Introduction In elite Team Handball, the physical capacity of the players has a crucial influence on playing performance. The central areas of physical training seem in general to be the same for male and female players, however physical demands may yet vary among the sexes. Therefore, the present study examined possible differences in physical demands between male and female elite TH players, which were closely monitored over a six and five season time span, respectively. Methods Each player was evaluated during match-play using video recording and subsequent computerized locomotive and technical match analysis. Further, physiological measurements during match-play, physical testing and anthropometric measurements were also carried out. Results Women ( $n=83$ ) performed a longer mean total distance covered (TDC) per match ( $4002 \pm 551$  m) (group means  $\pm$  SD) compared to men ( $n=83$ ) ( $3627 \pm 568$  m,  $p < 0.05$ ) despite less mean total effective playing time (TPT) ( $50.70 \pm 5.83$  min vs.  $53.85 \pm 5.87$  min). Women spent substantial less time standing still ( $10.8 \pm 3.8$  % of TPT per match) compared to men ( $36.9 \pm 8.6$  %,  $p < 0.001$ ) and worked with a greater mean relative physical load (RWL,  $79.4 \pm 6.4$  % of  $VO_2$ -max) than men ( $70.9 \pm 6.0$  % of  $VO_2$ -max,  $p < 0.05$ ). Women performed less amount of high-intensity running per match ( $2.6 \pm 1.8$  % of TDC) compared to men ( $7.9 \pm 4.9$  %,  $p < 0.01$ ) and also had markedly fewer number of activity changes ( $663.6 \pm 100.1$ ) than men ( $1482.4 \pm 312.6$ ,  $p < 0.001$ ). Men performed a higher number of high-intense playing actions per match ( $36.9 \pm 13.1$ ) than women ( $28.3 \pm 11.0$ ,  $p < 0.05$ ). In offence, men received more tackles ( $34.5 \pm 11.2$ ) and gave more tackles ( $29.9 \pm 8.2$ ) while in defence compared to women ( $14.6 \pm 5.7$ ,  $20.7 \pm 6.1$ ,  $p < 0.05$ ). Mean body height and body mass in the Danish Premier Team Handball League was significantly higher for men ( $189.6 \pm 5.8$  cm,  $91.7 \pm 7.5$  kg) compared to women ( $175.4 \pm 6.1$  cm,  $69.5 \pm 6.5$  kg,  $p < 0.001$ ). Identical positional differences in the physical demands were demonstrated irrespectively of gender, with wing players performing more high-intensity running and less physical confrontations than backcourt players and pivots ( $p < 0.01$ ). Conclusions In conclusion, substantial gender-specific differences in the physical demands were observed, where male elite TH players performed more high intense, strength-related actions and more high-intensity running than female elite TH players. Conversely, female players covered a greater total distance and worked with a higher RWL than their male counterparts. Consequently, female players should therefore focus relative more on aerobic training and relative less on anaerobic training and strength training. In both genders, wing players performed more high-intensity running and less physical confrontations than all other players. The planning of the physical training in both sexes should be directed at the specific playing position and the players' individual physical capacity.

**REPETITIVE SPRINT ABILITY IN ELITE ICE HOCKEY PLAYERS**

Tschopp, M.

*Swiss Federal Institute of Sports Magglingen*

Repetitive sprint ability in elite ice hockey players Tschopp, M1, Zryd, A2, Gassmann, N2, Bolszak, S2, Reinhard, A1 1: Swiss Federal Institute of Sports (Magglingen, Switzerland); 2: Swiss Ice Hockey Association (Zürich, Switzerland) Introduction: The repetitive sprint ability (RSA) is an important physical factor for ice hockey players (Noonan, 2010). However, there exists no validated test analyzing RSA in ice hockey players that mimics the actual work to recovery ratio of the game. The aim of the present study was twofold: 1) to explore whether an on-ice repetitive sprint test with a hockey-specific work to recovery ratio is able to discriminate between hockey players of different performance levels; and 2) to evaluate the relationship between the hockey-specific RSA, and aerobic and anaerobic fitness. Methods: 12 professional elite ice hockey players (PROF;  $25.4 \pm 2.4$  J.;  $90.1 \pm 5.9$  kg;  $184.6 \pm 4.1$  cm), and 15 non-professional elite ice hockey players (N-PROF;  $23.9 \pm 4.4$  J.;  $84.4 \pm 8.5$  kg;  $181.1 \pm 5.5$  cm) completed a repetitive shuttle sprint test (RISST) with full equipment on ice. The test includes 3 series of 4 all-out sprints with a  $180^\circ$  turn ( $2 \times 15$  m). Every 20 seconds, the players would begin the next sprint. Between the series, there was a 4 minute recovery period of 3 minutes. Within 3-7 days after the RISST the participants performed a  $VO_2$ max-test on a cycle ergometer, a Wingate-Test (WINGATE) and a jump test on a force plate (JUMP) in the laboratory. For statistical analysis, Cohen's effect size (ES), unpaired t-Test and Pearson's correlation coefficient were used ( $p < 0.05$ , \*). Results: Significant differences between PROF and N-PROF

were found for total sprint time (PROF 43.98±1.19 vs. N-PROF 44.99±1.08sec; ES 0.89, p=0.03), and for the sprint time of the second (ES 1.09, p=0.01) and third RISS series (ES 0.78, p=0.05). No relevant difference was found for the best RISS sprint time (3.40±0.11 vs. 3.43±0.10sec, ES 0.29). Only moderate to small ES were obtained in the laboratory tests with the smallest difference between PROF and N-PROF in VO2max (57.8±4.2 vs. 56.7±6.4ml/ kg min; ES 0.21; WINGATE Mean Power: ES 0.66; JUMP Peak Power: ES 0.73). Total RISS sprint time moderately correlated with WINGATE Mean Power (r=0.54\*) and JUMP Peak Power (r=0.55\*). VO2max significantly correlated with the decrement of the sprint time between series (r= - 0.50\*) but not with RISS total sprint time (r=0.38). Discussion: The RSA measured with a repeated shuttle sprint test on-ice with a hockey-specific work to recovery ratio is able to discriminate between ice hockey players of different performance levels to a greater extent than a single shuttle sprint or classic laboratory fitness tests. The hockey-specific RSA shows associations with anaerobic performance and anaerobic capacity. VO2max seems to have its importance in the ability to recover between series. References: 1. Noonan, B. ## QUANTIFICATION OF TACKLING DEMANDS IN ELITE AUSTRALIAN FOOTBALL USING INTEGRATED WEARABLE ATHLETE TECHNOLOGY

Gastin, P.1, Breed, R.2, McLean, O.1, Spittle, M.1

*Deakin University*

Introduction Australian football (AF) allows considerable physical contact between players and tackling is considered an important performance indicator in the sport. Despite increases in the speed of the game (Wisbey et al., 2010), the frequency of collisions and the number of shoulder and soft tissue injuries in AF (Orchard & Seward, 2010), no data is available to describe the nature and impact forces associated with tackling. This study categorised tackles into low, medium and high intensity using video technology as a criterion measure and then described and compared speed and accelerometer data between tackle groups. Methods Data was collected from twenty professional AF players during four in-season games. All tackles made by the player and those against the player were coded and time stamped at the point of contact (Sportscode v8.4, Sportstec, Australia) and then categorised into low, medium and high intensity impact groups based on defined criteria before further analysis of the data. Peak and mean GPS and accelerometer data (MinimaxX S4, Catapult Innovations, Australia) were collected at the point of contact and during a 3 s tackle zone (from 1 s before to 2 s after impact), respectively. Two-way analysis of variance was used to assess differences (p < 0.05) between tackle type (made and against) and tackle intensity. Results A total of 173 tackles made (low = 68, medium = 100, high = 5) and 179 tackles against (low = 47, medium = 118, high = 14) were recorded, with an average of 88 tackles per game and 7 tackles per player per game. No significant differences were observed between tackles made and against. Significant differences were found between all tackle intensity groups for peak and mean accelerometer g force (forwards, sideways, upwards and their resultant [3D load]) and velocity data. Peak velocity was significantly greater in high (mean ± SD; 18.2 ± 4.8 km/h) compared to medium (13.9 ± 5.3 km/h) and low intensity (10.1 ± 3.3 km/h) tackles. Peak 3D load was significantly greater in high (7.8 ± 1.3 g) compared to medium (4.9 ± 1.4 g) and low intensity (4.1 ± 1.3 g) tackles. Discussion High intensity tackles, although less frequent in AF, are significantly greater in speed of movement at contact and in the force of impact compared to tackles of lower intensity. Differences in accelerometer forces between tackles observed to be progressively greater in intensity suggest a level of environmental validity and provide preliminary support for the use of accelerometers to assess player load in field team sports. #### EFFECT OF RUNNING INTENSITY ON EXPRESSION OF MICRORNA-124 AND NRSF/REST IN THE HIPPOCAMPUS OF ADULT MALE RATS

Mojtahedi, Sh.1, Kordi, M.2, Soleimani, M.3, Hosseini, S.4, Fallah Omran, S.5, Shabkhiz, F.6

*Faculty of Physical Education and Sport Sciences, University of Tehran.1,2,5,6. Faculty of Medical Science, Tarbiat Modares University.3, The Islamic Azad University - Sabzevar Branch.4*

Introduction Sets of combinatorially expressed Transcription factors (TFs) and microRNAs precisely delineate individual cell types (Conaco et al., 2006). Recently has been shown that these elements play a crucial role in major cellular processes such as development and differentiation through post-transcriptional regulation. There is some evidence that miR-124 and NRSF/REST are involved in regulation of the transition from progenitor to mature neuron (Cheng et al., 2009). Our goal was examine the effect of the intensity of treadmill running on expression of miR-124 and REST in the hippocampus of adult male rat. Methods 18 adult male vistar rats following 1 week of familiarization with treadmill were randomly divided into three groups of control(n=6) and runner(n=6). In low intensity group (n=6), animals daily, were allowed to run on treadmill at a speed of 11 m/mni for 30 minutes, for 2 weeks. In high intensity group(n=6) the subjects were ran in the same conditions but at a speed of 25m/min. After 24 hours of the last session of exercise, the animals were sacrificed and the hippocampus of both side of hemisphere rapidly dissected out on ice cold PBS and flash frozen in -70 °C until processing for RNA purification. Changes in expression analyzed using the quantitative RT-PCR technique(Livak and Schmittgen., 2001 ). Results One way analysis of variance (ANOVA) and least significant difference (LSD) post hoc tests showed significant differences for expression of miR-124 between low intensity group and high intensity group related to control group (p≤0.05 ) so expression of miR-124was elevated in both of groups.Also observed significant reduced for expression of REST between low intensity group and high intensity group related to control group (p≤0.05)The elevation and reduction in high intensity group were more vigorous than the low intensity group. Discussion Expression of miR-124 and REST, in the hippocampus of adult rats, is associated with exercise intensity and running in higher intensity in comparison with lower intensity, leads to robust changes in some mechanisms that involve in exercise- induced neurogenesis. ### CAPN2 MEDIATED BREAKDOWN AND DISASSEMBLY OF MYOFIBRIL-CYTOSKELETAL PROTEIN COMPLEXES WITH EXERCISE

Belcastro, A.

*York University*

Angelo N. Belcastro<sup>1,2</sup>, Chad G. Ball<sup>1</sup> and Tracie Albisser<sup>1</sup>. School of Human Kinetics<sup>1</sup>, University of British Columbia, Vancouver, B.C., Canada, V6T 2B5 and School of Kinesiology and Health Science<sup>2</sup> and Muscle Health Research Centre, York University, Toronto, On, Canada, M3J 1P3. Introduction Several reports associating skeletal muscle exercise damage with increased calcium and calpain (CAPN2) activity exist; however evidence quantifying protein modifications and subsequent release from myofibril-cytoskeletal (MY-CY) complexes at rest and following exercise are scarce. The purpose of this study was to test the hypothesis that exercise will increase the rate of breakdown and release (i.e., disassembly mediated by CAPN2) of selected MY-CY proteins (i.e., desmin,  $\alpha$ -actinin, tropomyosin (TM) and myosin-binding protein C (MyBP-c)). Methods Rats were assigned to a control (n=8) and run exercise (n=8) group (25m/min; -160 grade). Following exercise purified MY-CY complexes (plantaris muscles) were subjected to proteolysis with purified CAPN2 (1.5U/40ug). The amount of protein remaining (% of total) was quantified at 30, 60, 300, 900 and 1800 seconds of proteolysis for desmin,  $\alpha$ -actinin, TM and MyBP-c normalized to actin. As well estimates of first order exponential rate constants (k) were measured. All parameters were tested using student t-test and/or ANOVA (SPSS) at a p=0.05. Results Rats ran for 45±4 minutes with a 2-fold increase in plasma creatine kinase activity (p<0.05) and 50-70% reduction in muscle glycogen (p<0.05). MY-CY protein yield was lower after exercise (65±5 vs 59±6 mg/g); as were the relative amounts of desmin (↓81%),  $\alpha$ -actinin (↓33%), TM (↓7%) and MyBP-c (↓13%). Following 30 minutes of CAPN2 digest the amount of desmin,  $\alpha$ -actinin, TM and MyBP-c remaining in MY-CY from control were 0%, 51%, 14% and 38%, respectively; the amount of protein remaining in exercise samples for each protein were 0%, 46%, 11% and 32% (p>0.05). Exponential rate constants (k) estimated for control and exercise showed that desmin (fastest) > TM > MyBP-c >  $\alpha$ -actinin (slowest) (p<0.05). Exercise was associated with an increase in k for  $\alpha$ -actinin (0.35 vs 0.52) and MyBP-c (0.97 vs 1.41) (p<0.05), with minimal differences for desmin and TM (p>0.05). Discussion The results support the hypothesis that there are selective proteolytic rates (k) and an order sequence of MY-CY protein breakdown. That a constant amount of CAPN2 activity is associated with different rates of proteolysis during exercise, points to the need to assess factors contributing to the heterogeneity of protein breakdown. Susceptibility of MY-CY proteins to CAPN2 degradation (k values) revealed that spatial arrangements and/or protein modifications, but not protein size, are implicated with exercise response. Supported by NSERC Canada

### AEROBIC TRAINING IN URBAN AND RURAL ENVIRONMENT: EFFECTS ON BRAIN-DERIVED NEUROTROPHIC FACTOR, INFLAMMATORY MARKERS AND COGNITION.

Bos, I.1,2, Vanparijs, J.1, De Boever, P.2,3, Pattyn, N.4, Int Panis, L.2,5, Meeusen, R.1

1, 4: *Vrije Universiteit Brussel (Brussels, Belgium)*; 2: *Flemish Institute for Technological Research (VITO) (Mol, Belgium)*; 3, 5: *Hasselt University (Diepenbeek, Belgium)*

Introduction: Particulate Matter (PM) exposure is linked to inflammation and cognitive decline (Calderón-Garcidueñas et al., 2011), while aerobic training improves cognition (Masley et al., 2009). It was found that Brain-Derived Neurotrophic Factor (BDNF) is a key mediator of the mechanism (Vaynman et al., 2004). Previously, the exercise-induced increase in BDNF serum level was not present after cycling near a busy road (Bos et al., 2011). The aim is to investigate effects of PM exposure during aerobic training on inflammatory biomarkers, BDNF in serum and cognitive performance. Methods: Two groups of inactive volunteers completed an aerobic training program of 12 weeks, 3 sessions/week, one group (n = 15) in an urban, another group (n = 9) in a rural environment. Ultrafine Particle (UFP) concentrations were measured during each training session. Before and after the program fitness levels (Cooper test), BDNF serum levels, blood leukocyte count, exhaled NO (eNO) and cognitive performance (Stroop task, Operation Span, Psychomotor Vigilance Task) were analyzed. Results: UFP concentrations were significantly higher in urban compared to rural environment (p = 0.003). Fitness levels improved (p < 0.0001) in both groups equally (p = 0.16). Leukocyte count (p = 0.022), and eNO (p = 0.003) increased after training in the urban group, whereas eNO (p = 0.85) and leukocyte count (p = 0.47) did not differ in the rural group. Reaction times in the Stroop task improved after training in a rural environment (p = 0.001), but not after training in urban environment (p = 0.58). No effects were found on BDNF levels, Operation Span and Psychomotor Vigilance test performances. Discussion: Aerobic training in urban environment with high traffic - related air pollution increased inflammatory biomarkers and, in contrast to aerobic training in rural environment, cognition did not improve. ### FLOOD-PRIMED CONTINUOUS TRACER INFUSION ALLOWS APPLICATION OF A SINGLE BIOPSY APPROACH FOR DETERMINATION OF MUSCLE PROTEIN FRACTIONAL SYNTHESIS RATE

Reitelseder, S., Dideriksen, K.J., Nielsen, R.H., Holm, L.

*Institute of Sports Medicine Copenhagen*

Introduction Muscle protein fractional synthesis rates (FSR) are measured by administering an amino acid stable isotope tracer as a primed continuous intravenous infusion. The prime serves to immediately obtain the target enrichment in the circulating pool of free tracee. Followed by a continuous infusion, time (e.g. 90 min) has to elapse for enrichment equilibration between circulating and intracellular compartments. Calculations of FSR rely on collection of muscle proteins at two distinct time points during the infusion period. Delta abundance of incorporated tracer is divided by an appropriate precursor's enrichment and the incorporation time. To shorten the time for tracer equilibration in all free tracee pools, the flooding approach has been introduced and validated. However, the flooding protocol allows only a limited tracer incorporation time. The single-biopsy protocol has also been introduced with the primed continuous infusion protocol, which, however, challenges some assumptions underlying the FSR calculations. Unsatisfied with these protocols, we aimed to create a flood-primed continuous tracer infusion protocol that allowed use of a single-biopsy approach and a prolonged incorporation

time. Methods Protocol I: 7 young males were given flood-primed (8.96 mmol, enriched 12.5% tracer/tracee ratio (TTR)) continuous (8  $\mu\text{mol}\cdot\text{kg LBM}^{-1}\cdot\text{h}^{-1}$ ) infusions of L-[ring- $^{13}\text{C}_6$ ]PHE, and muscle biopsies were obtained after 10, 30, 60, 120, and 360 min. Protocol II: To investigate if the PHE flood-prime affected the FSR, 5 other young males were given primed (9  $\mu\text{mol/kg LBM}$ ) continuous (9  $\mu\text{mol}\cdot\text{kg LBM}^{-1}\cdot\text{h}^{-1}$ ) infusions of L-[1,2- $^{13}\text{C}_2$ ]LEU from 0 to 480 min. After 120 and 300 min muscle biopsies were obtained to determine FSR. Hereafter, PHE flood-primed of 9.09 mmol, enriched 7% TTR with L-[15N]PHE was given followed by continuous infusions (8  $\mu\text{mol}\cdot\text{kg LBM}^{-1}\cdot\text{h}^{-1}$ ) of unlabeled PHE to mimic protocol I. A third muscle biopsy was obtained at 480 min to determine FSR during 3 h following the flood-prime. Results Protocol I: At 10, 30, 60, 120, and 360 min muscle free PHE enrichment were  $6.98\pm 0.70\%$ ,  $6.87\pm 0.71\%$ ,  $6.42\pm 0.58\%$ ,  $6.58\pm 0.70\%$ , and  $6.23\pm 0.81\%$  TTR, respectively. Protocol II: Myofibrillar FSR was  $0.079\pm 0.006\%$  /h and was unaffected by the PHE flood-primed continuous infusion ( $0.068\pm 0.009\%$  /h,  $p>0.05$ ). Discussion The flood-prime quickly introduced the PHE tracer into the intramuscular pools and secured the essential assumptions for the application of the single-biopsy approach in combination with the use of the continuous infusion approach, and, importantly, PHE administration did not affect muscle FSR.

### THE EFFECTS OF DIET RESTRICTION AND TREADMILL RUNNING EXERCISE ON EXPRESSION OF MCP-1 AND OXIDATIVE STRESS MRNA OF EPIDIDYMAL ADIPOSE TISSUE IN OBESE MICE

Ahn, N.

*Keimyung University*

THE EFFECTS OF DIET RESTRICTION AND TREADMILL RUNNING EXERCISE ON EXPRESSION OF MCP-1 AND OXIDATIVE STRESS mRNA OF EPIDIDYMAL ADIPOSE TISSUE IN OBESE MICE Ahn, N.1, Kim, K.1, Ko, J.1, Byun, J.1, Park, K.1, Kim, H.2, Chang, I.3 1: KMU (Daegu, Korea), 2: KMC (Daegu, Korea), 3: CUD (Daegu, Korea) Introduction Monocyte chemoattractant protein (MCP)-1 chemotactically recruits monocytes to sites of inflammation. This protein is traditionally thought to be expressed mainly by endothelial cells and macrophages (Zhu et al., 2008). However, it has recently been shown to be primarily expressed by adipose tissues. Therefore, this study analyzed the expression of MCP-1, HIF-1 $\alpha$ , NOX2, ERK1&2, and Mn-SOD mRNA of WAT induced high-fat diet obese mice. Methods Subjects were 44 four-week-old C57BL/6 mice. Obesity is induced using a high-fat diet (45% fat) for five weeks. And this study examined the effects of diet restriction and treadmill running exercise for eight weeks on the changes of MCP-1 and oxidative stress mRNA in epididymal adipose tissue. Results A high-fat diet for 13 weeks, HFD-DR group showed a significant higher ( $p<0.001$ ) expression MCP-1 mRNA than ND group and HFD group. After treadmill exercise and diet restriction, HFD-DR group showed a significant higher ( $p<0.01$ ) expression MCP-1 mRNA than Non-EX group and Ex group. And Ex group showed a significant lower ( $p<0.05$ ) expression HIF-1 $\alpha$  mRNA than Non-Ex group. Also, Non-Ex-HFD-DR group showed a significant lower ( $p<0.05$ ) expression NOX mRNA than Non-Ex-HFD group. And Ex-HFD-DR group showed a significant lower ( $p<0.01$ ) expression ERK2 mRNA than Non-Ex-HFD-DR group. Discussion This study shows that treated by exercise have a significant decrease in HIF-1 $\alpha$  and ERK2 mRNA. Especially, MCP-1 mRNA showed a significant decrease in exercise and diet restriction. Antioxidant effects and improvement of hypoxia through exercise can significantly reduce the expression of MCP-1 in WAT (Sakurai et al., 2009). It could be suggested the positive effects of exercise training on obesity by the changes of MCP-1 mRNA expression and oxidative stress. ## Invited symposia

### IS-PM03 Sports Nutrition Symposium: Sports Nutrition offered by Mother Earth sponsored by GSSI

#### BERRIES AND CHERRIES

Bowtell, J.

*Exeter University*

Cherries and berries and other fruits and vegetables are rich in a variety of phytochemicals such as flavonoids and anthocyanins. These biologically active compounds may underpin the reductions in clinical condition and mortality risk associated with fruit and vegetable consumption that is evident from epidemiological studies. For instance, the health benefits associated with consumption of the Mediterranean diet may at least in part rely upon the flavonoid content of dietary components such as olive oil, red wine, and tomatoes. Many of the phytochemicals including flavonoids and flavonols are vasoactive inducing vasodilatation via a nitric oxide dependent mechanism, and epidemiological evidence suggests that high dietary anthocyanin intakes reduce the relative risk for hypertension. Cherries, in particular sour or montmorency cherries, which are rich in anthocyanins also possess antioxidant and anti-inflammatory properties. Consumption of montmorency cherry juice prior to and following intensive exercise has consistently been shown to enhance the acute recovery of muscle function most likely through reduced oxidative damage and inflammation. Similar evidence is also emerging for other fruits and berries such as blueberries and pomegranate. The usefulness of chronic supplementation to support training adaptation, however, remains uncertain; although evidence from rodent studies is tantalisingly positive. Phytochemicals provided by Mother Earth offer great potential as key nutraceuticals of the future.

#### GREEN TEA

Hodgson, A.

*University of Birmingham*

Green tea (GT) is made from the leaves of the *Camellia sinensis* L plant which is rich in polyphenol catechins and caffeine. For some time now there has been an increasing interest in the capacity of GT to oxidise fats and promote weight loss which in turn may improve body composition, health and exercise performance. As a result, GT has become a popular dietary supplement on the sports nutrition market, especially as a fat burner and weight loss tool. Long term GT intake, in some but not all cases, has been shown to promote weight loss. It is believed that the anti-obesity effects of GTE intake may be attributed to elevated fat oxidation and total energy expenditure. In support

of this, it has been shown that in a number of cases, GT intake (short term and long term) at rest and during exercise may increase energy expenditure and fat oxidation. Although several studies have observed positive effects the literature is inconclusive. The precise dose, duration of intake, and population that elicit maximal effects are currently unknown. In addition the bioavailability of GT catechins in vivo and the subsequent bioactivity is less well understood. In humans, the bioavailability of GT following intake determines the bioactivity. GT catechins (parent compounds) are extensively metabolised (conjugated compounds) in the gut and liver, poorly absorbed and are found in low concentrations in vivo. The emergence of -omic technology is a new technique that can identify the interaction between the metabolic effects of GT and the association to the specific GT catechins following ingestion in vivo. This firstly will advance our understanding of GT bioavailability and bioactivity, but also provide support and comparison to the putative in vitro mechanisms. At present the precise mechanisms of GT and site of action are unclear. However the mechanisms behind the effects of long term GT may be different than those that explain the short term effects of GT. Short term intake of GT is thought to inhibit catechol-O-methyltransferase (COMT) in vitro, while caffeine is thought to inhibit phosphodiesterase (PDE) in vitro. Both of these mechanisms may act synergistically to increase lipolysis. Alternatively long term GT intake may involve changes in expression of specific fat metabolism genes, which have been supported only by animal data. Both mechanisms lack the use of GT catechin compounds and concentrations similar to what is observed in vivo as well as supporting human studies. Therefore the mechanisms of GT remain speculative. While GT may offer promising benefits to body composition, health and exercise performance, the lack of consistent evidence means that practical application of GT intake is currently not possible. Despite this, GT supplements are frequently used.

## BEETROOT AND OTHER SOURCES OF NITRATE

Jones, A.

*Exeter University*

Recent studies have addressed the influence of dietary nitrate supplementation on the physiological responses to exercise. We have shown that enhancing nitric oxide (NO) bioavailability through supplementation of the diet with nitrate-rich beetroot juice reduces resting blood pressure and the O<sub>2</sub> cost of exercise and improves exercise performance. Specifically, we found that 4-6 days of nitrate supplementation (0.5 L of beetroot juice per day containing ~ 6 mmol nitrate) reduced the steady-state O<sub>2</sub> cost of sub-maximal cycle exercise by 5% and extended the time-to-exhaustion during high-intensity cycling by 16%. These effects were highly surprising given that the O<sub>2</sub> cost of sub-maximal exercise has been considered to be essentially fixed. We and others have subsequently confirmed these findings in other populations and with different exercise modalities. The positive effects of nitrate supplementation on the O<sub>2</sub> cost of sub-maximal exercise can be manifest acutely (i.e. 2.5 h following ingestion) and this effect can be maintained for at least 15 days if supplementation is continued. Because beetroot juice contains compounds other than nitrate that might also be bioactive, we have developed a nitrate-depleted beetroot juice as a placebo. We found that nitrate-depleted juice had no physiological effects relative to a control condition whereas nitrate-rich beetroot juice reduced the O<sub>2</sub> cost of both walking and running and extended the time-to-exhaustion by 15%. These results confirm that nitrate is the key bioactive component of beetroot juice, though it cannot be discounted that other components (such as antioxidants and polyphenols) facilitate the bioconversion of nitrate to NO. Most recently, we and others have investigated the influence of acute dietary nitrate supplementation on time trial (TT) performance in competitive cyclists. These studies have shown a 1-2% reduction in the time to complete TT distances between 4 and 16 km. The dose of nitrate that has been shown to improve exercise efficiency can readily be achieved through the consumption of 0.5 L of beetroot juice (or an equivalent high-nitrate foodstuff). Following a 5-6 mmol bolus of nitrate, plasma [nitrite] typically peaks within 2-3 h and remains elevated for a further 6-9 h before declining towards baseline. Therefore, it is recommended that nitrate is consumed approximately 3 h prior to competition or training. A daily dose of a high-nitrate supplement is required if plasma [nitrite] is to remain elevated. It is presently unclear how sustained dietary nitrate supplementation might impact upon adaptations to training. There is the possibility that uncontrolled high doses of nitrate salts might be harmful to health. In contrast, natural sources of nitrate are likely to promote health. For this reason, it is recommended that athletes wishing to explore possible ergogenic effects of nitrate supplementation employ a natural, rather than pharmacological, approach.

### OP-SH06 Sociology

#### HEALTHY AGING: THE IMPORTANCE OF PLACE AND SPACE

Volkwein-Caplan, K.

*West Chester University of Pennsylvania*

In this presentation the relationship between culture and successful aging will be explored. Theories of aging have proposed that there is a dynamic relationship between the physical and social environment and the quality of the aging experience. The average life expectancy in Western societies is currently 76; one hundred years ago it was 49. One of the most serious economic considerations facing the world in the 21st century is how to cover the cost of health care for an increasing older adult population. Aging is not only a biological phenomena, it is also socially and culturally constructed. Age norms and expectations influence the ways in which later life is lived. Social integration and physical activity are two of the most important factors determining health and well being in later adulthood. Older adults who are able to stay active and maintain their sense of connection with their community have been shown to experience fewer chronic illnesses, experience less unhappiness, dissatisfaction, isolation, anxiety, and depression. Physical activity not only improves and heals the body, but it also influences psychological well-being in later life. Despite the strength of this relationship, only a small percentage of older adults engage in regular exercise. Clearly there are ethnic, social class, and gender differences in physical activity. As the number of older men and women continues to grow, it becomes increasingly important to address health related behaviors such as physical activity and to focus on life styles factors which affect older adults' health and happiness. Drawing from extensive cross-cultural studies conducted in Germany and the USA, the ways in which the social and physical environment can enhance well being and happiness for older men and women will be discussed.

### UNDERSTANDING INTER-INDIVIDUAL PROCESSES IN LOW THRESHOLD 'COMMUNITY' SPORTING CONTEXTS. AN ANALYSIS OF FLEMISH INITIATIVES

Schaillée, H., Theeboom, M.

*Vrije Universiteit Brussel*

Introduction At present, adolescents can engage in a number of sporting contexts, such as: traditional sports clubs, low threshold 'community' contexts (De Knop et al., 1996) and specific 'sport-plus' contexts (Coalter, 2010). It has been indicated that mere participation in sports does not automatically produce developmental experiences, as this largely will depend on how sports programs are delivered (Petitpas et al., 2005). It has been argued that inter-individual processes would directly influence how individuals experience a specific setting, and is therefore critical in order to improve setting outcomes (e.g., developmental experiences, social-psychological outcomes) (Tseng & Seidman, 2007). A study was set up to gain a better understanding of inter-individual processes within several Flemish low-threshold 'community' sporting contexts. Methods A qualitative methodological approach was used for the analysis of three broad dimensions (sport type, relationships, norms), hypothesized to influence inter-individual processes. The three dimensions evolved from several reflections in a number of social sciences. In order to examine these broad dimensions within several Flemish low-threshold 'community' sporting contexts, various setting level-features such as: aims, approaches, and personal experiences of both teachers and co-ordinators were analyzed. Results The analysis allowed more insight with regard to inter-individual processes in several Flemish low thresholds 'community' sporting contexts. Furthermore, results revealed different profiles for the three broad dimensions (sport type, relationships, and norms), which might facilitate different developmental experiences among the youth involved. Discussion The findings have helped to identify key areas for further investigation and intervention, and have contributed to the growing and much needed body of research with regard to inter-individual processes within sporting contexts. We assume that several dimensions might be in a dynamic transition with each other, resulting in specific developmental experiences among the individuals involved. Further research should focus on the impact of inter-individual processes on their sport participants. References Coalter, F. (2007). A wider social role for sport: Who's keeping the score? ### LOVE & HATE. CONSTRUCTING A NARRATIVE

Aage, R.

*Malmö University*

The purpose of this article is to interpret and analyse the concept of football hooliganism as presented in print media and digital media. As a case study I have used an event that occurred during a football match between two men's football teams in the Swedish Allsvenskan. I have analysed the coverage of this event in order to problematise the issue of who is allowed to distinguish between good football culture and hooliganism. Previous studies of old media coverage of hooliganism shows that journalism stigmatises the perpetrators, creates an atmosphere of panic and simplifies the underlying causes. One issue explored in this article is possible differences between descriptions of the event in the old and new media. Some researchers claim that the media landscape has been totally transformed by the new media, and that society is moving into a new, digital age. Others disagree, arguing that the term "new media" is inaccurate, since "new media" are still governed by the same financial, political and cultural forces as the "old media". In order to analyse the media narratives around the event I have used different theoretical approaches. Key words: Sportsmedia, hooliganism, oldmedia, newmedia, masculinity.

### LOST IN THE DESERT WITHOUT A COMPASS: METHODOLOGICAL CHALLENGES OF A NON-MUSLIM/NON-ARAB 'DOING' PHYSICAL ACTIVITY RESEARCH IN THE MIDDLE EAST

Knez, K.

*ASPETAR-Qatar Orthopaedic and Sports Medicine Hospital*

The last decade has seen a resurgence of literature focusing on sport, ethnicity and race, with a small yet growing number of researchers focusing specifically on the intersections of culture and religion. At the same time, there has been an increased focus on the importance of reflexive practice within the social sciences, with a call for researchers to question and deconstruct the authority of the 'author' and power differences within interviews and fieldwork. The anticipated outcome of this reflexive practice is that hidden agendas, values and power differences will be brought to the foreground, allowing the researcher to account for that which shapes the research process. The current author has previously 'engaged' in reflexive practice when conducting research among minority groups within a western context, however it was not until working as a minority in both a foreign country and foreign culture that the real complexity behind reflexive research became salient. This was particularly evident when questions arose surrounding different ways of knowing and ways of living, especially when these did not always align with dominant western belief systems surrounding gender, physical activity and to a lesser extent, social theory. Although anthropologists and ethnographers have been negotiating the challenges of working within different cultures for some time, it is only recently that this has been addressed within the field of sport and physical activity/education (see for example Dowling & Flintoff, 2011). The current paper will therefore provide a critique of reflexive practice as it has been conducted within the physical activity/education and sport literature to date, and re-position this critique within the context of Doha, Qatar. In doing so, the practical challenges of conducting qualitative physical activity research in a country and culture that is vastly different to the researcher's will be explored, and possible solutions or 'ways forward' highlighted. Dowling F, Flintoff A (2011). Qualitative Research in Sport, Exercise and Health, 3(1) 63-79.

### THE PERCEPTION OF MAGHRIBIAN IMMIGRANT ASSOCIATIONS IN CATALONIA ON THE PARTICIPATION OF THE MUSLIM MAGHRIBIAN WOMAN IN PHYSICAL ACTIVITIES

Nasri, K., Soler, S.

*Inefc - Barcelona*

Catalonia is one of the Spanish communities that welcomes more Maghribian population. According to IdesCat data (2010), more than 243,109 Maghribians (Morocco, Algeria and Tunisia) are living in Catalonia, and the 41.72 % are women. In spite of this, among other immigrant women, Muslim Maghribian women (MMW) in Catalonia are characterized by the limited participation within the society

(Cuentas & Vera, 2011). Following Nash (2005), despite the feminization of migration flows, these women remain in silence and invisible. In the field of sports, many studies highlight the low participation of MMW in formal physical activities (PA). However, various experiences and studies show that there are MMW doing sport and interested in it, but mainly in immigrant associations and other entities focused on supporting immigrants (Soler, Gaztelu, & Serra, 2010; Balibrea et al, 2002). Both types of entities are the main destination of immigrant women and their first information point, specially for MMW (Moreras, 2004). These places also offer a range of activities (workshops, language courses...), and become an important point to build and strengthen the bond between the catalonian society and the Maghribian immigrants. This contribution is an attempt to analyze what is the role of these entities in the field of sport and collect the perception of their leaders about MMW participation in sport. ### OP-PM30 Health and Fitness: Female population

#### THE EFFICACY OF PUBLICLY AVAILABLE WEBSITES FOR PHYSICAL ACTIVITY PROMOTION AMONG UNIVERSITY STUDENTS

Leung, F., Wong, H.S., Huang, J.

*The Chinese University of Hong Kong*

Purpose: Despite the numerous health benefits associated with regular physical activity (PA), an obvious decline in PA during the transition from secondary school to university has been reported (Bray & Born, 2004). The purpose of this study was to examine the effectiveness of the public access Internet for promoting PA among university students. Methods: One hundred and sixty-one Hong Kong university students were randomly assigned to one of the three groups, i.e. the public access Internet group (PAI), stage-targeted Internet group (STI), and control group (C). Participants of the PAI group received 5 links of publicly available websites relating to PA. Participants of the STI group received an on-line stage-targeted behaviour change programme entitled "Active Living Every Day (ALED)" (Blair et al., 2001). Group C did not receive any intervention treatment. The assessments of PA level, stage of change and self-efficacy for engaging in PA were conducted at baseline, 3rd month and 6th month after the commencement of the intervention. Three focus group interviews were conducted, a total of 15 participants were interviewed, and qualitative data were collected. Results: Increased PA was found in the STI group at the 3rd month assessment compared with baseline (PA score in MET•minutes/week:  $915.2 \pm 549.5$  Vs  $1359.6 \pm 918.8$ ,  $p < 0.05$ ). Improvements in stage of change ( $P < 0.05$ ) were found in the STI group at the 3rd and 6th month assessments and in the PAI group at the 6th month assessment. Decreased self-efficacy score ( $P < 0.05$ ) was found in the PAI group at the 3rd and 6th month assessments. Qualitative data were also collected. The contents of the public access websites could not arouse the PAI group participants' interest to read through the details and hence did not help in increasing their PA levels and stages of exercise change. The ALED course contents facilitated the STI group participants to increase their PA levels by leading them to set their own exercise goals and by emphasizing the importance and health benefits of regular PA. The ALED course contents had positive influences on stages of exercise changes of the STI group participants. The participants in the PAI and the STI groups did not perceive any positive influences from the intervention contents on their exercise self-efficacy. Conclusion: The results suggested that participants in the PAI group did not demonstrate improvement in PA to the same extent as their counterparts in the STI group. The public access websites were not effective for PA promotion among university students. References: Bray, S. R. & Born, H. A. (2004). #### UNDERSTANDING PHYSICAL ACTIVITY ACROSS THE LIFESPAN IN WOMEN: FINDINGS FROM THE AUSTRALIAN LONGITUDINAL STUDY ON WOMEN'S HEALTH

Brown, W.J., Hockey, R., Uijtdewilligen, L.

