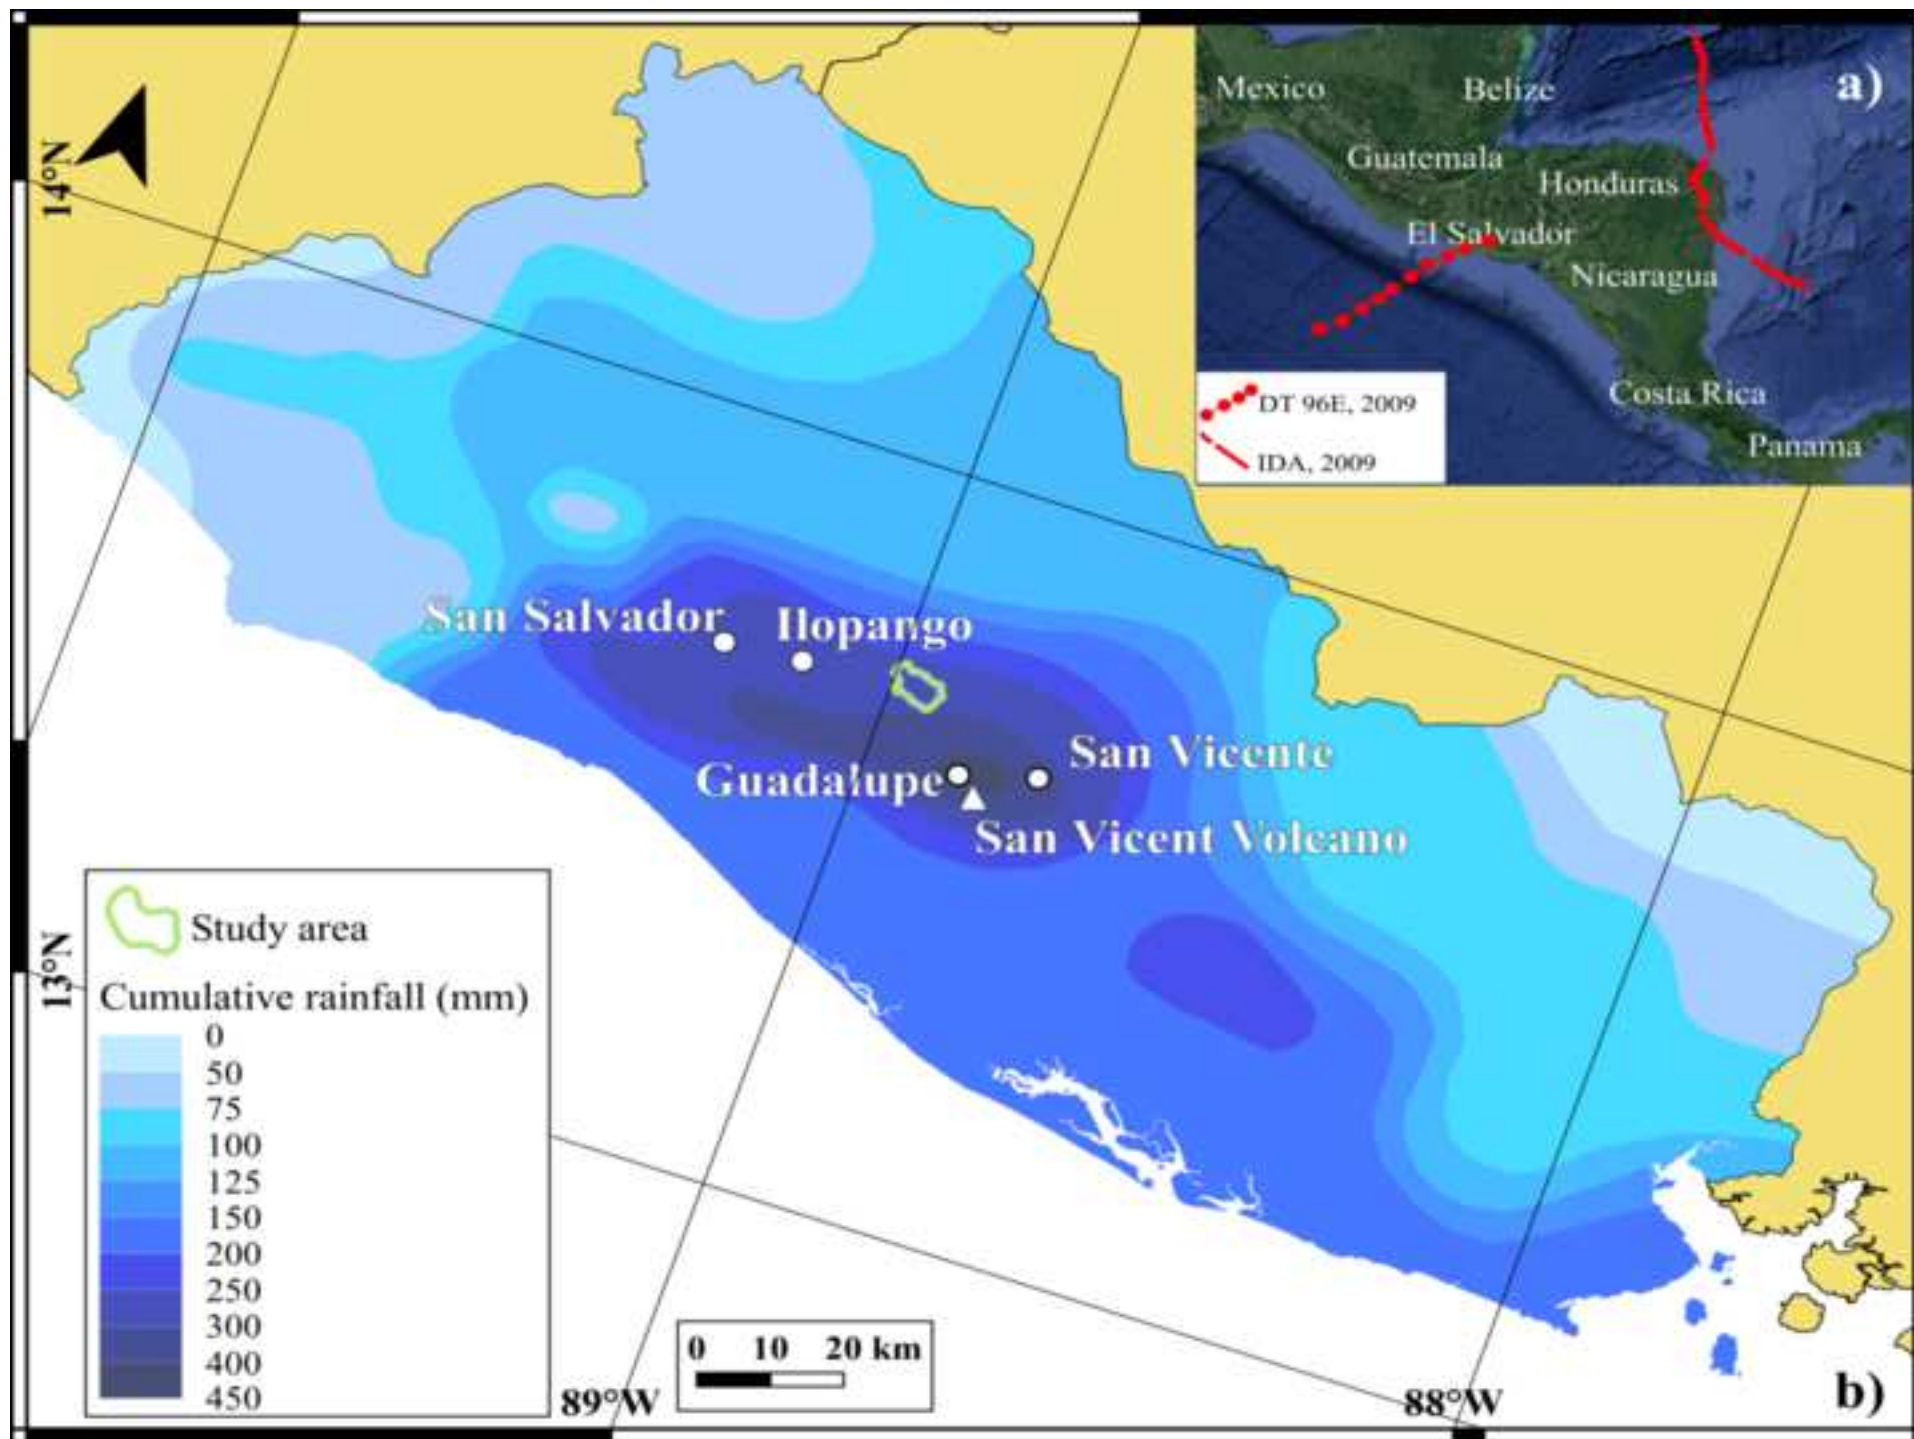

Tab. 1 – List of the DEM-derived predictors.

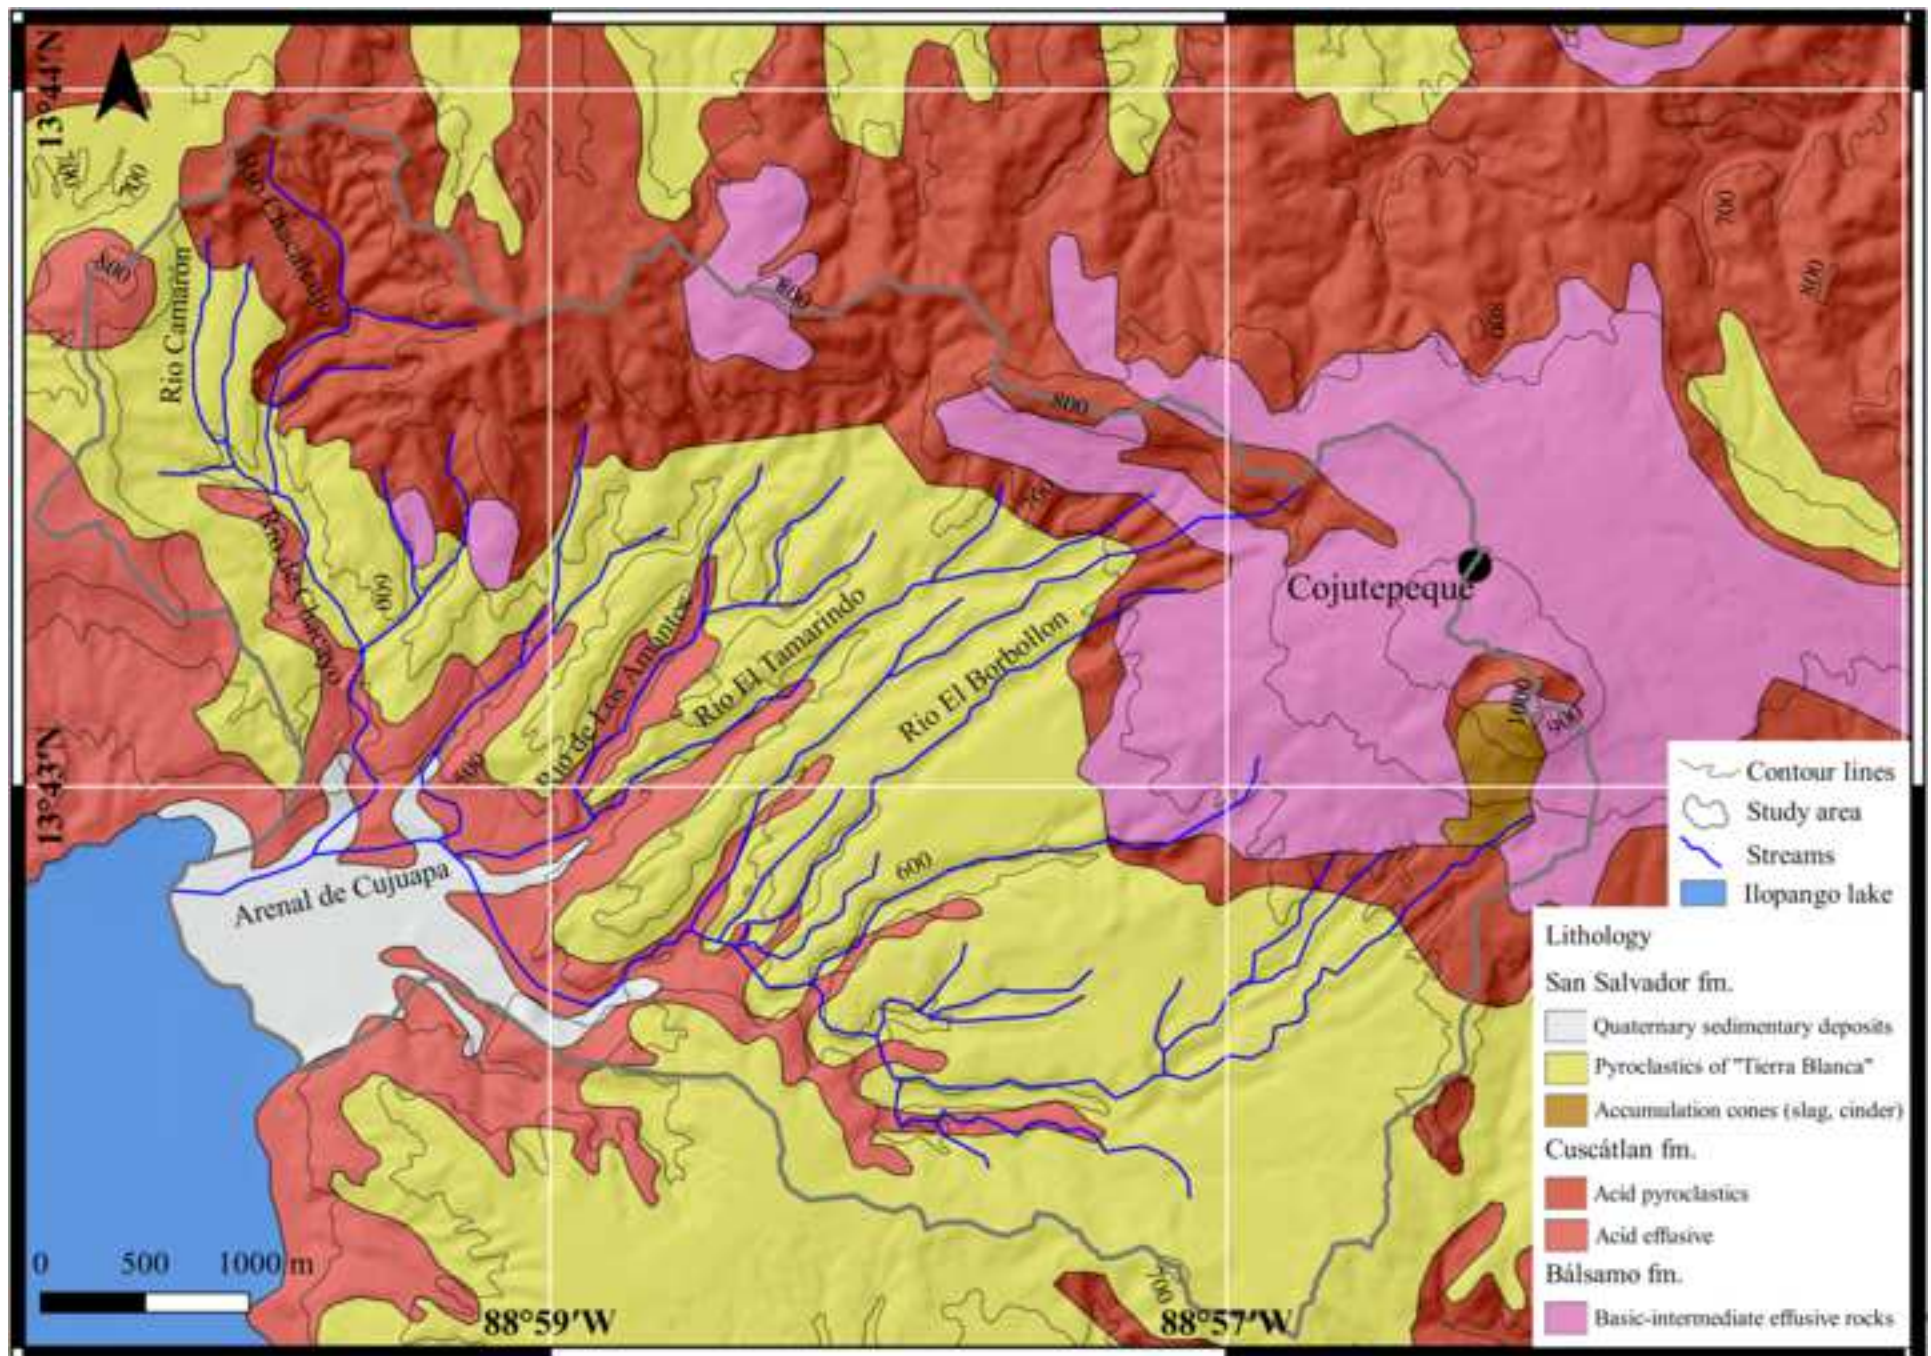

Tab. 2 – List of the categorical predictors.