*University of Queensland, Brisbane, Australia and VU University Medical Center, Amsterdam, NL*

Introduction It is well accepted that, at the population level, physical activity levels decline during adulthood. For example data from the US suggest that, for men and women combined, younger people are more likely to be active than older people, with the prevalence of those meeting recommendations declining from 60% of 18 - 24 year olds to 39% of those 65 years and older (1). The largest decline is when people are in their twenties. Methods Data were from women in the three cohorts (born 1973-78 [N=9436]; 1946-51 [N=10,694]; and 1921-26 [N=9050]) of the Australian Longitudinal Study on Women's Health who completed four surveys over a 9 year period when they were aged 22-27 to 31-36, 50-55 to 59-64 and 73-78 to 82-87 years. Activity status was assessed using adapted Active Australia questionnaire items about time spent walking and in moderate and vigorous activity, with a summary score in MET.minutes/week used to define meeting recommendations ( $\geq 600$  MET.mins/week = 'active'). Results In the younger and older cohorts, the proportions meeting guidelines declined from 55% (age 22-27) to 47% (age 31-36) and from 37% (age 73-78) to 24% (age 82-87) respectively. However, in the

middle cohort, the proportion of active women increased from 45% (age 50-55) to 56% (59-64). Importantly, of those who answered every survey, only 12% of each cohort was 'active' at every survey, across all cohorts. In contrast, while only 8-10% of the younger and mid-age women were consistently inactive, more than one quarter of the older women were consistently inactive. The complex changing activity patterns will be illustrated using mosaic plots. Changing activity status was associated with changes in factors that impact on free time, such as marital status and childbirth in the younger women, and retirement, widowhood and birth of grandchildren in the mid-age women. Among the older women decreasing activity was associated with declining health and moving into an aged care institution. Discussion In this large representative cohort, changes in physical activity did not follow the expected decline with age. While there was a trend for activity to decline when the women were in their 20s, as their family responsibilities increased, the data show a clear increase in activity in mid-age. This is a time when women have more free time, as their work and family responsibilities are reduced. Activity levels do however decline quite markedly from the mid-seventies into older old age. ## PHYSICAL ACTIVITY AS BEHAVIOR IN CONTROLLING WEIGHT

Bezerra, P., Venancio, C.

*Viana do Castelo Polytechnic Institute (IPVC); Research Centre in Sports Sciences, Health Sciences and Human Development (CIDESD)*

Introduction In recent years, the concerns with the body image, size and shape have promoted different behaviors that may contribute in the development of eating disorders. The physical activity performed in an excessive and intensive manner has been identified as one of the most relevant behaviors in controlling weight, in patients suffering eating disorders. This is particularly common in female adolescents where the practice of intense physical activity has been associated to body dissatisfaction. The aim of this study was to investigate the relationship between the body-image distortion, the body mass index (BMI) and the excessive practice of physical activity as behavior to lose weight, in female adolescents. Methods Two hundred and seventy nine female adolescents ( $16.6 \pm 1.2$  yrs,  $59.0 \pm 11.8$  Kg,  $1.63 \pm 0.06$  m,  $BMI = 22.4 \pm 4.1$ ) were recruited from Viana do Castelo. The subjects were asked to fulfill a questionnaire (Dixie, 2002) to collect information about the body-image distortion and behaviors to lose weight. The cross-tabs technique and Spearman coefficient of correlation were used to assess the relationship between BMI and behaviors to lose weight and the body-image distortion. The significance was set at  $p < 0.05$ . The Human Research Ethics Committee of the Institute approved testing procedures and the written informed consent was obtained from the subjects. Results Moderate to high risk of body-image distortion was found in 2.2% of the subjects. The female adolescents at moderate to high risk of developing eating disorders showed a  $BMI < 20$ . Furthermore, 50% of these subjects had reported the practice of intense physical activity as behavior in controlling weight. This behavior was also shown in 48% of the subjects in which 15% presented  $BMI < 10$  and 16% presented  $BMI > 25$ . Significant but moderate correlations were found between BMI and both the body-image distortion ( $r=0.33$ ,  $p<0.01$ ) and the practice of intense physical activity ( $r=0.20$ ,  $p<0.01$ ). Discussion Results showed that few subjects demonstrated deep body image distortion. Also, the physical activity as behavior to lose weight was the most common behavior among the subjects. BMI showed significant correlations with both body image distortion and physical activity as behavior to lose weight. However, no correlation was found between body image distortion and physical activity as a behavior to lose weight. It appears that rather than body image perception, the subject's BMI value is the main factor in promoting the physical activity as behavior to lose weight. References Dixie, M. A. (2007). Prevalência das doenças do comportamento Alimentar. *Análise Psicológica*, 4 (XXV): 559-569

## THE EFFECTS OF HIGH AND LOW LOAD UPPER BODY RESISTANCE TRAINING ON LIMB STRENGTH AND FLEXIBILITY IN WOMEN WITH BREAST CANCER RELATED LYMPHOEDEMA

Pumpa, K., Cormie, P., Rattray, B., Spry, N., Galvao, D.A., Newton, R.U.

*University of Canberra*

The Effects of High and Low Load Upper Body Resistance Training on Limb Strength and Flexibility in Women with Breast Cancer Related Lymphoedema Pumpa, K.L.1, Cormie, P.2, Rattray, B.1, Spry, N.3, Galvão, D.A.2, Newton, R.U.2 1: University of Canberra, AUSTRALIA; 2: Edith Cowan University, AUSTRALIA; 3: Sir Charles Gairdner Hospital, AUSTRALIA. Introduction Upper limb impairments such as decreased range of motion (ROM) and strength are evident in women after treatment for breast cancer. These differences are greater in women with lymphoedema (Smoot et al., 2010). Improvements in shoulder ROM without lymphoedema exacerbation have been identified in women with breast cancer after gentle strength and flexibility exercises (Kilbreath et al., 2012). This research compared the effects of high and low load resistance exercise on upper body ROM and strength in women with breast cancer related lymphoedema (BCRL). Methods Seventy women with a clinical diagnosis of BCRL participated in this investigation (age:  $57 \pm 9$  y, weight:  $77 \pm 15$  kg, bioimpedance spectroscopy [BIS] score:  $15 \pm 18$ , time since lymphoedema diagnosis:  $5 \pm 6$  y). Participants were stratified for age and lymphoedema status and then randomised into three groups; high load resistance exercise (HIGH  $n=24$ ), low load resistance exercise (LOW  $n=23$ ) or usual care (UC  $n=23$ ). Participants in the HIGH and LOW groups completed progressive resistance training twice weekly for 12 weeks, while participants in the UC group maintained their normal lifestyle. Training sessions involved 1-4 sets per exercise at loads equivalent to 6-10 repetition maximum (RM) for HIGH (~75-85% 1RM) and 15-20 RM for LOW (~55-65% 1RM). Assessments were conducted pre and post intervention using standard measurement techniques for physical function on both affected and non-affected limbs (grip strength; wrist, elbow and shoulder ROM; 1RM in chest press and seated row; and RM test in chest press and seated row at 70% 1RM). Standard descriptive statistics, two way (group x limb) analysis of variance and intention to treat analyses were utilised. Results Exercise was effective with no differences between the HIGH and LOW groups for any parameter or limb. Improvements in wrist flexion were evident in the HIGH ( $P \leq 0.004$ ) and LOW ( $P \leq 0.016$ ) groups; elbow extension and shoulder flexion improved in the LOW group ( $P = 0.001$ ; and  $P = 0.015$  respectively); improvements were identified in both the RM chest press and seated row in both HIGH and LOW groups ( $P \leq 0.021$ ); and increases in grip strength were evident in both HIGH and LOW groups ( $P \leq 0.015$ ) when compared to UC. Discussion Upper body resistance training involving high and/or low loads is effective for improving physical function in the upper bodies of women with BCRL. ## Oral presentations

### OP-PM31 Training and Testing 4

#### EFFECT OF CONCURRENT EXPLOSIVE STRENGTH AND ENDURANCE TRAINING ON SPRINT PERFORMANCE BEFORE AND AFTER A 5-MIN TIME TRIAL

Müller, B.1,2, Steiner, T.1, Wehrli, J.P.1

1: Federal Office of Sports (Magglingen, Switzerland), 2: Swiss Cycling Federation (Bern, Switzerland)

**Introduction** A fast starting phase can be crucial to overall performance in MTB Cross Country competition whereas in road cycling it is the final sprint which can determine whether someone is successful or not. This variable competition intensity with many needed accelerations creates high demands in muscular strength (Yamamoto et al., 2010). The purpose of this study was to examine the effect of explosive strength training on a 10 s sprint performance at rest and after a 5-min time trial (TT). **Methods** Eighteen male adolescent cyclists (age  $15.0 \pm 0.5$  yr) were matched to pairs and assigned either a combined strength and endurance group (S&E;  $n = 9$ ;  $VO_{2peak}$   $64.0 \pm 5.1$  ml/kg/min) or an endurance group (E;  $n = 9$ ;  $VO_{2peak}$   $64.7 \pm 1.8$  ml/kg/min). One-third of the training sessions in the S&E group consisted of explosive strength training. During the 6-week intervention the training load and duration as well as the intensity distribution were the same for both S&E and E groups. The following parameters were measured before and after the training intervention: Sprint performance for 10 s at rest and after a 5-min TT recording Peak power (Ppeak) and mean power for 10 s (P10s), power during the 5-min TT,  $VO_{2peak}$ , and squat jump (SJ) performance. **Results** Results after the intervention showed no significant differences within the groups for Ppeak (S&E  $+1.3 \pm 5.8\%$ ; E  $-3.0 \pm 5.9\%$ ) or within the E group alone for P10s ( $-1.5 \pm 5.2\%$ ). The S&E group showed  $+3.8 \pm 4.4\%$  higher P10s at rest. After the TT, the E group improved Ppeak ( $+15.7 \pm 20.4\%$ ) and P10s ( $+16.1 \pm 20.7\%$ ), whereas in the S&E group only P10s improved ( $+16.5 \pm 16.1\%$ ) significantly. Both groups improved their TT performance (S&E  $+11.5 \pm 5.4\%$ ; E  $+8.0 \pm 7.0\%$ ). The S&E group improved  $VO_{2peak}$  ( $+6.0 \pm 3.6\%$ ) and SJ performance ( $+7.8 \pm 5.2\%$ ). No changes were seen in the E group in these parameters ( $VO_{2peak}$   $+2.2 \pm 3.2\%$ ; SJ  $+1.9 \pm 5.8\%$ ). The development of  $VO_{2peak}$  and SJ performance before and after the intervention was different between the two groups. **Discussion** Concurrent explosive strength and endurance training showed an improvement in total sprint performance during 10 s at rest without compromising TT performance. In addition, the S&E group improved their explosive strength ability as well as  $VO_{2peak}$ . Accordingly, in bike disciplines where a high intensity start phase is crucial to performance, combined strength and endurance training can be recommended as part of the yearly training plan. Furthermore, negative effects of strength training on endurance performance in this age group are not to be expected. **References** Yamamoto, L.M., Klau, J.F., Douglas, C., Kraemer, W.J., Armstrong, L.E. & Maresh, C.M. (2010). *J. Strength Cond. Res.*, 24(2), 560-566.

#### EFFECT OF HIGH-SPEED POWER TRAINING ON IMPROVING MUSCULAR AND FUNCTIONAL PERFORMANCE IN OLDER WOMEN

Pereira, A., Silva, A., Costa, A., Monteiro, A.M., Marques, M.

UNIVERSIDADE DE TRAS OS MONTES

**Introduction** In older populations, maintenance of muscle power output is a key factor in everyday task performance, such as climbing stairs, rising from a chair and walking, as well as in decreasing the likelihood of falls, especially in women (Häkkinen et al., 1998; Izquierdo et al., 2001). The purpose of the study was to examine the effects of 12 weeks high-speed power training on maximal strength (1RM) and functional tasks of the arm and leg muscles (sit-to-stand and get-up and go) (Pereira et al., 2012). **Methods** Twenty-four women were assigned randomly to a control group (CG) ( $n=12$ ,  $63.3 \pm 5.9$ ) and an experimental (EG) ( $n=12$ ,  $60.3 \pm 9.3$ ). The experimental group was subjected to three sessions /week of strength training for 12 weeks). The control group did not do any physical activity. Data collection were in the pretest (T1) and post-test (T12). The evaluation consisted of strength exercises: 1-repetition maximum bench press (1RMBP), 1-repetition maximum in leg extension (1RMLE) and tests that evaluated the functional fitness: sit and stand up - 30 sec. (ST) and 'go up and go' (GUG), both the battery of tests Rikly & Jones (1999). The training plan consisted of bench press exercise (BP) and bilateral leg extension (LE) with progressive loads (40% -75%) and performing abdominal (3x12) and lumbar (3x10). **Results** During 12-weeks of high-speed power training, CG showed significant decreases in the test ST ( $-12.2\%$ ,  $p = 0.029$ ). For the EG, improvements were observed in the tests 1RMBP (38.6%,  $p = 0.001$ ), 1RMLE (24.6%  $p = 0.00$ ) and ST (17.1%,  $p = 0.003$ ). Although GUG test decrease in execution time of the course, but this was not significant ( $-4.3\%$ ,  $p = 0.259$ ). **Discussion** A program of strength training with maximum speed during the concentric phase allows significant gains in increased levels of strength in upper and lower limbs. Moreover, this approach contributes to the increased mobility and functional autonomy, as well as increasing neuromuscular coordination and power, which in old age seem to contribute significantly to reducing the risk of falls and consequently to increase functional independence and quality of life. **Conclusion** These data indicate that high-speed power training is an effective exercise approach leading to large gains in upper and lower extremity muscle performance and function capacity. **References** Häkkinen, K., Kallinen, M., Izquierdo, M., Jokelainen, K., Lassila, H., Malkia, E., Kraemer W.J., Newton, R.U., Alen, M., 1998. #### EFFECT OF DIFFERENT INCLINES ON SPRINTING, BOUNDING, AND ONE-LEG HOPPING PERFORMANCE IN ENDURANCE TRAINED ATHLETES

Sjövist, J., Sandbakk, Ø., Willis, S., Andersson, E., Holmberg, H.C.

Swedish Winter Sports Centre

Effect of Different Inclines on Sprinting, Bounding, and One-Leg Hopping Performance in Endurance Trained Athletes Sjövist, J(1), Sandbakk, Ø(2), Willis, S(1), Andersson, E(1), Holmberg, H.-C.(1) (1)Swedish Winter Sports Research Centre, Department of Health Sciences,

Mid Sweden University, Östersund, Sweden. (2)Department of Human Movement Science, Norwegian University of Science and Technology, Trondheim, Norway Introduction In cross-country skiing, uphill sprinting, bounding, and one-leg hopping is a common dry-land training method to improve skiing performance. However, the impact of different inclines on performance in sprinting, bounding and hopping in this population has not been investigated. Therefore, the aim of the study was to analyze the kinematics of sprinting, bounding, and hopping, and the effects of strength, power, and individual ranking on performance in three different inclines. Methods 14 male elite cross-country skiers performed 15 m sprinting (SPR), five-step bounding (5SB), and five one-leg hops (5OLH) on 0, 7.5, and 15° inclines. Moreover, a mid-thigh pull was used to measure maximal isometric strength and squat jumps (SQJ) and double and single-leg countermovement jumps (CMJ) for power. For kinematics, total cycle time, frequency, contact time, flight time, stride length during sprinting, bounding and hopping were analyzed. FIS-points were used to rank skiers. Results As expected, incline negatively affected performance in SPR, 5SB, and 5OLH ( $p < 0.05$ ). At 7.5 and 15° incline, contact time increased in SPR, 5SB, and 5OLH ( $p < 0.05$ ) and flight time decreased in 5SB and 5OLH ( $p < 0.05$ ) while remaining unaffected in SPR. Stride length decreased by 25-30% from 0 to 15° in SPR, 5SB, and 5OLH. Strength was correlated to 5SB and 5OLH at 7.5 and 15° ( $r = 0.60-0.83$ ) while power correlated to SPR at 0 and 15° ( $r = -0.56-0.63$ ), 5SB at 0 and 7.5° ( $r = 0.55-0.64$ ), and 5OLH at all inclines on the non-dominant leg ( $r = 0.58-0.72$ ). Higher ranked skiers' 5SB were longer at 7.5 and 15° and 5OLH were longer at 15° on the non-dominant leg. Discussion As incline increases, slower sprint times may be contributed to shorter stride length and increased contact times while shorter bounding and hopping distances to shorter stride lengths and flight times. Maximal strength positively affects bounding and one-leg hopping and power affect sprinting, bounding, and one-leg hopping performance at steeper inclines. Uphill bounding and one-leg hopping could be useful training methods for cross-country skiers. References Cronin JB, Hansen KT. ### IMPROVING REPEATED SPRINT ABILITY BY A SHORT PERIOD OF VERY HIGH INTENSITY INTERMITTENT EXERCISES TRAINING IN YOUNG SOCCER PLAYERS

Durand, T., Dellal, A., Pialoux, V., Hautier, C.  
*Sport Science Université de Claude Bernard*

Improving Repeated Sprint Ability by a short period of very high intensity intermittent exercises training in young soccer players DURAND T. (1), DELLAL A. (2), PIALOUX V. (1), HAUTIER C. (1) (1) Sport Science University of Claude Bernard, Lyon, France ; (2) Olympique Lyonnais FC (soccer) Introduction The Repeated Sprint Ability (RSA) is often considered as one of the most important skill to develop the physical performance of elite players. However, there is still a lack of study concerning others methods allowing the improvement of the RSA. Therefore, the aim of the present study was to examine the effect of 5-25 and 5-15 intermittent exercises with and without footwork exercises on the RSA performance but also on the maximal speed and an intermittent aerobic test. Methods Sixteen U19 soccer players (height: 178.0±6.0 m; body mass: 66.6±5.3 kg; body fat: 7.3 ±3.1%) took part in this experimentation. All players performed a 4 week-training period including 5-15-sec and 5-25-sec intermittent exercises with and without footwork exercises. The 5-25-sec and 5-15-sec consisted in 5-sec of work at maximal intensity followed by 25 or 15-sec of passive recovery during 2 blocks of 6 minutes and 4 minutes, respectively. Players performed each intermittent exercise once with specific footwork (consisting in lateral footwork, jumps with ground reaction, skipping, frequency, exercises with hoops) and another time in traditional conditions without specific footwork. Prior and after this 4 week-training period, each player performed a RSA Test (10 x 30-m interspaced by 30-sec of active recovery), an intermittent fitness test (30-15 IFT) and a 10-m and 30-m sprint performance test. Heart rate (HR) and rating of perceived exertion (RPE) were monitored during and after each test and intermittent exercises training. Results The 4-week training period of very high-intensity intermittent exercise induced a significant increase of the 30-15 IFT and RSA performances ( $p < 0.05$ ), whereas the 10-m and 30-m sprint performance was unchanged. Complementary, the 5-25 intermittent exercise without footwork exercises allows to reach similar HR and RPE values than during RSA. On the contrary, for the intermittent exercises with footwork exercise, the HR and RPE are less important than during the tests. Discussion According to these results, it appears that the short intermittent exercises at very high-intensity (combination of 5-25-sec and 5-15-sec) seems to be appropriate for the development of both the repetition of high intensity actions (RSA) and intermittent fitness performance (30-15 IFT). It should be suggested to alternate between very high-intensity intermittent exercises and RSA training in order to develop the physical performance in youth players. Furthermore, it could be interesting that future study will examine if a period of small-sided games training induce similar effects than RSA or short duration of intermittent exercises.

### ACUTE EFFECTS OF A CONVENTIONAL HIGH-INTENSITY STRENGTH TRAINING SESSION UNDER SIMULATED ORTHOSTASIS ON A NEW ROBOTIC LEG PRESS

Kümmel, J., Rosenberger, A., Mester, J., Gruber, M., Zange, J.  
*German Aerospace Center*

ACUTE EFFECTS OF A CONVENTIONAL HIGH-INTENSITY STRENGTH TRAINING SESSION UNDER SIMULATED ORTHOSTASIS (LBNP) ON A NEW ROBOTIC LEG PRESS Kümmel, J. (1,4), Rosenberger, A.(1,2), Mester, J.(2), Gruber, M.(4), Zange, J.(1,3) 1: German Aerospace Center (Cologne, Germany), 2: German Sport University Cologne (Cologne, Germany), 3: University of Cologne (Cologne, Germany), 4: University of Konstanz (Konstanz, Germany) Introduction Lower body negative pressure (LBNP) is a gravity independent method to simulate orthostasis. Due to the muscle pump function in exercising leg muscles, an increase in hydrostatic pressure by gravity or LBNP increases the arterio-venous pressure difference and in consequence muscle perfusion (Egaña et al., 2010). This study is the first application of combining a robotic leg press (RBL) that allows free modelled profiles of force and velocity with a LBNP chamber. We tested the hypotheses that LBNP during simulated high-intensity leg press exercise i) increases total hemoglobin content (tHb) and oxygen saturation (SmO<sub>2</sub>) for m. vastus lateralis, and ii) reduces the increase in systolic blood pressure (sBP) and cardiac output (CO). Methods Nine healthy male subjects (age: 28±4yrs) participated in this study. In a cross-over design, all subjects performed 3 sets of knee extensions in a supine position at 0 (CON), -20, and -40mmHg LBNP. The RBL produced a constant force at 80% of the individual 1RM. SmO<sub>2</sub> and ΔtHb were continuously measured by near-infrared spectroscopy. SBP and CO were determined from measurements of continuous finger blood pressure, thorax impedance, and electrocardiogram. Results After the first exercise set, ΔtHb increased in all three conditions indicating a reactive hyperemia. With LBNP, ΔtHb was higher when compared to CON (0mmHg: 3.5±0.9μmol/L, -20mmHg: 8.2±0.9μmol/L, -40mmHg: 12.7±0.9μmol/L,  $P < 0.05$ ) during LBNP baseline. Average ΔtHb did not significantly change during exercise sets in comparison to corresponding intervals of rest. During rest, no differences to baseline values in SmO<sub>2</sub> and sBP between LBNP and CON were observed, whereas CO was significantly lower with LBNP (0mmHg: 3.8±1.3L/min, -20mmHg: 2.2±1.5L/min, -40mmHg: 2.1±1.8L/min,  $P = 0.04$ ). Dur-

ing exercise, no differences in SmO<sub>2</sub>, sBP, and CO were found between CON and LBNP. Discussion The increase in  $\Delta$ tHb with LBNP indicates capillary blood pooling in the vastus muscle. However,  $\Delta$ tHb increase with LBNP did not affect the time course of SmO<sub>2</sub> during the entire test protocol. Moreover, only at rest but not during exercise, sBP showed the known modulations of the cardiovascular system to orthostasis. This indicates that the participants of the study were not able to profit from improved muscle perfusion using muscle pump and hydrostatic pressure during LBNP with the specific time course of force used in the present leg press training. ### OP-PM32 Neuromuscular Physiology: Fatigue

#### CHANGES IN CORTICAL ACTIVATION AND EXCITABILITY DURING PROLONGED CYCLING EXERCISE

Jubeau, M.1,2,3, Rupp, T.1, Perrey, S.4, Temesi, J.3, Wuyam, B.1, Verges, S.1, Millet, G.Y.1,3

1. HP2 (Grenoble, France), 2. MIP (Nantes, France), 3. LPE (Saint-Etienne, France), 4. M2H (Montpellier, France)

**Introduction** It has been previously demonstrated that prolonged cycling exercise induces muscle fatigue, i.e. decrease of maximal voluntary contraction (MVC) force, due to alterations of both peripheral mechanisms (contractile properties and action potential propagation) and central drive (1). However, it remains unknown whether a supraspinal deficit occurs throughout prolonged exercise. Therefore, the purpose of this study was to evaluate cortical excitability and cortical activation before, during and after a 4-h cycling exercise. **Methods** Ten healthy subjects performed three 80-min bouts on an ergocycle at 45% of their maximal aerobic power separated by 25 min bouts of neuromuscular function (NMF) testing. Before exercise and immediately after each bout, NMF was evaluated on the right quadriceps femoris under isometric conditions. Transcranial magnetic stimulation was used to assess cortical voluntary activation (VA, as proposed by 2), cortical excitability via motor evoked potential (MEP) and intracortical inhibition by cortical silent period (CSP). Electrical stimulation of the femoral nerve (single and paired stimuli) was used to measure peripheral VA and muscle properties. Mechanical and electromyographic (vastus lateralis, vastus medialis and rectus femoris) data were recorded during all NMF testing procedures. Results MVC was significantly reduced after the first bout ( $P < 0.01$ ) and was further decreased (-25%,  $P < 0.001$ ) at the end of exercise. As expected, single twitch and doublet peak torque were depressed after the first bout and remained so throughout the protocol ( $P < 0.001$ ). M-wave amplitudes were also reduced for the three studied muscles ( $P < 0.01$ ). In contrast, CSP and raw MEP amplitude remained unchanged throughout the protocol. However, MEP normalized to maximal M-wave significantly increased after the first cycling bout and remained elevated. Finally, a significant decrease in both cortical and peripheral VA was observed at the end of exercise (~ -7%,  $P < 0.01$ ) but these changes were not correlated. **Discussion** Alterations of both central drive and muscle function explain the large strength loss after prolonged cycling exercise. The main findings of this study are that reductions in peripheral VA measured here and in previous fatigue studies in cycling are partly explained by a deficit at the corticospinal level despite increased corticospinal excitability and similar intracortical inhibition. **References** 1. #### EFFECT OF 30-H SLEEP DEPRIVATION ON CYCLING PERFORMANCE AND CENTRAL FATIGUE

Temesi, J.1, Arnal, P.J.1, Verges, S.2, Millet, G.Y.1

1. Université de Lyon, F-42023, Saint-Etienne, France 2. HP2 Laboratory (INSERM U1042), Université Joseph Fourier, F-38000, Grenoble, France

**Introduction** Deterioration in endurance performance with sleep deprivation (SD) has been observed anecdotally and in previous studies (Martin, 1981). Numerous hypotheses have been proposed, including that SD increases perception of effort (RPE). Another effect of SD is the potential for alterations to central motor command during exercise. Although effects on maximal force with SD have not been found, effects of SD on central fatigue are unknown. The aim of this study was to test the hypothesis that increased supraspinal fatigue contributes to impaired exercise performance with SD. **Methods** 9 active males with normal sleep patterns performed 2 randomized and counterbalanced 2-day sessions. On day 1 (J1), subjects performed neuromuscular tests comprising maximal (MVC) and submaximal voluntary contractions of knee extensors with peripheral nerve (PNS) and transcranial magnetic stimulation. On day 2 (J2), after a night of complete SD or normal sleep (CO), subjects performed tests as per J1 before, after cycling 40 min at 65% maximal aerobic power (MAP) and then after cycling to exhaustion (65% MAP; + 5% MAP every 5 min). MVC, voluntary activation (VA), maximal M-wave at rest (Mmax) and during MVC (Msup), motor evoked potential (MEP) and potentiated twitch (TwPot) amplitudes, RPE and performance time were analyzed by repeated-measures ANOVA or t-test with significance at 0.05. **Results** No differences were observed between SD and CO or between J1 and J2 before cycling ( $p > 0.05$ ). On J2, RPE increased and MVC decreased with cycling time (both  $p < 0.001$ ). This was paralleled by the appearance of low-frequency fatigue ( $p < 0.001$ ) and decreasing TwPot ( $p < 0.001$ ) and %VA PNS ( $p = 0.04$ ). Vastus lateralis (VL) MEP/Mmax at 50, 75 and 100% MVC increased in amplitude with time on J2 ( $P < 0.05$ ). There were no differences in MEP/Mmax amplitudes in Rectus femoris or Vastus medialis, nor for MEP/Msup in any quadriceps muscle. Both Mmax and Msup amplitudes decreased in all quadriceps muscles with time on J2 ( $p < 0.05$ ). **Discussion** The results of this study showed no change in neuromuscular measures with SD. Endurance cycling to exhaustion produced a decrease in maximal force associated with low frequency fatigue and some central fatigue. At fatigue, cortical excitability was elevated in VL. These effects were not, however, accentuated with SD. Although exercise time to exhaustion with SD was 3.5% shorter than CO, this difference was not significant. Evidence of increased RPE and central fatigue, especially increased supraspinal fatigue, with SD were not observed, perhaps explaining the lack of performance difference between the two conditions. **References** Martin BJ. (1981). *Eur J Appl Physiol Occup Physiol*, 47, 345-354.

## NEUROMUSCULAR FATIGUE INDUCED BY WHOLE-BODY VIBRATION EXERCISE PERFORMED WITH MODERATE ADDITIONAL LOAD

Maffiuletti, N.A.1, Saugy, J.2, Cardinale, M.3, Place, N.2

(1) *Schulthess Clinic* (2) *University of Geneva* (3) *British Olympic Association*

**Introduction** Despite the fact that acute and chronic effects of whole-body vibration (WBV) exercise have received considerable attention in the last few years (see Rittweger, 2010), the mechanisms underlying the reduction in maximal voluntary contraction (MVC) strength induced by one WBV session are poorly known. The aim of this study was to investigate the origin and the extent of neuromuscular fatigue induced by half-squat static WBV exercise, and to compare it to a non-WBV condition. **Methods** Nine healthy adult volunteers completed two fatiguing protocols (WBV and non-WBV, randomly presented) separated by 48 hours. The fatiguing protocols consisted of five 1-min repetitions of static half squat with a load of 50% of individual body mass. The WBV was administered on a linear platform with a frequency of 30 Hz and an amplitude of 4-6 mm. Neuromuscular fatigue of knee and ankle muscles was investigated with a series of assessments completed before and immediately after each fatiguing protocol. The main outcomes were MVC torque, voluntary activation (twitch interpolation), M-wave amplitude and doublet peak torque. **Results** Knee extensor MVC torque decreased significantly and to the same extent after WBV (-23%) and non-WBV (-25%), while knee flexor, plantar flexor and dorsiflexor MVC torque did not decrease significantly. Quadriceps and triceps surae voluntary activation were unaffected by the two fatiguing protocols, and similarly vastus lateralis and soleus M-wave amplitude did not show any significant alteration. Doublet peak torque decreased significantly and to a similar extent following WBV and non-WBV exercise, for both knee extensors (-25%) and plantar flexors (-7%). **Discussion** The main finding of this study was the lack of difference between the extent and the origin of neuromuscular fatigue induced by WBV and non-WBV static half-squat exercise performed with additional loads. Both protocols undoubtedly induced muscle fatigue in knee extensors (but not in the other main muscles of the lower limb), as witnessed by considerable MVC torque losses. Knee extensor muscle fatigue was not due to activation failure (central fatigue) but rather to peripheral muscle contractile failure, which, again, did not differ between WBV and non-WBV conditions. Adding WBV to isometric resistance exercise with moderate loads does not induce additional neuromuscular effects compared to static exercise alone (see also Hannah et al., 2011). **References** Hannah R, Minshull C, Folland JP. (2011) *Scand J Med Sci Sports*, DOI: 10.1111/j.1600-0838.2011.01361.x Rittweger J. (2010). *Eur J Appl Physiol*, 108, 877-904.

## FATIGUE AND NEUROMUSCULAR STRATEGIES IN SUBMAXIMAL ISOMETRIC CONTRACTIONS IN CHILDREN WITH CEREBRAL PALSY

Doix, A.C., Gulliksen, A., Braendvik, S.M., Roeleveld, K.

*Norwegian University of Science and Technology*

**INTRODUCTION** It has been recently suggested that lower limb muscles would be more fatigue resistant in cerebral palsy (CP) children than in healthy control (HC) peers (Moreau et al., 2008). Voluntary activation in CP is shown to be impaired during fatiguing contractions and leads to lower force production and incomplete activation of the muscles, reflected in hampered motor unit (MU) recruitment (Stackhouse et al., 2005). Yet, up to 25% of maximal voluntary contraction (MVC), MU recruitment seems to be similar in CP and HC (Rose and McGill, 2005). The aim of this study was to investigate whether CP children would recruit additional MUs as HC would to compensate for muscle fatigue during a sustained contraction at a low force level. **METHODS** Twelve children with CP and seventeen healthy-controls (HC) of similar age participated in this study. Participants performed isometric MVCs in elbow flexion and extension, and a submaximal isometric contraction until exhaustion at about 20% MVC. Surface electromyography (EMG) of biceps brachii (BB), triceps longus (MTB) and triceps lateralis (LTB) were collected. Data from accelerometer were recorded to measure vertical variations of accelerations of the elbow flexion/extension. **RESULTS** The average flexion and extension peak torques during the MVCs were lower in the CP group than the HC group. Time to exhaustion in the endurance task was similar in both groups. The CP group experienced less acceleration fluctuations and a lower increase in this variable from start to end than the control group ( $p=0.007$ ). The change of EMG amplitude of BB ( $p=0.017$ ), MTB ( $p=0.001$ ) and LTB ( $p=0.021$ ) was significantly greater during the task in the HC group than in the CP group. The median frequency of the MTB had a larger decrease from start to end in the HC group ( $p=0.002$ ). **DISCUSSION** The lack of EMG amplitude increase in CP subjects shows that even at a contraction level as low as 20 % MVC, CP subjects were not able to recruit additional motor units to compensate for muscle fatigue throughout the task. The similar endurance time in CP can be explained by the fact that the external load was determined as a percentage of MVC, which is a relatively lower load of their maximal muscle capacity (Rose and McGill, 2005), also supported by the lower amount of acceleration fluctuations at the start of the contraction. Therefore CP participants would stop their task at a lower level of muscle fatigue, indicated by the lower change in median frequency EMG and acceleration fluctuations from start to exhaustion. **REFERENCES** Moreau NG, Li L, Geaghan JP, Damiano DL. ## ANALYSIS OF AUTONOMIC FUNCTION AND SELF-REPORTED FATIGUE IN PATIENTS WITH CHRONIC FATIGUE STATES UNDERTAKING AEROBIC EXERCISE.

Keech, A., Vollmer-Conna, U., Barry, P., Lloyd, A.

*University of New South Wales*

**Objective:** Chronic fatigue syndrome (CFS) is a debilitating illness with unknown pathophysiology and characterised by pathological fatigue and related symptoms. Autonomic dysfunction is associated with worsened symptoms and poor sleep in patients with CFS (Burton, Rahman et al. 2010). Although evidence is inconsistent, autonomic dysfunction may act to perpetuate fatigue across a range of functional somatic syndromes (Tak, Riese et al. 2009). We examined a role for autonomic dysfunction in post-exertional exacerbation of symptoms in CFS following sustained, moderate-intensity aerobic exercise. **Methods:** The study included a well-characterised sample of patients with CFS (N=10) and healthy control subjects (N=11). Self-report of fatigue (using an 11-pt scale designed to measure multi-dimensional characteristics in real-time), physical function and sleep quality were obtained twice at baseline and immediately, 1hr, 4hrs, 24hrs and 72hrs after 25 minutes of cycling exercise at 70% of age-predicted maximum heart rate. Heart rate was recorded continually via electrocardiogram for a 24 hr baseline period and the first 24hrs of recovery following exercise. Heart rate variability (as %HF power) was determined as an index for parasympathetic (vagal) activity. **Results:** CFS was associated with substantial fatigue, functional impairment and poor sleep (all  $p<0.02$ ) at baseline. The exercise trial immediately exacerbated fatigue in patients, which briefly subsided but then returned and peaked 24hrs after exercise. No significant differences in autonomic parameters were apparent from analyses of group differences. Results from preliminary multiple regression modelling suggest that post-exertional fatigue at 24 hrs was best

predicted by the condition of CFS ( $p=0.002$ ), the workload performed during the exercise ( $p=0.02$ ), fatigue ratings ( $p=0.003$ ) and higher HRV ( $p=0.002$ ) immediately after the exercise, and low HRV ( $p=0.03$ ) as well as high HR ( $p<0.001$ ) around the time of falling asleep during that night. Conclusions: As expected patients reported exacerbated fatigue, functional impairment and poor sleep following the exercise. More research with larger sample size is needed to draw definitive conclusions regarding the role of autonomic dysfunction in post-exertional fatigue. Given the variance in physiological data, it is clear that statistical approaches based on individual differences will provide better insights into these complex relationships than group comparisons.