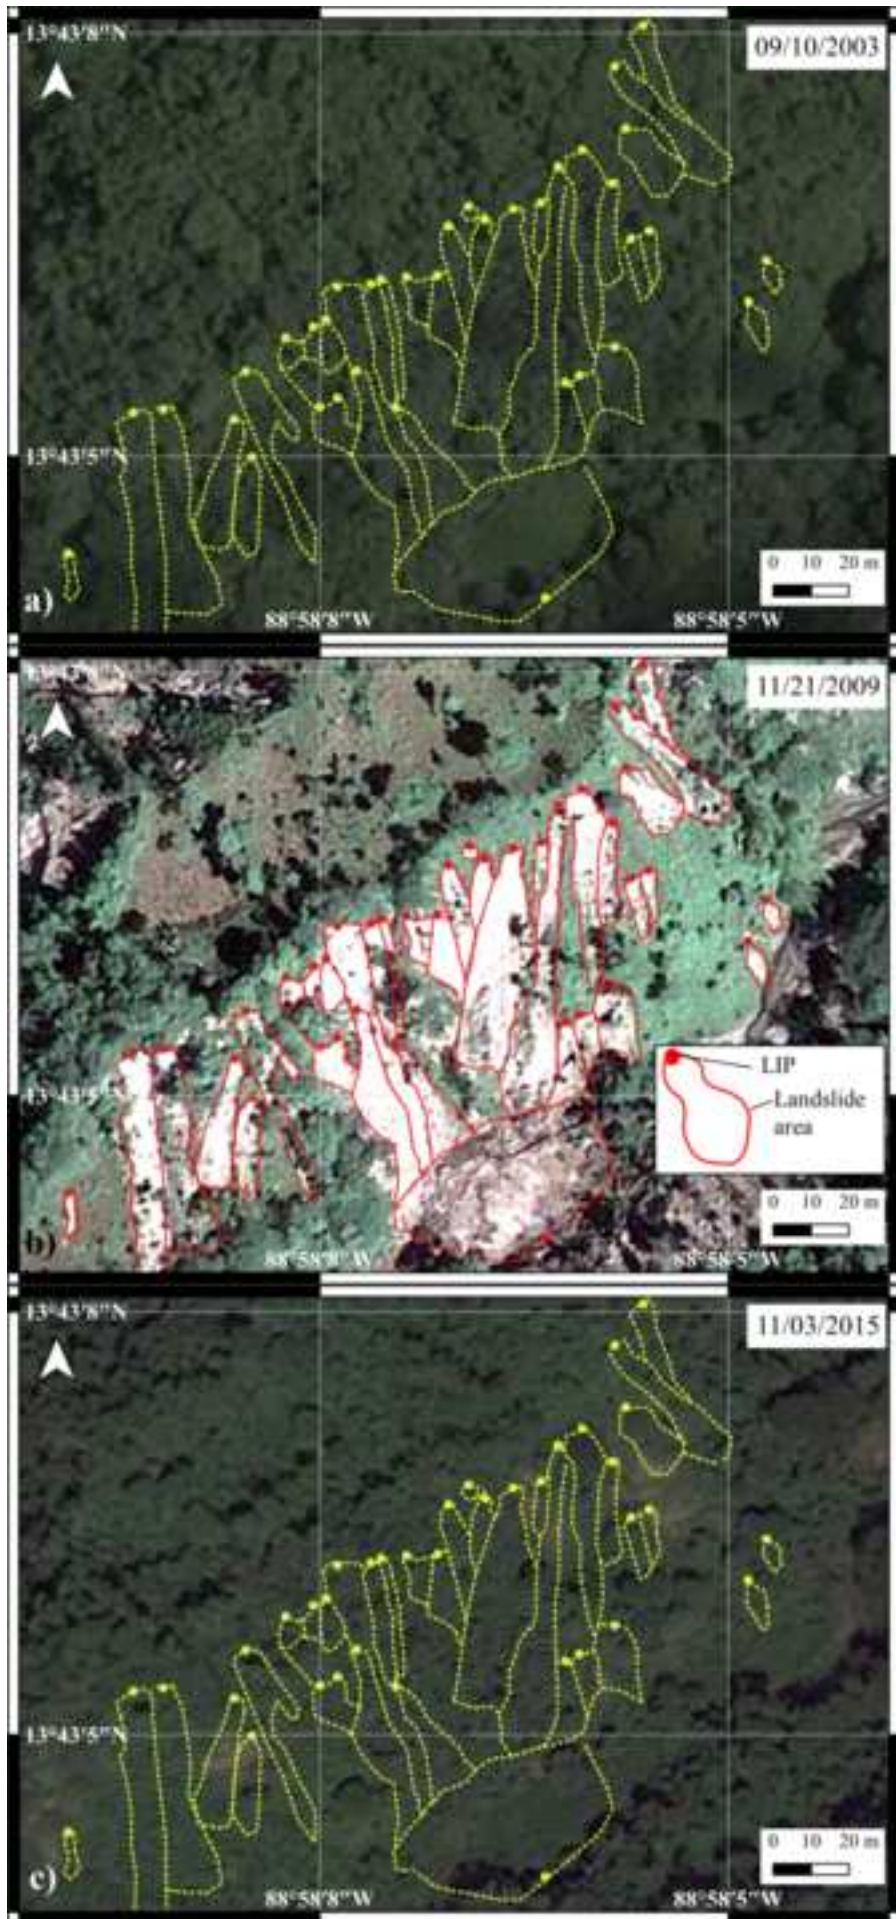

Tab. 3 – Characteristics of the validation schemes adopted for the six susceptibility models.

Tab. 4 – Summary of the variable importance index for the three calibrated models (NS = not selected).

Tab. 5 – Summary of the validation metrics for the six susceptibility models.

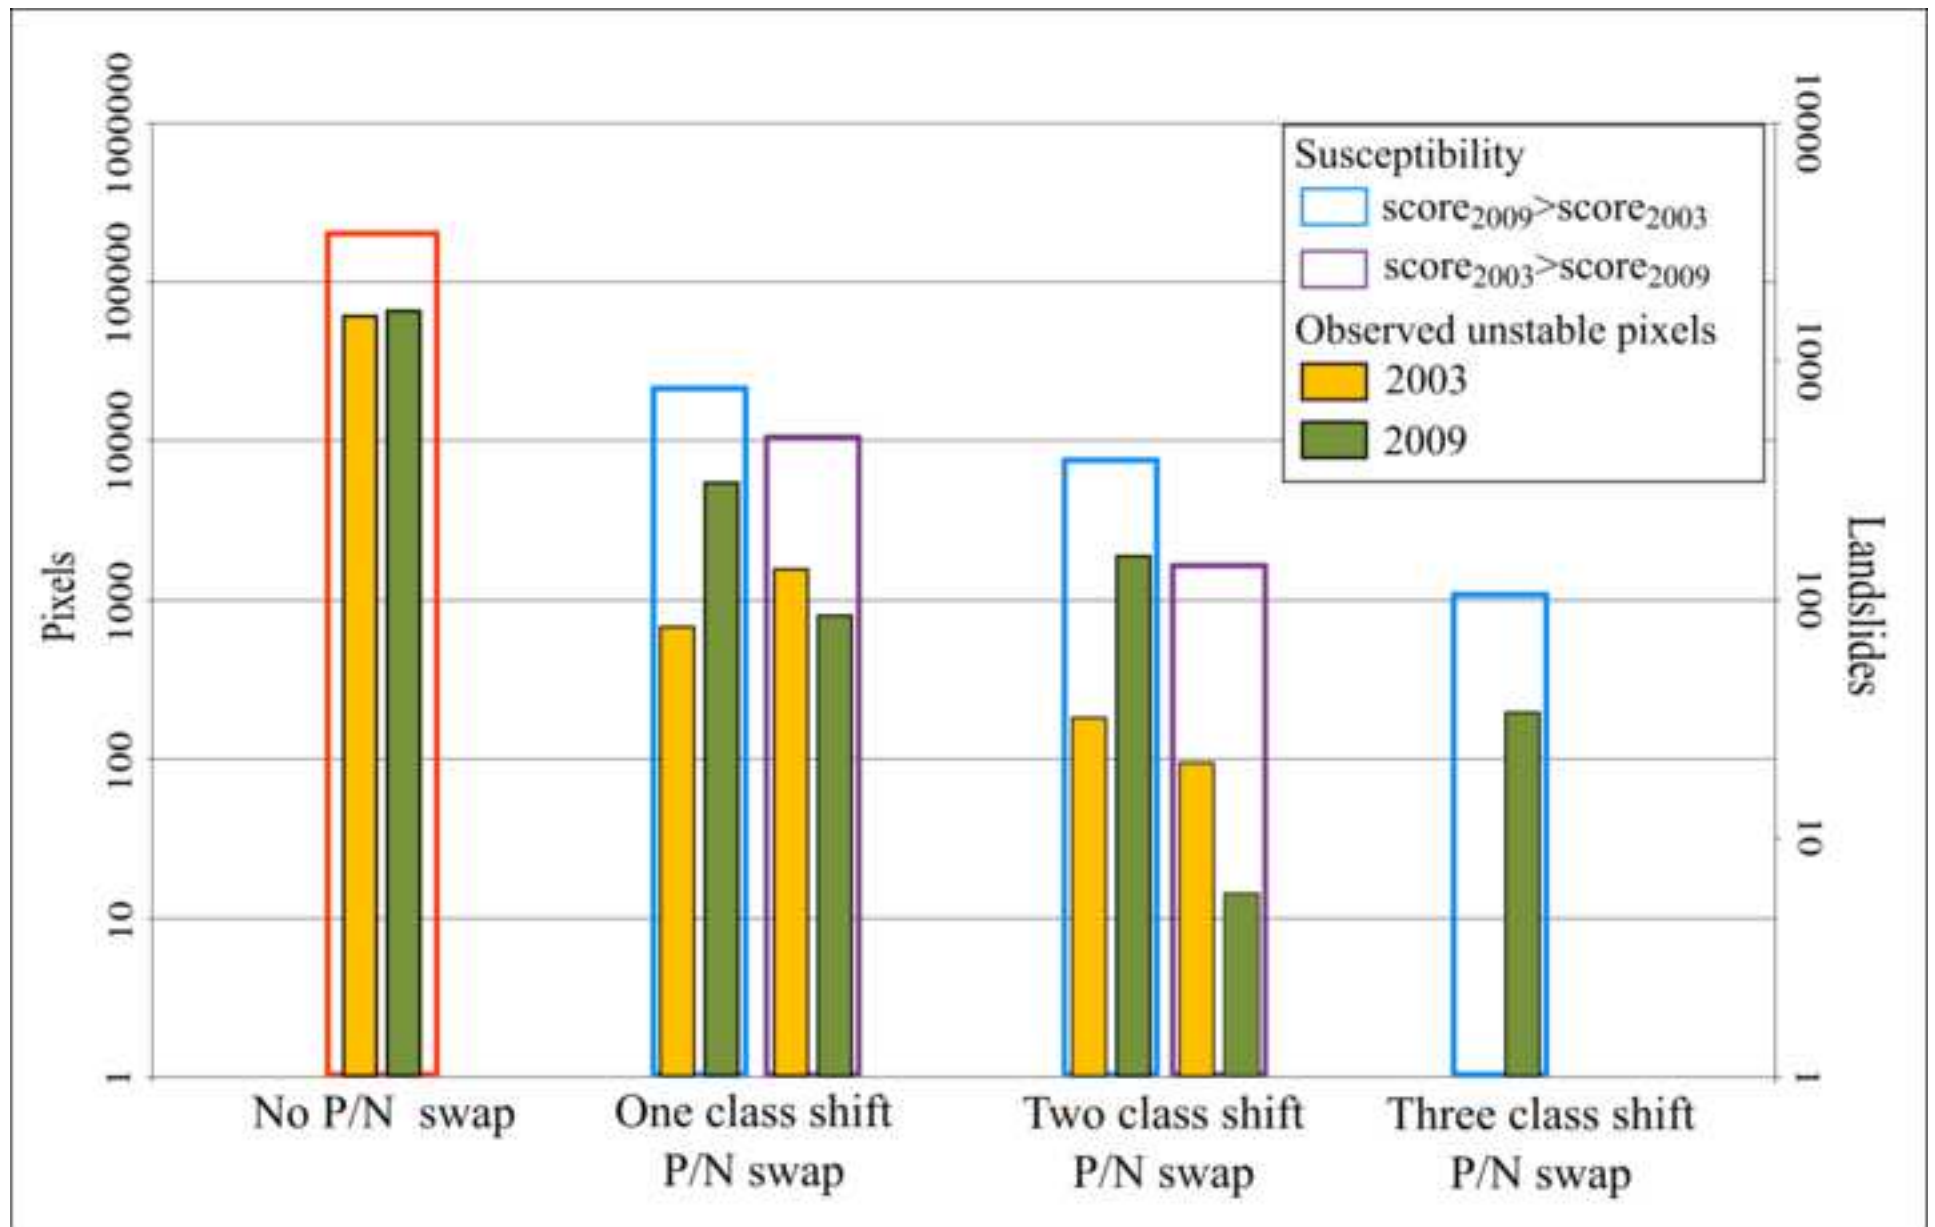

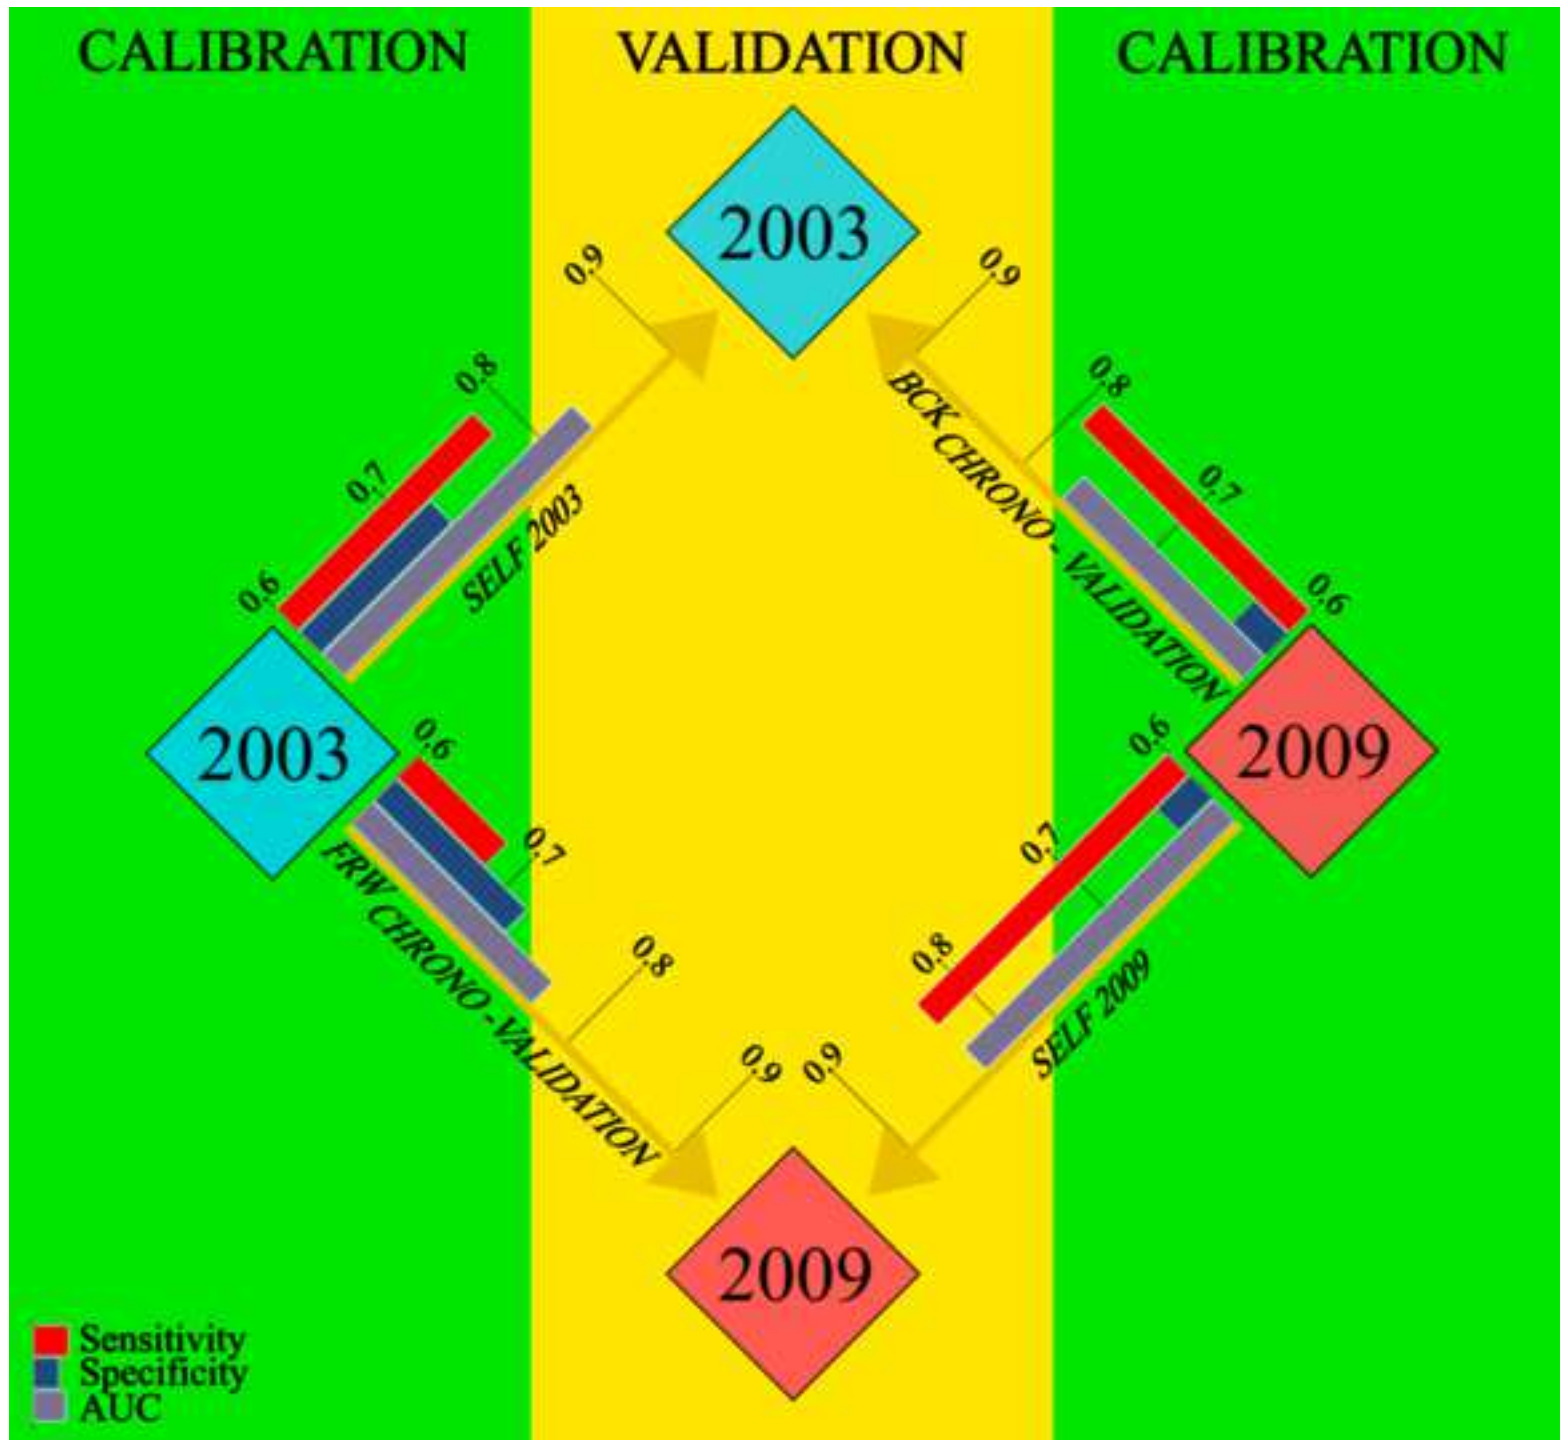

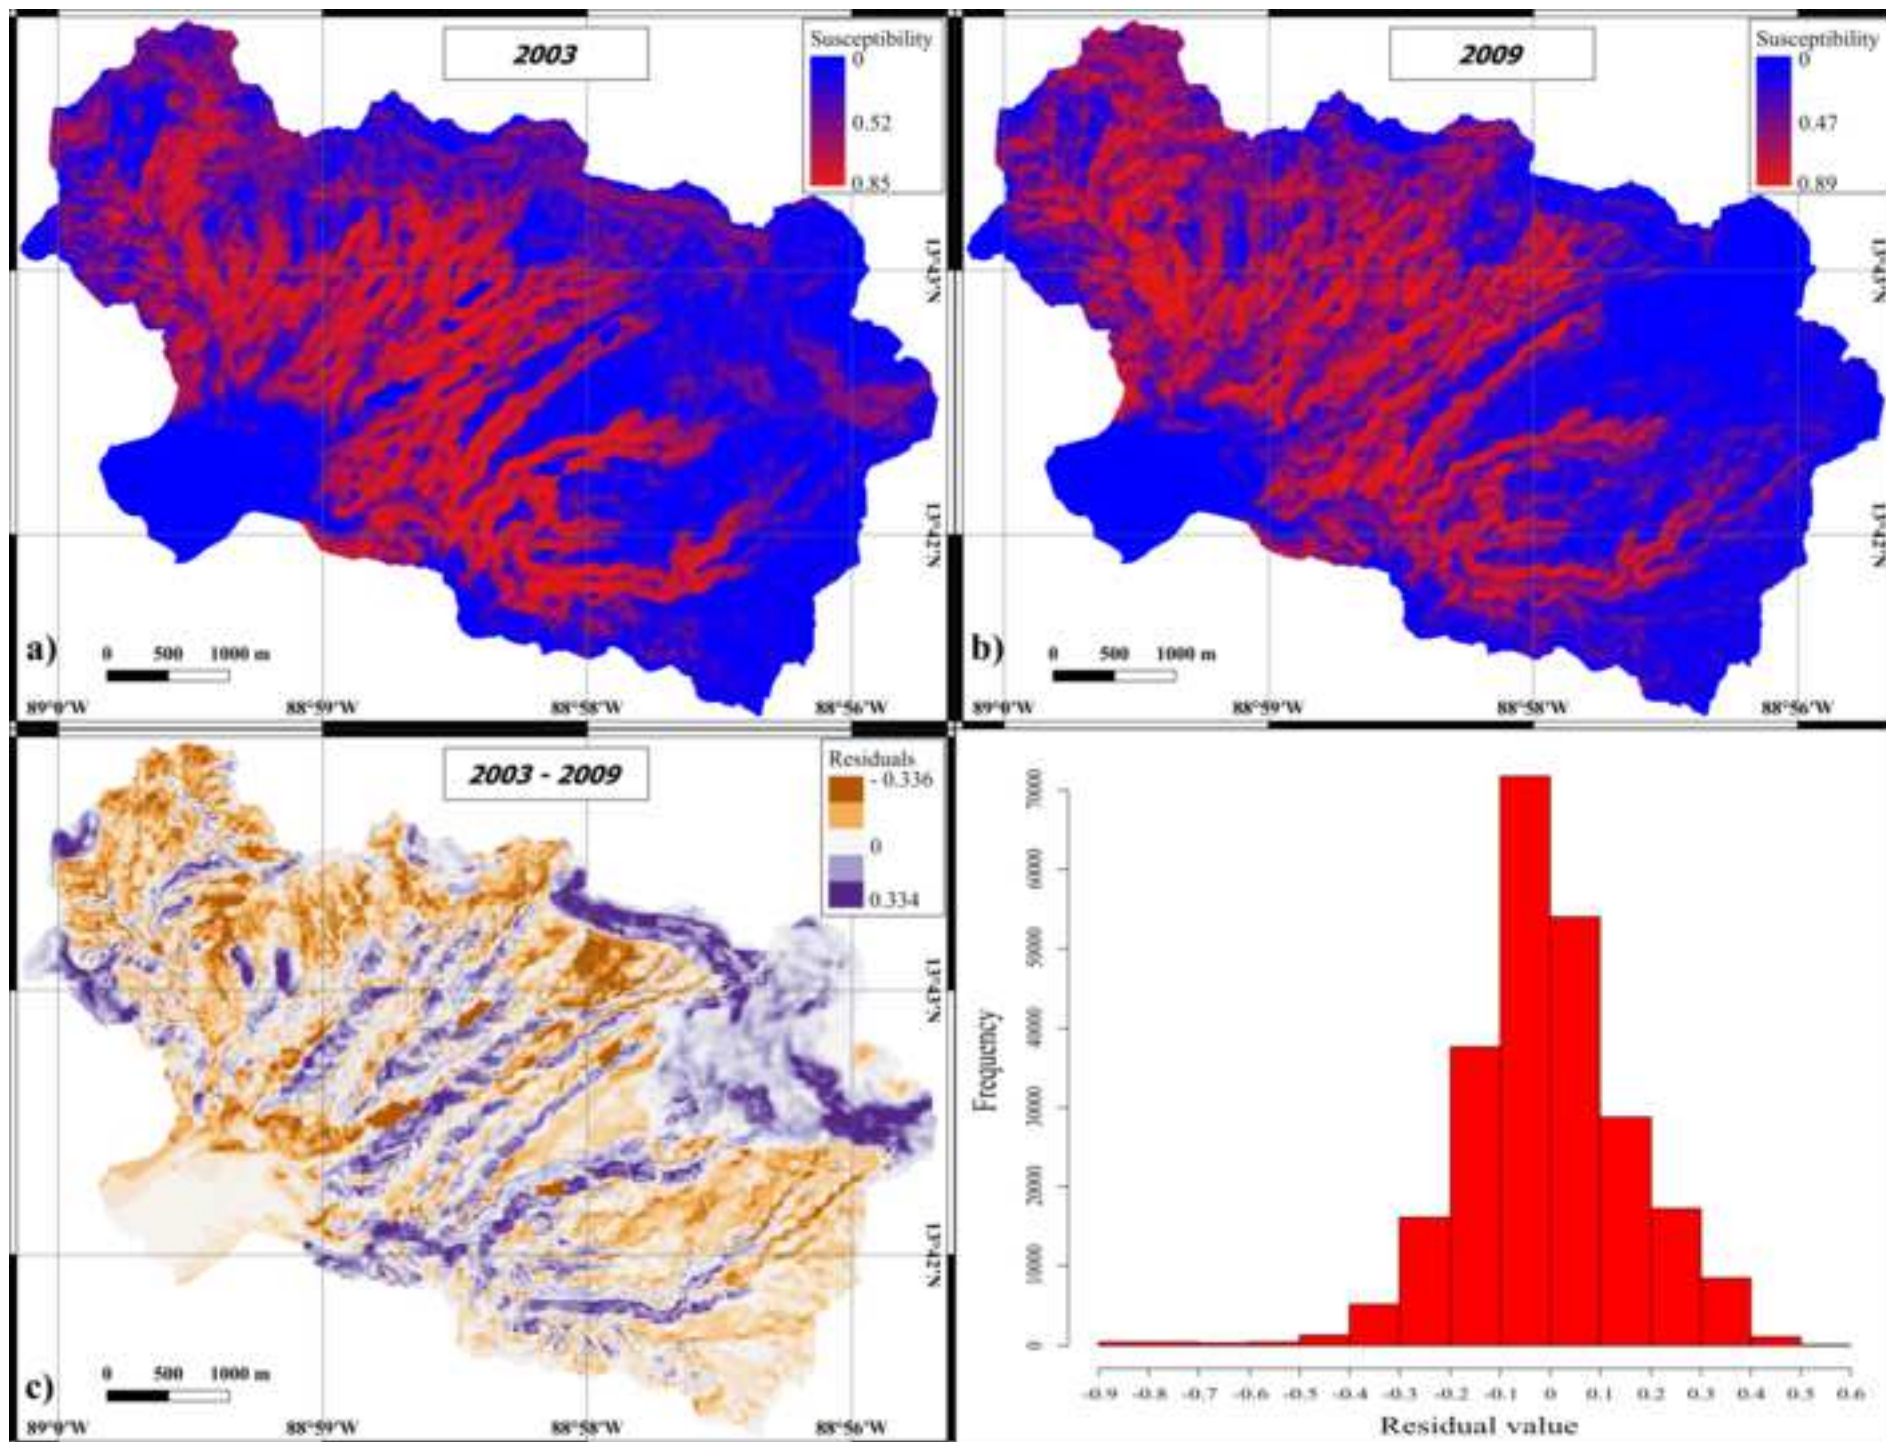

Figure10

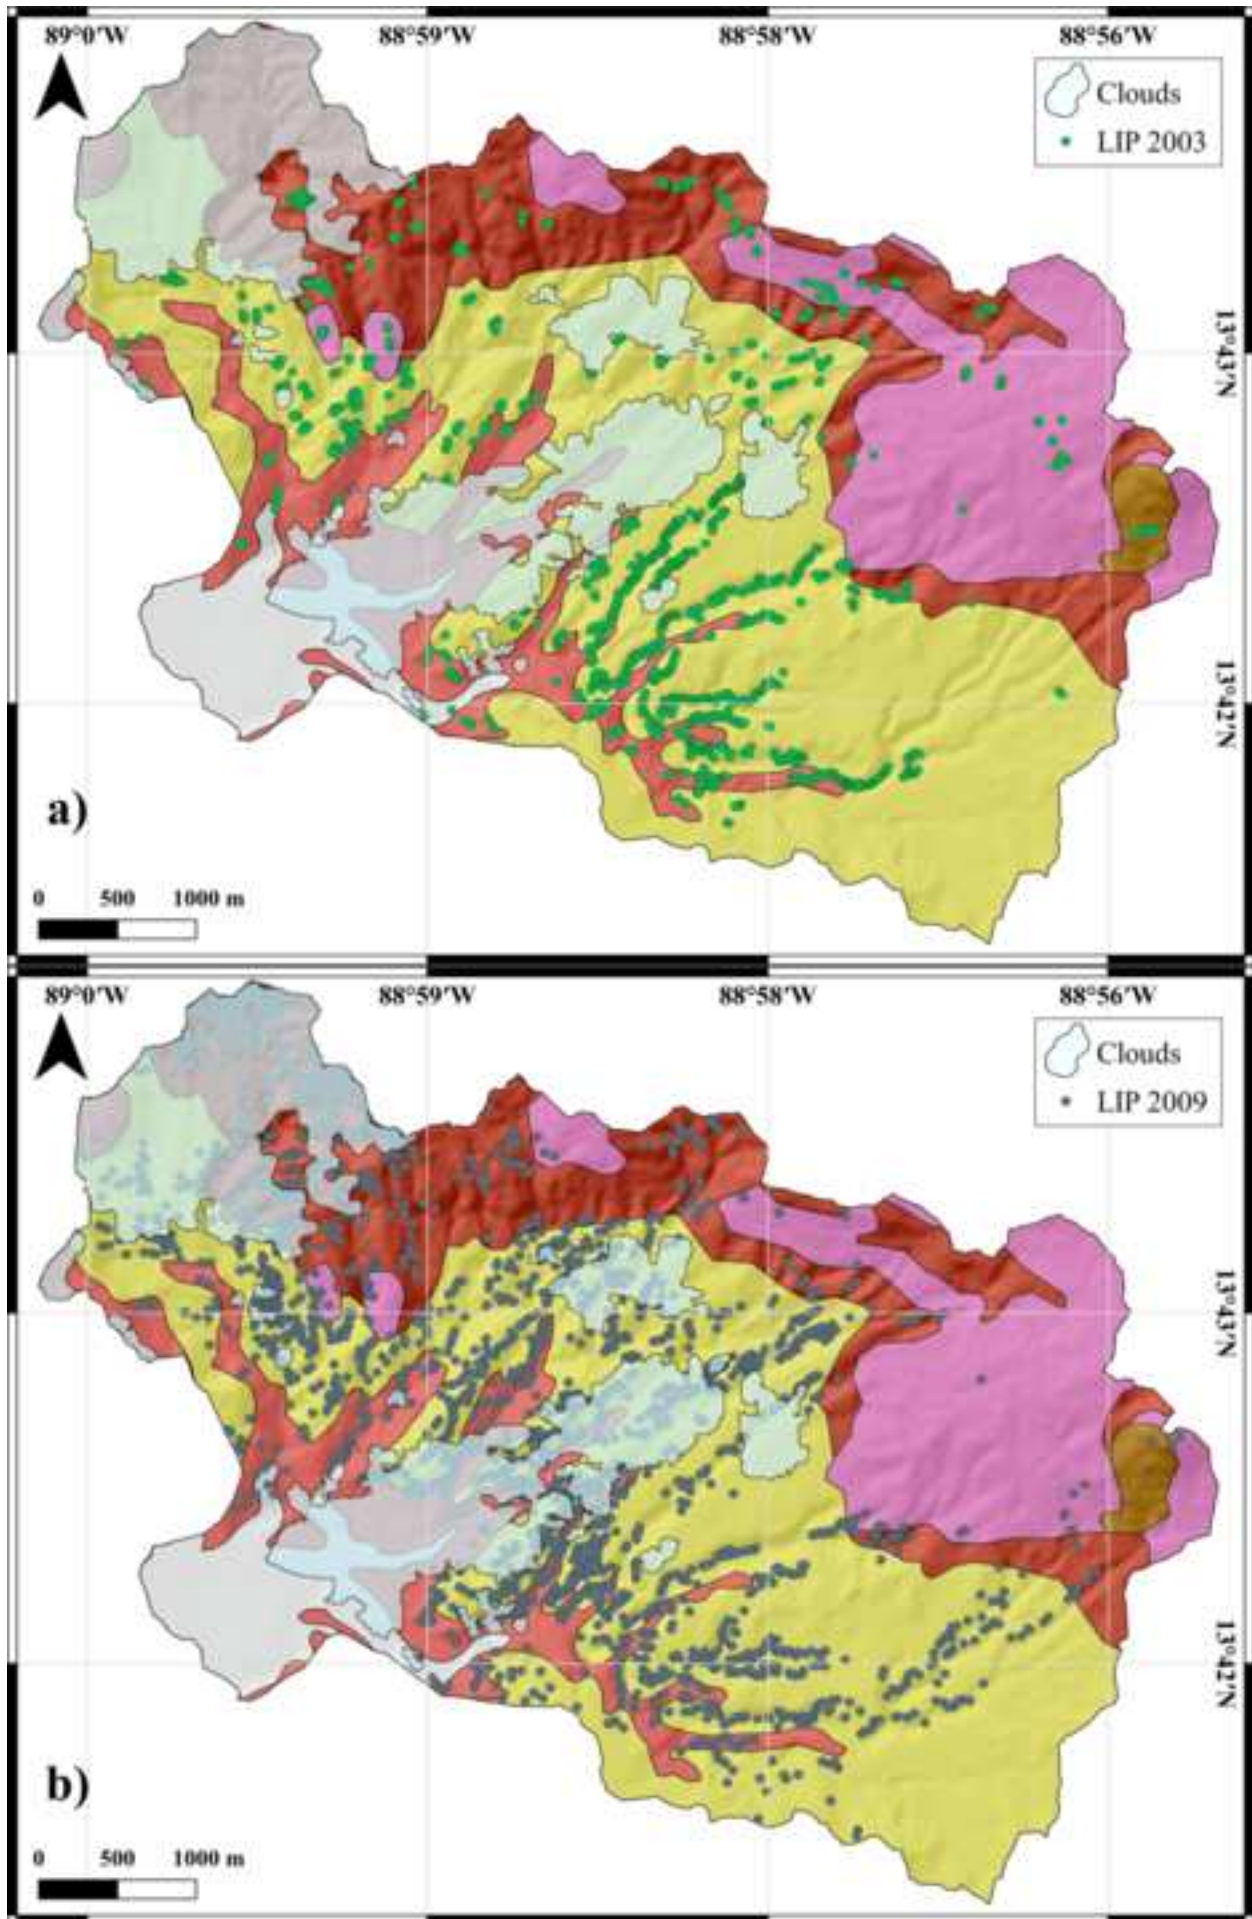

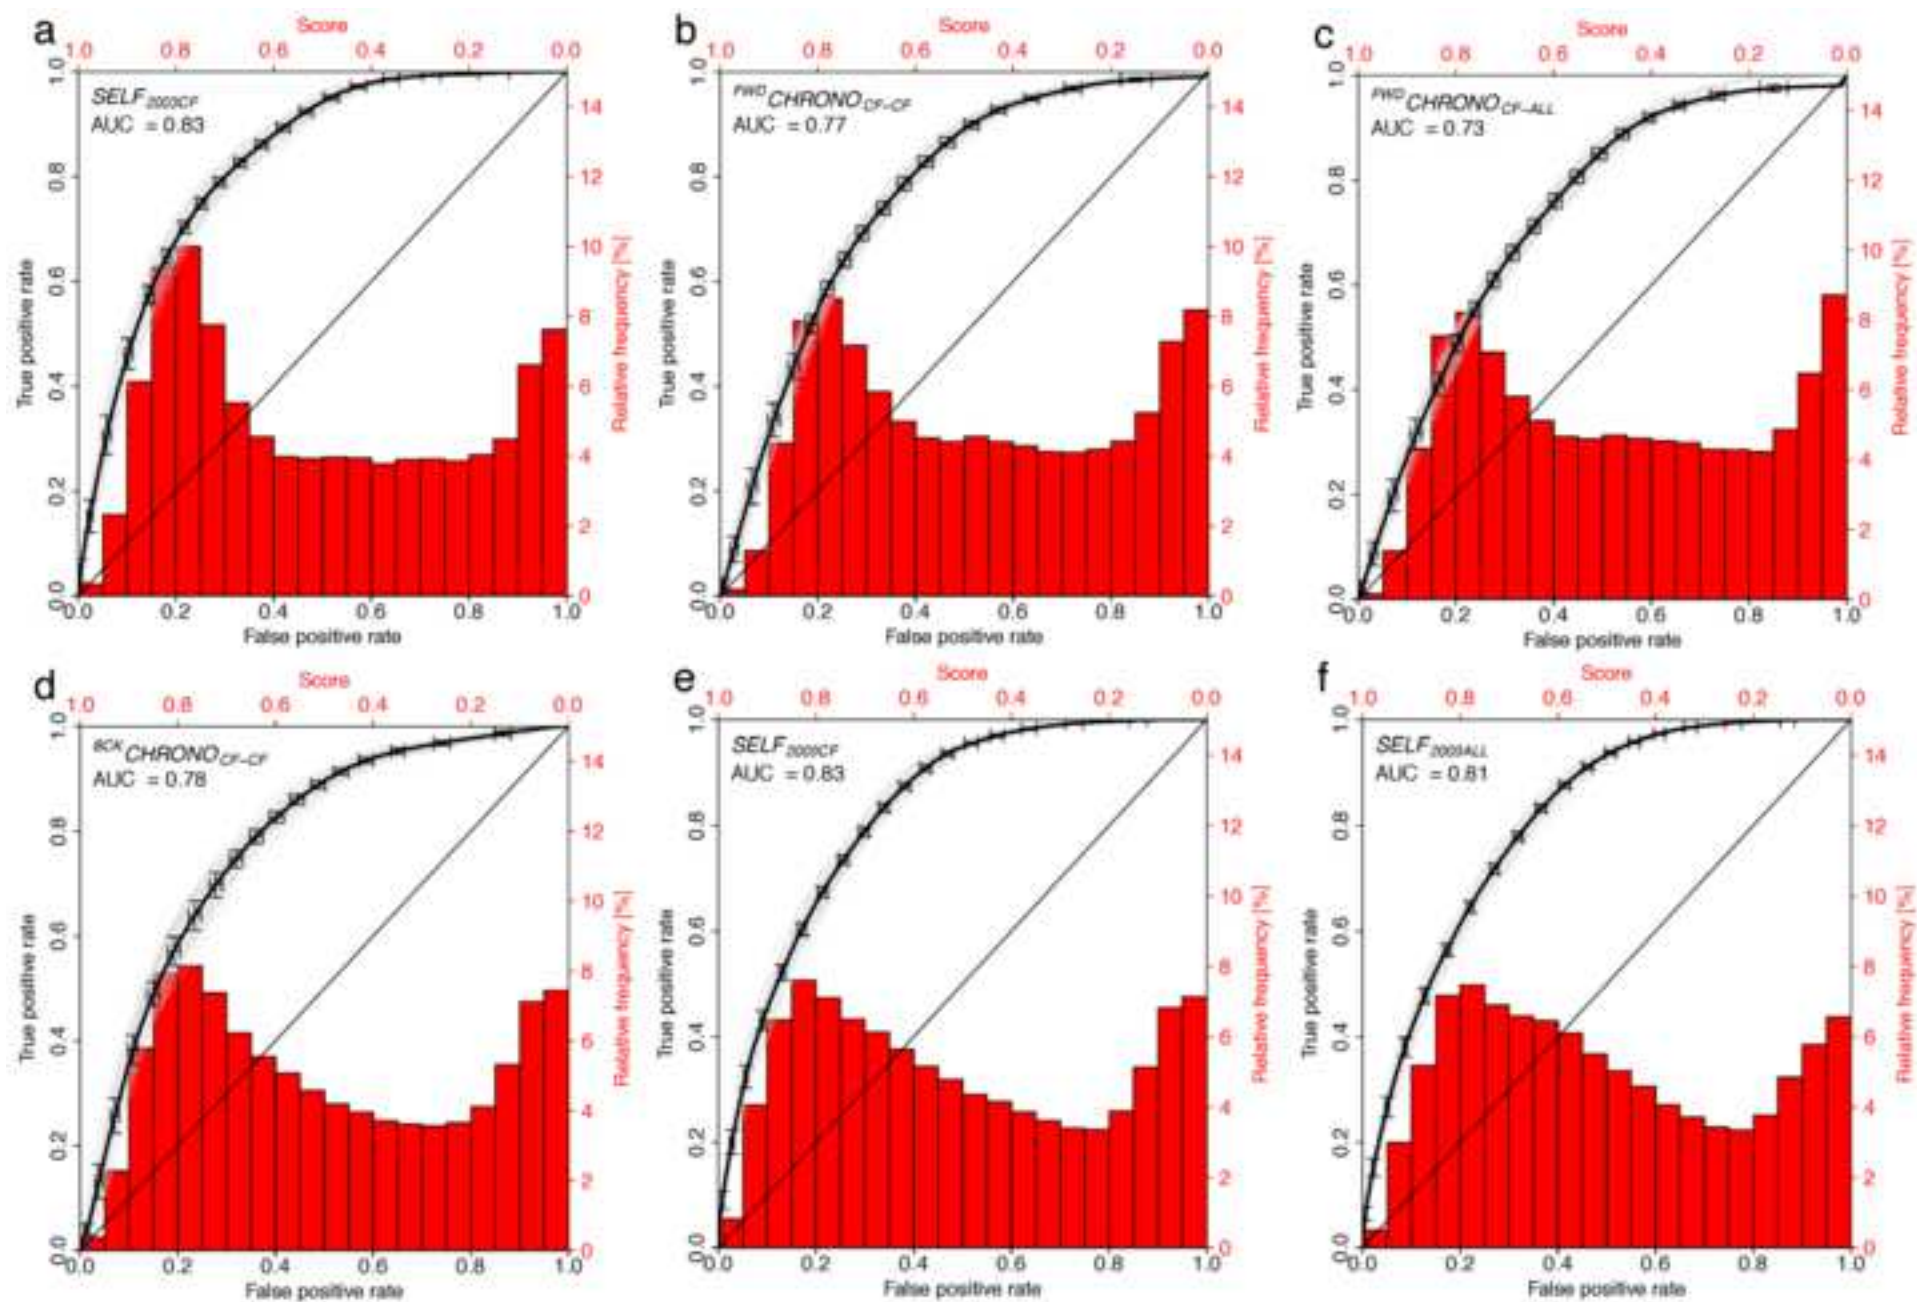

<i>Factor</i>	<i>Source layer</i>	<i>Description of source parameter</i>	<i>Units</i>	<i>References</i>
LCL	Landform classification	Outcome of an automated procedure that recognise landforms on a gridded elevation distribution (TPI)		Wilson and Galland 2000
STP	Slope gradient	Highest first derivative of elevation	degree	Burrough and McDonell 1998