### COMPARATIVE ANALYSIS OF METABOLIC AND FUNCTIONAL CHANGES RESULTING FROM VOLUNTARY AND ELECTRICALLY-EVOKED CONTRACTIONS OF THE KNEE EXTENSORS

GONDIN, J.1, JUBEAU, M.1,2, LE FUR, Y.1, VILMEN, C.1, COZZONE, P.J.1, DUHAMEL, G.1, BENDAHAN, D.1

1: Aix Marseille Université, 2: Université de Nantes

**Introduction :** It has been previously suggested that neuromuscular electrical stimulation (NMES) was related to a greater metabolic demand, i.e. a larger phosphocreatine (PCr) depletion and acidosis as compared to voluntary contractions (VOL). Given that the corresponding metabolic changes were not accurately localized, one could expect that they were sampled from a mixture of activated and non-activated muscle areas. In addition, one could also expect additional biases since NMES is linked to a preferential activation of muscle fibers close to the stimulating electrodes<sup>2</sup>. On that basis, localized metabolic (<sup>31</sup>P chemical shift imaging: CSI) and magnetic resonance transverse relaxation time (T<sub>2</sub>) changes were compared between VOL and NMES contractions. **Methods:** Sixteen healthy subjects completed both NMES and VOL protocols inside a 3T MR scanner (Siemens) for two testing sessions and were asked to perform 232 isometric contractions (750-ms on-off ratio) of the knee extensors (~30% of MVC force). The NMES protocol (frequency: 30Hz) was performed with similar characteristics while electrodes were placed over the vastus lateralis (VL) and vastus medialis muscles. During the first session, metabolic changes (i.e., PCr consumption and acidosis) were recorded using localized <sup>31</sup>P CSI. Voxels of interest were selected from the VL muscle (i.e., directly stimulated) and from the rectus femoris muscle (RF) (i.e., non-directly stimulated). During the second visit, a SE-EPI sequence was used to obtain images from the thigh muscles at rest and immediately after each exercise bout. T<sub>2</sub> maps illustrating muscle activation were then generated. **Results:** A larger PCr consumption and acidosis were observed for the VL after NMES as compared to VOL. On the contrary, both PCr depletion and acidosis were similar for the RF regardless the contraction mode. Consistently, T<sub>2</sub> maps showed a significant activation of the VL only after NMES while the RF was similarly activated by the two exercises. **Discussion:** The localized measurements reported in the present study demonstrated that the larger metabolic demand previously observed after NMES as compared to VOL was actually due to larger changes occurring within the stimulated muscle area. No difference was observed for the muscle area located outside the stimulated region. Interestingly, the metabolic changes were largely explained by the spatial distribution of muscle activation as illustrated by the T<sub>2</sub> maps. **References:** 1Vanderthommen M, Duteil S, Wary C, Raynaud JS, Leroy-Willig A, Crielaard JM, Carlier PG (2003), *J Appl Physiol*, 94, 1012-1024. 2Vanderthommen M, Depresseux JC, Dauchat L, Degueudre C, Croisier JL, Crielaard JM (2000), *Muscle Nerve*, 23, 482-489.

### IS-SH05 Social-Psychological Issues in Team Sports

#### EFFECTS OF COACH-ATHLETE RELATIONSHIP AND COACH LEADERSHIP ON TEAM EFFICACY

Jowett, S.

Loughborough University

**Effects of Coach-Athlete Relationship and Coach Leadership on Team Efficacy** Jowett, S. & Hampson, R. Loughborough University **Introduction** The phenomenon of mediocre players outperforming teams of seemingly superior talent during a match, series or possibly an entire season is something that researchers have recently started to explore through the notion of collective efficacy. Collective efficacy is viewed as a group's shared confidence in their conjoint capabilities to successfully organise and perform collective tasks. Feltz and Chase (1998) highlighted a number of sources of collective efficacy within the context of sport including past performances, leadership/verbal persuasion, vicarious experiences, motivational climate, group cohesion, and team size. While coach-athlete relationships were not mentioned as a potential source of collective efficacy, this study examined the independent and combined effects of coach-athlete relationships and coach leaderships on team efficacy. The rationale for it was that quality relationships is essential for effective and successful leadership (Schrujijer & Vansina, 2002). **Methods** A total of 150 British footballers participated in the study. They responded to instruments measuring the quality of the coach-athlete relationship (CART-Q), coach leadership (LSS), and collective efficacy (CEQS). In order to reveal the contribution of athletes' perceptions of coach leadership and coach-athlete relationship upon perceived collective efficacy, a hierarchical multiple regression analysis using a step-wise method was performed. **Results** The results indicated that leadership behaviours ( $F(5, 144) = 10.16, p < .01$ ), direct-perspectives of the coach-athlete relationship ( $F(8, 141) = 7.78, p < .01$ ), and meta-perspectives of the coach-athlete relationship ( $F(11, 138) = 6.7, p < .01$ ) all significantly predicted collective efficacy. **Discussion** Results highlighted that leadership variables and relationship variables together accounted for more efficacy variance than did each set of variables separately. Thus the coach-athlete relationship just like coach leadership is a potential psychosocial source of collective efficacy and thus could be added to the antecedents of collective efficacy. This study has both theoretical and practical significance. **References** Feltz, D.L., & Chase, M.A. (1998). The measurement of self-efficacy and confidence in sport. In J.L. ## SUCCESSFUL TALENT DEVELOPMENT IN SOCCER: THE CHARACTERISTICS OF THE ENVIRONMENT

Larsen, C.H., Alfermann, D., Christensen, M.K.

*University of Southern Denmark*

**Introduction** A number of more recent studies have investigated talent development environments and the way in which such environments underpin the nurturing of athletic talent. Martindale and Mortimer (2011) highlighted coherent communication and support, ensuring that philosophies, aims and daily practices are coherently linked, which suggests a strong focus on overall strategy and culture of the club. Henriksen, Stambulova and Roessler (2010) have introduced a holistic ecological approach to talent development, which highlights the central role of the overall environment as it affects a prospective elite athlete, and investigated a number of successful athletic talent development environments in different sports and in different Scandinavian countries. Among the common characteristics found in these successful environments was the fact that the environments were characterized by a strong group culture that pervaded every aspect of the environment's functioning. This presentation will present a description of a successful soccer environment (a) provide a holistic description of the environment and (b) highlight the factors influencing its success in the development of elite soccer players. **Methods** The study was organized as an explorative integrative and qualitatively-oriented case study. Methods of data collection included interviewing coaches, prospect soccer players, professional soccer players, parents, and also observations of daily life in the environments to obtain systematic and detailed knowledge of the environment as it occurs in the real world. **Results** The environment was centered on a strong relationship between prospects and a community of coaches, experts, team assistants and club house manager. A learning environment focused on teaching the players a holistic approach, self awareness and the ability to work very hard. **Discussion** These characteristics as well as a strong and cohesive family atmosphere were perceived as essential for success in the environment. We argue that the holistic ecological approach opens new venues in talent development research and holds the potential to change how sport psychology practitioners work with prospective elite athletes. **References** Henriksen, K., Stambulova, N., & Roessler, K. K. (2010). Holistic approach to athletic talent development environments: A successful sailing milieu. *Psychology of Sport and Exercise*, 11, 212-222. Martindale, R. J. J. & Mortimer, P. (2011). ## CAREER DEVELOPMENT IN TEAM SPORTS: PSYCHOLOGICAL AND CULTURAL PERSPECTIVES

Alfermann, D.

*University of Leipzig*

**Introduction** The development of athletic careers is subject to several sources of influence from the athletes themselves, the micro-environment (e.g., parents and coaches) and the macro-environment (e.g., culture). In contemporary sport psychology, emphasis is placed on psychosocial variables, with particular focus on the "athletic triangle" — the athlete, the parents, and the coaches (Wylleman and Reints, 2010). As for young athletes' personal resources, the current literature suggests that adherence and success in sport are largely related to measures of achievement motivation and of self-concept. Less emphasis, however, has been placed on possible cultural differences. This presentation will therefore focus on psychosocial factors in different cultural contexts. **Methods** Male adolescent soccer players from China (n = 274, M = 15.8 yrs, SD = 1.0) and Germany (n = 248, M = 14.9 yrs, SD = 1.7), and male adolescent field hockey players from Pakistan (n = 144, M = 16.2 yrs, SD = 1.4) and Germany (n = 127, M = 14.4 yrs, SD = 2.0) who were all in the developmental phase of their career filled in standardized scales of motivation (goal orientation and competitive anxiety), and of physical self-concept. **Results** It was hypothesized that due to the high emphasis on collectivistic values in China and Pakistan, players from these countries would score higher on competitive orientation and competitive anxiety, but lower on physical self-concept. As expected, Chinese and Pakistan players showed higher ego and lower task orientation and higher cognitive anxiety than German players. With regard to physical self-concept, results showed the expected large differences in all subscales between German and Chinese players, and small, but significant differences in three subscales between German and Pakistan players, with Germans scoring higher than players from China and Pakistan. **Discussion** The recommended or/and typical empirical pattern of results in Western countries for a promising athletic career shows a relatively high physical self-concept, higher task than ego orientation, and low cognitive anxiety in competitions. In both studies, German athletes showed this "recommended" pattern of results. In contrast, Chinese and Pakistan athletes scored differently on these variables. The question is, if this would hinder their career or if this pattern of results is functional for the players within their cultural environment. It is suggested to consider culture as an important social influence factor in career development and to be sensitive to cultural differences in players' development. **References** Wylleman, P., Reints, A. ### IS-BN04 Balance Control in Elderly: Fall Risk and Prevention

#### EXERCISE FOR PREVENTING FALLS IN OLDER PEOPLE: SYSTEMATIC REVIEW AND DISCUSSION OF CRUCIAL COMPONENTS OF EFFECTIVE PROGRAMS

Lord, S.

*Neuroscience Research Australia*

Exercise is recommended in evidence-based guidelines for fall prevention. However, there are many different types of exercise; some of which are likely to result in greater reductions in falls than others. It is therefore important to identify exercise types and components that are optimal for maximising physical functioning and preventing falls in the elderly. This presentation will initially provide a summary of the findings from a recent systematic review of 54 randomised controlled trials that have evaluated the effectiveness of exercise interventions in preventing falls in older people. The review meta-analysis revealed that exercise as a single intervention was effective in preventing falls (OR=0.84, 95% CI=0.77-0.91) and meta-regression revealed that programs that included (a) challenging balance exercises (exercises

conducted while standing in which people aimed to stand with their feet closer together or on one leg, minimize use of their hands to assist, and practice controlled movements of the centre of mass), (b) a higher total dose of exercise (>50 hours over the trial period) and (c) did not include a walking program, to have the greatest effect on reducing falls. Resistance, endurance and flexibility training provide additional benefits if combined with balance exercises. Whether the exercise is conducted in a group or on an individual basis was unimportant. The presentation will conclude by providing examples of effective exercise fall prevention programs evaluated in randomised controlled trials in Australia and New Zealand. These trials have included diverse exercise programs (home-based physiotherapy, group exercise and Tai Chi), but all have included the crucial component of high intensity balance training.

### **GAIT STABILITY AND FALL RISK IN THE ELDERLY, THE IMPORTANCE OF MUSCLE STRENGTH**

van Dieën, J.

*VU University Amsterdam*

Falls are common incidents, which can have major consequences. Especially among older adults, falls occur frequently, even in the large group of relatively fit and healthy elderly. Consequences of falls are known to contribute substantially to the prevalence of health problems, to health care costs, and to lost quality of life. The fact that the population of elderly is rapidly growing in the industrialized world suggests that the scope of this problem can be expected to increase in future decades. To develop effective and efficient approaches towards fall prevention in the elderly, causal factors for falls among the elderly need to be determined. Many epidemiological studies have been published on predictors of falls in the elderly. However, given the limitations of such observational designs, these studies often only provide general directions for prevention. Experimental studies can complement data from observational studies with more detailed insight, which can be used to determine who are at risk for falls and which are the modifiable factors determining fall risk. I will present evidence from a series of experimental studies to show that muscle strength may be a key factor in preventing falls after a perturbation of gait. Inverse dynamics analysis of recovery reactions after a trip showed that rapid development of high joint torques is necessary to prevent a fall. In older adults, and in older fallers in particular, the rate of moment development was reduced. In addition, isometric strength measurements were shown to differentiate older adults that fell during the experiments from those that did not fall. While recovery reactions after major perturbations of gait clearly require high muscle strength, it is less obvious to what extent strength is a determinant of stability of steady-state gait, which is a sub-maximal task for most individuals. Therefore, we have recently performed a cross-sectional study relating muscle strength to gait stability in a cohort of older adults and an experimental study on the effects of unilateral leg muscle fatigue on gait stability in older adults. The observational data show a moderate but significant correlation between muscle strength and stability of steady-state gait. In addition, leg muscle fatigue caused a decrease in gait stability in older adults, in spite of compensatory changes in the gait pattern. In conclusion, both the ability to recover from major mechanical perturbations of gait and the ability to deal with the small perturbations that occur continuously even in steady-state gait appear to be limited by muscle strength.

### **BALANCE AND AGEING: NEUROMUSCULAR ASPECTS**

Baudry, S.

*Université Libre de Bruxelles*

One of the functional consequences of the ageing process is a decrease in balance stability, as evidenced by the greater sway amplitude during upright standing in elderly compared with young adults. This decrease in balance stability has been attributed to alterations in muscular, vestibular, visual and proprioceptive systems. For example, the responsiveness of the muscle afferent pathway is reduced at rest in elderly adults, suggesting an alteration in the efficacy of this pathway to activate spinal motoneurons. Moreover, the modulation of this pathway for leg muscles in upright stance also differs with age (Koceja & Mynark, 2000) likely due to a distinct control at a presynaptic level that reduces the direct contribution of muscle spindle afferents to the motoneuron activation in elderly adults. In addition, the spinal pathway that conveys inhibition from muscle spindle afferents of a muscle group to its antagonist counterpart is less active in elderly adults and should contribute to the greater leg muscle co-contraction observed in elderly adults when standing. Nonetheless, compared with the expected role of the stretch reflex in balance control, recent work reported paradoxical muscle movements during upright stance. Indeed, based on the pioneer work of Sherrington at the beginning of the 20th century, it was assumed that reflex activities originating from muscle sensors play a key role in controlling upright posture. However, the observation that plantarflexor muscles shortened during forward sways and lengthened during backward sways questions whether the stretch reflex contribute by itself to postural sways (Loram et al. 2004). Furthermore, the magnitude of muscle length changes is decreased in elderly adults while no significant differences were observed for tendon lengthening and shortening during sways (Baudry et al. 2012). This suggests that elderly adults increase muscle stiffness when standing, likely to compensate for the age-related decrease in tendon stiffness (Narici et al. 2008). Such observations indicate an age-related change in the control of leg muscle activity to provide the adequate ankle joint stiffness for maintaining upright standing. Such a shift could be responsible for the progressive increase in cognitive demand required by balance control, as attested by the greater postural instability of elderly adults when performing a cognitive task while standing upright (Shumway-Cook & Woollacott, 2000). Together, these changes impair the performance of elderly adults in daily living tasks that require balance control and challenge the independence of this growing part of the population. ### OP-BN07 Coaching

#### PASSING IN FOOTBALL: FAST OR SLOW, HOW TO DECIDE?

Vicente, A., Fernando, C., Lopes, H.

*University of Beira Interior, University of Madeira, CIDESD*

**Introduction** It's common to believe that success in football depends on the speed at which problems are solved: it is accepted that players need to be faster, shoot with greater speeds, dribble faster or pass the ball with higher speeds. We have already verified (e.g. Vicente et al., 2010; Vicente et al., 2011) that in the feint and in the penalty kick in football there is a relation between the velocity of the stimulus and the response time: higher stimulus velocity tend to involve higher response times and vice-versa. Does the same occur in a passing situation in football where players also need to take into account other players actions (teammates and opponents) to act? The aim of this study was to verify whether a correlation exists between the velocity of the stimulus in a passing situation in football and the player's response. **Methods** We've used a software (MeSiR1.2) designed to measure the relation between the velocity of the stimulus and the time to respond it. In a very simplified way, the test was based on a stimulus that consisted on a defender that moved from the center of the screen to each side (overcoming 3 meters in a real football field) at different velocities (5, 3 and 1 meter per seconds) randomly. The players (45 university football players) had to press one of six matching letters in the keyboard previously known for six possible passing ball velocities (Q(10km/h), W(30km/h) and E(50km/h) for left, and I(10km/h), O(30km/h) and P(50km/h) for right) for 24 trials. Each test data was automatically collected by the software which provided the response time (and correspondent ball velocity) to each stimulus velocity. **Results** From the 1080 trials performed, the results showed that for the fastest stimulus the average response time was 280 milliseconds; for the 3m/s velocity players took in average 328ms to respond, and for the slowest stimulus the average time to respond was 343ms. Players choose the faster ball velocity in 79% of the fastest stimulus, and 84% of the times the slowest ball speed in the parallel slowest stimulus. **Discussion** The results showed that the stimulus velocity influenced the response time and the hypothetic passing ball velocity. As the stimulus was faster or slower, the response was also faster or slower respectively; also as the stimulus was faster or slower, the ball velocity chosen was also faster or slower. This may suggest, as indicated by ecological studies that we are still carrying out, that in passing in football where players are permanently exchanging stimulus with the opponents and teammates in order to get advantage over the first ones and trying to coordinate to the second ones, players should be trained to relate with the opponents and teammates being aware that they can influence their actions and their response time. **References** Vicente A., Lopes H., Fernando C. #### COMPARISON OF DIFFERENT FORMAT OF 15-SEC INTERMITTENT EXERCISES IN YOUTH SOCCER PLAYERS – WITH A SPECIAL REFERENCE TO THE PHYSIOLOGICAL IMPACT

Chardon, F.

*Université Claude Bernard Lyon 1*

**Comparison of different format of 15-sec intermittent exercises in youth soccer players – with a special reference to the physiological impact.** Chardon F. (1), Dellal A. (2), Pialoux V. (1), Hautier C. (1). (1) Sport Science University of Claude Bernard, Lyon, France; (2) Olympique Lyonnais FC (soccer) **Introduction** The ability to repeat high intensity actions is an essential characteristic in elite soccer. In this context, intermittent exercises (i.e. 15-15-sec) are commonly used in order to improve this capacity but there is not a consensus of their characteristics, especially in youth categories. Therefore, the aim of this study was to compare different type of 15-15-sec intermittent exercises and to examine their physiological impacts on elite young soccer players. **Methods** Twelve U17 players (172.9±5.8 cm; 64.5±5.8 kg, HRmax: 198.6±7.9 bpm, MAS: 15.6±0.9 km.h-1) from the same elite team participated in this study. During a 5-a-week period of competitive season, players have performed according to their individual maximal aerobic speed (MAS) the following different format of 15-sec intermittent exercises during 2 blocks of 8 min with active recovery: 1) 15-15-sec in-line running at 115% of MAS; 2-3) 15-15-sec including 180° turns at 110% and 115% of MAS; 4) a 15-15-15-sec at 115% of MAS; and 5) 15-45-sec including in-line running at 115% of MAS and specific physical (footwork) and technical actions (with the ball) according to the playing position. Players were tested in the Vameval test, 30-15 intermittent fitness test (30-15IFT) and a repeated sprint ability (RSA) test before and after the 5-a-week period. Heart rate responses during the exercise (HRres), heart rate recovery (HRR) post-exercise and ratings of perceived exertion (RPE) were monitored during all the tests and intermittent exercises. **Results** The intermittent exercise including 180°directional changes induced higher HRres responses and RPE values than during the others intermittent exercises (p<0.05). The lower HR responses, HRR and RPE values were observed during the 15-15-sec including the ball (p<0.001). Furthermore, the combination of the different format of intermittent exercises during the 5 weeks not improved the performance in the different tests (NS). **Discussion** The present study revealed that the 15-sec intermittent exercises with directional changes allow to reach higher HR response and RPE in youth soccer players whereas it is was the opposite for the format including the ball. These greater physiological responses are probably due to this format including 180° turns induced a deceleration, a block and a re-acceleration, and therefore a greater peripheral and anaerobic solicitation. In conclusion, it is suggested that coaches could include and combine different format of 15-15-sec (in-line, with ball and including footwork exercises) without altering the physiological solicitation. However, coaches should pay a special attention to the format including 180° directional changes.

#### IS THE COMMUNICATION OF CORRECTIVE FEEDBACK RELATED WITH ATHLETES' PERCEIVED JUSTICE OF THE COACH

De Backer, M.

*KULeuven*

**IS THE COMMUNICATION OF CORRECTIVE FEEDBACK RELATED WITH ATHLETES' PERCEIVED JUSTICE OF THE COACH** De Backer, M. 1, Ceux, T. 1, Callens, F. 1, Vandebroek, G. 1 1: KULeuven (Leuven, Belgium) **Introduction** Perceived justice of the coach is a key predictor of elite athletes' team identification and cohesion (De Backer, 2011). Considering the fact that both team identification and team cohesion have shown to be linked with performance (Carron, Colman, Wheeler, & Stevens 2002; Walumbwa, Cropanzano, & Hartnell, 2009), coaches

must be concerned about their players' perception of fairness. Therefore, the aim of the present study was to examine if the communication style of corrective feedback (i.e., autonomy supportive or controlling) and the transparency of the coach would affect team athletes' perceived justice. Method Elite female volleyball players ( $N = 56$ ;  $M = 22.33$ ) and elite male handball players ( $N = 35$ ;  $M = 23.59$ ) from Belgian top level teams completed one general and five weekly web-based questionnaires during consecutive midseason weeks. We used MLwiN software to perform the multilevel analyses. Results The results showed that autonomy supporting corrective feedback positively predicted overall perceived justice ( $p < .01$ ). In contrast, controlling corrective feedback negatively predicted perceived justice ( $p < .05$ ). Furthermore, coaches' transparency was positively related to athletes' perceived justice ( $p < .01$ ). This positive effect was stronger when coaches used controlling feedback than when they communicated their feedback in an autonomy-supportive way. Discussion The style of providing corrective feedback and the transparency of the coach are significant predictors of team athletes' perceived justice of the coach. Our results might be explained by the fact that, players who get autonomy supporting feedback will understand the purpose of this feedback and as a result, perceive their coach as fair. However, players who get controlling feedback lack this understanding. Consequently, it is vital for coaches to be transparent and explain this controlling corrective feedback afterwards. Otherwise athletes can misinterpret the coach's motives and intentions and perceive him as unfair. References Carron, A. V., Colman, M. M., Wheeler, J., & Stevens, D. (2002). ### TACTICAL ANALYSIS ON 9 WOMEN WATER POLO MATCHES DURING THE 2011-2012 REGULAR SEASON

Napolitano, S., Di Tore, A., Raiola, G.

*University of Salerno*

Introduction The coaches of team sports analyze matches and performances of team and opposing teams to get useful data in coaching (Hughes&Franks, 2008). Water polo have some distinctions, compared to other team sports because it develops in water that has much more resistance than in other fluids. So it has a significant impact on game development, allowing a detailed analysis of attack and defense patterns. However, in water polo lacks a codified tactic system for training, which is thus only left to the coaches' expertise This work examined 9 women water polo matches during season 2011/2012 (Italian female Serie A1), considering tactical patterns suggested by the coach in relation to tactical patterns implemented during the game and to actions number and outcome, in order to acquire elements useful to create a codified tactic system Methods It uses pilot work and the research approach is integrated and consists of 3 distinct methods: case study (9 matches of Italian Serie A1 Women's Championship, season 2011/2012, played by Volturno) for the analysis of matches, action research method for coach contribution, and theoretical-argumentative to deduce a theoretical framework in which define the data processing The survey of data is entrusted to performance analysis, carried out by a team: performance analyst, coaches and statistical analyst "The practical value of performance analysis is that well-chosen performance indicators highlight good and bad techniques or team performances" (Hughes 2008) The tool used for measuring is the Dartfish TeamPro software The assessment of compliance for the tactical patterns has prescribed by the coach with the tactical patterns implemented in training session, based on previously determined parameters Results The performance analysis was performed to evaluate parameters as frequency of occurrence of actions, time duration, number, result, position and type of shots in relation to tactical patterns, and an evaluation table was constructed by combining the Boolean evaluation of the coach on the compliance of patterns with the action final outcome. The results show a positive and statistically significant correlation ( $p > 0.6$  for up to now processed data) coefficient between tactical compliance and action outcome "The correlation coefficient indicates magnitude or amount of a relationship and the direction of relationship" (Morrow 2010) Discussion The results confirm the need for developing a shared tactical system to analyze waterpolo through tactics References Hughes, MD, Franks I. (2008) Notational Analysis of Sport: Systems for Better Coaching and Performance in Sport, Routledge Hughes, M. (2007). The essentials of performance analysis: an introduction, Taylor & Francis. ### MANAGING ATHLETES ON THE EDGE: OVERTRAINING AND THE COMPLEXITIES OF COACHES' DECISION MAKING

Smith, T., Pope, C., Penney, D.

*University of Waikato*

Introduction In many elite sport performance contexts it is acknowledged that overtraining is a critical issue for coaches to understand, be able to recognise and respond to. While much scientific research has been conducted on overtraining, no diagnostic test exists that reliably predicts impending overtraining. The research reported in this study anticipated that successful endurance coaches have developed effective strategies for managing overtraining amongst elite athletes. In a first of its type, this study explored in depth the practices and beliefs of three highly successful professional elite rowing coaches as they managed the risk of athlete overtraining during crucial periods of intensive training. Methods The coaches took part in a series of open-ended semi-formal interviews that explored their practices, philosophies and experiences. This study draws on sociological perspectives pertinent to coaching pedagogy and more specifically, the tenets of naturalistic decision making in exploring how the coaches define and make decisions about overtraining. This framework reflects recognition that coaching involves decision-making in complex and demanding situations. Results The coaches were found to monitor the fatigue of their rowers through observation, communication and measures of training pace. In general, the intuitions and cues for overtraining employed by them had little in common with those promoted in the sport science and medical literature. Discussion We contend that the coaches' decision-making is based largely on subjective processes and influenced by various stressors unique to their positions, which may explain the differences between their definitions and practices and those of the sport science and medical fraternity. We suggest that successful coaches have unique insights into this topical area that is worthy of further exploration.

**09:50 - 11:20****Oral presentations****OP-PM33 Training and Testing: Pacing Strategies****MATCH FATIGUE IN ELITE AUSTRALIAN FOOTBALL, RUGBY LEAGUE AND SOCCER PLAYERS**

Varley, M.C., Aughey, R.J., Gabbett, T.J.

*Victoria University*

MATCH FATIGUE IN ELITE AUSTRALIAN FOOTBALL, RUGBY LEAGUE AND SOCCER PLAYERS Varley, M.C. 1, Aughey, R.J. 1,2, Gabbett, T.J. 3,4 1: School of Sport and Exercise Science, Institute of Sport, Exercise and Active Living (ISEAL) Victoria University, Melbourne, Australia 2: Western Bulldogs, Melbourne, Australia 3: School of Exercise Science, Australian Catholic University, Brisbane, Australia 4: School of Human Movement Studies, The University of Queensland, Brisbane, Australia Introduction Players in all football codes may experience fatigue during a match, however it is unclear whether between-code differences exist in any performance decrements. Our aim was to investigate the reductions in physical performance in footballers during soccer, Australian football and rugby league matches, played at the highest level of competition in Australia, using the same analysis technique and movement definitions. Methods Movement data were collected via 5-Hz global positioning systems from 28 elite Australian football, 36 rugby league and 30 soccer players competing in the Australian Football League (AFL), National Rugby League (NRL) and Australian A-League. Distance covered in the first and second halves were reported for the movement categories; low-intensity activity (LIA; 0.1–5.4 m.s<sup>-1</sup>) and high-velocity running (HiVR; ≥5.5–10 m.s<sup>-1</sup>) as well as the number of maximal accelerations (>2.78 m.s<sup>-2</sup>). All data were expressed relative to playing time. Main effects were tested for code and half using a two-way mixed method ANOVA. Tukey post hoc testing was used to determine specific between-code differences and paired samples t-tests for within code-differences. Results Australian footballers covered a greater HiVR distance than NRL and soccer players in the first half ( $P<0.001$ ,  $14.5 \pm 4.7$  vs.  $5.2 \pm 3.1$  vs.  $5.6 \pm 2.8$  m.min<sup>-1</sup> respectively). While NRL and AFL players experienced a 12 and 13% decrement in HiVR distance ( $P<0.001$ ) during the second half, HiVR distance was maintained by soccer players ( $P=0.896$ ). The LIA distance performed by soccer and AFL players was significantly reduced ( $P<0.001$ ) in the second half by 6% and 5% respectively, but no first half to second half decrements in LIA were observed in NRL players ( $P=0.455$ ). All codes performed fewer accelerations ( $P<0.05$ ) in the second half (-14%; AFL, -18% NRL and -8% soccer) compared to the first half. Discussion Australian footballers experienced decrements in all running activities in the second half despite being allowed unlimited player rotations. This is likely due to the large HiVR distances covered per minute. Similarly, the reduction in HiVR distance in NRL may be due to the high number of accelerations per minute or other physically demanding tasks such as collisions and rapid changes in direction. In soccer, players must physically prepare with the expectation of playing a full match, thus players may adopt a pacing strategy to conserve energy by reducing LIA in order to maintain HiVR.

**PACING STRATEGY DURING A SIMULATED MOUNTAIN BIKE RACING**

Viana, B.1, Impellizzeri, F.M.2,3, Inoue, A.1, Santos, T.M.1

*1:PPGCEE-UGF (Rio de Janeiro, Brazil), 2: Schulthess Clinic (Zurich, Switzerland), 3: University of Verona (Italy)*

Introduction Mountain biking is a high-intensity endurance event. Studies have shown very high heart rates at the beginning of Olympic cross-country (XCO) competitions, corresponding to the fastest lap time (Impellizzeri and Marcora, 2007; Stapelfeldt et al. 2004). However, the pacing strategy of XCO simulations has not been purposely examined. The aim was to examine the pacing strategy adopted during a simulated XCO race by bikers with different performance levels. Methods Regional and national level bikers from Brazil ( $n=17$ ,  $30.2 \pm 5.6$ yr,  $174.8 \pm 5.5$ cm,  $67.9 \pm 6.3$ kg,  $292.4 \pm 21.9$ Wmax and  $64.4 \pm 4.5$ ml/kg/min) performed an incremental exercise test and an XCO race simulation on Computrainer™ (Seattle, USA). The simulation consisted of four laps (9.9km and 0-10% grade each). All athletes were asked to complete the race in the shortest time as possible. Heart rate (HR) was monitored using Polar®RS800CX. Subjects were divided into two groups (high and low) based on performance time. Results No group x time interactions were found in lap time ( $p=0.153$ ; linear), RPE ( $p=0.551$ ; linear), HR ( $p=0.145$ ; linear and cubic), power in W/kg ( $p=0.584$ ; linear). The decrease in performance every lap was linear ( $p<0.001$ ), with the last lap being slower than the first lap ( $3.49 \pm 0.6$ min; [CI95% 1.57, 5.42];  $p=0.001$ ). Based on a regression analysis, the riders decreased power every lap by 0.21W/kg corresponding to a lost of 1.6min. The power output decreased in the last lap compared to the first ( $42.9 \pm 7.2$ W; [CI95% 20.3, 65.5];  $p=0.000$ ). Both HR and RPE increased linearly with the last lap showing higher values than the first ( $4.4 \pm 0.9$ beats/min; [CI95% 1.5, 7.2];  $p=0.003$  and  $32.8 \pm 3.6$ ; [21.3, 44.5];  $p=0.000$ ). The mean power and HR of the simulation was  $234.9 \pm 31.1$ W ( $3.5 \pm 0.5$ W/kg) and  $173.7 \pm 10.8$ beats/min. Discussion During the simulation a pacing strategy similar to that reported for real events was found (Impellizzeri et al., 2002; Stapelfeldt et al., 2004). Furthermore, the pacing seems to be not influenced by the performance level. Although the strategy adopted (first laps faster) has been demonstrated to be detrimental to performance (Foster et al., 1993), the use of a faster start is technically important for the success in XCO because the cyclists can gain the first positions for avoiding to be slowed down by other riders, especially in the single tracks. In conclusion the study showed that the simulation has a good external validity and may be potentially useful for investigating the effect of interventions in controlled laboratory conditions.

**RELIABILITY OF PACING PROFILES DURING COMPETITION IN TOP-LEVEL SWIMMERS**

Skorski, S.1, Faude, O.1,2, Meyer, T.1

*1University of Saarland, 2University of Basel*

Introduction Estimates of the variation in performance between competitive events are useful for coaches and scientists to determine the size of a performance enhancing strategy (Stewart & Hopkins, 2000). Since it is assumed that pacing has a major effect on competition (CO) performance, the aim of this study was to analyze the consistency of pacing profiles (PP) in elite swimmers during 200m front-crawl, butterfly, backstroke and breaststroke CO. Methods Finals of 65 elite male swimmers (age:  $23.6 \pm 2.9$  y, front-crawl:  $n=25$ , butterfly:  $n=15$ , backstroke:  $n=16$ , breaststroke:  $n=15$ ) from 12 different nations in 29 international and national CO during the year 2010 were analysed using the website swimrankings.net. The Pan Pacific Games (PPG) were chosen as the main CO, since it is the international top meeting in non-Olympic and non-WorldChampionship years. Additionally, a CO as close as possible to the PPG (at least national Championships)

was analysed for each swimmer; both were on average  $6.7 \pm 5.8$  weeks apart. Typical error (TE) between COs as well as coefficient of variation (CV) with 90% confidence limits (CI) for each 50m split time as well as for total time between COs were calculated. Results Showing a fast-start profile in all races, no significant differences in PP were observed between COs for all strokes ( $p > 0.63$ ). CV for total time was small: front-crawl: 1.0% (CI=0.8-1.4%), butterfly: 0.8% (CI=0.6-1.1%), backstroke: 2.0% (CI=1.6-2.9%), breaststroke: 1.4% (CI=1.1-2.1%). Regarding split times crawl showed a consistent PP in all sections: CV range 1.3-1.4%. During butterfly and backstroke CVs were low in the first three sections; CV range between 1.5-1.8% and 1.6-1.9%, respectively. The last 50m-section showed greater variability in both strokes (butterfly: 2.0%, backstroke: 2.2%). In breaststroke variability between COs was higher in all sections compared to all other strokes (CV range 2.0-3.0%), except the first one (CV=1.7%). Discussion PP of elite swimmers are consistent during the first 3 sections in 200m front-crawl, butterfly and backstroke. Variability increases towards the end of a race. Breaststroke showed greater variability during the whole race. These results are in accordance with data on the consistency of PP during simulated swimming competitions (Skorski et al., 2011) and support the assumption that pacing is a combination of anticipatory forecasting and actual sensory feedback (Tucker, 2009). ### PACING PROFILES RELATIVE TO INTERCHANGES IN ELITE RUGBY LEAGUE

Highton, J.1, Waldron, M.1,2, Daniels, M.2, Twist, C.1

1: University of Chester (Chester, UK), 2: St Helens Rugby League Football Club (St Helens, UK)

Introduction Differences in high-intensity ( $> 14$  km/h) movement between playing positions in elite rugby league match play are well documented (Sykes et al., 2011; Waldron et al., 2011), yet little information exists on the exercise profile of interchanged players. Understanding exercise intensity during multiple interchanges is important for match conditioning, but also offers an opportunity to explore the potential for pacing in team sports due to the unstable nature of the exercise end-point (Edwards & Noakes, 2009). Accordingly, the aim of this study was to document pacing profiles of elite rugby league players relative to the nature of their playing bout. Methods Thirty-five performances from 18 elite males during 14 Engage Super League matches were analysed. Movement characteristics and heart rate (HR) were recorded via a portable 5 Hz GPS device (SPI-Pro; 5Hz, GPSports, Canberra, Australia). Match performances were analysed by quartile and separated in to three categories: whole match ( $n = 19$ ; players who completed  $\geq 80$  min), interchange 1 ( $n = 16$ ; the initial match play bout; mean =  $20.2 \pm 3.9$  min) and interchange 2 ( $n = 9$ ; players coming on for their second bout; mean =  $22.5 \pm 11.0$  min). Results In interchange 2, high intensity m/min declined from quartile 1 to quartile 3 only ( $18 \pm 4.1$  c.f.  $13.4 \pm 5$  m/min), whilst whole match players declined from quartile 1 ( $18.3 \pm 4.7$  m/min) to quartile 4 ( $14 \pm 4.6$  m/min). In contrast, interchange 1 players had a higher initial high intensity m/min in quartile 1 ( $24.2 \pm 7.9$  m/min), which declined progressively between match quartiles. Whole match players' %HRpeak progressively decreased across match quartiles, and was lower at quartile 3 ( $81.7 \pm 4.5\%$ ) and 4 ( $79.9 \pm 7\%$ ) compared to interchange 2 ( $86.3 \pm 5.4\%$  and  $90.3 \pm 2.9\%$ ) and at quartile 3 compared to interchange 1 ( $87.3 \pm 4.2\%$ ). Discussion In agreement with previous rugby league data (Sykes et al., 2011), whole match players demonstrate a subtle progressive decline in high intensity movement. In contrast, players in their first interchange adopt a higher initial exercise intensity followed by a rapid decline. During their second interchange, players exercise at an intensity which is closer to that of whole match players and that can be maintained until the exercise end-point. These data have implications for rugby league interchange strategy and the development of match-specific conditioning programs, and provide preliminary evidence of variable macro-pacing strategies in rugby league (Edwards & Noakes, 2009). ### COMPARISON OF THE PACING PROFILE DURING INTERMITTENT SINGLE- AND DOUBLE-LEG CYCLE TRAINING

Abbiss, C.R., Peiffer, J.J., Laursen, P.B., Martin, J., Martin, D.T.

Edith Cowan University

Introduction It has been suggested that fatigue during high-intensity exercise may have both central and peripheral origins. Intermittent self-paced single-leg cycling exercise offers a unique model to examine fatigue because it has previously been shown that greater leg blood flow during single-leg cycling permits higher individual-leg cycling power outputs but reduced cardiac load, compared with double-leg cycling. However, how work is self-regulated during intermittent single and double leg cycling is not known. The aim of this study was to examine the self-selected distribution of work during six repeated intermittent double and single leg cycling protocols. Methods In a randomised counterbalanced order, eight endurance-trained cyclists (mass:  $83 \pm 15$  kg,  $VO_{2max}$ :  $55 \pm 7$  ml/kg/min) performed six intermittent cycling sessions (S1-6) using either single- or double-leg cycling. The intermittent cycling protocol consisted of 3 (double) or 6 (3 right and 3 left; single) maximal 4 min intervals, with 6 min recovery between efforts/intervals. Total work and the decrement in work over consecutive intervals and throughout each minute of each interval were calculated. Participants were instructed to complete each of the intervals and each session at their highest sustainable power output. Significance was accepted at  $p < 0.05$ . Results Total work completed in each session was highly reliable (CV: mean S1-6 = 2.5 and 1.8% for single and double-leg training, respectively) and significantly greater in the single compared to the double-leg training condition ( $384 \pm 58$  vs.  $330 \pm 36$  kJ, respectively). The decrement in work each minute during the intervals was greatest during double, compared with the single-leg training condition in S1 ( $4.9 \pm 5.1$  vs.  $-1.3 \pm 5.2\%$ , respectively), but was similar for the remaining trials (S2-6; 0.6 to 2.2%). The decrement in work over consecutive intervals was greater in double, compared with single-leg cycling during all training sessions (mean S1-6:  $3.2 \pm 3.1$  and  $-0.2 \pm 3.2\%$ , respectively). Discussion Following familiarisation, the distribution of pacing during the four minute high-intensity intervals was similar between the single and double leg cycling. Despite, a low per leg power output during the double leg cycling, the decline in work during repeat intervals was greater in double, compared with single leg cycling. It therefore appears that localised fatigue during high-intensity intervals may be reduced when using a reduced muscle mass, possibly by due to greater blood flow and more rapid recovery.

### DO CHANGES IN BRAIN NEUROTRANSMITTER CONCENTRATIONS INFLUENCE PACING STRATEGY IN THE HEAT?

Roelands, B., de Koning, J., Foster, C., Hettlinga, F., Meeusen, R.

Vrije Universiteit Brussel; Funds for Scientific Research Flanders (FWO)

Do changes in brain neurotransmitter concentrations influence pacing strategy in the heat? Bart Roelands, de Koning, J., Foster, C., Hettlinga, F., Romain Meeusen Introduction/purpose: Exercise-induced changes in the concentrations of dopamine, noradrenaline and serotonin have been linked to central fatigue (Roelands and Meeusen, 2010), with the most pronounced outcomes measured when

exercise is performed in the heat. Little is known about the changes in pacing strategy induced by administration of central nervous system drugs acting on these neurotransmitter systems. Methods: Data were collected from 41 subjects ( $W_{max} 341 \pm 37W$ ). All subjects were endurance-trained cyclists and performed 60 min fixed intensity exercise (55%  $W_{max}$ ) followed by a time trial that was started at 75%  $W_{max}$ , but subjects were free to change resistance. Environmental temperature was set at 30°C (relative humidity 50%). Power output was measured continuously and averaged in 5% intervals for statistical analysis. The pharmacological agents bupropion (2x300mg), methylphenidate (20 mg), reboxetine (2x8mg), citalopram (2x10mg) were compared to a placebo administration. Results: Methylphenidate and bupropion (mainly dopamine reuptake inhibitors, noradrenaline to a lesser extent) improved performance and increased core temperature, while no change in RPE and thermal comfort was apparent. The initial decrease in power output – observed in the placebo trial in the heat – was much smaller in the drug conditions. Reboxetine (noradrenaline reuptake inhibitor) significantly decreased performance. Power output during the reboxetine trials decreased more from the outset of exercise compared to the placebo situation. It remained parallel during the middle part of the time trial and was still lower during the end sprint. During the initial ten minutes of exercise, power output declined more in the citalopram trial (serotonin reuptake inhibitor); furthermore, subjects are unable to produce an end sprint after citalopram administration. Discussion/Conclusion: Dopaminergic drugs appear to override a central safety switch and allow athletes to use a reserve capacity that is not present in a normal (placebo) situation as it is a mean to avoid catastrophic outcomes. Manipulations of serotonin but most obviously noradrenaline have an opposite effect and force subjects to decrease power output early in the time trial. Despite the lower power output during the citalopram trial, subjects do not possess the drive and motivation to augment power output when approaching the end point. #### EFFECT OF STIMULATING SALIVA FLOW ON THE CHANGES IN CORTISOL AND $\alpha$ -AMYLASE WITH PROLONGED EXHAUSTIVE EXERCISE

Allgrove, J., Oliveira, M., Gallen, A., Gleeson, M.

*University of Greenwich at Medway*

Saliva analysis is a useful non-invasive tool commonly used to monitor the stress hormone response to exercise (Chicharo et al., 1998). Athletes frequently consume food and beverages during exercise; however, stimulating saliva flow via mechanical or gustatory stimuli during exercise may alter the quantity and quality of saliva (Allgrove et al., 2007). This study examined the effect of stimulating saliva flow on the levels of cortisol (a marker of the hypothalamic-pituitary-adrenal axis) and  $\alpha$ -amylase (a marker of sympathetic nervous system activity) in response to strenuous exercise. Twelve fit, healthy, men (mean  $\pm$  SD age: 21  $\pm$  2 years; maximal oxygen uptake,  $VO_{2max}$ : 59.1  $\pm$  4.6 ml/kg/min) cycled for 2.5 hours at 60%  $VO_{2max}$  (with regular water ingestion) and then cycled to exhaustion at 75%  $VO_{2max}$ . Timed collections of whole saliva were made immediately before exercise, mid-exercise, after completion of the 2.5 hour moderate exercise bout and immediately after the exhaustive exercise bout. After each unstimulated saliva collection (three minutes) a stimulated saliva flow sample was collected following chewing mint-flavoured gum for one minute. Saliva was analysed for cortisol and  $\alpha$ -amylase activity via ELISA technique and secretion rates were calculated. Data were analysed using a 2-factor repeated measures ANOVA with post-hoc t-tests. Saliva flow rate was ~3-fold higher when saliva flow was stimulated ( $P < 0.01$ ). Saliva flow rate decreased 20% with exercise for stimulated saliva flow only ( $P < 0.01$ ). Exercise was associated with increases in cortisol (52%) and  $\alpha$ -amylase (170%) (all  $P < 0.01$ ). Stimulating saliva flow had no effect on the concentration or variability of cortisol and  $\alpha$ -amylase, though the secretion rates were greater (~3-fold higher) compared with unstimulated saliva flow (both  $P < 0.01$ ). In conclusion, stimulating saliva flow during exercise increased the quantity of saliva but had no effect on the concentration and variability of cortisol and  $\alpha$ -amylase. These findings suggest that stimulating saliva flow via mechanical or gustatory stimuli does not affect the stress hormone response to exercise. Allgrove, et al. (2007) 8th ISEI Symposium. Background: Nitric oxide ( $NO$ ) exerts key regulatory functions including vasodilation and glucose uptake. Thus reduced  $NO$  levels are associated with insulin resistance and hypertension. In this preliminary work we aimed to measure the levels of  $NO$  metabolites in serum and skeletal muscle of obese and non-obese subjects, with or without T2DM. Methods: Fifteen sedentary male participants [7 obese controls (C) vs. 5 obese and 3 non-obese T2DM; age 54 $\pm$ 9 years] were selected according to their BMI (30kg/m<sup>2</sup> for obese and 23-27kg/m<sup>2</sup> for non-obese participants) and evaluated for fasted values of erythrocyte glutathione (GSH), adiponectin, leptin and cytokines, serum and skeletal muscle nitric oxide metabolites (tNOx) and skeletal muscle nNOS and iNOS expression. Results: In the obese control and obese T2DM group a higher level of leptin (ng/mL) was observed (13.2 $\pm$ 4.7 and 26.3 $\pm$ 1.6, respectively) when compared with non-obese T2DM (2.8 $\pm$ 0.12). The opposite behavior was found for adiponectin concentrations where the non-obese group presents higher levels. TNF $\alpha$  concentration was higher in both obese groups when compared to the non-obese T2DM. Reduced glutathione was highly decreased in the obese T2DM group when compared to the obese control and non-obese T2DM. We found that serum tNOx (total nitrite/nitrate;  $\mu$ M) was lower in obese T2DM group (12.7 $\pm$ 3.5) when compared with their controls (21.1 $\pm$ 2.4), although the non-obese group presented higher concentration of tNOx (33.8 $\pm$ 7.2). Skeletal muscle nNOS was higher in obese controls, lower in non-obese T2DM and undetected in obese T2DM. On the other hand, expression of iNOS had an inverse relationship with nNOS, showing higher expres-

sion in obese T2DM, decreased in non-obese T2DM and absence in obese control group. tNOx levels ( $\mu\text{mol}/\text{mg}$  protein) were decreased in the non-obese T2DM group ( $12.07 \pm 0.59$ ) when compared with the obese control ( $21.68 \pm 6.2$ ) and the obese T2DM group ( $26.3 \pm 7.26$ ). Conclusions: We conclude that the decreased serum NO $\cdot$  production in obesity and T2DM seems to be associated with adipose mass as lower adiposity was associated with normal NO $\cdot$  which was reduced in the skeletal muscle of the non-obese T2DM patients. We suggest that the lower adiposity (and higher adiponectin) in non-obese T2DM could be responsible for differential levels of NO $\cdot$  production and insulin resistance.

### ERYTHROPOIETIN INCREASES FAT OXIDATION IN LEAN RATS AND IMPROVES GLUCOSE REGULATION IN HIGH FAT FED ANIMALS

Ainge, H.1, Madsen, A.3, Simar, D.2, Ruell, P.1, Barres, R.3, Caillaud, C.1

1:USYD (Sydney, Australia), 2:UNSW (Sydney, Australia), 3:NNF-CBMR (Copenhagen, Denmark)

Introduction. Clinical trials using recombinant Erythropoietin (EPO) for the treatment of anaemia report that, in addition to the resolution of anaemia, insulin sensitivity is increased (Khedr et al., 2009), but the mechanism by which EPO influences glucose metabolism is unclear. The aim of this study was to investigate the acute and chronic effects of EPO on glycaemic control using a rodent model of high fat diet (HFD)-induced insulin resistance. Methods. Male Sprague Dawley (SD) received intraperitoneal injections of EPO (Eprex, 500IU/kg) or saline (CON). Physical activity (PA) and energy expenditure (EE) were recorded for 24hrs. In a separate experiment, male SD rats were fed either standard chow (CC, n=16) or HFD for 7 weeks. For 3 weeks, HFD rats received twice a week either an injection of EPO (HFE, n=16) or saline (HFC, n=16). Prior to the first EPO injection, fasting blood glucose (FBG) was measured in all animals. Blood glucose (BG) was also recorded at 15, 30, 45, and 60 min post acute EPO injection in HFE rats. At week 7, all animals underwent an intraperitoneal Glucose Tolerance Test (IPGTT). Muscle tissues were collected 48 hours after the last EPO injection. Results. In chow fed rats, there was no change in PA activity, yet in animals that received EPO, EE increased and respiratory exchange ratio (RER) was reduced during the 12hr dark phase compared to CON. In HFD fed rats, acute EPO injection lowered BG ( $11.9 \pm 2.2\%$ ,  $p < 0.003$ ) during the 60 min post injection. Chronic EPO treatment lowered FBG (CC  $6.3 \pm 0.7$ , HFC  $7.6 \pm 0.5$ , HFE  $5.1 \pm 0.5$ mm,  $p < 0.001$ ), total cholesterol (CC  $69.1 \pm 8$ , HFC  $75.6 \pm 11$ , HFE  $59.6 \pm 5$ mg/ml,  $p < 0.05$ ) and serum TNF- $\alpha$  levels (CC  $0.7 \pm 0.6$ , HFC  $2.26 \pm 0.7$ , HFE  $1.06 \pm 0.7$ pg/ml,  $p < 0.05$ ). During IPGTT, glucose levels were reduced in HFE as compared to HFC ( $p = 0.002$ ). As compared to HFC, HFE rats showed strong trends towards elevation of HSP72 expression, reduced activation of JNK and increased activation of AKT. Conclusion. Here we report that acute EPO treatment enhances fat oxidation and chronic EPO ameliorates glucose metabolism in insulin resistant rats. The fact that normalisation of glucose tolerance was associated with lower cholesterol and TNF $\alpha$  levels strongly suggests that chronic EPO treatment alters glucose tolerance via changes in lipid metabolism and systemic inflammation levels. This effect could be promoted through the elevation of HSP72 expression and the associated reductions in JNK activation, leading to a better insulin action (Chung et al., 2009). ### EFFECT OF MUSCLE BIOPSY SITE ON GENE EXPRESSION IN PATIENTS UNDERGOING TOTAL HIP REPLACEMENT FOR OSTEOARTHRITIS

Okoro, T.1,2, Andrew, J.G.2, Stewart, C.3, Al-Shanti, N.3, Maddison, P.1, Lemmey, A.B.1

1:Bangor University (Bangor, UK), 2: Gwynedd Hospital (Bangor, UK), 3: MMU (Manchester, UK)

EFFECT OF MUSCLE BIOPSY SITE ON GENE EXPRESSION IN PATIENTS UNDERGOING TOTAL HIP REPLACEMENT FOR OSTEOARTHRITIS Okoro, T.1, 2, Andrew J.G.2, Stewart C.3, Al-Shanti N.3, Maddison P.1, Lemmey A.B.1 1: Bangor University (Bangor, UK), 2: Dept. Orthopaedics, Betsi Cadwaladr University Health Board (Bangor, UK), 3: Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University (Manchester, UK) Introduction Severe hip osteoarthritis is associated with increased inflammation and pain. This study aimed to assess the preferential local and distal effects of known hip inflammation on gene expression in the vastus lateralis (VL) muscle of patients undergoing total hip replacement surgery (THR) Methods Following local research committee approval, 17 patients awaiting THR were recruited (average age (mean  $\pm$  SD)  $65.3 \pm 8.8$  years in men (n=9) and  $59.8 \pm 13.3$  years in women (n=9)). Muscle biopsies were obtained from the proximal (3cm distal to insertion on greater trochanter; via the surgical wound) and distal VL (~5cm proximal to suprapatellar pouch) at the time of operation. RNA was isolated from the muscle biopsies obtained and real-time quantitative PCR performed using a panel of genes including those coding for inflammation (TNF- $\alpha$ , IL-6), hypertrophy (JunB, Calpain1 (CAPN1), calpain2 (CAPN2), calpastatin (CAST)), atrophy (myostatin (MSTN), cathepsin 2 (CTSL2)) and lipid metabolism (lipoprotein lipase (LPL), peroxisome proliferated-activated receptors alpha and gamma (PPARA, PPARG)). Gene expression was assessed using the comparative Ct method. Results 17 proximal VL samples and 15 distal VL samples were obtained. Distal vs. Proximal VL analysis revealed little impact of biopsy site on comparative gene expression, with no significant differences evident. Elevations of TNF (%fold increase/decrease (p value)) +16% ( $p = 0.71$ ) and IL-6 +15% ( $p = 0.97$ ), CAPN1 +63% ( $p = 0.71$ ), CAPN2 +110% ( $p = 0.64$ ), CAST +130% ( $p = 0.64$ ) were apparent, but far from significant. Jun B expression declined distally -27.5% ( $p = 0.79$ ), as did MSTN expression (-27%,  $p = 0.54$ ), but again without approaching significance. CTSL2 (+0.1%,  $p = 0.99$ ) showed near equivalence. Non-statistically significant changes were observed with markers of lipid metabolism (LPL (+6.7%), PPARG (+15%) and PPARA (-26.3%). Conclusions Hip joint inflammation appears to have no statistically significant effect on expression of the genes assessed in the VL muscle in this population, suggesting that for these analyses, single site muscle sampling is appropriate for subsequent analyses of training effects.

### IS ELECTRON TRANSPORT ACTIVITY REGULATED BY CONTRACTION? EVIDENCE THAT MITOCHONDRIAL COMPLEX I SENSITIVITY TO NADH INCREASES IN RESPONSE TO EXERCISE IN HUMAN SKELETAL MUSCLE

Perry, C.G.R.1, Herbst, E.1, Wright, D.C.1, Heigenhauser, G.J.F.2, Spriet, L.L.1, Holloway, G.P.1

University of Guelph, Guelph, Ontario

1: University of Guelph (Guelph, ON, Canada), 2: McMaster University (Hamilton, ON, Canada) Introduction Classic models pinpoint the major sites of skeletal muscle metabolic regulation during exercise at key enzymatic control points upstream from the entry point of electrons into the electron transport chain (ETC). The prevailing belief has been that the affinity of respiratory protein complexes (ie. Complex I) to electron entry from reducing equivalents (ie. NADH) is not subject to regulation by signals generated during contraction. One challenge in isolating potential effects of contraction on respiratory complexes is to monitor their activity in real-time while preserving mitochondrial structure and organization within their local environment in situ. Through the use of permeabilized muscle fibre bundles (PmFB) we tested the hypothesis that the sensitivity of complex I to NADH provision increases in response to exercise in human skeletal

muscle, consistent with improved coupling of oxidative phosphorylation to ATP turnover during contraction. Methods Muscle biopsies (vastus lateralis) were taken before and immediately after 2 hr of cycling exercise (~60% VO<sub>2</sub>peak) as well as 3 hr into recovery in 5 lean recreationally active males (mean age, weight, height and BMI: 21.8 ± 0.6 y, 1.78 ± 0.03 m, 76.4 ± 3.9 kg and 24.1 ± 0.9 kg•m<sup>-2</sup>, respectively). PmFB (~2 mg wet weight) were prepared from each biopsy and used to assess mitochondrial respiratory kinetics using high resolution respirometry (OROBOROS Oxygraph-2k). Specifically, in the presence of malate and saturating ADP, pyruvate and glutamate were titrated into separate PmFBs to permit the assessments of the respiratory sensitivity (Km) to each substrate. Results Exercise increased the respiratory sensitivity (decreased Km) for pyruvate by 38% immediately after exercise (p<0.05). However, 3 hr of recovery was sufficient to return pyruvate Km to resting values. Likewise, exercise increased the respiratory sensitivity to glutamate immediately after exercise (26% lower Km, p=0.07), with no effect observed at 3 hr recovery. Exercise did not change the respiratory control ratio (Pre, 11.1 ± 0.9; Post, 9.8 ± 1.0; 3hr Post, 9.1 ± 0.9). Discussion These results provide compelling evidence that exercise transiently increases Complex I sensitivity to NADH as it is unlikely that exercise altered both pyruvate and glutamate metabolism upstream of Complex I (ie. PDH and GDH sensitivities). These findings provide a strong basis for future investigations into the regulation of the ETC in response to exercise, a potential regulatory system which has previously been underappreciated.

#### PS-PL03 Olympism & Sport (\*)

##### THE IOC AND THE OLYMPIC ATHLETE

Engebreetsen, L.

*University of Oslo Medical School*

Since 2007 the International Olympic Committee is developing various programs for prevention of injuries and diseases in high level and recreational sports. This development is occurring with the cooperation of IFs such as FIFA, IHF, IAAF and FINA as well as with renowned research institutions worldwide. The Medical and Science Department of the IOC is currently developing research in the prevention field with several major institutions to focus on research, education and implementation of the new knowledge to all NOCs around the world (2). This strategy is highlighted with the IOC support of special issues of the British Journal of Sports Medicine. Every year at least two consensus conferences will be held- recently on Pre Participation Exams and on Age Determination in young athletes. Finally, the IOC has developed an injury and disease surveillance system for the Olympic Games- successfully conducted in Beijing and Vancouver (1). Through these initiatives, The International Olympic Committee (IOC) will increasingly emphasize the protection of the athletes' health and the prevention of injuries. REFERENCES 1.Engebreetsen L et al Br J Sports Med. 2010 Sep;44(11):772-80. 2. Bahr R, van Mechelen W, Kannus P. Prevention of sports injuries. In: Kjær M, Krogsgaard M, Magnusson P, et al. ##### CAN THE OLYMPIC GAMES CONTRIBUTE TO A BETTER WORLD? LESSONS FROM BEIJING 2008

Brownell, S.

*University of Missouri-St. Louis*

Since the end of the Cold War, the significance of the Olympic Games as a vehicle for inter-state diplomacy has lessened, while greater emphasis has been placed upon the "legacy" of the games for the host city and country. To a degree unprecedented in the Olympic context, human rights advocacy groups utilized the Beijing 2008 Olympics as a platform to exert pressure upon the Chinese government to improve its human rights record. Based on ethnographic fieldwork in Beijing in 2007-2008, interviews, and organizational analysis, this paper examines the relationships among the International Olympic Committee, Beijing organizing committee, Chinese government, human rights groups, and other actors, to provide an empirically-based answer to the question of whether the Olympic Games have the potential to contribute to a better world. It argues that attempts to answer the question have failed to identify the concrete organizational structures and event management strategies that would be necessary for the Olympic Games to fulfill the potential for positive social impact that is claimed for them. Academics have a responsibility to promote a more accurate understanding of the Olympic phenomenon in all its complexity.

Introduction The understanding of the mechanisms that occur at the exercise intensity correspondent to the maximal balance between lactate production and removal, and the intensities above (metabolic imbalance) and below (prolonged metabolic stability), is important

to understand the respiratory adjustments that occur in parallel with the lactate responses during aerobic capacity training exercise. The objective of this study was to analyze in a case study, the respiratory adjustments required to perform the maximal lactate steady state test (100%MLSS), and compare them with what happens at intensities above (102.5%MLSS) and below (97.5%MLSS) that gold standard intensity for the evaluation of aerobic capacity. Methods One elite female endurance swimmer (16 yr; 56 kg; 1.64 m) performed in different days: 1) a intermittent incremental protocol until voluntary exhaustion, with steps of 200m, increments of 0.05m.s<sup>-1</sup> and 30s rest intervals to determine the velocity (v), blood lactate concentration ([La-]), expiratory ventilation (VE) and the peak oxygen uptake (VO<sub>2peak</sub>); 2) three to five 30min sub-maximal continuous tests to determine v, [La-], VE and oxygen uptake (VO<sub>2</sub>) corresponding the 100%MLSS, 97.5%MLSS and 102.5%MLSS (Pelarigo et al., 2011). The VO<sub>2</sub> and VE values were directly and continuously measured using a telemetric portable gas analyser (K4 b2, Cosmed, Italy), connected to a special respiratory snorkel (Baldari et al., 2011). The values were analyzed at the 3rd and the last minute of the continuous test. Results At the intensities corresponding the 97.5%MLSS and 100%MLSS (1.30 and 1.33m.s<sup>-1</sup>), a stability in [La-] was observed (1.4 – 1.3 and 1.7 – 1.9mmol.l<sup>-1</sup>, respectively) and a slightly decrease in VO<sub>2</sub> and VE from the 3rd to the last minute of exercise (respectively: 50.81/49.7 – 72.68/69.91 and 56.70/51.66 ml.kg.min<sup>-1</sup> – 76.71/71.5 l.min<sup>-1</sup>). At an intensity of 102.5%MLSS (1.36m.s<sup>-1</sup>), any stability of physiological parameters was not observed – exhaustion at the 27th min ([La-] = 3.3 – 4.1mmol.l<sup>-1</sup>) with a slightly decrease in VO<sub>2</sub> and increase in VE between the 3rd and the last minute of exercise (57.90/57.30 ml.kg.min<sup>-1</sup> and 82.94/97.12 l.min<sup>-1</sup>). At the intensity corresponding the VO<sub>2peak</sub> (1.44m.s<sup>-1</sup>), the values of VO<sub>2</sub>, VE and [La-] were, respectively, 72.59 ml.kg.min<sup>-1</sup>, 90.74 l.min<sup>-1</sup> and 4.4mmol.l<sup>-1</sup>. Conclusions Thus, even the exercise being conducted or in stability or in metabolic imbalance, it seems that the swimmer adopts other adjustments (hydrodynamic drag / propulsive efficiency) to decrease the oxygen uptake between the 3rd and the last minute of exercise during the 30min test, making the aerobic bioenergetic system apparently more efficient along time. ### OXYGEN UPTAKE KINETICS DURING DIFFERENT SWIMMING INCREMENTAL PROTOCOLS

de Jesus, K., Sousa, A., Ribeiro, J., Machado, L., Vilas-Boas, J.P., Fernandes, R.J.

*Faculty of Sport Sciences, University of Porto*

Introduction The maximal oxygen uptake (VO<sub>2max</sub>) is one of the areas of interest in swimming performance and training diagnostic. Despite being widely assumed as a standard for maximal aerobic power, less attention has been given to its kinetics, namely during swimming incremental protocols of different step lengths. Since some authors refer to the necessity of using steps of longer duration, it was aimed to compare the VO<sub>2</sub> kinetics in three variants of a swimming incremental protocol to assess VO<sub>2max</sub>. Methods Four national level swimmers (20.5±3.4yrs, 1.84±0.07m, and 76.5±5.7kg), performed 7x200, 7x300 and 7x400m front crawl incremental protocols until exhaustion, with increments of 0.05m/s and 30s rest intervals between steps, and 24h between each protocol. O<sub>2</sub> was measured bxb (averaged every 5s) using a gas analyzer (K4b2) connected to a snorkel. VO<sub>2</sub> kinetics was estimated using a double exponential regression model. Amplitudes for exponential terms (A1 and A2), time delays (TD1 and TD2) and time constants (τ1 and τ2) were assessed, representing the fast (1) and slow (2) components of VO<sub>2</sub> kinetics. Significance was set at p≤0.05. Results VO<sub>2</sub> kinetics had a similar behavior along the 7x200, 7x300 and 7x400m, respectively: (i) A1 values of 48.7±2.5, 48.5±1.7 and 49.1±1.1ml.kg<sup>-1</sup>.min<sup>-1</sup>; (ii) A2 values of 11.2±2.7, 11.9±1.9 and 11.7±1.7ml.kg<sup>-1</sup>.min<sup>-1</sup>; (iii) TD1 values of 11.3±2.3, 11.6±2.0 and 11.8±2.0s; (iv) TD2 values of 96.5±5.5, 98.7±2.5, 99.2±2.1s; (v) τ1 values of 48.7±1.5, 50.1±1.6 and 54.3±3.4s; and τ2 values of 95.7±1.5, 96.5±1.9 and 99.2±1.7s. Discussion There were no differences in the amplitudes of the VO<sub>2</sub> response corresponding to fast (A1) and slow component (A2), corroborating data observed in running and cycling incremental protocols with 6 vs. 4 and 3 min steps duration (Burnley et al., 2001). No differences were observed for TD1, TD2, τ1 and τ2. Carter et al. (2000), conducting different incremental running and cycling protocols to assess VO<sub>2max</sub>, showed that time parameters remains remarkably constant as exercise intensity increased. Moreover, it has been suggested that the constant time parameters obtained in heavy exercise of long duration, might be related to an increase in lactic acidosis (Burnley et al., 2001). These current results suggest that 200 and 300m should be used in detriment of 400 m steps for VO<sub>2max</sub> assessment in swimming. Furthermore, short steps duration are easy to implement and more specific to the training and competitive swimming requirements. ### TIME OF DAY EFFECT ON THE LACTATE MINIMUM ASSESSMENT AND TIME TO EXHAUSTION IN SWIMMING RATS

Beck, W., Scariot, P., Dos Reis, I., Gobatto, C.

*UNICAMP*

Introduction Forced swimming in rats has been used in sports and medicine sciences by presenting several advantages, however, some experiments do not attempt to the nocturnal habits of these animals. Unfortunately, time of day effect on exercise performance in rats has been neglected in the specific scientific literature, despite the potential possibility of influence on the results. The aim of this study was to compare the lactate minimum test (LMT) variables and time to exhaustion at lactate minimum intensity (TTE) at two different times of the day in swimming rats. Methods Eighty rats were used in this study, which was approved by the institutional review board (UNESP protocol 018/2010). Rats were housed under 12/12 h light-dark cycle and were divided in two groups: handled and assessed at 12:00 h (G12, n = 40) or 20:00 h (G20, n = 40). For G20 assessment was used a red filter for the light (>600nm; <15lux). After two weeks of adaptation, at 90 days old, all animals performed the LMT according to De Araujo et al., (2007). LMT intensity (LMI) determination success rate (%S) was accepted for animals that complete at least 3 incremental loads, elicited the "a" positive for polynomial function and the coefficient of determination was greater than 0.80. Forty-eight hours after LMT, 20 rats per group were submitted to an exhaustive trial at the lactate minimum intensity at group's hour. Individual time to exhaustion was taken as the moment at which all coordinated movements ceased and the animal could no longer return to the surface (McArdle and Montoye, 1966). Blood lactate samples (25µl) were analyzed by enzymatic method and all data were compared using unpaired t test (p<0.05). Results LMI determination success rate was 65 % for G12 and 85 % for G20. LMI was 4.94±0.38%bw and 4.89±0.44%bw for G12 and G20 (p=0.71), respectively, being lactatemia equal to 7.29±1.72mM and 6.73±1.96mM (p=0.34). G12 shown lactate peak (lF) at 9.22±1.83mM and G20 at 9.16±2.36mM (p=0.92). The TTE was correspondent to 77.96±30.81min for G12 and 108.89±46.33min for G20 (39.67% greater for G20, p=0.03). Discussion To our knowledge this is the first study addressing the time of day effect on the time to exhaustion at an individualized intensity in rodents. We found that only %S and TTE are affected by the circadian rhythm. LMI do not suffer variations caused by time of day, however, the %S and TTE were greater at dark period, showing this like the ideal moment to aerobic assessment in swimming for rats. **Introduction** In recent decades, one of the most debated topics in sport sciences has been the anaerobic threshold (AnT), with several researchers using different methods (and concepts) to find the intensity associated to the maximal aerobic pace, defined as the highest intensity of exercise that can be maintained without continuous accumulation of lactate along the time (Heck et al., 1985). The aim of this case-study was to compare the generally recognized gold-standard method for the evaluation of the aerobic capacity, i.e., the maximal lactate steady state test (MLSS) with different methods of evaluation of AnT in swimming. **Methods** A female elite endurance swimmer (16 yr; 56 kg; 1.64 m) performed in different days a intermittent incremental protocols until voluntary exhaustion, with steps of 200m, increments of 0.05m.s<sup>-1</sup> between steps and 30s rest intervals, and two to four 30min sub-maximal tests at imposed pace to determine the MLSS, with a 2.5% difference between intensities (Pelarigo et al., 2011). In the incremental test, the blood lactate and the heart rate were analyzed during the 30s rest intervals and, in the MLSS, at the 10th and the 30th minute. MLSS was defined as the exercise intensity correspondent to the highest [La<sup>-</sup>] value that do not increase by no more than 1mmol.L<sup>-1</sup> between the 10th and 30th minute, and calculated as the average of the two [La<sup>-</sup>] values. The individual anaerobic threshold (IAnT) was calculated by the [La<sup>-</sup>] vs velocity curve modeling method (Machado et al., 2006) and the swimming velocity corresponding to 3.5 (3.5AnT) and 4mmol.L<sup>-1</sup> (4AnT) (Heck et al., 1985). **Results** The values of MLSS (1.33 m.s<sup>-1</sup>, 1.80 mmol.L<sup>-1</sup> and 194 bpm) showed that the IAnT (1.30 m.s<sup>-1</sup>, 1.46 mmol.L<sup>-1</sup> and 186 bpm) slightly underestimate the gold standard outcomes, while the 3.5AnT (1.41 m.s<sup>-1</sup> and 201 bpm) and 4AnT (1.43 m.s<sup>-1</sup> and 203 bpm) overestimate the correspondent exercise intensity. **Conclusions** Therefore, when compared the anaerobic threshold assessed through fixed [La<sup>-</sup>] values (3.5 and 4mmol) with the gold-standard method to evaluate the aerobic capacity (MLSS), the difference is higher than when IAnT is used. When MLSS is not possible to implement, the present case study results suggests that the IAnT will allow a more reliable prescription of exercise intensity for the evaluation of elite endurance athletes. **References** Pelarigo JG et al. ## RESPIRATORY BEHAVIOR OF SWIMMERS USING A SPIOMETRIC SNORKEL SYSTEM

Götz, J.K., Sperling, W., Schlicht, K., Hartmann, U.

*Universität Leipzig, Faculty of Sport Science*

**Introduction** In front crawl swimming, the timing and duration of breathing, especially for inspiration (Ins), highly depends on the swimming motion. If a snorkel is used, this constraint is canceled. Therefore, it is relevant to know whether the coupling between respiration and swimming movement (CRM), while swimming with the snorkel system, keeps equal or changes to arbitrary breathing. The aim of this study is to investigate the respiratory behavior using a snorkel system for gas analysis in swimming front crawl. We want to determine if there are any differences in the CRM at different performance levels of the athletes and if the increase in movement frequency affects the CRM. Furthermore it should be clarified whether the time of Ins is similar to swimming without snorkel. **Methods** A total of 17 subjects (12 ♂/5 ♀; age 17.7±5.4/16.6±3.4 years; height 185.2±7.1/167.0±4.2 cm; weight 73.3±12.9/55.6±6.4 kg) performed a step test swimming front crawl in the swimming flume. They were divided into three groups, elite, juniors and young swimmers. The test started at a speed of 75% of the actual best time in 200 m front crawl (BT2C), followed by a speed increase of 0.05 m/s every minute until subjective exhaustion. In order to collect the flow-volume curve (FVC) the snorkel system MetaSwim (Cortex, Leipzig) was used. The FVC and the swimming movements were simultaneously recorded on video. Using a double-blind video evaluation the last 30 s of each step were analyzed. In the process the FVC was tracked for the duration of Ins and expiration (Exp). Additionally the swimming movement was checked for the duration of the recovery phase of the arm, in which the swimmer inhaled. The duration of the respiratory cycles were compared with those of the movement cycles. Paired t-tests were used for comparison with a 95% level of confidence. **Results and Discussion** It could be shown that a CRM was not implemented by all athletes. Differences between movement and breathing cycle amounted up to 0.18-0.60 s. The performance level and the increase of the movement frequency were found not to be relevant factors. It was striking, that for all swimmers, who named their main stroke front crawl a CRM could be shown. With prevailing CRM the time of the start of Ins is comparable to swimming without a snorkel. The duration of Ins in swimming with a snorkel is high significantly longer ( $p \leq 0.001$ ) than the duration of the recovery phase of the according arm, which can be explained by the increased dead space of the snorkel. It was noticeable that in exception of one, all swimmers with CRM held their breath after Ins. This means that by increasing the movement frequency not only the duration of Ins and Exp was reduced, but also the duration of the breath holding. This was not seen by swimmers with arbitrary breathing.

## A METHOD FOR DETERMINING CRITICAL FORCE AND ANAEROBIC IMPULSE CAPACITY IN TETHERED SWIMMING

Papoti, M.1, Silva, A.S.R.2, Vitório, R.3, Araújo, G.G.3, Santhiago, V.3, Martins, L.E.B.4, Cunha, A.S.4, Gobatto, C.A.5

*1:UNESP (Presidente Prudente, Brazil), 2:USP (Ribeirão Preto, Brazil), 3:UNESP (Rio Claro, Brazil), 4:UNICAMP (Campinas, Brazil) e 5: UNICAMP (Limeira, Brazil).*

**Introduction** The critical power model has been used to measure aerobic and anaerobic capacity. The aerobic and anaerobic capacities measured in tethered swimming by the critical power model are named critical force (CriF) and anaerobic impulse capacity (AIC), respectively. The objective of this study was to determine whether CriF and AIC - estimated by tethered swimming - reflect the aerobic and anaerobic performance of swimmers. **Methods** Twelve swimmers performed incremental test in tethered swimming until exhaustion to determine lactate threshold (LT), maximal oxygen uptake (VO<sub>2</sub>max) and force of swimming associated with the VO<sub>2</sub>max (iVO<sub>2</sub>max). The swimmers performed four exhaustive (flim) exercise bouts (100, 110, 120 and 130% ) to compute the CriF and AIC (F vs. 1/flim model); a 30-s all out tethered swimming bout to determine their anaerobic fitness (ANF); 100, 200, and 400-m time-trials to determine the swimming performance. **Results** CriF (57.09 ± 11.77 N) did not differ from LT (53.96 ± 11.52 N,  $P > 0.05$ ) but was significantly lower of iVO<sub>2</sub>max (71.02 ± 8.36N). In addition, CriF presented significant correlation with LT ( $r = 0.76$ ;  $P < 0.05$ ) and ( $r = 0.74$ ;  $P < 0.05$ ). On the other hand, AIC (286.19 ± 54.91 N.s) and ANF (116.10 ± 13.66 N) were significantly correlated. In addition, CriF and AIC presented significant correlations with all time-trials. **Discussion** In the present investigation, CriF did not differ from LT, but presented significant correlation with the same

variable. Perandini et al. (2007) found significant correlations between CritF values determined from different mathematical models and CV ( $r=0.89$  to  $0.91$ ), concluding that CritF could be used as an indicator of aerobic capacity. Another interesting finding of our investigation was the significant correlation between AIC and ANF ( $r=0.81$ ;  $P=0.001$ ), and between AIC and maximal free swimming performances. These significant correlations contradicted results generally found in associations between AIC and ANF and between AIC and free swimming performances (Soares et al. 2003, Toussaint et al. 1998, Dekerle et al. 2001). In summary, this study demonstrate that CritF and AIC can be used to evaluate LT and ANF and to predict 100, 200, and 400-m free swimming. References Dekerle J, Sidney M, Hespel JM, Pelayo P. ## SWIMMERS SOMATOTYP PROFILE

Leko, G., Siljeg, K.