ASP	Slope aspect	Direction of steepest downwards slope from each cell to its neighbours	degree	Wilson and Galland 1996
PLN	Plan curvature	Second derivative of elevation, computed along the horizontal plane	rad/m	Zevenbergen and Thorne 1987
PRF	Profile curvature	Second derivative of elevation, computed along the direction of the highest slope gradient	rad/m	Zevenbergen and Thorne 1987
TWI	Topographic wetness index	Calculated as $\ln[A/\tan\beta]$ , where A and $\beta$ , computed on each cell, correspond to the area of upslope drained cells and the slope gradient, respectively	m	Beven and Kirkby 1979
TRI	Terrain Ruggedness Index	Topographic height difference of a cell compared to the adjacent ones	m	Riley et al. 1999

Tab. 1 – List of the DEM-derived predictors.

<i>Factor</i>	<i>Source layer</i>	<i>Classes of the variable</i>
LCL	Landform classification	LCL_1 (Streams)
		LCL_2 (Midslope Drainages)
		LCL_3 (Upland Drainages)
		LCL_4 (Valleys)
		LCL_5 (Plains)
		LCL_6 (Open Slopes)
		LCL_7 (Upper Slopes)
		LCL_8 (Local Ridges)
		LCL_9 (Midslope Ridges)
		LCL_10 (High Ridges)
ASP	Slope aspect (degree)	ASP_flat (-1)