*Faculty of Kinesiology*

**Introduction** Morphological structure plays an important role in competitive swimming. Creating a large propulsive force with minimal frontal resistance ensures maximum swimming speed. It is therefore very important to achieve the optimum relationship between muscle mass and adipose tissue in order to achieve maximum results. The aim of this research was to determine the somatotype profiles of 14-16-year-old male swimmers. **Methods** In that regard, 68 swimmers from swimming clubs in Zagreb were examined using 10 anthropometric measurements that were subsequently used to determine the somatotype according to the method proposed by Heath and Carter. **Results and discussion** The results point towards somewhat increased body fat percentage in comparison to swimming population. The somatotype of the examined swimmers indicates strong ectomorphic (3,31) component while the endomorphic (2,21) and mesomorphic (2,34) components are similar in their values. The results indicate that all swimmers evaluated in this research have not completed their pubertal development and that the significant positive relationship can be evident only in the mesomorphic component which is characterized by larger muscle mass and butterfly technique which is the most demanding in terms of energy expenditure. **References** Carter JEL, Heath BA. *Somatotyp-development and applications*. ## ANALYSIS OF THE PERCEPTION OF THE EFFORT IN FRONT CRAWL AND BREASTSTROKE SWIMMING

Invernizzi, P.L., Michielon, G., Longo, S., Scurati, R.

*Università degli studi di Milano*

**Introduction** Fatigue is generally defined as a decreased performance due to physiological or psychological limitations. Among them, the intensity and the duration of the exercise and the conscious perception of the effort are very relevant. CR10 scale (Borg, 1982) is useful to measure the perception of the effort during the exercise. This study aimed to assess some subjective features of the perception of effort in breaststroke and front crawl swimming. **Methods** Ten swimmers (18.2±0.2 years, 67.9±3.6 kg, 180±1.0 cm, 21.07±0.66 kg/m<sup>2</sup>) participated in the study. Swimmers were asked to perform 50, 100 and 200 meters front crawl (FC) and breaststroke (BR), at the maximum velocity. The subjective perceptions of the general, muscular and respiratory efforts were assessed through the CR10 scale and compared with respect to the distance and to the swimming technique. **Results** The perception of the effort was higher ( $p<0.001$ ) after the trial on 100m than after the trial on 50m, both in front crawl and breaststroke (AU±SD; general effort: 6.70±1.34 vs. 4.00±0.94 and 8.20±0.79 vs. 3.70±1.16; muscular effort: 6.30±0.95 vs. 3.05±0.90 and 7.50±1.08 vs. 3.90±1.37; respiratory effort: 6.20±1.48 vs. 3.80±1.01 and 7.40±1.17 vs. 3.80±1.03, FC and BR, respectively). The perception of the effort surveyed after the trial on 100m did not differ with respect to the trial on 200m. In the between-technique comparison of the general perception of the effort, CR10 showed lower values in FC than in BR after the 100m trial ( $p<0.05$ , 6.70±1.34 vs. 8.20±0.79, AU±SD). The perception of the muscular effort was also lower in FC than in BR, but only after the 50m trial ( $p<0.05$ , 3.05±0.90 vs. 3.90±1.37, AU±SD). No difference was found between FR and BR in the respiratory effort, in all trials. **Discussion** In front crawl and in breaststroke, the distance seems to have the same effect on the perception of the general, muscular and respiratory effort, measured by CR10 scale. However, these differences are noticeable only comparing the efforts between 50m and 100m. Moreover, even if the energetic demand of front crawl and breaststroke are quite different (Capelli et al, 1998), the participants of the present study seemed to perceive only partially this difference in the general and in the muscular effort perception (in 100m and 50m trials, respectively). In the respiratory effort, subjects scarcely discriminate between the techniques, as expected from the literature. **References** Borg GA (1982). *Psychophysical bases of perceived exertion*. *Medicine and Science in Sports and Exercise*. 1982; 14:377-381. ## RELATIONSHIP BETWEEN POWER DECREASE AND SWIMMING PERFORMANCE: A PILOT STUDY

Dias, P., Costa, A., Morouco, P., Garrido, N., Amaro, N., Marinho, D., Marques, M.C.

*Polytechnic Institute of Leiria*

**Introduction** Evaluation of athletes should be specific to nature of the sport. Apart from being used in dry-land, biokinetic swim bench tries to replicate the swimming arm movement. Indeed, Stager and Coyle (2005) stated that the decrease in power production may indicate sprint vs. distance profiles. Therefore, the aim of the present study was to analyse possible relationships between power production in swim bench and swimming performance. **Methods** Five male national level swimmers (age: 18.4 ± 2.3 years; body mass: 73.1 ± 7.7 kg, stature: 1.78 ± 8.3 m) volunteered to take part in the study. After a 600 m standard warm-up, each swimmer performed a 30 s maximum effort in a classic Vasa Swim Ergometer (Vasa, Essex Junction, USA). Individual power to time - P(t) - curves were assessed and registered to obtain the following parameters: maximum power (Pmax), average power (Pavg), average power in first 10 s (10Pavg), average power in last 5 s (5Pavg) and fatigue index (Findex). Additionally, fatigue slope (Fslope) was calculated as proposed by Morouço et al. (2012). One day after each subject executed one 50 m maximum crawl swim in a 25 meters swimming pool, being time registered (t50). After Shapiro-Wilk normality test, paired-samples t-Test to identify differences and Pearson's correlation coefficient (r) to establish relationships between variables were used. The level of statistical significance was set at  $p < 0.05$ . **Results** Swimmers took 3.4 ± 2.2 s to reach maxi-

mum power ( $204.2 \pm 37.5$  W). Average power in first 10 s was significantly higher than in last 5 s ( $181.4 \pm 29.4$  W;  $127.7 \pm 21.6$  W,  $p < 0.001$ ), with an associated Index of  $28.8 \pm 5.7\%$  and an Fslope of  $-2.63 \pm 0.88$ . Swimming performance was  $25.7 \pm 0.75$  s and it presented high correlations with time to reach Pmax ( $p < 0.01$ ), Pmax, Pavg, 10Pavg, 5Pavg and Fslope ( $p < 0.05$ ). Discussion Present data corroborate the studies suggesting that performance in short duration efforts is well related to the stroking power that a swimmer can generate (e.g., Costill et al., 1983). The assessment of this data may be an individual approach to performance in sprint distance races and, therefore, a helpful procedure to coaches. The presented parameter (Fslope) association with swimming performance induces the idea that short distance swimmers present higher decreases in P(t) curve, than long distance counterparts. ### ASSOCIATIONS BETWEEN PARTIAL TIMES AND TOTAL TIME IN 50 M FRONT CRAWL, ACCORDING TO AGE

Amaro, N., Dias, P., Marques, M.C., Marinho, D., Morouco, P.

*Polytechnic Institute of Leiria*

Introduction In Portugal there are several clubs training in 25 m swimming pools and competing in 50 m ones. Concerning the 50 m front crawl training bouts, it is expected that different velocities are obtained in the first and second 50 m. Coaches are aware of that and estimate differences without taking into consideration the start, turn and gliding. Therefore, the aim of the present study was to analyze possible relationships between times to accomplish 4 m before turn and before finish, with overall 50 m time. Methods Two groups of 6 male swimmers each (G1:  $13.5 \pm 0.32$  years of age,  $49.0 \pm 7.9$  kg,  $1.64 \pm 6.8$  m; G2:  $18.8 \pm 2.64$  years of age,  $73.3 \pm 8.6$  kg,  $1.81 \pm 8.1$  m) took part in the study. After an 800 m warm-up, each subject performed a maximum 50 m front crawl swimming, assessing swimming time (t50). Tests took place in a 25 m swimming pool and two cameras recorded the trials at 60 fps (Casio Exilim, FH1). A PVC structure (15 x 2 m) allowed the calibration of video images. Utilius easy inspect (CCC software, Germany) was used to estimate swimming time in two separate fractions: from 16 to 20 m (t1) and from 41 to 45 m (t2). Since the reduce sample size and the rejection of the null hypothesis in the normality assessment, non-parametric procedures were adopted. The level of statistical significance was set at  $p < 0.05$ . Results In younger swimmers the difference between t1 and t2 presented high correlations with t1 ( $\rho = 0.94$ ,  $p < 0.01$ ) and t50 ( $\rho = 0.81$ ,  $p < 0.05$ ). Were assessed significant correlations between t1 with t50 for G1 ( $\rho = -0.88$ ,  $p < 0.05$ ) and G2 ( $\rho = -0.83$ ,  $p < 0.05$ ). In older swimmers no other relationships were assessed. Coupling groups, multi factorial analysis obtained an adjusted  $R^2 = 0.838$ ,  $p < 0.001$  for  $t50 = 6.464 + (3.968 \times t1) + (5.554 \times t2)$ . Predicted times presented an estimated error of  $0.36 \pm 0.12$  s for G1 and  $-0.36 \pm 1.22$  s for G2. Discussion The main finding of the present study is that in 50 m maximum front crawl can be predicted by partial times. The association between the difference in partial times and the overall time in G1 indicate that faster swimmers in the beginning of the bout obtain higher performances, even if they aren't able to maintain velocity, presenting higher decrease. This data points that race tactics should be trained in order to enhance performance in young swimmers.

### EFFECTS OF DIFFERENT COMPOSED SQUAT RESISTANCE TRAINING ON LEGS STRENGTH AND START POWER PERFORMANCE IN COLLEGE SWIMMERS

CHO, C.J.1, TAI, Y.J.2, WU, C.M.3, YE, C.C.4

1: NUTN (Tainan, Taiwan), 2: NKMU (Kaogsiung, Taiwan), 3: CSU (Kaogsiung, Taiwan), 4: NKFUST (Kaogsiung, Taiwan)

Introduction Many swimming competition results indicate that legs strength also influence turn performance, but how to improve by training still controversy. Therefore, the aim of this study was to realize the effect of six weeks different composed squat resistance training in addition to the habitual swimming program on legs strength (LS) and start power (SP) performance. Methods Twenty college swimmers were average assigned to two groups according to 1RM legs strength, groups A (n= 10; age:  $20.00 \pm 3.40$  y; body mass:  $70.27 \pm 12.37$  kg; height:  $170.90 \pm 6.24$  cm; body fat:  $23.66 \pm 7.63\%$ , GA) and groups B (n= 10; age:  $20.80 \pm 3.71$  y; body mass:  $65.32 \pm 10.65$  kg; height:  $168.40 \pm 7.47$  cm; body fat:  $22.77 \pm 8.33\%$ , GB) were trained two times a week for six weeks. In weeks 1-3 and 4-6, GA performed 65% 15RM plus 90% 4RM (Wathen, 1994) GB performed 90% 4RM plus 65% 15RM squat weight training. Body fat, LS, and SP (calculate with body mass, 5m push wall start time, and  $75 \text{ kg} \cdot \text{m/s}$  for hp) were measured before and after training, t-test was applied to analyze these data in group and group. Results The results of this study indicated that two groups were effective at increasing LS after training ( $p < 0.05$ ), GA improved from 83 to 144.5kg, GB improved from 83 to 130kg. In SP, only GB improved from 3.14 to 3.60hp ( $p < 0.05$ ), all the swimmers decreased body mass (67.79 to 66.92kg) and body composition (23.21% to 22.70%) significantly ( $p < 0.05$ ). Discussion Results suggested a positive effect of GA and GB training program, because of these swimmers did not accept the routine training before, so the different composed course should increase the strength, off season national football player correspond to have a positive influence (Brechue and Mayhew, 2012). GB set training program from muscle strength to endurance and significant increase in SP, which was in accordance with previous studies that the importance of lower body strength and power to start time (west et al., 2011), we did not find the same effect in GA, probably due to the testing distance and other start skills. Previous reports have found that sprint swimming performance was related to body mass, lean body mass (Geladas et al., 2005), this study showed that both training programs transferred fat to muscle mass and increased strength, further study need to consider the swimmers' lever, resistance training experience, and sprint performance test is necessary. 1: CSU(Kaohsiung, Taiwan), 2: PCCU(Taipei, Taiwan), 3: NKMUI(Kaohsiung, Taiwan)

Introduction Simulated hypoxia chamber had been use for improve human performance in many years, no matter via resting or sleeping strategy, or intermittent hypoxic training (IHT). In other aspects, it may improve energy efficiency; our purpose of this study was to investigate the effects of combined 16 week IHT via hypoxic chamber on lipid metabolism, cardiopulmonary fitness on middle-aged obese adults. Methods Thirty obese (BMI >25 or body fat percentage >30%) subjects(38.9±9.2years old, 163.2±8.4cm, 68.1±15.2kg) were recruited and randomly assigned into two exercise groups (oxygen concentrations of 16% and 14%, respectively) and underwent 16weeks IHT program, including 4weeks of normoxia, 8weeks of IHT, and 4 weeks of follow-up period. Exercise protocol consisted of 10 minutes warm-up, 30 minutes brisk walking on treadmill at 50%VO<sub>2</sub>max, and 10 minutes cool-down, 3 times a week. Cardiopulmonary fitness, total cholesterol, HDL, LDL, triglycerides were collected at pre-training, 4th, 8th, 12th and 16th week, respectively. Two-way ANCOVA with mixed design was used for statistics. Results Weight and %body fat did not show significant difference between groups; however, %body fat of 16% group significantly decreased in 8th week compared with that of pre-training (30.45± 6.72 vs. 31.87± 6.91%), whereas %body fat of 14% group in 12th week was significantly lower than pre-training (27.59± 6.69 vs. 28.85± 7.25%). Cholesterol in 12th week was significantly lower than that of the 4th week; however, it returned to the baseline and reversed higher in 16th week (mean differences= -13.50,-8.71 mg/dL). No difference between-group in TG response at stages. Only TG of 12th week was significantly lower than that of pre-training in 16% group (79.58± 29.69vs. 91.25± 32.73 mg/dL). After hypoxic training, LDL of 16% group showed significant improvement from 8th to 12th week, compared with 4th week (118.75± 26.09,120.33± 27.75vs. 133.17± 20.23 umol/L). Discussion IHT could improve blood lipids metabolism for obese adults, especially in total cholesterol and LDL (Tin'kov, et al., 2002). In also, cardiopulmonary fitness was improved after training (Glazachev, et al., 2010). However, although both groups had improved during IHT, but within each stage, non significant difference were found in this results, these maybe resulted from oxygen concentrations and exercise intensity that had cross effects, or even the physiological accommodations(Wilber, et al., 2007). We suggested future study could focus on exercise intensity interaction with oxygen concentrations. References Glazachev, O. S., Zvenigorodskaja, L. A., Dudnik, E. N., Iartseva, L. SHORT-TERM INTERMITTENT HYPOXIA DOES NOT AFFECT VENTILATION BUT REDUCES BLOOD LACTATE CONCENTRATION DURING SUBMAXIMAL EXERCISE AT SIMULATED ALTITUDES UP TO 4000 M Faulhaber, M. 1, Dünwald, T. 1, Gatterer, H. 1, Bernardi, L. 2, Burtcher, M. 1 1 Department of Sport Science, University Innsbruck, Austria 2 Department of Internal Medicine, University of Pavia and IRCCS San Matteo, Italy Introduction Acute high-altitude exposure reduces endurance performance whereas chronic high-altitude exposure improves endurance performance at high altitude predominantly by ventilatory acclimatization (Burtcher et al. 2006). Intermittent hypoxia (IH), applying repeated passive hypoxic short-term ( $\leq 1$  hour) exposures, induces ventilatory acclimatization by increasing the hypoxic ventilatory response (HVR). This increase in HVR seems to increase exercise ventilation and improve arterial oxygen saturation (SaO<sub>2</sub>) depending on the test altitude (Katayama et al. 2001, 2007). No study evaluated IH effects at different altitudes within the same group of persons. Therefore, we tested in the same group of persons whether IH affects submaximal exercise responses depending on different altitudes. Methods Eight volunteers participated in the study (25±3 years, 179±4 cm, 74±5 kg). Measurements before IH included the determination of HVR and hypercapnic ventilatory response (HCVR) and 4 submaximal cycle ergometer tests at different simulated altitudes (1000m, 2000m, 3000m, and 4000m) in a randomized order. The subjects cycled for 10 minutes at 2 different work loads (corresponding to 40% and 60% of VO<sub>2</sub>max in normoxia). Ventilatory parameters, SaO<sub>2</sub>, and blood lactate concentrations (LA) were determined at each intensity. The subsequent IH application comprised 7 resting 1-hour sessions at 4500 m. Measurements after the IH application were the same as before and took place one day after finishing the IH application. Results The applied IH protocol resulted in a significant increase in HVR whereas HCVR remained unchanged. Submaximal exercise ventilation was not affected, but carbon dioxide production and LA were reduced after IH independent of altitude. SaO<sub>2</sub> improved slightly after IH. We found no interaction between the effects of altitude and those of IH. Discussion Our results suggest that there are no ventilatory effects of the applied IH protocol during submaximal exercise at altitudes up to 4000 m. However, it might be possible that the effect of an increased HVR was opposed by the reduced blood lactate concentration and carbon dioxide output. Further research has to investigate if the reduced blood lactate concentrations result in an improved endurance performance at high altitude. References Burtcher M, et al. (2006). **PAO<sub>2</sub> IS MORE IMPORTANT THAN CAO<sub>2</sub> IN FATIGUE DEVELOPMENT DURING EXERCISE IN SEVERE ACUTE HYPOXIA**

Losa-Reyna, J., Ponce, J., Siebenmann, C., Rasmussen, P., Torres, R., Morales, D., Guadalupe, A., Rodríguez, L., Feijóo, D., Pérez, I., De la Calle, J., Sheel, A.W., Lundby, C., Calbet, J.A.L.

University of Las Palmas de Gran Canaria

Aim: To determine if fatigue during exercise in severe acute hypoxia is more influenced by arterial O<sub>2</sub> pressure (PaO<sub>2</sub>) or arterial O<sub>2</sub> content (CaO<sub>2</sub>). Methods: Eleven healthy men (age: 20±2 yrs, VO<sub>2</sub>max: 3.8±0.4 L/min, mean±SD) performed 2 incremental cycle ergometer tests (80 rpm;  $\Delta 20$ w/2 min) in acute hypoxia (FIO<sub>2</sub>=0.108; Barometric pressure: ~730 mmHg; PaO<sub>2</sub>: 33±2 mmHg; SaO<sub>2</sub>: 62±5%) to

exhaustion on different days (H1). At exhaustion (E1), when they were unable to keep a pedaling rate above 60 rpm despite strong verbal encouragement, the gas mixture was swiftly changed to FIO<sub>2</sub>=0.135 to overcome fatigue, and subjects instructed to continue pedalling. In few seconds they overcame fatigue as evidenced by the ability to continue cycling and achieve the desired pedalling rate. On the first experimental day the FIO<sub>2</sub>=0.135 gas mixture contained carbon monoxide (CO) in order to increase the carboxyhemoglobin (COHb) to 15±4% in 10-15 s; and on the second day, the FIO<sub>2</sub>=0.135 gas mixture contained only O<sub>2</sub> and N<sub>2</sub>. In both experiments, at E1, after two minutes of breathing hypoxia (FIO<sub>2</sub>=0.135), the intensity was increased again ( $\Delta$ 20w/2 min, FIO<sub>2</sub>=0.135, H2) and continued until exhaustion (E2). At exhaustion E2, subjects were swiftly switched to a normoxic inspirate (FIO<sub>2</sub>=0.21). After two minutes of breathing room air the intensity was increased ( $\Delta$ 20w/2 min) until exhaustion (E3). Results: Subjects cycled slightly longer while breathing CO+hypoxia (84 s) compared with hypoxia alone (72 s, p=0.56). A greater 12% VO<sub>2</sub>max was achieved without CO in H2 (p<0.05), although the PETO<sub>2</sub> at E2 was identical (65 mmHg) between conditions. The administration of CO+hypoxia at E1 increased SaO<sub>2</sub> to 71.3±5.0 and PaO<sub>2</sub> to 47.0±4.7 mmHg. However, arterial CaO<sub>2</sub> was 13% lower when the subjects breathed CO+hypoxia compared to hypoxia without CO, due to an increase of COHb (+14.6±3.5%). At E2, increasing the FIO<sub>2</sub> to 0.21 relieved fatigue instantaneously, allowing the continuation of the incremental exercise to a new exhaustion (E3). At E3 all subjects achieved their normoxic VO<sub>2</sub>max in the condition without CO. Conclusion: Fatigue during exercise in hypoxia is predominantly caused by a reduction in PaO<sub>2</sub>. This conclusion is based on the rapid relief of fatigue caused by small increases in PaO<sub>2</sub> even in the presence of an experimentally reduced CaO<sub>2</sub> Supported by MICINN, Spain (DEP2009-11638).

### EFFECTS OF NORMOBARIC HYPOXIC CONDITIONS ON SLEEP DURATION AND QUALITY IN PROFESSIONAL AUSTRALIAN FOOTBALL LEAGUE PLAYERS

Herrera, C.P.1, Farooq, A.1, Coutts, A.2,3, Bilsborough, J.C.3, Hocking, J.3, Cordy, J.3, Racinais, S.1, Buchheit, M.4

(1)Aspetar-Qatar Orthopaedic & Sports Medicine Hospital, (2)University of Technology (UTS), Sydney, Australia, (3)Carlton Football Club, Melbourne, Australia, (4)ASPIRE - Academy of Sports Excellence

Introduction Sleeping at simulated hypoxic environments in athletes is a common strategy to enhance performance as part of a 'live high-train low' camp but may be associated with reduced sleep duration and poor sleep quality. The purpose of this study was to investigate, in professional Australian Football League players, the effects of sleeping in a normobaric hypoxic dormitory on sleep using wrist actigraphy. Methods Actigraphy sleep was measured during a 2-week 'live high-train low' camp. After one night at 0m for laboratory adaptation and recovery from travel, sleep data were analyzed from a control group sleeping at normoxia (n=9, 22±2 y, 24.3±1 kg/m<sup>2</sup>) and compared with a second group sleeping at hypoxia (n=9, 22±2 y, 24.9±1 kg/m<sup>2</sup>); there was a progressive increase in simulated altitude - two nights at 2500m, two nights at 2800m, and subsequent nights at 3000m. A sleep diary was administered each morning to assess subjective sleep quality. Results There was a general decline in sleep duration and reduction in sleep quality across the study period in all players. Time in bed, total sleep time, and sleep efficiency were significantly reduced whereas the number of awakenings and total time spent awake after sleep onset were increased (all p<0.05). Comparing groups, time in bed was significantly lower in hypoxia (521.4±13.6) than normoxia (538.6±14.2, p<0.05). Excluding nights (4, 8, and 12) when there was an unrestricted sleep opportunity, total sleep time was significantly lower in hypoxia (430.7±5.0) than normoxia (453.0±5.1, p<0.01). All subjects reported a reduction in subjective sleep quality throughout the training camp but there were no group differences. Discussion This study provides novel evidence using actigraphy to confirm that sleep duration is reduced under normobaric hypoxic environments between 2500-3000m in Australian Football League players. The reduction in sleep duration was demonstrated only when the sleep period was fixed. In other words, when the sleep period was unrestricted there was no difference in total sleep time. These findings suggest that an extended sleep opportunity may attenuate possible sleep loss in athletes during a 'live high-train low' camp.

### TIME COURSE OF BLOOD PRESSURE AND VASCULAR ADAPTATIONS TO INTERMITTENT HYPOBARIC HYPOXIC EXERCISE

Ogita, F.1, Kurobe, K.1, Huang, Z.1, Nagira, A.1, Nishiwaki, M.2, Tanaka, T.1, Tamaki, H.3

1 National Institute of Fitness and Sports, 2 Prefectural University of Kumamoto, 3 Niigata University of Health and Welfare

Introduction Recently, we have observed that aerobic exercise in hypobaric hypoxia of 4 weeks could induce beneficial circulatory adaptations, such as a reduction of total peripheral resistance and blood pressure, and an increase in flow mediated vasodilation (FMD) response, stroke volume, and cardiac output (Ogita 2008). However, time course of such cardiovascular adaptations have not been clarified. Therefore, the present study evaluated the time course of blood pressure and vascular adaptations to intermittent hypobaric hypoxic exercise. Methods Twelve healthy male adults (22±1 yrs) were matched for physical fitness level into two groups, and then randomized to normobaric normoxic exercise group (N, n=6) and hypobaric hypoxic exercise group (H, n=6). The subjects had aquatic exercise training in swimming pool located in a chamber where atmospheric pressure could be regulated. The exercise was performed at the intensity of around 50%VO<sub>2</sub>max for 30 minutes/training session, 4 days/week, for 4 weeks. H had the exercise in hypobaric hypoxia corresponded to 2000m above sea level, and was exposed to the condition for 2 hours/session. Before and after the training, systolic (SBP), diastolic (DBP), and mean blood pressure (MBP) were determined at rest and during cycling exercise at 50%VO<sub>2</sub>max, which was determined before the training. Also, arterial stiffness was assessed by cardio ankle vascular index (CAVI), and FMD was evaluated by peak diameter of the popliteal artery during reactive hyperemia, which was measured by ultrasound imaging system. Results After the 4 weeks of training, no significant changes were observed in most variables in N through the training period. On the other hand, a significant decrease in SBP and MBP during moderate exercise was found within one week in H (P<0.05). A significant decrease in arterial stiffness assessed by CAVI was also observed within 2 weeks (P<0.05), whereas no significant changes were observed in %FMD through the training period. Discussion Our findings suggest that intermittent hypobaric hypoxic exercise could bring beneficial vascular adaptations within 1-2 weeks, such as a significant reduction of blood pressure associated with a decrease in arterial stiffness. **RHYTHMIC INTERACTION OF THE HEART AND PRE-AND-AFTERLOAD INDICES IN NORMOBARIC HYPOXIC EXPOSURE IN HEALTHY MALES**  
Radchenko, A.S.<sup>1,2</sup>, Kalinichenko, A.N.<sup>4</sup>, von Duvillard, S.P.<sup>5</sup>, Rodionova, Y.Y.<sup>4</sup>, Golubev, V.N.<sup>3</sup>, Korolev, Y.N.<sup>3</sup> 1: SpbSRIPC, 2: HC "Gladiator" (Saint-Petersburg, Russia), 3: MMA (Saint-Petersburg, Russia), 4: EU (LETI) (Saint-Petersburg, Russia), 5: NSSS (Oslo, Norway) Introduction The peripheral vascular resistance (SPR) and the left ventricular end-diastolic pressure (EDP) variability play a central role in the arterial blood pressure and cardio-rhythm regulation (Shibata et al., 2006). We investigated the normobaric intermittent hypoxia exposure (IHE) associated with the rhythmic interaction of pre-and-afterload heart indices calculated from the heart beat-to-beat as result of adaptation. Methods Seven healthy young males underwent 20 IHE sessions. Subjects were exposed for 5 min of hypoxia (FIO<sub>2</sub>=0.1) combined with 5 min of normoxia 6 x each hour. The hypoxia tests (HT) were conducted pre and pos IHE sessions. The HT consisted of the same O<sub>2</sub> breathing concentration (FIO<sub>2</sub>=0.1) for 15 min in hypoxic condition. In HT, the SaO<sub>2</sub>, HR, central hemodynamics indices (tetrapolar rheography via impedance plethysmography), and ECG were recorded. SPR, EDP (Elizarova et al., 1987), minute blood flow (MBF), RR intervals were recorded and calculated in beat-to-beat in the last 3 min of HT. The estimation of pair oscillation in SPR-EDP, SPR-RR, EDP-RR interaction at dominant frequency component (DFC) in low and high frequency (~0.03–0.15 Hz and ~0.15–0.35 Hz) range of spectra was implemented via mutual spectral power density (SPD), phase (•°) and coherence (Coh) and square of sector (S) that was formed by Coh as radius and angle of •° mismatch in DFC. The mathematical calculations were derived from the analog of work (Shibata et al., 2006). Results The adaptation from IHE significantly changed SaO<sub>2</sub> and MBF. •° advance of EDP changes before RR fluctuations were increased significantly in DFC in all subjects (p<0.5). The alterations in Coh and S were unidirectional too, but there were large variations of individual data similar as in SPR-EDP. SPD increased significantly (p<0.05) in SPR-RR fluctuations in all cases and in this couple were no change in rhythmical interaction of •°, Coh, and S. Discussion We postulate that the decrease in MBF from hypoxic adaptation is related to alterations in vessel lumen that depends on oxygenation of hemoglobin (Jensen, 2009). The myoglobin expression in hypoxia at rest was only present in cardiomyocytes (Kanatous et al., 2009). These mechanisms may be the basis for unidirectional augmentation of phase lead EDP fluctuations before SPR and RR. References Elizarova N et al. Bulletin of USSR AMS Allun Cardiol Sci Center. ## HYPOXIA IMPAIR GLUTAMINE LEVELS AFTER ACUTE EXERCISE

Machado, P.P., Lira, F.S., Santos, S.A., Silva, E.T., Caris, A., Tufik, S., de Mello, M.T., Santos, R.V.T.

*Unifesp*

**Introduction** The glutamine of performance a role key in the immune system at rest and during periods of stress. Is known that, during and after exercise glutamine levels can be modulated. However, the modulation this amino acid during and after exercise in the hypoxia exposure is unknown. Our hypothesis is that exercise performance in the hypoxia exposure may impair glutamine levels. **Methods** Eight male subjects were exposed to normobaric hypoxic exposure at 4,200 m or sea level and performance treadmill exercise for 1 hour (~50% VO<sub>2</sub>peak). The glutamine, glutamate, insulin and cortisol levels were determined at rest, and immediately and 1 h after exercise bouts. **Results** Insulin levels did not show time-dependent changes under the different altitudes (p>0.05). Cortisol levels showed increased immediately after exercise than rest and 1 hour after exercise (p<0.05), only exercise performance hypoxia exposure. The glutamine and glutamate levels were decreased 1 hour after exercise than rest and immediately after performance exercise in sea level. However, in hypoxic exposure at 4,200 m glutamine and glutamate levels were increased immediately after exercise than rest (p<0.05), and decreased 1 hour after exercise when compared with rest and immediately after exercise (p<0.05). **Discussion** Glutamine is a conditionally essential amino acid that comprises 20% of the total plasma amino acids and is actively produced in organs such as the liver, kidneys, lungs, and skeletal muscle (Parry-Billings et al. 1990). The mechanism by which this decrease in plasma glutamine concentration occurs during prolonged physical exercise and recovery is not well understood, but is suggested that hormonal alterations can modulate this amino acid concentrations. During prolonged exercise, it has been suggested that lower glutamine plasma concentration is promoted by increases in glutamine uptake in several tissues, mainly the liver, kidneys and some immune cells, while other hypotheses suggest that glutamine release changes in skeletal muscle because of a partial impairment in glutamine syntheses (Newsholme and Calder 1997, Neto et al 2011). Our data the exercise in sea level to be accord with literature, demonstrated that glutamine and glutamate levels are reduced after exercise. However, the state is impairing when exercise is performance in hypoxic exposure at 4,200 m. This alters may, least in part, favor the immunosuppression state. These findings can help to better knowing upon effects the hypoxic exercise regimen on immune system response. References Neto JC, Lira FS, de Mello MT, Santos RV. (2011) Amino Acids, 41(5):1165-72. ## HYPOXIC EXPOSITION INFLUENCE IN LENGTHENING PERFORMANCE INDICATORS IMPROVEMENT AFTER INTERMITTENT HYPOXIC TRAINING

NAKAMOTO, F.

*FEDERAL UNIVERSITY OF SAO PAULO*

Nakamoto FP, Lira CA, Andrade MS, Silva AC. Department of Physiology - UNIFESP (São Paulo, Brazil) **Introduction** The persistence of the enhanced performance endurance capacity obtained with intermittent hypoxic training (IHT) is a topic of extensive debate. **Methods** to lengthen positive effects of IHT should be studied. The aim of this study is to investigate the influence of intermittent hypoxic exposition (IHE) following IHT on lengthening its benefits. **Methods** Twenty well-trained runners (WTR) were assigned to either a hypoxic/hypoxic (HH) group (n = 9), a hypoxic/normoxic (HN) group (n = 6), or a normoxic/normoxic control (C) group (n = 5). Into their usual normoxic training schedule, athletes included two weekly training sessions, performed either in normoxia [C group, inspired O<sub>2</sub> fraction (FIO<sub>2</sub>) = 20.9%] or in normobaric hypoxia (both HH and HN groups, FIO<sub>2</sub> = 14.5%), for 6 wk. Following the 6th wk, only HH subjects were exposed to normobaric hypoxia during rest, for 60 min, twice a wk for 4 wk (IHE). The athletes in all groups continued their normal training program in normoxia during the study. Lactate threshold velocity (LTv), 1st and 2nd ventilatory threshold velocities (1VTv and 2VTv), running time to exhaustion (Tlim), maximal oxygen uptake (VO<sub>2</sub>max) and resting hematological (HT) status were measured before IHT (Pre IHT), after IHT

(Post IHT), and after IHE (Post IHE) in all athletes. Results show increase ( $p < 0.05$ ) in  $VO_{2max}$  values, LTv, 1TVt, 2TVt and Tlim in both HH and HN groups (Pre IHT x Post IHT values) in normoxia. The C group displayed no improvements. No significant changes were observed in all groups concerning Post IHT x Post IHE values. HT values were unaltered during the study. Discussion Successful results were obtained from IHT in WTR. Similar results had been found in competitive runners (Dufour et al., 2006). However, IHE procedures adopted in this study were not able to lengthen the adaptations of IHT, probably due to their low frequency or intensity. It's known that IHE produces physiologic adaptations and enhancement in endurance performance at sea level (Katayama et al, 2004; Bonetti et al., 2009). Once the purpose of our study was not eliciting further changes following IHT, it was thought that this amount of IHE could be enough to increase the persistence of IHT benefits. We either need more athletes participating in the study or a different IHE approach, which might lengthen the benefits of IHT. ## EARLY OXYGEN DESATURATION IS RELATED TO ACUTE MOUNTAIN SICKNESS DEVELOPMENT DURING ACUTE HIGH ALTITUDE EXPOSURE

Mandolesi, G.1, Pomidori, L.1, Giovanni, A.1, Bernardi, E.1, Bartesaghi, M.2, Cogo, A.1

1: University of Ferrara, 2: University of Milano Bicocca

**Introduction** Early oxygen desaturation during HA exposure (both in the field and during HA simulated test) has been reported to be significantly related to AMS development. **Aim:** to monitor oxygen saturation (SpO<sub>2</sub>) and AMS development during the ascent from Alagna (1200m) to Capanna Regina Margherita (4559m) with an overnight stay in Gnifetti Hut (3647m). **Methods** Sixty-six subjects (11F, age 18-67), intending to climb M. Rosa, were recruited at the cable car station in Alagna, informed of the purpose of the study and equipped with a 24-h data memory pulse oximeter (Pulsox-3Si, Minolta, Japan). They were also asked to fill the Lake Louise questionnaire at the arrival, in the evening and in the morning in Gnifetti Hut and at the arrival in Capanna Regina Margherita. Twenty-five subjects (37.8%) showed a LL score  $\geq 3$  (AMS+). The remaining 41 are the AMS- group. **Results** In Alagna at rest, the SpO<sub>2</sub> values were similar between AMS+ and AMS- ( $94.6\% \pm 1.9$  vs  $95.1\% \pm 1.2$  n.s.) but during HA exposure the AMS+ showed a significantly lower SpO<sub>2</sub>: at Punta Indren (3275m) after 30-45 minutes of cable car ascent ( $85.5\% \pm 4.1$  vs  $87.7\% \pm 3.5$ ,  $p = 0.035$ ); in Gnifetti Hut during 3 hours at rest after the arrival ( $84.5\% \pm 2.3$  vs  $86.4\% \pm 2.4$ ,  $p = 0.003$ ) and during the subsequent night ( $76.9\% \pm 4.6$  vs  $79.5\% \pm 3.7$ ,  $p = 0.01$ ). No significant difference was found in the SpO<sub>2</sub> values during the 2 hours climb to Gnifetti Hut ( $81.7\% \pm 2.8$  vs  $82.4\% \pm 2.5$  n.s.). As regard the monitoring, the AMS+ group always spent more time with a lower SpO<sub>2</sub>: percentage of total time spent with SpO<sub>2</sub>  $< 80\%$  at rest in Gnifetti Hut was  $15.8\% \pm 13.8$  vs  $7.2\% \pm 7.7$ ,  $p = 0.001$ ; with SpO<sub>2</sub>  $< 75\%$  during the night was  $33.2\% \pm 32.9$  vs  $15\% \pm 18.5$ ,  $p = 0.008$  and with SpO<sub>2</sub>  $< 70\%$  was  $11.8\% \pm 19.3$  vs  $2.7\% \pm 6.2$ ,  $p = 0.01$ . Concerning the ascent to Capanna Regina Margherita only data of 34 subjects (8F, 26M) were available (14 AMS+, 20 AMS-). The difference in SpO<sub>2</sub> was maintained significantly lower in AMS+ group ( $73.4\% \pm 5.1$  vs  $76.8\% \pm 3.8$ ,  $p = 0.03$ ) and significant differences were also found in time (expressed in hours) spent with SpO<sub>2</sub>  $< 80\%$  ( $3.5 \pm 1.2$  vs  $2.7 \pm 0.9$ ,  $p = 0.03$ ) and with SpO<sub>2</sub>  $< 75\%$  ( $2.5 \pm 1.4$  vs  $1.57 \pm 0.8$ ,  $p = 0.02$ ). **Discussion** Lower SpO<sub>2</sub> in AMS+ occurs very early at the beginning of HA exposure after 30-40 min. of ascent. The new finding is that 24-hours SpO<sub>2</sub> monitoring, showing that subjects which subsequently develop AMS always spend more time with SpO<sub>2</sub> significantly  $<$  healthy subjects (AMS-). ## TOTAL HAEMOGLOBIN MASS, HYPOXIC VENTILATORY RESPONSE, AND CEREBRAL AND MUSCLE OXYGENATION BEFORE AND AFTER A TWO-MONTH MT. EVEREST EXPEDITION

Cheung, S.S.1,2, Mutanen, N.E.2,3, Karinen, H.M.2,4, Koponen, A.S.2, Kyrolainen, H.5, Tikkanen, H.O.2,3, Peltonen, J.E.2,3

1: Brock University, (Canada) 2: University of Helsinki (Finland), 3: Foundation for Sports & Exercise Medicine (Finland), 4: University of Tampere (Finland), 5: University of Jyväskylä (Finland)

**Introduction** We investigated the effects of chronic hypobaric hypoxic acclimatization, performed over the course of a 72-day self-supported Everest expedition, on total haemoglobin mass (tHb-mass) and cardiorespiratory adaptation in nine elite climbers (age  $37 \pm 7$  y, peak aerobic capacity  $55 \pm 7$  mL/kg/min). **Methods** PRE and POST ( $< 15$  days) expedition, participants performed separate tests for tHb-mass and exercise with graded hypoxia. tHb-mass was measured using carbon monoxide-rebreathing. Exercise-hypoxia was tested using a constant treadmill exercise of 5.5 km/h at 3.8% grade with 3-min steps of progressive normobaric poikilocapnic hypoxia (159, 120, 105, 90, 86, 80, 75 mmHg) to simulate the different camp altitudes (0, 2,400, 3,500, 4,800, 5,200, 5,800, 6,400, 7,100 m) during an ascent. The test was terminated upon volition or when arterial oxygen saturation (SpO<sub>2</sub>) fell to 62%. Breath-by-breath ventilatory responses, SpO<sub>2</sub>, and cerebral (frontal cortex) and active muscle (vastus lateralis) oxygenation were measured throughout the exercise-hypoxia. Acute hypoxic ventilatory chemosensitivity (AHVR) was determined by linear regression slope of ventilation vs. SpO<sub>2</sub>. **Results** Post-expedition, exercise-hypoxia tolerance improved ( $11:32 \pm 3:57$  to  $16:30 \pm 2:09$  min,  $P < 0.01$ ). Absolute tHb-mass ( $973 \pm 153$  g PRE and  $1026 \pm 125$  g POST,  $P = 0.27$ ) did not significantly differ. AHVR was elevated ( $1.25 \pm 0.33$  to  $1.63 \pm 0.38$  L/min per % decrease in SpO<sub>2</sub>,  $P < 0.05$ ). SpO<sub>2</sub> decreased throughout exercise-hypoxia at 2,400 and 3,500 m equally in both trials, but was preserved at higher values at 4,800 m post-expedition. Cerebral oxygenation decreased progressively with increasing exercise-hypoxia in both trials, with a lower level of deoxy-haemoglobin POST at 2,400, 3,500 and 4,800 m. Muscle oxygenation also decreased throughout exercise-hypoxia, with similar patterns PRE and POST. No relationship was observed between the slope of AHVR and cerebral or muscle oxygenation either PRE or POST. **Discussion** We observed a wide inter-individual variability in tHb-mass responses, ranging -14.5 to 20.2% from PRE to POST, with three of the nine participants exhibiting a decrease and a fourth participant demonstrating no change. This suggests that haematological adaptation is not a consistent response to chronic hypoxic acclimatization. We also conclude that ventilatory chemosensitivity changes from altitude acclimatization did not influence cerebral or muscle oxygenation during acute exercise-hypoxia.

**CHANGES IN ADIPOSE TISSUE ADRENOCEPTOR GENE EXPRESSION AND LIPID MOBILIZATION DURING A MULTI-PHASE DIETARY INTERVENTION IN OBESE WOMEN**

Koppo, K.1,2, Czudkova, E.2, Van de Voorde, J.1, Combes, M.3, Valle, C.3, Langin, D.3, Stich, V.2

*1 Ghent University (Ghent, Belgium), 2 Charles University (Prague, Czech Republic), 3 Université Paul Sabatier (Toulouse, France)*

Introduction Calorie restriction is considered to be an effective treatment to lose weight in obese patients. It is believed that catecholamines are one of the key players that regulate lipid mobilization and mediate the remodeling of subcutaneous adipose tissue (SCAT). However, conflicting results are found regarding the changes in adrenergic control following a dietary intervention (DI) dependent on the duration of the diet and/or magnitude of the diet-induced calorie restriction. Therefore, the aim of this study was to investigate the evolution of the adrenergic regulation of lipolysis and to evaluate the expression of the beta2-, and alpha2A-adrenoceptor genes (ADRB2 and ADRA2A, respectively) in SCAT during different phases of a multi-phase DI. Methods Fifteen obese women underwent a 6-months DI consisting of 1 month very low calorie diet (VLCD), followed by 2 months low calorie diet (LCD) and 3 months weight maintenance diet (WM). At each phase of the DI, a biopsy of the abdominal SCAT was obtained to evaluate mRNA expression of the adrenoceptor genes ADRB2 and ADRA2A. In a subgroup of eight subjects, SCAT microdialysis was performed at each phase of the DI. Dialysate glycerol concentration (DGC) was determined at baseline and during local perfusions with adrenaline (a non-selective adrenoceptor agonist) in the absence or presence of phentolamine (an alpha1,2-adrenoceptor antagonist). Results The DI induced a significant body weight reduction and an improved insulin sensitivity. mRNA levels of ADRB2 increased at the end of VLCD and then decreased at the end of LCD and WM towards the pre-diet levels. The expression of ADRA2A was lower at the end of VLCD and LCD compared to the pre-diet or WM levels. Similarly, the adrenaline-induced increase in DGC was higher at the end of VLCD and LCD compared with the pre-diet and WM condition. In the probe with adrenaline and phentolamine, the increase in DGC was higher than that in the adrenaline probe at pre-diet and WM. No difference between the 2 probes was observed at VLCD and LCD. Discussion The results show that the responsiveness of SCAT lipid mobilization changes during a multi-phase DI, i.e. the adrenaline-stimulated lipolysis increases during the calorie-restricted phases due to a reduction of the alpha2-adrenoceptor mediated antilipolytic action of adrenaline. At the end of WM, adrenaline-stimulated lipolysis returned to the pre-diet levels. A similar pattern was observed at the transcriptional level of the adrenoceptor genes. These findings suggest that the regulation of lipolysis varies in function of the energy balance of the body.

**IMPACT OF ANDROID TO GYNOID FAT MASS RATIO ON FUEL UTILIZATION DURING EXERCISE IN NORMAL-WEIGHT WOMEN**

Isacco, L., Thivel, D., Meddahi Pelle, A., Lemoine-Morel, S., Duclos, M., Duche, P., Boisseau, N.

*Blaise Pascal University*

Impact of Android to Gynoid fat mass ratio on fuel utilization during exercise in normal-weight women Isacco L1, Thivel D1, Meddahi Pelle A2, Lemoine-Morel S3, Duclos M4, Duche P1, Boisseau N1 1: University Blaise Pascal (Clermont-Ferrand, France), 2: INSERM unit (Paris, France), 3: Rennes University (Rennes, France), 4: Auvergne University, INRA, CHU (Clermont-Ferrand, France). Introduction Abdominal and gynoid fat mass tissues exhibited particular metabolic profiles (Despres & Lemieux 2006; Sasai et al., 2009). If the scientific literature shows that higher android to gynoid fat mass ratio in obese individuals may alter whole body lipid oxidation during exercise (Kanaley et al. 1993), such data is missing concerning normal weight healthy subjects. Thus, the aim of this study was to investigate the impact of low (LA/G) and high (HA/G) android to gynoid fat mass ratio on metabolic and hormonal responses during exercise in normal weight healthy women. Methods Substrate oxidation (Respiratory Exchange Ratio, lipid and carbohydrate oxidation rates), metabolic (glycerol, free fatty acids, glucose) and hormonal (insulin, growth hormone, atrial natriuretic peptide, adrenaline and noradrenaline) responses were determined in a postprandial state during a 45 min exercise performed at 65% of VO2max in 21 young normal weight women including 10 HA/G women and 11 LA/G ones (determined from DXA measurements). Results No difference in anthropometric, VO2max and resting blood values were observed between the two groups. LA/G group exhibited greater reliance on lipid during exercise as compared to HA/G one. This occurred in presence of lower plasma insulin and glucose concentrations and higher plasma FFA, glycerol, GH, ANP levels in LA/G group as compared to HA/G one. Discussion To our knowledge, this is the first study to investigate the influence of fat mass ratio in lean women on substrate metabolism at rest and during exercise. Our results showed that android to gynoid fat mass ratio may impact on fuel oxidation and metabolic and hormonal responses during exercise as LA/G women female subjects showed an increase in whole-body lipid mobilization and utilization during exercise as compared to their HA/G counterparts. This may lead to a better body fat control, and a higher glycogen store sparing in LA/G individuals. References Despres JP, Lemieux I. (2006) *Nature*, 444, 881-887. **RELATIONSHIPS BETWEEN FATMAX, MAXIMAL FAT OXIDATION, PHYSICAL ACTIVITY, VO2PEAK AND BODY FATNESS IN PRE-PUBERTAL CHILDREN**

Campolier, M.

*Coventry University*

Campolier, M1., Duncan, M.J1., Hankey, J. 1, Birch, SV, Tolfrey, K. 2 1(Coventry University, UK) 2(Loughborough University, UK) Introduction It is well known that FATmax i.e. the exercise intensity that elicits maximal fat oxidation (MFO) is an individual parameter that depends on several factors e.g. gender, training status in adults (Venables, et al., 2005). However, less is known about the variables affecting this concept in children (Zakrzewski and Tolfrey, 2011). The aim of this research was to study whether FATmax and MFO were correlated to VO2peak, physical activity (PA), BMI and body fat percentage (%BF) in pre-pubertal children. Methods Twenty-eight pre-pubertal children (16 boys and 12 girls, aged 10-11) from a primary school in England completed a 3-min-incremental cycling test on a cycle ergometer to

estimate their VO<sub>2</sub>peak, FATmax and MFO. %BF was calculated by the measurement of skinfolds (Slaughter et al. 1988) and PA was estimated by the average of 4-d step count (2 weekdays and 2 weekend days) using pedometer (New Lifestyles NL-800Activity Monitor Pedometer). Physical Maturation (PM) was assessed from anthropometric measurements (Mirwald et al., 2002) and confirmed that all children were in the pre-pubertal stage of development. Results Results from Pearson's correlations showed that FATmax was negatively correlated to VO<sub>2</sub>peak ( $r=-0.532$ ) and body weight ( $r=-0.546$ ) ( $p<0.01$ ). In contrast, MFO was positively correlated to VO<sub>2</sub>peak ( $r=0.507$ ). However, when MFO is controlled by gender, the relationship between MFO and VO<sub>2</sub>peak is dismissed ( $p>0.05$ ). FATmax or MFO showed no significant correlations with BMI, PA or %BF ( $p>0.05$ ). VO<sub>2</sub>peak and MFO were significantly higher in boys compared to girls ( $p<0.05$ ). Discussion Our findings indicated that boys had a higher MFO compared to girls. That coincided with previous studies with pubertal and postpubertal children (Lazzer et al., 2007) and might be related to the higher VO<sub>2</sub>peak observed in boys compared to girls. Contrary to expectations, this study showed a negative correlation between FATmax and VO<sub>2</sub>peak which might be explained by the protocol used to identify FATmax or by other variables that might confound this association. To conclude, further research is needed to identify and understand the different variables that might affect it. References Lazzer, S., Busti, C., Agosti, F., De Col, A., Pozzo, R., & Sartorio, A. ### WHEEL RUNNING EXERCISE ENHANCES FATTY ACID OXIDATION IN THE RAT SKELETAL MUSCLE DURING THE GROWING PHASE

Yamauchi, H.1, Takeda, Y.1, Tsuruoka, S.1, Abo, M.1, Minato, K.2, Shiroya, Y.2, Kitamura, H.2, Kurosaka, Y.2, Kimura, M.3, Kariya, F.4

1: Jikei University School of Medicine (Tokyo, Japan), 2: Wayo Women's University (Chiba, Japan), 3: Keio University (Tokyo, Japan), 4: International Budo University (Chiba, Japan).

Introduction: AMP-activated protein kinase (AMPK), locating at the upstream signaling pathway, regulates carbohydrate and fatty acid oxidation. Diet restriction (DR) and endurance exercise have been known to activate AMPK. However few report has been available as to whether DR+exercise produce AMPK activation efficiently to generate marked metabolic effect. Therefore, the aim of the present study is to evaluate how DR+exercise influence metabolic effects and AMPK activation in rat skeletal muscles. Methods: Twenty three F344 female rats (6-week) were divided into voluntary exercise-loaded (VE) (n=13) and control groups (n=10). The rats of VE group was further divided to 2 groups: DR to similar intakes of rats of control group (VE-DR, n=6) and no DR (free-intakeVE; VE-F, n=7) for 8 weeks. Voluntarily running on a wheel ergometer was applied with a load of 30% on their body weight. After the experiments plantaris muscle was extracted and weighed. Activities of citrate synthase (CS) and beta-hydroxyacyl-CoA dehydrogenase (beta-HAD), and composition of myosin heavy chain (MHC) isoforms were measured. Additionally the expression levels for fatty acid translocase (FAT/CD36), AMPKalpha, and peroxisome proliferator-activated receptor gamma co-activator 1 (PGC-1) were also determined using a western blotting method. Results: Average daily food intake of VE-F group (15.5 g) was higher than those of control (11.7 g) and VE-DR groups (12.5 g). Average daily running distance of VE-DR group (5198 m) tended to be higher than that of VE-F group (4194 m). Body mass was not significantly different among three groups, but muscle mass of VE-F group was significantly higher than the other two groups. In both VE groups, CS activities and beta-HAD and FAT/CD36 protein expressions were significantly higher than those of control. Beta-HAD activity of VE-DR group was higher than that of VE-F group. The ratios of MHC IIb / MHC IIa were lowered in both VE groups compared to control. And the % content of MHC I was higher only in VE-DR than that of control group. AMPK activation (phosphorylated to pan protein ratio) and expression level of PGC-1 in both VE groups were higher than those of control, but no significant difference was observed between both VE groups. The beta-HAD activity correlated with AMPK activation, but not with average daily running distance. Conclusion: The present results suggest that exercise-load with DR efficiently enhances fatty acid oxidation mediated by AMPK activation.

### THE EFFECTS OF EXERCISE AND RESTRICTED DIET ON HEPATIC FAT ACCUMULATION IN FATTY RATS

Umetsu, Y., Kitamura, H., Shiroya, Y., Minato, K., Yamauchi, H.

Wayo Women's University

THE EFFECTS OF EXERCISE AND RESTRICTED DIET ON HEPATIC FAT ACCUMULATION IN FATTY RATS. Umetsu Y.1, Kitamura H.1, Shiroya Y.1, Minato K.1, Yamauchi H.2 1: Wayo Women's University (Chiba, Japan), 2: Jikei University School of Medicine (Tokyo, Japan) Purpose Diet restriction and exercise are commonly recommended for the prevention and amelioration of obesity and lifestyle-related diseases such as fatty liver. Zucker fatty rats are a commonly studied model for obesity and fatty liver. The purpose of the present study was to investigate whether hepatic fat metabolism in Zucker fatty rats was improved with diet restriction and/or voluntary exercise. Methods Male Zucker lean rats were used as the control group (L: n = 8). Male Zucker fatty rats were divided into obese (Ob: n = 8), restricted diet (DR: n = 8), and restricted diet + exercise (DR + Ex: n = 8) groups. The rats in the L and Ob groups had free access to food. The food intakes in the DR and DR + Ex groups were restricted to 67% and 70% of the Ob group level, respectively. The rats in the DR + Ex group were made to exercise voluntarily on the wheel ergometer with a load of 30% of their body weights. After six weeks, all rats were prepared for the experiment. Blood was collected to measure serum leptin and free fatty acid (FFA) levels. Liver tissue sample was excised to measure hepatic triglyceride (TG) level and hepatic fatty acid synthase (FAS) activity. Results Body weight was significantly lower in the DR + Ex groups than that in the Ob group. There were no significant differences between the DR and DR + Ex groups in body weight and total food intake. Ob rats developed fatty liver and hyperlipidemia caused by excessive food intake. Hepatic TG level was significantly higher in the DR group than that in the Ob and DR + Ex groups. Hepatic TG level was significantly lower in the DR + Ex group than that in the Ob group. Hepatic FAS activity was significantly lower in the DR + Ex group than that in the DR group. Both serum leptin level and FFA levels were significantly higher in the DR group than those in the Ob and DR + Ex groups. Hepatic TG level was strongly correlated with hepatic FAS activity serum leptin, and FFA levels. Discussions Our results indicated that diet restriction in the Zucker fatty rats may facilitate fat accumulation in the fasted liver. And, voluntary exercise may suppress the accumulation of liver fat via inhibition of hepatic FAS activity. Although we demonstrated that diet restriction did not suppress the accumulation of liver fat, its cause is not yet to be identified. Further studies are required. The present results suggested the necessity of exercise for obesity prevention. References Rector R S, et al. (2011). *Am J Physiol Gastrointest Liver Physiol*. 300, 874-883. Luan Y, et al. ## EFFECTS OF EXERCISE TRAINING AND INTERLEUKIN 6 UPON PANCREATIC ISLETS PROTEINS: EVIDENCE FOR A POSSIBLE SKELETAL MUSCLE AND ENDOCRINE PANCREAS CROSSTALK

Zoppi, C., Costa Jr, J., Paula, F., Oliveira, C., Carneiro, E.

*UNICAMP and UNIFESP*

EFFECTS OF EXERCISE TRAINING AND INTERLEUKIN 6 UPON PANCREATIC ISLETS PROTEINS: EVIDENCE FOR A POSSIBLE SKELETAL MUSCLE AND ENDOCRINE PANCREAS CROSSTALK Zoppi, C.1, Costa-Junior. J.1, Paula, F.1, Oliveira, C.2, Carneiro, E.1 1:UNICAMP (Campinas, Brazil), 2: UNIFESP (Santos, Brazil) Introduction Endurance training (ET) and incubation with interleukin 6 (IL6) were reported to alter pancreatic islets function and growth. Considering that contracting skeletal muscle increases blood IL6 release, we hypothesized that the crosstalk between skeletal muscle and endocrine pancreas might be mediated by this cytokine. Here we aimed to investigate the effects of ET-induced adaptations upon key proteins involved with pancreatic islets, mainly regarding beta cells, function and growth, suggesting a possible involvement of IL6 on that process. Methods Male Swiss mice were allocated into a sedentary control or an ET group. Mice were submitted to an 8 weeks ET swimming protocol. At the end of the protocol, mice swam for 1h per day, five days per week. After that, animals were sacrificed; soleus and gastrocnemius homogenate was used for citrate synthase (CS) activity measurement. Pancreatic islets were isolated by collagenase digestion of the pancreas for static insulin secretion by radioimmunoassay and western blot analysis of several proteins involved with islets function and growth. In addition, MIN6 cells were incubated or not with IL6 (5ng/ml) for 30 min and 24 h. Total content of protein kinase A (PKA), protein kinase C (PKC) and vesicle associated membrane proteins 2 (VAMP2), and the phosphorylation level of the signal transducers and activators of transcription protein 3 (pSTAT3), AKT (pAKT) and ERK1/2 (pERK1/2) were measured in isolated islets and MIN6 cells. Results ET mice showed 40% higher skeletal muscle CS activity and 50% lower insulin secretion. Significant increase in pSTAT3, pAKT, pERK1/2, PKA and VAMP2 by 33, 65, 50, 100 and 70%, respectively, from ET islets were reported. IL6 treated MIN6 cells pSTAT3, pAKT and pERK1/2 were 200, 25 and 25%, respectively increased, after 30 min of incubation, whereas PKA and VAMP2 had their total content increased by 40 and 22%, respectively, after 24 h of IL6 incubation. In addition, PKC content was not altered by any of the treatments. Discussion ET and IL6-incubated MIN6 cells displayed IL6-STAT3 signaling pathway activation and similar profile of secretory machinery and growth proteins modulation, suggesting a possible ET-induced pancreatic islets adaptations signaling by this cytokine. Thus our results provide preliminary evidence for a possible IL6-mediated contracting skeletal muscle and endocrine pancreas crosstalk.

## THE EFFECT OF UNDERWATER ENVIRONMENT ON CARDIAC PARASYMPATHETIC NERVOUS ACTIVITY DURING ARM CRANKING EXERCISE AMONG DIABETES PATIENTS

ONO, K., KUNIYOSHI, H., OKUSHIMA, Y.

*Kobe University*

The Effect of Underwater Environment on Cardiac Parasympathetic Nervous Activity during Arm Cranking Exercise among Diabetes Patients Ono, K.1, Kuniyoshi, H.2, Okushima, Y.2 1: Graduate School of Health Sciences, Kobe University (Kobe, Japan), 2: Kobe University (Kobe, Japan) Introduction It is believed that 22.1 million people are strongly suspected having diabetes or not able to deny the possibility of having diabetes in Japan (2007). Majority of the patients who undergo artificial dialysis are those who have the diabetic renal disease. Many diabetic patients also suffer from obesity. The amount of kidney blood flow is maintained during exercise in water. And by the action of buoyancy the weight which is loaded on the joint of the legs decreases. The purpose of this study is to make clear that the effect of an underwater environment on cardiac parasympathetic nervous activity during arm cranking exercise is beneficial for diabetes patients. Methods Six diabetes patients (age:  $57.5 \pm 12.3$  yrs, height:  $162.6 \pm 8.7$  cm, weight:  $75.1 \pm 23.5$  kg; mean  $\pm$  SD) participated in this study, voluntarily. They started at rest on land in a sitting position for 5 minutes. After that, they entered the tub and rested in a sitting position for 10minutes. After rest in the tub, they started arm cranking exercise for 20 minutes. The exercise intensity was at 80% of Anaerobic Threshold. Two conditions were set; exercise in the water (around 30°C) ; W-condition and exercise on the ground; C-condition. The W-condition's water depth was xiphoid process. After exercising, they recovered for 5 minutes continuously as a same position. The measurements were heart rate (HR), cardiac parasympathetic nervous activity (high frequency: HF) and blood pressure (BP) during the experiment and a time constant of HR attenuation for 30 seconds after exercise. Results HR of W-condition at the rest was lower than that of C-condition. The changes of HR during exercise were not significant in the two conditions, through HR at the end of exercise in W-condition was lower than C-condition. W-condition's HF during post exercise for 30 seconds showed lower than that of C-condition significant ( $P < 0.01$ ). There was not significant change through W-condition's systolic BP at post exercise phase was lower than that of C-condition. Discussion The water level in W-condition was kept below the subjects' upper extremities to match the C-condition's exercise pattern. It is suggested that since these were not affect from water resistance, there wasn't difference of the exercise intensity by the condition. At the recovery phase, it is suggested that since the subjects at W-condition were affected by water pressure and lead to an increase of the amount of venous return, W-condition's HF showed lower than that of C-condition's. With these factors, it is suggested that cardiac parasympathetic nervous activity plays a role in the early recovery of HR immediately following exercise in water.

## RESISTANCE TRAINING AND OVARIECTOMY ON GENE EXPRESSION OF MOLECULES RELATED TO FAT OXIDATION AND LIPOGENESIS IN THE LIVER OF RATS

PEREZ, S., RODRIGUES, M., STOTZER, U., TOMAZ, L., MARINE, D., BERTUCCI, D., BALDISSERA, V., DOMINGOS, M., SOUZA, D.

*FEDERAL UNIVERSITY OF S. CARLOS*

Introduction Decreased levels of estrogen is associated with hepatic steatosis (HS) (Volzke et al., 2006), through changes in gene expression of molecules related to fat oxidation and lipogenesis (Paquette et al., 2008). Both resistance training (RT) (Leite et al., 2009) and endurance training (ET) (Pighon et al., 2010) prevents the HS in ovariectomized (Ovx) rats. However, the molecular events were only investigated for ET but not for RT. Thus, the aim of this study was to investigate the effects of Ovx and RT on the gene expression of molecules related to fat oxidation and lipogenesis in the liver of rats. Methods Sprague-Dawley adult female rats were grouped into four groups (n = 6 per group): sham sedentary (S-S); Ovx sedentary (Ovx-S); sham RT (S-RT) and Ovx-RT. A 10-week RT period, during which the animals climbed a 1.1-m vertical ladder with weights attached to their tails, was used. The sessions were performance once every 3 days, with 4-9 climbs and 8-12 dynamic movements per climb (Hornberger and Farrar, 2004). The animals were sacrificed 48 hours after the last session of RT. The gene expression was analyzed by RT-PCR by the delta delta cycle threshold ( $\Delta\Delta Ct$ ) method. Fisher's post hoc test was used in the event of a significant ( $P < 0.05$ ) ratio. Results The Ovx decreased the gene expression of molecules related to fat oxidation, carnitine palmitoyltransferase I (53%) and  $\beta$ -hydroxyacyl-CoA dehydrogenase (27%), and increased of molecules related to lipogenesis, sterol

regulatory element-binding protein-1c (106%), acetyl-CoA carboxylase (ACC) (72%) and stearoyl CoA desaturase-1 (109%), which had their expression restored to the RT, with the exception of the ACC. Discussion Increased synthesis of new lipids is the primary disorder in HS, which is strongly stimulated by lipogenic molecules (Pighon et al., 2010). Additionally, recent results indicate that fatty acid oxidation is reduced in the liver of Ovx animals (Paquette et al., 2008). The present results indicate that the RT have important effects similar to estrogen on the prevention of HS in Ovx animals, through changes in gene expression of molecules related to hepatic lipid metabolism. Introduction Ovariectomy promotes impairment redox balance, with higher levels of oxidative stress (OS) (Maltais et al. 2009). It has been proposed that hepatic OS in postmenopausal women is related to higher prevalence of hepatic diseases such as nonalcoholic fatty liver (NAFLD) (Gutierrez-Grobe et al. 2010). Resistance training (RT) in humans has shown similar results to aerobic training in up-regulation of antioxidant system defense and protection against the oxidative damage. Therefore, the aim of this study was to assess the effects of RT on OS markers in the liver of ovariectomized rats (Ovx). Methods Sprague-Dawley adult female rats were grouped into four groups (n = 8 per group): sham sedentary (S-S); Ovx sedentary (Ovx-S); sham RT (S-RT) and Ovx-RT. A 10-week RT period, during which the animals climbed a 1.1-m vertical ladder with weights attached to their tails, was used. The sessions were performed once every 3 days, with 4-9 climbs and 8-12 dynamic movements per climb (Hornberger and Farrar, 2004). The animals were sacrificed 48 hours after the last session of RT. The OS was measured by levels of reduced glutathione (GSH) and oxidized glutathione (GSSG), the lipid peroxidation (LP), the concentration of vitamin E and gene expression of glutathione peroxidase (GSH-Px). Results The estrogen deficiency associated to Ovx decreased in the (GSH / GSSG) ratio (28%), vitamin E concentration (45%), and gene expression of GSH-Px (49%), no significant change was detected of the LP in the liver of the Ovx rats compared to Sham-Sed rats. On the other hand, the RT program adopted did not reverse the hepatic oxidative damage caused by Ovx and also provided an increase in hepatic OS. Discussion Estrogen deficiency is associated with increased oxidative stress (OS), which in turn is involved in the physiopathology of diseases such as fatty liver disease (NAFLD). (Gutierrez-Grobe et al. 2010). Resistance training (RT) may reduce oxidative damage by promoting an up-regulation in the antioxidant defense system. (Cakir-Atabek et al. 2010). The present results indicate that the resistance training program did not reverse the hepatic oxidative damage caused by Ovx. Additionally, the proposed resistance training also increased OS in the liver. ### IS THE LAST EXERCISE DONE IN TRAINING SESSION RESPONSIBLE FOR THE INCREASE IN INSULIN-SENSITIVITY AFTER ENDURANCE-TRAINING IN GÖTTINGEN MINIPIGS?

Vincent, S.1,2, Blat, S.3,4, Lemoine-Morel, S.1,2, Lefevre, L.1,2, Malbert, C.H.3,4, Delamarche, A.1,2

Introduction Endurance Training (ET) is known to induce a transient increase in insulin sensitivity (IS). This increase in IS could be due to the last exercise realized in the training period (TP) or to the adaptations induced by the global TP. Moreover, the duration of this-protective effects is controversial (24 hours to 7 days) (Arciero et al. 1998, Shojaee-Moradie et al. 2007, Goulet et al. 2005), probably because of the diet, the training program and the body and/or fat masses' changes. So, the aim was to study the persisted effects of training on IS and the role of the last exercise done in TP. An animal model Göttingen minipigs (MP) was taken as models for humans in order to control diet and to limit body and fat masses' modification as confounding factors. Methods 12 adult MP (18-24 month-old, 30-35 kg) were placed on a standard diet during 16 weeks. They followed or not endurance training (ET). ET was individualized and consisted in a 1h/day, 5days/week running during 12 weeks at 150 bpm heart rate on a motor-driven treadmill. Food was supplied to cope energy expenditure in order to keep the body and fat masses constant throughout the protocol. Intravenous glucose tolerance tests (IVGTT) were performed at T0, T1, T24 and T72 for immediately, 1, 24 and 72 hours post exercise, respectively, before and after the TP. We followed the residual effect of ET, 7 days and 1 month after the last exercise of TP by additional IVGTT. The HOMA-IR was used as an index of glucose tolerance. The area under the curve of glucose (AUCG) and the glucose disappearance (KG) were determined as dynamic insulin-sensitivity indexes. The acute insulin response (AIR) and AUC of insulin (AUCI) were used as indexes of insulin secretion. Results - Discussion The acute exercise realized before ET was able to induce an increase in IS judged on the improvement of HOMA-IR, AUCG, KG and AUCI at T1, T24 and T72. So, the improvement of IS can persist until 72h after an acute exercise in MP. After 12 weeks of ET, these indexes were not significantly different between T0, T1, T24 and T72 but improved vs. before ET. This data argue in favor of beneficial adaptations of all exercises realized during TP on IS more than the effect of the last acute exercise. In MP with no change in body and fat masses, the improvement of IS and insulin secretion by ET, persisted 7 days but had disappeared one month after the last exercise. In fact, 12 weeks-ET induced a significant increase in KG and decrease in AIR (p=0.01) explained by an increase in IS at the end of ET. In conclusion, ET induced an increase in IS that cannot be explained by changes in body and fat masses. These beneficial effects of ET seemed to be due to all exercises and not to the last acute exercise realized at the end of the TP. The increase in IS persisted 7 days after training but disappeared after 1 month of detraining. References Arciero et al. (1998) *J Appl Physiol* 84(4):1365-1373. Shojaee-Moradie et al. **INSULIN ANTILIPOLYTIC EFFECT IS NOT CHANGED DURING A WEIGHT-REDUCING MULTI-PHASE DIETARY INTERVENTION IN OBESE WOMEN**

Czudkova, E.1, Langin, D.2, Stich, V.1, Kopko, K.1,3

*1 Charles University (Prague, Czech Republic), 2 Université Paul Sabatier (Toulouse, France), 3 Ghent University (Ghent, Belgium)*

**Introduction** Insulin is the major antilipolytic hormone in vivo. It acts through activation of phosphodiesterase-3B (PDE3B) which controls the activation state of lipases and lipid droplet-associated proteins. It has been shown that subjects who are less insulin sensitive are also less sensitive to the antilipolytic effect of insulin in the subcutaneous adipose tissue (SCAT) (1). Therefore, the aim of this study was to examine whether during a multi-phase diet the improvement in whole body insulin sensitivity coincided with an increased antilipolytic effect of insulin and a higher expression of PDE3B mRNA in SCAT. **Methods** Fifteen obese premenopausal women underwent a 6-months dietary intervention (DI) program consisting of a 1 month very low calorie diet (VLCD), followed by 2 months low calorie diet (LCD) and 3 months weight maintenance (WM). During each phase of the DI a 3-h hyperinsulinaemic euglycaemic clamp (HEC) was performed. Furthermore, needle micro biopsy of the abdominal SCAT was obtained to determine mRNA expression of PDE3B. In a subgroup of eight subjects, SCAT microdialysis was performed at each phase of the DI. The dialysate glycerol concentration (DGC) was evaluated at baseline and during the HEC. **Results** The body weight was significantly reduced by 9.8% at the end of WM. Compared with the pre-diet condition, glucose disposal rate was higher at the end of VLCD, LCD and WM (i.e.  $3.1 \pm 0.4$  in pre-diet condition,  $3.8 \pm 0.5$ ,  $p = 0.053$  at the end of VLCD,  $4.2 \pm 0.4$ ,  $p < 0.05$  at the end of LCD,  $4.3 \pm 0.4$ ,  $p < 0.05$  at the end of WM). At all phases of the diet, DGC progressively decreased during HEC (i.e. by  $30 \pm 11\%$  before the diet,  $37 \pm 4\%$  after VLCD,  $35 \pm 12\%$  after LCD and  $30 \pm 17\%$  after WM) and this decrease was not significantly different between the different phases of the diet. The mRNA levels of PDE3B did not significantly change throughout the DI. **Discussion** The results suggest that the sensitivity to the anti-lipolytic action of insulin in SCAT during the DI seems not to be directly related to the evolution of the whole body insulin sensitivity with respect to the carbohydrate metabolism. Also at the transcriptional level, PDE3B was unaffected by the changes in calorie intake during the DI. **Reference** 1. Eriksson JW, Smith U, Waagstein F, Wysocki M, Jansson P. Glucose turnover and adipose tissue lipolysis are insulin-resistant in healthy relatives of type 2 diabetes patients. *Diabetes* 48:1572–1578, 1999.

**13:45 - 14:45****Poster presentations****PP-PM30 Health & Fitness: Children****THE EFFECTS OF THE COMBINED EXERCISE IN WATER AND ON LAND ON BODY POSTURE OF PRESCHOOL CHILDREN**

Torlakovic, A., Simikic, I., Muffic, M.

*Olympic Swimming Pool Center-Sarajevo*

**Introduction:** Poor body posture of children of preschool and early school age is steadily increasing and is more and more present as a possible indicator of health problems in the second phase of intense growth and development. The aim of this study was to determine the effects of the transformation processes on posture of preschool children, under the combined influence of exercise in water and on land. **Methods:** The study included 80 children of both sexes, 41 male ( $n = 41$ , mean age =  $5.3 \pm 0.7$  yrs.; mean height =  $115 \pm 6$  cm; mean weight =  $21.6 \pm 4.5$  kg) and 39 female ( $n = 39$ , mean age =  $5.4 \pm 0.7$  yrs.; mean height =  $115 \pm 7$  cm; mean weight =  $21.3 \pm 4.4$  kg) which, due to decreased muscle tone, had a predisposition to poor posture. Assessment of postural status of the subjects were made according to the Wolanski method, while the estimation of basic elements and skills needed to move in the water was carried out according to a scale of 1 to 3 (non-swimmers, buoys and semi-swimmers). The combined programmed of corrective exercise, Pilates and games in water was carried out within the period of 14 weeks, twice a week per 60 minutes. For the analysis of initial and final testing, T-test for dependent samples has been used (marked differences are significant at  $p < .0500$ ). **Results:** The results of t-test for dependent samples showed that the children in final test had a statistically significant positive changes in the assessment of body posture ( $p = .000$ ). Analysis of the dynamics of learning the basic skills necessary to navigate in water, showed statistically significant increase in results for the initial and transitive ( $p = .012$ ), and the initial and final ( $p = .008$ ) test. **Conclusions:** Doctors recommend swimming as an activity which can possibly prevent poor body posture or postural disorders. As expected, based on the results and confirmed in this study, applying a coordinated program with complemented exercises of remedial gymnastics, Pilates, games and exercises in water leads to a large extent of positive effects in improvements of poor body posture of children at this age. We can conclude from this that the program is very effective and useful in practice. Since the program contains various moving exercise, it is manageable to retain children's interest, attention and positive emotions during exercise which is especially important for achieving the desired results. It is important to note that part of the program that was implemented in water was very successful for learning basic swimming skills and psychological preparation of children for active participation in advanced aquatic programs in the future. **References:** Melody, O., Schofield, G.M., & Kolt, G.S. **PREDICTION OF TOTAL AND REGIONAL FAT-FREE MASSES OF JAPANESE PREPUBERTAL CHILDREN BY BIO-ELECTRICAL IMPEDANCE METHOD.**

Ohta, M.1, Midorikawa, T.2, Hikiyama, Y.3, Masuo, Y.4, Sakamoto, S.4, Kawakami, Y.4, Kanehisa, H.5, Fukunaga, T.5

*1: Kanazawa Seiryō University, 2: J.F. Oberlin University, 3: Chiba Institute of Technology, 4: Waseda University, 5: National Institute of Fitness and Sports in KANNOYA*

**Background:** In the research field of growth and development, the assessment of body composition is essential. Bio-electrical impedance (BI) method is a convenient and non-invasive way to predict body composition. However, only a few studies have tried to equation for predicting fat-free mass (FFM) in children by adopting BI method, and the accuracy of prediction equations reported in these studies are unsatisfactory due to the lack of assessing segmental FFM, which is a cause producing estimation errors. At present, since child obesity is

one of the major health-related problems, developing an accurate prediction equation of FFM in children, including over-weight children, is crucial. Objective: To investigate the validity of estimating segmental and total FFM in children using segmental BI analysis. Methods: A total of 145 Japanese children aged 6-12 years participated in this study. They were divided into three groups: a validation group (46 boys; 30 girls), a cross validation group (23 boys; 15 girls) and an over-weight group (17 boys; 14 girls). Using the dual energy X-ray absorptiometry (DXA) method, the FFMs of the arm, the trunk, the leg and the total-body were determined and used as reference data. The electrical impedance was measured by a BI apparatus (500 $\mu$ A, 50kHz). A BI index was calculated as the ratio of the segment length squared ( $L^2$ ) to the impedance ( $Z$ ). Results and discussion: For the validation group, a single regression analysis showed a significant correlation between the BI index and measured FFM in each segment ( $r = 0.929 - 0.968$ ,  $p < 0.001$ ), and it produced a prediction equation with an estimate SE, 0.2 -1.0 kg (4.3 - 8.2%). There were no significant differences between the measured and estimated FFMs in the validation and the cross-validation groups without systematic error. The application of the prediction equation to the over-weight group did not produce significant difference between the measured and estimated FFMs without systematic error. Electrical impedance varies depending on the volume of the conductor (i.e. the human body), the conductor's length (i.e. the subject's height), the components of the conductor (i.e. FFM), and its impedance ( $Z$ ); i.e. shapes and sizes of various body segments affect the measured impedance values. For example, arms and legs together account for about 50% of the FFM and contribute at least 91% of the measured whole-body resistance. The current results indicate that the segmental BI analysis is essential for achieving an accurate prediction of the total and segmental FFM in children.