		ASP_N (North: 0-22.5 337.5-360)
		ASP_NE (NorthEast: 22.5-67.5)
		ASP_E (East: 67.5-112.5)
		ASP_SE (SouthEast: 112.5-157.5)
		ASP_S (South: 157.5-202.5)
		ASP_SW (SouthWest: 202.5-247.5)
		ASP_W (West: 247.5-292.5)
ASP_NW (NorthWest: 292.5_337.5)		
LIT	Lithology	LIT_Qf (Quaternary sedimentary deposits)
		LIT_s4 (Pyroclastics of "Tierra Blanca")
		LIT_s5b (Accumulation cones)
		LIT_c1 (Acid pyroclastics)
		LIT_c2 (Acid effusive)
USE	Land use	LIT_b3 (Basic-intermediate effusive rocks)
		USE_1 (Wood)
		USE_2 (Crop cultivation)
		USE_3 (Vegetables cultivation)
		USE_4 (Crop cultivation and pasture)
USE_5 (Pasture cultivation)		

	USE_6 (Pasture)
	USE_7 (River)
	USE_8 (Continuous urban fabric)
	USE_9 (Discontinuous urban fabric)
	USE_10 (Precarious urban fabric)
	USE_11 (Growing urban fabric)
	USE_12 (Low shrubs)
	USE_13 (Mine areas)
	USE_14 (Uncultivated areas)

Tab. 2 – List of the categorical predictors.

MOD.	VALIDATION SCHEME	CALIBRATION	VALIDATION	DATASET	REPLICATES
A	<i>SELF</i> <sub>2003CF</sub>	2003 <sub>CF</sub> RND(90%)	2003 <sub>CF</sub> RND(10%)	10-folds cross-validation	100