### CARDIOVASCULAR RISK FACTORS IN BOYS AND GIRLS

Brito, L., Titski, A.C.K., Moser, D.C., Mascarenhas, L.P.G., Góes, S.M., Mattos, F., Carvalho, H.M., Coelho-e-Silva, M.J., Leite, N.

*Federal University of Parana and CAPES*

**Introduction** The risk factors for cardiovascular disease (CVD) have been increased in children and adolescents due to overweight and sedentary lifestyle. The assessment of these factors can be accomplished by anthropometrics measuring, which allows early diagnosis in children and adolescents. (ANDERSEN et al., 2011). The aim of this study was to determine CVD risk factors in scholar and verify differences between genders. **Methods** Cross-sectional epidemiological study was conducted with 1325 scholars (591 boys and 734 girls) from five schools in Curitiba-PR-Brazil. Height, body mass, waist circumference, blood pressure (BP), cardiorespiratory fitness and physical activity history (PAH) was assessed. Student's t-test for independent sample, Chi-square test and Pearson's partial correlation were performed. These statistical procedures were calculated with significance set at  $p < 0.05$ . Results In the total sample we found 31.9% of overweight ( $X^2 = 1.60$ ;  $p = 0.205$ ), 28.5% of visceral obesity ( $X^2 = 16.6$ ;  $p = 0.000$ ), 16.9% of hypertensive levels ( $X^2 = 1.29$ ;  $p = 0.525$ ), 47.3% of low fitness ( $p = 0.000$ ) and 45.3% were below 300min/week of physical activity ( $X^2 = 17.02$ ;  $p = 0.000$ ). We found greater proportion of time expended in physical activity and cardiorespiratory fitness in the boys group, while girls showed greater incidence of visceral obesity. **Discussion** This study showed high frequency of CVD factors in south Brazilian young subjects. In addition, epidemiologists have shown that CVD risk factors traditionally associated with cardiovascular morbidity in adult life are especially common in children and adolescents today (TERRES et al., 2006). In this study there were no CVD risk factors difference between boys and girls, except in the visceral obesity, which was higher in girls compared to boys. References Andersen L B, Riddoch C, Kriemler S. Hills. (2011) Brazilian Journal Sports Medicine, 45, 871-876. Terres NG, Pinheiro RT, Horta BL, Amaral K, Pinheiro T. ### THE INFLUENCE OF BIOLOGICAL MATURATION ON SPORTS PARTICIPATION, PHYSICAL ACTIVITY, SEDENTARY BEHAVIOUR AND BODY COMPOSITION

Drenowatz, C.1, Kettner, S.1, Kobel, S.1, Fischbach, N.1, Steinacker, J.M.1

*Ulm University*

1: Ulm University Medical Centre (Ulm, Germany) **Introduction** The rising prevalence of childhood overweight and obesity has been largely attributed to environmental constraints but biological factors need to be considered as well. Specifically changes in body composition during puberty have been associated with changes in physical activity (PA) and sedentary behaviour. In younger children the effect of biological maturation on behavioural aspects is less clear. The purpose of this study, therefore, was to examine the influence of maturity status on sports participation, physical activity, sedentary behaviour and body composition in primary school children. **Methods** Baseline data including 1968 first and second grade children from a large school-based intervention in southern Germany funded by the Baden-Württemberg Stiftung was used. A sample of 1045 children (502 male; 543 female) 7.0 $\pm$ 0.6 years of age provided complete data including reported parental height to determine maturity (Khamis & Roche 1994). Sports participation, physical activity (PA), and screentime (ST) (computer and TV use) was assessed via parent questionnaire. Fitness was determined based on the results of the DKT fitness test (Graf et al. 2004). Subject height and weight was measured by trained technicians and converted to BMI percentiles (BMIPCT). Differences between early, average and late mature participants were assessed via ANCOVA, controlling for sex and age, using Bonferroni adjustment for post-hoc analysis. Results There was no difference in maturity scores between boys and girls. BMIPCT differed across all groups with highest values for early mature and lowest values for late mature children. No difference occurred in sports participation or PA but average mature subjects displayed higher fitness scores. ST was significantly higher for early maturers compared to average or late maturers but these differences disappeared after adjusting for BMIPCT. **Discussion** While no difference in PA or sports participation was observed, early mature children displayed higher body composition, which could lead to lower fitness scores. The increased sedentary behavior in addition to increased body weight in early mature children puts these children at higher risk for various chronic diseases even if PA is not different from their peers. More research, however, is necessary to clearly determine the effect of maturity on sedentary behaviour and physical activity at younger ages in order to address children at risk accordingly. ## THE ABILITY OF DIFFERENT MEASURES OF ADIPOSITY TO DISCRIMINATE BETWEEN LOW/HIGH MOTOR COORDINATION

Lopes, L.1, Santos, R.2, Pereira, B.1, Lopes, V.P.3

1: CIEC-UMinho (Braga, Portugal), 2: CIAFEL-FADEUP (Porto, Portugal), 3: CIDESD-IPB (Bragança, Portugal)

**Introduction** Several anthropometric measures, indices and other techniques have been used in the literature on associations between adiposity and MC. Therefore, the aim of this study was to determine the ability of different measures of adiposity to discriminate between low/high motor coordination (MC). **Methods** A cross-sectional school-based study was conducted on 596 Portuguese children's, aged 9-12 years during the 2009/2010 academic year. Weight, height and waist circumference (WC) were objectively measured by standardized protocols. Body fat percentage (BF%) was estimated by bioelectric impedance. Body mass index (weight/height<sup>2</sup>) and waist-to-height ratio (WHtR) were computed. MC was assessed with the Körperkoordination Test für Kinder (Kiphard & Schiling, 1974). Cardiorespiratory fitness was predicted by a maximal multistage 20m shuttle-run test of the Fitnessgram Test Battery (Welk & Meredith, 2008). A questionnaire was used for assess mother's educational level. Receiver operating characteristic (ROC) and logistic regression were performed. Results ROC curve analysis showed that all measures of adiposity performed well on average in identifying low MC, as indicated by the area under the curve greater than 0.6. The ROC performance of BF% showed a slightly better discriminatory accuracy than BMI, WC and WHtR in predicting low MC in girls. In boys, the ROC performance of WC showed a slightly better discriminatory accuracy than BMI, BF% and WHtR in predicting low MC. After adjustments, logistic regression analyses showed that BMI, WC, %BF and WHtR were positively and significantly associated with MC in both sexes, with exception of WHtR in girls. **Discussion** Measurement issues may potentially play a role in obscuring the relationship between adiposity and MC. BF% and WC showed a slightly better discriminatory accuracy in predicting low MC, for girls and for boys, respectively. **References** Kiphard, E. J., & Schiling, F. (1974). ## INFLUENCING FACTORS OF SEDENTARY BEHAVIOUR IN EUROPEAN PRESCHOOL SETTINGS. AN EXPLORATION THROUGH FOCUS GROUPS WITH TEACHERS

De Decker, E.

Ghent University

**Introduction** Preschool children are sedentary for 50 to 80% of the time, in the classroom as well as during recess. Qualitative studies examining influencing factors of preschoolers' sedentary behaviour at preschool are lacking. This study was executed to explore teachers' opinions on potentially influencing factors of preschoolers' sedentary behaviour in preschool settings. **Methods** Eighty-seven teachers of 4-6 year old preschoolers from six European countries participated in a total of 18 focus groups between October 2010 and January 2011. Key findings were reported by each country separately, and were independently analyzed by two researchers using qualitative content analysis. **Results** According to the teachers, preschoolers do not sit a lot at preschool. Teachers perceive the lack of play space and the small classroom size as potentially influencing factors of preschoolers' sedentary behaviour. Play equipment and teachers' prompts are mentioned to be potentially stimulate children to be less sedentary on the playground. Computer use is reported to be more common in preschool compared to TV watching. Reported reasons for computer use in preschool are educational purposes and computers being part of daily life. **Discussion** Interventions should first focus on increasing teachers' awareness on how sedentary preschoolers are during the preschool day. Teachers should also be informed on strategies to decrease this behaviour in the classroom and at the playground. **References** Hinkley T, Salmon J, Okely AD, Trost SG (2010). ## FOLLOW-UP STUDY OF OBJECTIVELY MEASURED PHYSICAL ACTIVITY LEVELS IN 3- TO 4-YEAR-OLD FINNISH CHILDREN

Mehtälä, A., Soini, A., Säkäslähti, A., Tammelin, T., Kulmala, J., Villberg, J., Poskiparta, M.

University of Jyväskylä

**FOLLOW-UP STUDY OF OBJECTIVELY MEASURED PHYSICAL ACTIVITY LEVELS IN 3- TO 4-YEAR-OLD FINNISH CHILDREN** Mehtälä, A.1, Soini, A.1, Säkäslähti, A.2, Tammelin, T.3, Kulmala, J.3 Villberg, J.1, Poskiparta, M.1. 1: Research Centre for Health Promotion, 2: Department of Sport Sciences, University of Jyväskylä, Finland, 3: LIKES Research Center for Sport and Health Sciences, Jyväskylä, Finland **INTRODUCTION** In previous studies, most of which were cross-sectional, age has been found to associate with physical activity (PA). The aim of the present study was to evaluate whether the PA of 3-year-old children changed over the course of a one-year follow-up. **METHODS** Physical activity levels of children born in 2007 were assessed during two measurement periods: from August to October in 2010 and in 2011. The accelerometer (ActiGraph GT3X) data was collected on 5 consecutive days (3 weekdays and 2 weekend days). Valid, 8h/d, PA data for at least 3 days (2 weekdays and 1 weekend day) were obtained from 46 children (23 boys) in both years. During the first measurement the children were 39 (4) months old and during the second 50 (4) months old. Parents were instructed to keep the accelerometers on their children's hip during all waking hours except during water-based activities. The cut-points established by van Cauwenberghe (2010) and 5-second epoch duration were used in this study. The Mann-Whitney U-test and Independent t-test were applied to identify differences between genders, weekdays and age. **RESULTS** Overall daily PA was calculated as mean counts per minute (cpm) for genders, weekdays, weekend days and both measurement sections separately. The overall PA was significantly higher among 4-year-old children (735±148 cpm) than among 3-year-olds (618±121cpm) (P<.001), but when viewing activity levels separately significant differences were observed only in vigorous activity spent during the week (P=.010). At the age of 4, but not 3, boys spent significantly more time than girls for all other activity levels (light, moderate and vigorous) except for the vigorous activity level on weekdays. Girls spent significantly less time in MVPA-level activity on weekend days than weekdays. **DISCUSSION** Children were physically more active at the age of 4 than 3 on average, and boys were more active than girls at the age of 4. Girls' lower activity levels on weekends are inconsistent with previous studies. Only few previous studies have reported an increase with age in children under school age (Jackson et al. 2003). The reason for this inconsistency between the results remains unclear, but it may be due to interindividual variation. Gender segregation seems to begin early in childhood. **REFERENCES** Jackson D, Reilly J, Kelly L, Montgomery C, Grant S & Paton J (2003) *Obes Res*, 11(3):420-5. ## EXAMINATION OF INDIRECT LIFESTYLE INTERVENTION PROGRAM USING CORRESPONDENCE EDUCATION FOR OBESE CHILDREN AND THEIR PARENTS

Kawata, Y.1, Togashi, K.2, Hanaki, K.3, Iguchi, K.4

1:Teikyo University of Science, 2:Mie University, 3:Tottori University, 4:National Mie Hospital

**INTRODUCTION** There are two main methods of weight-loss instruction for obese children. One is the outpatient consultation for individuals (individual guidance), and the other is the weight-loss instruction for the group (group guidance). However, both methods are not easy to improve lifestyle as instructed, and reach to the point to make it change at home since the patients are children. In this study, we examined the indirect lifestyle intervention program to prevent obese progress for obese children and their parents, and evaluated the effectiveness. **METHODS** 34 obese children (age 9.3 years old, percentage of overweight (POW)  $38.8 \pm 20.9\%$ ) and their parents participated in this program for the totally of 3 sessions (1session 4-week). At each session we requested them to set their lifestyle goal, check the weight and the lifestyle by themselves, wear the pedometer with an uniaxial accelerometer (Lifecorder EX, Kenz, Japan) to set the aim of step counts. We also supported them by periodical telephone communication, and advised instruction by mail. We compared their height, weight, POW, percentage of body fat (BF%), blood pressure, blood biochemistry values, and step counts before and after the program. Moreover, their parents filled out questionnaires about the lifestyle and the contents of the program. **RESULTS** The number of those who declined participation before the program was eight in the 34 candidates. Five participants dropped out at the first session, and one participant dropped out at the second session. The number of those who finished the program was 20 out of the 26 participants (77%). After the program, height had significantly increased ( $140.0 \pm 7.8$  to  $142.5 \pm 8.0$  cm,  $p < 0.001$ ) and both POW and BF% had significantly decreased ( $35.8 \pm 18.1$  to  $29.8 \pm 15.2\%$ ;  $33.9 \pm 10.5$  to  $28.6 \pm 5.5\%$ ,  $p < 0.01$ , respectively) while body weight did not change ( $46.9 \pm 10.1$  to  $46.9 \pm 8.1$  kg) from pre- to post-program. AST and ALT were significantly decreased ( $p < 0.05$ ) while systolic or diastolic blood pressure, total cholesterol, HDL-C, LDL-C, or uric acid level did not change with the improving of obese. Step counts increased significantly from pre- to post-program ( $12,945 \pm 3,653$  to  $14,284 \pm 2,973$  steps/day,  $p < 0.05$ ). According to the questionnaires for parents, the program seemed to receive favorable review about having the children wear the pedometer and receiving the results of step counts. Moreover it seems to heighten the lifestyle consciousness of both the obese children and their parents. **CONCLUSION** It suggested that this program increased the life style consciousness of both the children and their parents and lead to improve of obese by carrying out the communicative program including the parents. The long-term follow-up is considered to be necessary to see the decrease of the POW is not temporary and if they could acquire the obesity prevention lifestyle through this program.

#### ASSESSMENT OF ANTHROPOMETRIC AND CARDIOMETABOLIC PROFILE IN MALE INDIVIDUALS WITH TYPE 2 DIABETES AFTER 12 WEEKS OF WATER TRAINING PROGRAM

Cugusi, L.1, Deidda, M.1, Caria, A.2, Cabras, S.3, Massidda, M.4, Mercurio, G.1

University of Cagliari

**Introduction:** The favorable role of exercise on health improvement and cardiometabolic profile in patients with type 2 diabetes mellitus (T2DM) is well established (ACSM and ADA, 2010). However, little is known about the effects of a specific program of aquatic physical exercise in patients with T2DM. The aim of this study was to analyze the anthropometric and physiological changes during and following 12 weeks of supervised water exercise program in a group of 15 men with T2DM. **Methods:** Fifteen men with T2DM ( $51.4 \pm 9.38$ , years) were enrolled in the study. We evaluated the daily average values of systolic and diastolic blood pressure (Spacelabs 90207 [•Spacelabs, Washington, USA]; Amoores et al., 2005) and determined the average weekly blood levels of fasting glucose (FreeStyle Freedom Lite [•Abbot Diabetes Care]; Tack C et al., 2012), before and after 12 weeks of supervised water exercise program. **Results:** We observed a significant reduction in body mass index ( $31.147 \pm 5.10$  vs.  $29.94 \pm 4.84$   $p < 0.01$ ), waist circumference ( $109.33 \pm 15.23$  vs.  $103.72 \pm 14$ ,  $51$   $p < 0.05$ ) and waist-hip ratio ( $1.01 \pm 0.06$  vs.  $0.99 \pm 0.05$   $p < 0.01$ ). As for the cardiometabolic profile, we detected a significant decrease in systolic blood pressure ( $149.66 \pm 17.99$  vs.  $142.44 \pm 13.04$   $p < 0.01$ ), diastolic blood pressure ( $88.55 \pm 10$ ,  $45$  vs.  $82 \pm 6.74$   $p < 0.01$ ) and fasting blood glucose levels ( $132.53 \pm 24.28$  vs.  $119.58 \pm 17.06$   $p < 0.01$ ), after 12 weeks. **Discussion:** Our results show that 12 weeks of supervised water exercise program are able to produce benefits for both optimization of the anthropometric profile, and improvement of the cardiometabolic profile in patients with type 2 diabetes. **References:** 1. #### USE OF A SHORT-TERM ECCENTRIC CYCLING INTERVENTION IN THE TREATMENT OF NEWLY DIAGNOSED TYPE 2 DIABETICS

Ben, R.

University of Canberra

Use of a short-term eccentric cycling intervention in the treatment of newly diagnosed type 2 diabetics Rattray, B.1, Steele, J.1, Abhayaratna, W.2,3 1: University of Canberra, Australia, 2: Australian National University, Australia, 3: ACT Health, Australia **Introduction** Eccentric exercise may provide a promising tool in the combat of many lifestyle diseases (Paschalis et al., 2011) enabling high muscular loads at low cardiovascular strain. These advantages may assist in minimizing risk in complex disease conditions (Meyer et al., 2003) and diabetic populations in which physical activity compliance is poor (Plotnikoff et al., 2006). This study aimed to investigate the benefits of a short eccentric training period in a group of newly diagnosed type 2 diabetics. **Methods** Our preliminary data includes six female and four male newly diagnosed type 2 diabetics (age:  $50.0 \pm 15.0$  y, BMI:  $31.3 \pm 7.1$ , HbA1c:  $6.3 \pm 0.4\%$ ; mean  $\pm$  SD) in this fully controlled

randomized trial. Participants undertook an initial oral glucose tolerance test (OGTT) in which extra fasting blood samples were taken. Participants were matched for gender and randomly allocated to either a concentric (CON) or eccentric (ECC) cycling 2 wk intervention period. Supervised exercise of up to 30 min on each week day of the intervention was performed in 5 min bouts at an intensity aimed at eliciting a heart rate of 120 bpm. The OGTT and fasting blood measures were repeated the day after the last exercise session. Student *t*-tests were used to compare groups. Results There was no difference in total exercise time ( $196.0 \pm 21.3$  v  $216.0 \pm 31.9$  min; CON v ECC respectively) or exercise RPE ( $12.6 \pm 1.2$  v  $12.8 \pm 1.1$ ) between the interventions although the total work performed during ECC ( $2966.1 \pm 1026.5$  kJ) was higher than CON ( $892.1 \pm 261.9$  kJ). Greater work was performed in ECC despite not being able to match exercise heart rates ( $132 \pm 9$  v  $103 \pm 13$  bpm). There was no change in any fasting or OGTT measures including the homeostatic model assessment insulin resistance (change score:  $-0.78 \pm 1.96$  v  $0.92 \pm 0.88$ ), 2 hr glucose ( $+0.78 \pm 3.09$  v  $-0.18 \pm 2.22$  mM) or insulin ( $-47.5 \pm 75.4$  v  $+13.8 \pm 23.0$  mU/L). Discussion Preliminary data suggests that a short term bout of eccentric training is not likely to result in measurable changes in diabetic status in those newly diagnosed. Eccentric exercise enables high loads with low cardiovascular strain which may provide a safer and more compliant option for some patients. It is unclear if other advantages of eccentric exercise exist although anecdotal reports from the eccentric group were very positive. ### PLASMA HEAT SHOCK PROTEIN 72 AS A BIOMARKER OF SARCOPENIA IN ELDERLY PEOPLE.

Ogawa, K., Hun-kyung, K.1, Takahiko, S.1, Sigeaki, A.2, Yumi, S.3

1:Tokyo Metropolitan Institute of Gerontology (Tokyo, Japan), 2: Nippon Sports Science University (Tokyo, Japan), 3: Musashino University (Tokyo, Japan)

Introduction Sarcopenia is a geriatric syndrome in which there is a decrease of muscle mass and strength with ageing. In age-related loss of muscle strength, there are numerous observations supporting the assertion that neural factors mediate muscle strength. A possible contributing cause may be that aging changes systemic extracellular heat shock protein (eHsp)72 activity. The present study was designed to assess the plasma levels of eHsp72 in elderly people, and to investigate its potential interaction with components of sarcopenia. Methods A total of 665 men and women participated in an official medical health examination and an integrated health examination, including psychological and physical fitness tests. Blood samples were assayed for levels of plasma Hsp72, serum C-reactive protein, interleukin 6, tumor necrosis factor alpha, and regular biomedical parameters. The subjects were classified according to tertile levels of eHsp72. Results We found that higher Hsp72 in plasma is associated with lower muscle mass, weaker grip strength, and slower walking speed, and may be a potential biomarker of sarcopenia in elderly people. This finding was supported by other results in the present study: (i) older age and shrinking body and lower hemoglobin levels, all of which characterize sarcopenia, were related to higher eHsp72 tertiles; (ii) the ORs of the highest tertile of eHsp72 for the lowest tertiles of muscle mass, grip strength, and walking speed were 2.7, 2.6, and 1.8, respectively. These ORs were independent of age, sex, and the incidence of related diseases. Discussion Our results would reveal that eHsp72 in plasma is linked to sarcopenia factors and is a potential biomarker or predictor of sarcopenia. We also found that inflammatory cytokines and eHsp72 were independent and potentially associated with prevalent sarcopenia. Group (IL-6 middle + eHsp72 top, and IL-6 top + eHsp72 middle) had a significantly higher risk for being in the weaker grip strength group [OR, 3.31, 95% CI, 1.48-7.41,  $P=0.004$ ] compared to Group (IL-6 top + eHsp72 top). One possible explanation is that IL-6 and eHsp72 negate each other. These results might imply that eHsp72 reflects the opposite status of inflammation. It might be that inflammatory cytokines are related to muscle mass changes per se (i.e., sarcopenia), including muscle catabolism and synthesis, whereas eHsp72 is related to muscle strength for the protection of motor neurons (i.e., dynapenia). Geriatric syndromes have a biological basis and are considered to be highly prevalent and carry a high risk for adverse health outcomes. The present results could lead to the development of methods for screening those who require effective, targeted care.

### EFFICACY OF ONE EXERCISE PROGRAM TO IMPROVE THE PHYSICAL CONDITION IN PATIENTS WITH CARDIOVASCULAR RISK.

Meseguer Zafra, M., Manzanares Serrano, A., Menárguez Puche, J.F., Gil Pérez, T., Manzano Hernández, F.Y., Vives Hernández, J.J.

*universidad catolica san antonio*

Introduction In this is a paper we present the program "ACTIVA" and the results obtained in the same. The program "ACTIVA" is an initiative conducted by Ministry of Health from Region of Murcia (Spain). The purpose of this exercise program is promoting a moderate physical exercise habit to improve health indicators in patients with cardiovascular risk factors (CVRF). The aim of the present investigation was to confirm the short-term efficacy of this training program on physical fitness. Method The subjects in this study were 139 (35-65 years), patients of two medical centers, municipality of Molina de Segura (Spain). The criteria for inclusion in the program were the presence of two or more CVRF (hypertension, lipid disorders, overweight and smoking) and sedentary lifestyle. The subjects were included on the program for their family doctor or nurse. The program "ACTIVA" consisted of 30 sessions (10 weeks) of training on strength, flexibility and aerobic endurance, 3 days per week on circuit training. The program was designed by graduates for sport science and medical. The sessions had been in municipal places. Physical fitness was measured using the Rockport test (aerobic endurance) launching medical test ball (force) and Wells test (flexibility), made at the beginning and end of the program. For the analysis we used the T-Student test and Pearson lineal correlation. Result When we compare the results obtained at the beginner and at the end of the program, we observed that subjects improved in strength, through the launch of an average of  $5.18 \pm 1.31$  to  $5.54 \pm 1.27$  meters ( $p < 0.001$ ). Flexibility increased from a mean of  $-3.48 \pm 8.62$  to  $0.12 \pm 8.06$  cm ( $p < 0.001$ ). In relation to aerobic endurance the differences in VO<sub>2</sub> Max improved from values of  $30.43 \pm 7.95$  ml / (kg × min) at the beginning to  $32.30 \pm 6.68$  ml / (kg × min) at the end of the program ( $p < 0.001$ ). When we compared the results of men and women, we found that both sexes improved strength, flexibility and aerobic endurance similarly. Discussion The results show that following to realization of the program "ACTIVA", subjects with CVRF and sedentary obtained significant improvements in strength, flexibility and aerobic endurance, training on circuits for 30 seasons. Work protocol circuit produces improvements in physical condition, as shown by many authors (Paoli, Pacelli, Bargossi, Marcolin, Guzzinati, Neri, Bianco & Palma, 2010). ## METS EQUIVALENT OF RESISTANCE TRAINING SESSIONS EXECUTED AT TWO INTENSITIES. DIFFERENCES BETWEEN HEALTHY SUBJECTS AND TYPE 2 DIABETIC PATIENTS

Benvenuti, P.1, Bergamin, M.2, Jimenez, A.3, Pugliese, G.4, Nicolucci, A.5, Balducci, S.4, Zanuso, S.3

1: University of Verona (Italy), 2: University of Padova (Italy) 3: University of Greenwich (UK), 4: La Sapienza University, Rome (Italy), 5: Consorzio Mario Negri Sud, Chieti (Italy)

**Introduction:** Metabolic equivalents (METs) are typically used to measure the caloric cost of aerobic exercises, rarely that of resistance exercises. Aim of this study was to investigate the metabolic equivalents of resistance training executed at light-moderate or vigorous effort respectively in type 2 diabetic patients and young subjects. **Methods:** Twenty type 2 diabetic patients ( $62.9 \pm 6.1$  years) and twenty-two young subjects ( $22.6 \pm 1.9$  years) performed two training sessions with 2-day recovery between each other: one at vigorous intensity (80% of 1-RM) and one at moderate intensity (60% of 1-RM) at Leg Press, Chest Press and Lat Pull Down. Oxygen consumption was continuously measured from fifteen minutes before the session, during the actual resistance training and for fifteen minutes after the session. **Results:** In both diabetic patients and young subjects no differences on METs intensities were found between vigorous and moderate intensities. A statistical difference was detected in between groups analysis, with young subject showing a statistical higher METs intensities in both 60% and 80% of 1-RM training sessions when compared with diabetic subject ( $+66.33\%$ ,  $P < 0.01$ ;  $+60.01\%$ ,  $P < 0.01$ ). METs values at rest at the end of the study were significantly higher than baseline values in both groups at both intensities:  $+0.30 \pm 0.25$  METs at 60% of 1RM ( $P < 0.01$ ) and  $+0.19 \pm 0.19$  METs at 80% of 1RM in type 2 diabetes group, and  $+0.59 \pm 0.34$  METs at 60% of 1RM ( $P < 0.01$ ) and  $+0.50 \pm 0.34$  METs at 80% of 1RM in young subject group. After 15 minutes of quiet rest, both diabetic patients and young subjects revealed no significant differences on METs in within group analysis. However in the between group comparison, at both intensities, data analysis indicated a post-exercise METs significantly higher in young subjects than type 2 diabetes patients ( $+22.43\%$ ,  $P < 0.01$ ;  $34.31\%$ ,  $P < 0.01$ ). **Discussions:** In both diabetic patients and young subjects there are no differences in executing a resistance-training program at 60 or 80% of 1-RM. The METs value that best represent training intensities is 5 METs for young subjects and 3 METs for diabetic patients. **References:** Ainsworth et al. ## HOW DOES PHYSICAL ACTIVITY AND FITNESS INFLUENCE GLYCAEMIC CONTROL IN YOUNG PEOPLE WITH TYPE 1 DIABETES?

Cuenca García, M.1,2, Jago, R.2, Shield, J.P.H.3, Burren, C.P.3

1: Department of Medical Physiology (Granada University, Spain), 2: Centre for Exercise, Nutrition & Health Sciences (Bristol University, UK), 3: School of Clinical Sciences (Bristol University, UK)

**Aims:** To assess physical activity and fitness levels of young people with type 1 diabetes compared to siblings without diabetes, and to investigate the association between physical activity, physical fitness and glycaemic control (HbA1c) in those young people with diabetes. **Methods:** The study consisted of 97 young people aged 8 to 16 years (62% males) from a Paediatric Diabetes Service in South West England. 60 participants (67% males) had type 1 diabetes and 37 participants (54% males) were siblings without diabetes (control group). We measured weight, height and waist circumference, calculated body mass index and waist-to-height ratio and recorded pubertal status, blood pressure and current insulin regimen information. We assessed physical activity by accelerometry, from which we calculated light and moderate-to-vigorous intensity activity. We measured physical fitness by multi-stage sub-maximal bicycle ergometer test. We obtained HbA1c by venipuncture. **Results:** There were no differences between the young people with diabetes and siblings without diabetes in body composition, blood pressure, physical activity and fitness. Moderate-to-vigorous physical activity (MVPA) was associated with better glycaemic control, accounting for 30-37% ( $R^2 = 0.295-0.374$ ) of the variance for HbA1c. Physical fitness was not associated with HbA1c. **Conclusions:** MVPA was associated with better glycaemic control while fitness was not. Findings suggest that developing strategies to increased MVPA may prove an effective method of improving glycaemic control in young people with diabetes.

## TO MOVE JUST ENOUGH OR FAST ENOUGH - A STUDY OF THE PHYSICAL ACTIVITY LEVELS AND PATTERNS IN SINGAPOREAN ADOLESCENTS

Mukherjee, S., Chia, Y.H.M., Lye, C.T.J.

National Institute of Education, Nanyang Technological University, Singapore

**To move just enough or fast enough - A study of the physical activity levels and patterns in Singaporean adolescents** **Introduction** For children and adolescents, daily 60 minutes or more of moderate to vigorous physical activity (MVPA) is recommended for beneficial health and behavioural outcomes. However, the rising prevalence and incidence of metabolic syndrome in children suggests that children are not achieving the recommended levels of physical activity. The aim of this study was to determine the physical activity levels and patterns of Singaporean adolescents. **Methods** Physical activity of 233 students (122 boys and 111 girls) aged 13-15 years was determined using the triaxial accelerometry, over a period of five consecutive days (three weekdays and two weekend days). Weight categorisation of acceptable, overweight and obese was done according to the BMI for age criteria. **Results** Results showed that none of the participants accumulated 60 minutes of daily MVPA, with a significant difference between average time spent in MVPA on weekdays compared to weekends (Mean  $\pm$  SD;  $18.1 \pm 11.6$  minutes versus  $7.6 \pm 13.0$  minutes,  $P < 0.005$ ). Compared to boys, girls were less likely to engage in MVPA (Mean  $\pm$  SD;  $21.9 \pm 12.3$  versus  $13.9 \pm 9.1$  minutes,  $P < 0.005$ ) during weekdays, though no significant difference was seen in the time spent in MVPA on weekends. Average steps during-school hours were 16% higher than after-school hours (Mean  $\pm$  SD;  $4255 \pm 1709$  steps versus  $3117 \pm 1557$  steps,  $P < 0.005$ ), with no significant difference between girls and boys. Students in the highest quintile for average accumulated daily MVPA had an odds ratio of 2.15 for being overweight or obese. On the contrary, students in the lowest quintile for average accumulated daily MVPA had an odds ratio of 0.226 for being overweight or obese. **Discussion** The results of this study imply that Singaporean adolescents may not be achieving the recommended level of MVPA and it is a crucial issue to address. The results also suggest the large potential schools possess to provide physical activity opportunities for the students, and this should be considered during curriculum planning. In addition, the low level of physical activity after school hours and on weekends highlights the significance of parental roles to increase physical activity participation in adolescents. The higher odds ratio of physically active students being overweight or obese challenges the popular notion that the overweight or obese engage in less physical activity than their non-overweight peers. This suggests that adolescents in the healthy weight category may be disregarding importance of physical activity. **References** Rowlands A. (2007). *Pediatric Exerc Sci*, 19, 252-256. ### EFFECTS OF 12 WEEKS OF WATER TRAINING PROGRAM TO PHYSICAL ACTIVITY LEVELS, HRQOL AND DIABETES-SPECIFIC EMOTIONAL DISTRESS IN MEN WITH TYPE 2 DIABETES

Cugusi, L.1, Deidda, M.1, Caria, A.2, Mercurio, G.1

*University of Cagliari*

**Introduction:** The role of general physical activity on improving cardiovascular profile and QoL in patient with type 2 diabetes is widely demonstrated (ACSM and ADA, 2010). However, little is known about the effects of specific water exercise program in patients with type 2 diabetes. Therefore, the aims of the study were to evaluate Physical Activity Levels, HRQoL and Diabetes-specific Emotional Distress in a group of 15 Men with Type 2 Diabetes after 12-weeks of supervised water exercise program. **Methods:** Fifteen men affected by type 2 diabetes (51,4±9,38, years), were enrolled in a program of 12-weeks of supervised water training. We used International Physical Activity Questionnaire (IPAQ) (Mannocci et al., 2010) to determine energy expenditure in walking (Met/min/week), in general physical activities (Kcal/week) and in the time spent sitting (h/day). The Short-form Health Survey 36 with items (SF-36) was completed to establish the Mental Summary Component (MSC) and Physical Summary Component (PSC) (Apolone et al., 1997). The Problem Areas in Diabetes Questionnaire (PAID) (Welch et al., 2003) was used to evaluate the diabetes-specific emotional distress before and after 12-weeks of supervised water exercise program. **Results:** The results showed a significant increase in general physical activity (1239,53±1730,59 vs 3888,73±5222,71 Kcal/week p<0,05), while a significant decrease in time spent sitting (6,77±3,99 vs 5,61±2,78 h/day, p<0,01). SF-36 highlighted a significant increase in the MSC (67±18,88 vs 72,28±15,92 p<0,05) only and the diabetes-specific emotional distress have showed a significant decrease (33,19±19,40 vs 20,13±18,83 p<0,001) at 12-weeks. **Discussion:** Our findings showed that structured and supervised physical activity performed in water, produced benefits both in improving of the HRQoL and in increasing of the energy expenditure in walking and in general physical activity in patients affected by type 2 diabetes. **References:** 1.American College of Sports Medicine (ACSM) and the American Diabetes Association (ADA). #### WHY DO HIGH OXIDATIVE MUSCLE FIBERS REMAIN SMALL – A ROLE FOR A HIGH RATE OF PROTEIN DEGRADATION?

Van Wessel, T.1,2, Offringa, C.1, Kos, D.1, Jansen, R.J.1, De Haan, A.1, Jaspers, R.T.1

*1: VU University Amsterdam, 2: University of Twente*

**Introduction** Muscle fiber size and oxidative capacity are inversely related [1], and training induced hypertrophy and increased mitochondrial density are mutually exclusive [2]. Paradoxically, high oxidative fibers contain a large potential for protein synthesis, but remain small compared to low oxidative fibers [1]. The aim of this study was to obtain insight in the mechanisms underlying this paradox. **Methods** Soleus muscle (SOL, largely containing high oxidative fibers) and extensor digitorum longus muscle (EDL, largely containing low oxidative fibers) from 6 male Wistar rats were used to determine mRNA concentrations of growth factors, their binding proteins, E3-ligases and their transcription factors by qPCR. Activation of translational signaling pathways was assessed by Western blot. **Results** IGF-I mRNA concentration was 2.7-fold higher and myostatin concentration 2.5-fold lower (p<0.02) in SOL than in EDL, indicating higher growth factor induced protein synthesis in SOL. mRNA levels of respective growth factor inhibitors (IGFBP-4, follistatin) were also higher in SOL (p<0.005), which suggests that growth factor signaling in SOL is more inhibited than in EDL. PGC-1alpha concentrations (involved in mitochondrial biogenesis) were higher in SOL (p<0.01). Protein levels of total (t-)AKT and phospho(p-)AKT, p-mTOR, and t-S6 were similar. P-S6 and p-AMPK concentrations were higher in SOL (p<0.02). Surprisingly, despite inhibited growth factor signaling in SOL, we found a higher ratio p-S6/t-S6 (p<0.01) indicating a high capacity for protein translation compared to EDL. mRNA concentrations of factors involved in proteasome-mediated degradation (Mafbx, MuRF, NF-kB, FOXOs) were higher in SOL than in EDL (p<0.02). **Discussion** Several mechanisms may underlie the paradox between size and oxidative metabolism in a steady state situation: 1) inhibitors of IGF-I and myostatin are abundantly expressed in high oxidative fibers, and may attenuate the AKT-mTOR pathway; 2) the AKT-mTOR pathway may be inhibited by high PGC-1alpha and p-AMPK levels [3]; 3) elevated expression levels of FOXOs, NF-kB and the E3-ligases suggest that in high oxidative SOL, a large capacity for protein synthesis is accompanied by high E3-ligase activity and subsequent proteasome-mediated degradation. We conclude that signaling for biosynthesis of mitochondria is likely accompanied by an enhanced rate of degradation of contractile protein and hence limited hypertrophy. **References** 1. #### THE ACE AND BDKRB2 GENE POLYMORPHISMS IN RUSSIAN ATHLETES

Mustafina, L.J.1,2, Timshina, Y.I.3, Astratenkova, I.V.3, Ahmetov, I.I.1,2,3

*1Volga Region State Academy of Physical Culture, Sport and Tourism, 2Kazan State Medical University, 3St Petersburg Research Institute of Physical Culture*

**Background** Human physical performance phenotypes are classical quantitative traits influenced by many gene variants and environmental factors. Studies suggest that insertion-deletion (I/D) polymorphisms in ACE and BDKRB2 genes are associated with aerobic capacity and elite endurance athlete status. Angiotensin-converting enzyme (encoded by ACE gene) exerts a tonic regulatory function in circulatory homeostasis, through the synthesis of vasoconstrictor angiotensin II, which also drives aldosterone synthesis, and the degradation of

vasodilator kinins. The presence (I allele) rather than the absence (D allele) of a 287 bp Alu-sequence insertion fragment of the ACE gene is associated with lower serum and tissue ACE activity and improved endurance performance (Puthuchery et al. 2011). Bradykinin is a potent endothelium-dependent vasodilator and acts via the bradykinin B2 receptor (encoded by BDKRB2). The absence (-9), rather than the presence (+9), of a 9 bp repeat sequence in exon 1 has previously been shown to be associated with increased gene transcription, higher BDKRB2 mRNA expression and higher efficiency of muscular contraction (Williams et al. 2004). The aim of the study was to investigate ACE and BDKRB2 gene polymorphisms in combination in a large cohort of Russian athletes. Methods One thousand three hundred and sixty four athletes from 45 sporting disciplines and 507 controls were involved in the study. Genotyping was performed by PCR. To assess the combined impact of 2 gene polymorphisms, all athletes were classified according to the number of 'endurance' alleles they possessed. Results The proportion of subjects with a high (3-4) number of 'endurance' alleles was greater but not significantly in endurance-oriented athletes (n=131) compared to controls (34.4 vs 26.8%; P=0.088). The same trend was observed in athletes with mixed endurance/power activity (n=1032; 29.5%, P=0.283) and a whole group of athletes (n=1364; 30.1 vs 26.8%; P=0.162). Conclusion. Thus, we found a trend toward an association between ACE and BDKRB2 polymorphisms and endurance athlete status. Our data suggest that each DNA locus can explain a very small proportion of the phenotypic variance. Therefore, the use of very large sample sizes and the genotyping of many genes are needed to detect associations between gene variants and sport-related phenotypes. ### GENETIC VARIATION OF THE HUMAN ACE AND ACTN3 GENES IN CONNECTION WITH VO2MAX AMONG HUNGARIAN ELITE ATHLETES

Bosnyák, E., Trájer, E., Udvardy, A., Protzner, A., Komka, Zs., Györe, I., Tóth, M., Szmodis, M.

*Faculty of Physical Education and Sport Sciences, Semmelweis*

**Introduction** Nowadays it is well recognized that athletic performance highly depends on genetic background. Among those, angiotensin-converting enzyme (ACE) and the  $\alpha$ -actinin-3 (ACTN3) genes are considered strong candidate genes associated with human physical performance, although their influence has not been described completely. The aim of our study was to evaluate the differences of these genetic variants and to reveal possible connections between the gene polymorphisms' combinations and the Vo2max values. **Methods** The study involved 155 Hungarian elite athletes from endurance, team, middle-distance and power sports. Human genomic DNA was isolated from blood, genotyping was performed by polymerase chain reaction. The examination consisted of a *vita maxima* test to exhaustion on treadmill with constant velocity (10 km/h) starting from a 1,5 % gradient ascending with 1,5 % every minute. During the examination we registered the maximal oxygen uptake (Vo2max). To measure the differences between the groups One-way Anova and Tukey HSD tests were performed using Statistica 9.0 for Windows® (significance level:  $p < 0,05$ ). **Results** Only 2% of the athletes (all of them are kayaking/canoeing athletes) had the combination of ACE II and ACTN3 XX genotypes with the average Vo2max value of 56.23 ml/kg/min, which was the lowest value. ACTN3 XX genotype was the least frequent in the whole sample compared to the other ACTN3 genotypes. We found significant differences between each group apart from the case of kayaking/canoeing vs. power athletes considering the average Vo2max values. Athletes with both ACTN3 XX and ACE DD genotypes had the highest Vo2max values (64.53 ml/kg/min) but there were no significant differences while comparing them with the other 8 combination. In the team sports the ACTN3 R allele occurrence was clearly dominant, whereas only 15% of these athletes presented XX genotype. 4 out of the highest 5 Vo2max results (avg: 80.56 ml/kg/min) were presented by athletes possessing ACE ID+ACTN3 RR genotype combination. **Discussion** The connection of the ACE I allele to the endurance performance has been published many times. It is well known that high maximal oxygen uptake volume is essential for a long-distance athlete. Despite this statement we found the lowest Vo2max values in the ACE II + ACTN3 RR/RX/XX group, but there were no significant differences comparing these values to that of other groups' results. Furthermore, only 8% of the athletes in the endurance group have ACE II genotype, which – based on the literature – would be preferable. The R allele is "responsible" for sprint and power. In team sports speed and muscular strength play a very important role: the ACTN3 RR genotype and R allele occurrence were determinant in this group.

### ACUTE PHYSICAL EXERCISE AND BLOOD-BRAIN BARRIER PERMEABILITY

Fontes-Ribeiro, C.A., Pinheiro, V., Baptista, S., Gonçalves, J., Leitao, R., Silva, A.P.

*Faculty of Medicine of the University of Coimbra*

**Introduction** Sports with intensive physical activity are performed around the world. Nowadays, more than ever, physical activity is widely accepted as a behavioral strategy to enhance health. Although exhaustive exercise causes oxidative stress in muscle and other tissues, references are conflicting whether or not strenuous exercise could generate oxidative stress in brain. On the other hand, doping substances have gained a great popularity in competition sports, besides the fact that they can be toxic to the brain. It is known that the blood-brain barrier (BBB) protects the brain against hazardous molecules and pathological organisms, and is also critical for brain homeostasis. Its dysfunction can lead to several and harmful consequences, such as irreversible damage of brain cells that can be translated into neurological and psychiatric abnormalities. Tight Junctions (TJs) together with Adherens Junctions (AJs) are the main components of the BBB, being responsible for its integrity. TJs are constituted by transmembrane proteins, like claudin and occludin, and by intracellular proteins, like zonula occludens (ZO). Claudin-5, the smallest protein (24 kDa), is responsible for the primary seal of the TJ, and occludin (64 kDa) is responsible for additional support. Taking into account that there is no solid information regarding the impact of exercise on these BBB proteins, the present work aims to study alterations of TJ proteins during an acute physical exercise. **Methods** Young Wistar rats (8 weeks old) were used. Half of them were subjected to an acute exercise program (forced running in a treadmill for 35 min, with a 20 cm/s speed and a 15° of inclination) (exercise group), and the other half was not subjected to exercise (control group). The rats of the experimental group were sacrificed right after exercise, and alternated with controls. The alterations of tight junction protein levels, occludin and claudin-5, were determined by western blot and in the frontal cortex, striatum and hippocampus. **Results** As far as claudin-5 protein levels are concerned, there were no significant differences between exercise and control groups in the three cerebral regions studied. In addition, there were no significant changes of occludin protein levels in the frontal cortex and hippocampus. However, there was a statistical significant decrease of the occludin protein levels in the striatum in the exercise group when compared with the control one. **Discussion** Our results suggest a slight increase of the BBB permeability during the acute physical exercise, which may lead to the entry of harmful substances into the brain, impairing in some way the normal brain function, and in particular the striatal dopaminergic system.

**ACUTE EXERCISE MODULATION OF BDNF AND HSPS CONTENT IN PBMCs FROM ELDERLY SUBJECTS**

Caporossi, D., Brunelli, A., Beltran Valls, R.M., Parisi, A., Dimauro, I.

*University of Rome Foro Italico*

Introduction Despite it is well demonstrated that acute exercise can increase the peripheral concentration of BDNF (Knaepen et al., 2010), it is matter of debate what can be the physiological meaning of such increment and from which tissues it is produced and utilized (Pedersen BK, 2009). The aim of this research is to investigate the effect of one bout of intense exercise on BDNF level in PBMCs of elderly subjects and to verify the possible correlations with intracellular changes of other proteins involved in stress response. Methods After informed consent and medical examination, 16 sedentary, healthy elderly subjects (8 males and 8 females, 72 ± 4 years old) were selected to participate. Subjects exercised on a cycle ergometer, while their heart rate HR, blood pressure BP and electrocardiogram data were continuously monitored. They started at 30 W for 2', after which the load was increased by 10 W every minute. Subjects had to cycle until the attainment of the 85% of their theoretical HRmax. After that HR target was reached they were requested to continue cycling up to voluntary withdrawal. Blood was sampled immediately before the exercise session (PRE), immediately (POST), 60 minutes (T.60) and 24 hours (T.24h) after the exercise session. The PBMCs' expression of BDNF, hsp70, hsp27 and alpha B crystallin were analysed by ELISA or Western Blot analyses. Results The average duration of exercise was 11.9 ± 3.2 min for elderly (14.4 ± 2.2 min for men vs. 8.9 ± 1.1 for women,  $p < 0.05$ ). The average power reached at the moment of maximal effort was 89.6 ± 26.1 W (110.7 ± 14.2 for men vs. 65.0 ± 5.5 for women,  $p < 0.05$ ), remaining significant different also when controlled for the subjects' body mass. No statistical differences were detected for PBMCs concentration of BDNF (PRE: 58.36 ± 27.3 pg/ml; POST: 58.7 ± 37.5; T.60: 55.9 ± 18.6 pg/ml), hsp27, alpha B crystallin and hsp70, although a trend toward an increase of hsp70 content was observed 24 hours after exercise (PRE: 0.77 ± 0.08, POST: 0.83 ± 0.08, T.60 0.84 ± 0.08, T.24h 0.91 ± 0.11) (PRE vs. T.24h,  $p < 0.097$ ). Discussion We failed to find any significant difference between baseline and post exercise values, as in PBMCs the amount of BDNF and HSPs did not show any significant change overtime. The exercise intensity and duration utilised, which is considered to be maximal and safe in this age group from a cardiovascular point of view, seems not be enough to stimulate those systemic changes at physiological level which appear to be necessary to induced the BDNF and HSPs modulation in immune cells. Introduction The number of individuals affected by type 2 diabetes is projected to increase to 522 million in 2030 (Whiting et al., 2011). Exercise is a fundamental lifestyle modification to prevent diabetes in high-risk populations. Traditionally, research has employed prolonged aerobic exercise to investigate molecular mechanisms underpinning the preventive effects of exercise. However, aerobic exercise might not appeal or be motivating to many individuals (Deci and Ryan, 1985). We investigated the effects of 8 weeks of indoor football (futsal, FUT) versus moderate-intensity, continuous treadmill training (MOD) on skeletal muscle and systemic adaptations associated with the prevention of diabetes in middle-aged, sedentary males. Methods Twenty men (age 35-55 years) were allocated to either FUT or MOD for 8 weeks, 3 times per week. Before and after the training interventions, participants underwent an oral glucose tolerance test (OGTT), a resting muscle biopsy, and an incremental exercise test. Plasma glucose and insulin concentrations and peripheral insulin sensitivity were measured in response to the OGTT. Key mitochondrial biogenesis and glucose transport protein abundance in resting muscle was measured via western blotting. Blood lipids, HbA1c, blood pressure, anthropometry and self-reported dietary intake were also assessed. Results Peripheral insulin sensitivity was improved only in FUT (+31%, effect size (ES) ± 90% confidence interval: 0.67 ± 0.53). Mitochondrial complex IV, subunit II resting protein abundance was increased in FUT only (+16%, ES 0.79 ± 0.24), while glucose transporter 4 was equally increased in FUT and MOD (+45%, ES 0.78 ± 0.57; and +44%, ES 0.67 ± 0.57, respectively). Only FUT training resulted in a lowered plasma total cholesterol and triglycerides concentration (-8%, ES 0.44 ± 0.24; and -32%, ES 0.52 ± 0.3, respectively). No changes were detected for BMI, waist circumference, and self-reported dietary intake for either group. Discussion Futsal training may be employed as an effective and enjoyable exercise model to assist in the prevention of diabetes in middle-aged sedentary males.

**CHARACTERIZATION OF MITOCHONDRIAL PROTEINS IN HEART OF SPONTANEOUS HYPERTENSIVE RATS SUBMITTED TO MODERATE TREADMILL RUNNING.**

Rocha, L.A.O.1,2, Franco, O.L.2,3

<sup>1</sup> Curso de Educação Física, UCB; <sup>2</sup> Pós-graduação em Patologia Molecular, Curso de Medicina, UnB; <sup>3</sup> Pós-graduação em Biotecnologia e Ciências Genômicas, UCB.

Concentric hypertrophy of left ventricle consists in an important sustained hypertension consequence. This hypertrophic process may be initially adaptive, in that it enables heart tissue to maintain normal pump performance. However, this hypertrophic process leads to a wide number of maladaptive modifications that occur in the extracellular matrix and also at cardiac myocytes. Despite of enormous importance of metabolic modifications, the molecular mechanisms are still insufficiently clear specially when related to mitochondrial role. Otherwise, the exercise training positive effects lead to functional capacity enhance on hypertension patients, being recognized as an important side treatment. In order to understand the molecular modifications of mitochondrial protein expression in animals models before and after hypertension development and the exercise effects over this process, twenty isogenic male SHR were randomly divided into four groups with 5 animals each. Groups with 6 (normotense group) and 35 weeks old (symptomatic group) were shared in exercised and non-exercised groups. Exercised animals were submitted to moderate treadmill running during four weeks, 30 min per day, five days per week. The exercise training progress was measured by using a progressive lactate test. The blood pressure was measuring using a non invasive method. Firstly, SDS-PAGE showed few differences in protein patterns of exercise groups when compared with sedentary groups. Furthermore bidimensional electrophoresis also suggests that some mitochondrial proteins could be modulated in response to exercise. In summary data suggests the positive effects of exercise in hypertension could be associated to mitochondrial protein modifications.

**AEROBIC EXERCISE TRAINING IMPROVES THE FINGER-PINCH FORCE CONTROL IN OLDER ADULTS**

Critchley, K.1, Kokubu, M.2, Iemitsu, M.1, Fujita, S.1, Isaka, T.1

*1: Ritsumeikan University (Shiga, Japan), 2: Osaka University of Health and Sport Sciences (Osaka, Japan)*

**Introduction** The age-related reduction in muscular strength and neuromuscular function is an obvious contributing factor to the decline in finger-pinch force control in older people (Sosnoff et al., 2006). Keogh (2007) indicated that upper-limb strength training may improve the finger-pinch force control. It is not clear, however, moderate training improves the finger-pinch force control or not. Therefore, the aim of this study was to investigate the effect of lower-limbs aerobic exercise training on the finger-pinch force control in older adults. **Methods** Thirty nine right handed older adults ( $65.9 \pm 7.7$  y, 18 male, 21 female) participated in this study. The aerobic exercise training group ( $n=22$ ,  $65 \pm 8.4$  y) trained for 8 weeks, performing either bicycle ergometer exercise three times a week for 40 minutes or playing tennis twice a week for 45 minutes, while the control group subjects ( $n=17$ ,  $67.1 \pm 6.9$  y) maintained their normal activities. In the experiment task, subjects were requested to maintain a constant force output at 10% of each subject's maximal voluntary pinch force with visual feedback on the computer monitor. All subjects performed the task with both hands together. Changes in force variability, targeting error, mean power frequency and proportional power were assessed during a series of finger-pinch tasks. **Results** There was no significant change in maximal voluntary pinch force between aerobic exercise group and control group after the training period. Pinch force variability and targeting error were significantly reduced in aerobic exercise training group, while no significant change was observed in control group. **Discussion** Upper-limb strength training reduced pinch force variability and targeting error, as well as increased maximal voluntary pinch force (Keogh et al, 2007). In contrast, there was no significant change in maximal voluntary pinch force by aerobic exercise training, while finger-pinch force variability and targeting error were reduced by this training. Current study suggests that aerobic and resistance exercise may influence the finger-pinch force control through different mechanisms. In fact, moderate exercise lead to an increased cortical activation in the left DLPFC and it cause to improve cognitive performance (Hiroki et al, 2010). Therefore, aerobic exercise may have contributed to an elevated brain function and motor control that resulted in an improved finger-pinch force control without a significant increase in muscular strength and neuromuscular function. **References** Yanagisawa H, Dan I, Tsuzuki D, Kato M, Okamoto M, Kyutoku Y, Soya H. **CHANGES IN SURFACE MOTOR UNIT ACTION POTENTIALS DURING FATIGUING ISOMETRIC CONTRACTIONS OF THE VASTUS MEDIALIS MUSCLE**

Gonzalez-Izal, M., Negro, F., Farina, D.

*Public University of Navarre*

**CHANGES IN SURFACE MOTOR UNIT ACTION POTENTIALS DURING FATIGUING ISOMETRIC CONTRACTIONS OF THE VASTUS MEDIALIS MUSCLE** Gonzalez-Izal, M.1, Negro, F.2, Farina, D.2 **1: UPNA (Spain), 2: UMG (Germany)** **Introduction** Motor unit surface action potentials reflect the intracellular properties of the muscle fibers. During fatiguing contractions, the concentration of  $Ca^{2+}$  increases in the muscle and this causes the lengthening of the intracellular action potential (IAP) profile (Dimitrova et al., 2003). The influence of this change in IAP on the characteristics of the surface EMG (sEMG) is not known. In this study, we analysed the changes in amplitude of the motor unit action potential (MUAP), as obtained by spike triggered averaging (STA) of the sEMG, during a sustained fatiguing contraction. **Methods** 8 men (age, mean $\pm$ SD,  $31.3 \pm 4.4$  yr, body mass  $69.9 \pm 8.0$  kg, height  $173.4 \pm 7.2$  cm) participated in the study. The subjects performed a maximal voluntary contraction (MVC) of the knee extensors at the beginning and at the end of the protocol. They performed two isometric contractions at 30% MVC of 20s, followed by a sustained contraction at 30% MVC until task failure. During each contraction, force, sEMG and intramuscular EMG (iEMG) were concurrently recorded from the vastus medialis obliquus muscle (VMO). sEMG signals were recorded using a grid of 64 electrodes in a monopolar configuration and iEMG was recorded using 4 pairs of fine-wire electrodes in a single differential configuration. The iEMG signals were decomposed in individual MUAP trains using the EMGLAB software (McGill et al., 2005) and the sEMG was averaged using the times of occurrence of the MUAP as triggers. **Results** The MVC force decreased from baseline (mean $\pm$ SD) by  $21.1 \pm 9.8\%$  ( $P < 0.05$ ) after the sustained contraction. 148 motor units were identified at the sustained contraction. The correlation coefficients between the STA of the same motor units during the two contractions of 20s, were  $0.87 \pm 0.09$ , assuring a stable recording. The STA potential amplitude (averaged across the matrix) did not change ( $3.0 \pm 26.9\%$ ) at the middle of the contraction but increased significantly with respect to baseline at the end of the fatiguing contraction  $6.7 \pm 24.9\%$  ( $P < 0.05$ ). **Discussion** The MVC force decreased significantly after the sustained contraction until task failure due to fatigue. The STA for the identified motor units increased in the last part of the sustained contraction. This can not be related to movement artefacts of the intramuscular electrodes because this was excluded from the high correlation coefficients estimated between intramuscular STA in different contractions. These changes are compatible with the increase of afterpotentials in the IAP profile due to fatigue that has been suggested to increase the amplitude of the sEMG during a fatiguing contraction (Dimitrova et al., 2003). **References** McGill KC, Lateva ZC, Marateb HR. (2005). *J Neurosci Methods*, 149(2), 121-133. Dimitrova NA, Dimitrov GV. (2003). *J Electromyogr Kinesiol*, 13, 13-36.

**LOCAL OXYGEN SUPPLY AND UPTAKE DURING INCREMENTAL NEUROMUSCULAR ELECTRICAL STIMULATION**

Gobbo, M., Gaffurini, P., Neviani, C., Orizio, C.

*University of Brescia*

**Introduction** Near InfraRed Spectroscopy (NIRS) has been widely applied to investigate local oxygen supply and uptake in active skeletal muscles. Despite the extensive literature on NIRS parameter changes during volitional efforts, only few studies have focused on changes in intramuscular oxygenation and microvascular blood flow due to neuromuscular electrical stimulation (NMES). Aim of our work was to provide further insight into metabolic adaptations to NMES. **Methods** The tibialis anterior of 20 moderately active subjects (males, age 23-

35 yo) was electrically stimulated at the main motor point. The stimulation protocol involved five single twitches at maximal stimulus amplitude (full motor unit recruitment) and five 90-s steps with increasing amplitude and frequency of the intermittent stimulation. Basal oxygenated hemoglobin+myoglobin (O<sub>2</sub>Hb) prior to stimulation and changes in force and deoxygenated hemoglobin+myoglobin ( $\Delta$ HHb) due to stimulation were recorded. Contraction time (CT) of single twitches and fatigue index (FI) of the stimulated muscles were calculated. Results F-statistics allowed to define two groups of TA muscles: group F (more fatiguable, FI<0.69) and group R (less fatiguable, FI>0.69). For group F, CT was 36.4±4.2 ms, basal O<sub>2</sub>Hb was 87.4±16.3  $\mu$ mol and  $\Delta$ HHb was 15.8±2.3  $\mu$ mol. For group R, CT was 47.1±5.8 ms, basal O<sub>2</sub>Hb was 103.3±14.7  $\mu$ mol and  $\Delta$ HHb was 9.0±1.2  $\mu$ mol. The differences between groups were statistically significant (p<0.05) for each parameter. Discussion The proposed method revealed different metabolic responses to incremental NMES in the two identified groups of TA muscles. Group R, more resistant to fatigue, showed slower contraction velocity (higher CT), higher O<sub>2</sub> supply (higher basal O<sub>2</sub>Hb) likely due to higher capillary density and myoglobin concentration, and lower relative O<sub>2</sub> uptake (lower  $\Delta$ HHb) during muscle activity. Conversely, TA muscles belonging to group F were faster (lower CT) and showed greater fatigability: this was likely related to inadequate blood and O<sub>2</sub> supply (lower basal O<sub>2</sub>Hb) to working muscles which is essential to support the metabolic requirements and avoid decrease in performance caused by lactic acid accumulation. Moreover, group F showed higher HHb changes suggesting greater fractional O<sub>2</sub> extraction in the active muscles as a compensatory mechanism for poor muscular microvascularization. The proposed method and data interpretation may represent an objective, independent of motivation and non-invasive tool to assess muscle metabolic adaptations to training as well as oxygen supply and/or consumption impairments in specific neuromuscular diseases.

### COGNITIVE FUNCTION SEEMS TO MEDIATE THE PERCEIVED EXERTION DURING LIGHT AND MODERATE HANDGRIP PERFORMANCE

Oishi, L.M.1, Oliveira, W.G.A.1, Matsudo, S.M.M.2, Raso, V.1,3

1: UNOESTE (Presidente Prudente, Brazil); 2: CELAFISCS (Sao Caetano do Sul, Brazil); 3: ANHANGUERA-UNIBAN (Sao Paulo, Brazil)

Introduction The rating of perceived exertion (RPE) as well as handgrip (HG) dynamometry have been employed as a very easy and useful tool for a widely different purposes (Pritchett et al., 2009; McGorry et al., 2010), but both seem to be dependent of cognitive function which, in turn, is influenced by age, socioeconomic and educational levels (Alfaro-Acha et al., 2006; Leibovici et al., 1996). Therefore, the purpose of this preliminary study was to determine the power of RPE to predict light, moderate and vigorous HG dynamometry in community-dwelling elderly individuals. Methods We measured cognitive function (mini-mental state examination [MMSE]) and RPE (0 to 10) during HG dynamometry performance in 28 community-dwelling elderly individuals. Volunteers were familiarized with HG performance, and subsequently, a maximal HG (MaxHG) was performed; the RPE was reported at the end of this trial. Subsequently, in a randomized order, volunteers were asked to carry out a HG at 4 (HG4RPE), 6 (HG6RPE) and 8 RPE (HG8RPE). The results of HG at HG4RPE were associated to 40% MaxHG (40MaxHG), and so on (i.e., HG6RPE versus 60MaxHG and HG8RPE versus 80MaxHG). Results We developed prediction models to estimate HG as a function of RPE for each different score (i.e., HG4RPE, HG6RPE, and HG8RPE) and matched for important covariates as age, body mass index and cognitive function. HG at RPE was consistently associated with HG regardless of MaxHG percentage. The prediction power of the models were very satisfactory (HG4RPE: R=.85, R<sup>2</sup>=.72, P<0.0005; HG6RPE: R=.84, R<sup>2</sup>=.72, P<0.0005; and R=.88, R<sup>2</sup>=.77, P<0.0005) and mediated by cognitive function at HG4RPE (P=.008) and at HG6RPE (P=.052). Discussion HG strength can be easily measured and has been associated with multiple health outcomes in elderly individuals (Ling et al., 2010; Bohannon, 2008; Sayer et al., 2006). Our results permit to conclude that the rating of perceived exertion could represent an important predictor of handgrip strength, but cognitive function seems to exert an important mediating effect, mainly on light and moderate handgrip performance. ### CAN A PROLONGED COGNITIVE TASK ALTER MAXIMAL FORCE CAPACITY?

ROZAND, V.1, Pageaux, B.2, Marcora, S.2, Papaxanthis, C.1, Lepers, R.1

1:INSERM 1093 (Dijon, France), 2:Centre for Sport Studies (Kent, United Kingdom)

Introduction The effects of a physical exercise on cognitive performance are well established. In contrast, the influence of a prolonged cognitive task on physical performance has been less investigated. For example, it has been shown that a mentally fatiguing task could alter the subsequent endurance performance in humans during cycling exercise (Marcora et al., 2009), and isometric contraction (Pageaux et al., 2011), without alterations of neuromuscular properties. Interestingly, Bray et al. (2012) has recently evidenced a decrease in maximal voluntary contraction (MVC) force during a handgrip squeezing task, alternated with a demanding cognitive task. The mechanisms responsible of this decrease in force were unclear and needed to be clarified, especially the possible relationship between mental fatigue and central fatigue. In this context, the aim of the present study was to investigate the effects of a demanding cognitive task on maximal force capacity and neuromuscular properties. Methods Ten subjects performed three randomized sessions lasting 27 minutes: i) a high-demanding cognitive task (modified Stroop test), ii) a moderate cognitive task (congruent Stroop task), iii) a control cognitive task (watching a movie). Every 3 minutes, the cognitive task was stopped to perform neuromuscular tests on the knee extensor muscles. Psychological state of subjects was assessed before and after the task by questionnaire (NASA Task Load Index). Results The modified Stroop task was significantly (p<0.001) more mentally demanding than the congruent Stroop task and the control task. There was no significant decrease in MVC force and voluntary activation level (VAL) at the end of 27 minutes, whatever the session. No peripheral alteration was found. Discussion Contrary to Bray's study, our results showed no influence of a prolonged demanding cognitive task on maximal force production. According to the results of Marcora et al. (2009) and Pageaux et al. (2011), a prolonged mentally fatiguing task did not induce any loss in VAL (i.e. central fatigue). The difference with Bray's study could be explained by the different muscle group tested (lower versus upper limb), although the exercise duration was longer in the present study. We assume that the amount of energy expended in the central nervous system could be quickly regenerated, during the recovery period (5-10 seconds) between the cognitive task and the maximal voluntary contraction. ## EFFECTS OF DIFFERENT GRAVITY LEVELS ON STRETCH- AND H-REFLEXES IN MAN

Kramer, A., Gollhofer, A., Ritzmann, R., Taube, W., Gruber, M.

*University of Konstanz*

EFFECTS OF DIFFERENT GRAVITY LEVELS ON STRETCH- AND H-REFLEXES IN MAN Kramer, A.1, Gollhofer, A.2, Ritzmann, R.2, Taube, W.2, Gruber, M.1 1: University of Konstanz (Germany), 2: University of Freiburg (Germany) Introduction Previous studies suggest that the reflexes using the Ia afferent pathways are modulated by gravitational loading and unloading of the human body (Ferris 2001; Miyoshi 2003). However, most of this research has been conducted under artificial loading or unloading conditions (immersion, additional weights or counterweights, suspension). Furthermore, these studies only examined the Hoffmann-reflex (H-reflex), thus bypassing the muscle spindle. The aim of the present study was to examine both the H-reflex and the stretch reflex under true gravitational loading and unloading induced by parabolic flights. Methods Stretch- and H-reflex responses in the soleus muscle were recorded in 15 healthy subjects (11 male and 4 female; age  $36 \pm 9$  years; height  $176 \pm 7$  cm; body mass  $71 \pm 10$  kg) during upright stance for three different gravity levels: normal gravity (NG, 1g), hypergravity (HG, 1.8g) and microgravity (MG, 0g). The stretch reflexes were evoked by a dorsiflexion movement ( $5^\circ$  amplitude,  $200^\circ/\text{s}$ ) generated by a custom-made ankle ergometer. Ten to fifteen parabolas were available per subject, which resulted in an average of  $26 \pm 6$  stretch reflexes and  $11 \pm 4$  H-reflexes per subject per gravitational condition. Statistical analyses included a repeated measures analysis of variance with the three-level factor gravity and Bonferroni corrected post-hoc tests. Results Normalized to the values during NG, the H-reflexes elicited in the soleus muscle showed a decrease during HG (-18%) and an increase during MG (+17%). Compared to NG, the stretch reflexes were reduced during HG (-12%) but showed no changes during MG. Discussion The size of the stretch and H-reflex responses was affected by the gravity level, which suggests a load-dependency of the reflexes using the Ia afferent pathway: the increased load during HG reduced the excitability of the stretch- and H-reflex, probably due a reduced Ia afferent transmission and the decreased load during MG increased the excitability of the H-reflex. The increased size of the H-reflex responses during MG is in line with the observations of Miyoshi (2003). However, the size of the stretch reflexes remained unchanged in MG compared to NG. Possible explanations include the additional influence of the fusimotor system or differences in the susceptibility to presynaptic inhibition. In conclusion, the results of the present study support the notion that reflexes are modulated to meet the requirements of the specific situation, in this case the gravitational loading. ## MOLECULAR ADAPTATION OF SKELETAL MUSCLE IN POST-SURGICAL OSTEOARTHRITIS PATIENTS: MARKERS OF INFLAMMATION, HYPERTROPHY, ATROPHY AND LIPID METABOLISM

Okoro, T., Andrew, J.G., Stewart, C.E., Al-Shanti, N., Maddison, P., Lemmey, A.B.

*Bangor University*

MOLECULAR ADAPTATION OF SKELETAL MUSCLE IN POST-SURGICAL OSTEOARTHRITIS PATIENTS: MARKERS OF INFLAMMATION, HYPERTROPHY, ATROPHY AND LIPID METABOLISM Okoro, T.1 2, Andrew JG.2, Stewart CE.3, Al-Shantii N.3, Maddison P.1, Lemmey AB.1 1: Bangor University (Bangor, UK), 2: Department of Orthopaedics, Betsi Cadwaladr University Health Board (Bangor, UK), 3: Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University (Manchester, UK) Introduction Patients typically present with significant muscle wasting as a consequence of pain and disuse atrophy prior to total hip replacement (THR). This study aimed to characterise the changes in genetic markers of muscle inflammation, atrophy and lipid metabolism in the early rehabilitation phase after surgery. Methods After local research ethics committee approval, patients undergoing THR were prospectively recruited. Muscle biopsies were obtained from the distal vastus lateralis (VL; ~5cm proximal to suprapatellar pouch) during surgery and at 6 weeks postoperatively. RNA was isolated from the muscle biopsies and real-time quantitative PCR performed using a panel of genes including those coding for inflammation (TNF- $\alpha$ , IL-6), hypertrophy (calpain1 (CAPN1), calpain2 (CAPN2), calpastatin (CAST)), atrophy (muscle atrophy F-box (FBX032), calpain 3 (CAPN3) and 20S proteasome alpha7 subunit (PSMA7)) and lipid metabolism (lipoprotein lipase (LPL), peroxisome proliferated-activated receptor alpha (PPARA)). Gene expression was assessed using the comparative Ct method. Results 14 patients were recruited (average age (mean  $\pm$  SD)  $65.3 \pm 8.8$  years in men (n=9) and  $59.8 \pm 13.3$  years in women (n=5)). 14 muscle biopsies were collected during surgery and 10 obtained at 6 weeks postoperatively. At 6 weeks, there was a comparative reduction in TNF expression, compared to baseline (%fold increase/decrease (p value); -30% (p=0.02)). Significant changes were observed in markers of cell atrophy (reduction in PSMA7 (-45% (p=0.015)), with increased CAPN3 (+103% (p=0.004)) and lipid metabolism (LPL (-45% (p=0.015) and PPARA (-79% (p=0.0001)). Despite decreases in other markers of inflammation and atrophy (IL6 (~80%; FBX032 (30%)), with increases in hypertrophic markers (CAPN1 ~70%, CAPN2 ~130%, CAST ~50%), significance was not achieved for any of these genes in this model. Conclusions At the 6 week time point in this THR population, muscle inflammation in the VL was reduced. Despite apparent increases in markers of hypertrophy, these did not reach significance, although the balance in favour of hypertrophy is apparent, with the significant reduction of CAPN3 and reduced inflammation. The significant reductions in markers of lipid metabolism are of interest and warrant further investigation, with regard to metabolic efficiency in this group. It is interesting to speculate that increased exercise during this phase of recovery may facilitate hypertrophic responses and potentiate functional gains.

## POTENTIATION OF AGONIST MUSCLE ACTIVITIES BY ANTAGONIST CONDITIONING CONTRACTION

Kamimura, T.1, Muramatsu, K.2

*1: Tokyo University of Social Welfare, 2: Health Science University*

Introduction Preceding antagonist conditioning contraction (ACC) have been shown to potentiate the contraction force, electromyography (EMG) activity, and other outputs of an agonist muscle. We previously reported that the rate of force development of agonist contraction was increased by isometric ACC (Kamimura et al, 2009). The purpose of this study was to further characterize the potentiating effects of ACC on agonist muscle activities. Methods Healthy male subjects performed isometric maximal voluntary dorsal or plantar flexion from 90 degrees flexion position of the ankle joint. Then, maximal isometric plantar flexion for 3 s immediately after maximal isometric dorsal flexion for 1 s was performed. The force signal during the plantar flexion phase was recorded and numerically differentiated to estimate the rate of the force development (RFD). EMG signals were also recorded from gastrocnemius muscle and the integrated EMG (iEMG) and rate of rise of EMG amplitude (RRE) were calculated. The posterior tibial nerve was electrically stimulated and the H-wave was recorded from soleus muscle during plantar flexion with or without ACC. The statistical analysis was done using paired t-test and correlation analysis of Pearson. Results The peak torque and iEMG during plantar flexion were not significantly affected by the ACC. However, RFD, RRE and H-wave amplitude during the plantar flexion phase with preceding ACC were significantly higher than the corresponding control

values without ACC. In addition, RFD and RRE were significantly positively correlated. Discussion The muscle force outputs have been shown to be potentiated by isokinetic or isometric ACC (Sale, 1986., Kamimura et al., 2009). The present study also demonstrated that the rate of force development, but not the peak torque, was increased by ACC in the ankle joint movement. The facilitation effect of ACC may be due to neuronal influences and/or biomechanical properties of muscle-tendon complex, such as increase in elastic energy during ACC. This study further showed that electromyographic activities, RRE and H-wave, were also potentiated by ACC. This suggested that increased neural activities might contribute to the antagonist conditioned facilitation of force development. References Kamimura T, Yoshioka K, Ito S, Kusakabe T. ### ACUTE MODULATION OF THE SOLEUS H-REFLEX IN UPRIGHT STANCE AFTER CALF MUSCLE STRETCHING

Olbrechts, N.

*Université Libre de Bruxelles*

Acute modulation of the soleus H-reflex in upright stance after calf muscle stretching Olbrechts, N., Baudry, S., Duchateau J., Guissard N. Laboratory of Applied Biology, Université Libre de Bruxelles (Belgium). Introduction Previous work indicates that repeated stretches of the calf muscles can decrease torque steadiness by increasing muscle compliance and EMG activity of muscles around the ankle joint (Kato et al. 2011), and can affect balance stability during upright stance (Behm et al. 2004). However, a lower balance stability is accompanied by a reduced amplitude of the Hoffmann (H) reflex indicating a decrease in muscle spindle afferents input at the spinal level (Earles et al. 2000). The present study investigated the acute effect of repeated stretches of the calf muscles on balance stability and H-reflex modulation. Methods The stretching bout comprised five 60-s passive stretches of the non-dominant leg, separated by 30-s rest. Time-domain parameters of the centre of pressure, surface electromyogramme (EMG) of calf muscles and tibialis anterior were recorded for 10 adults that kept 1-leg upright stance on a force platform. In addition, soleus H reflex and Mmax (maximal M wave) were recorded in similar conditions. Measurements were performed before and immediately after the repeated stretches, and after 15 min of recovery. Results The repeated stretches did not influence significantly the parameters of balance stability ( $p > 0.05$ ). Regardless of the vision condition, the EMG activity of the calf muscles was increased (+17.7%;  $p < 0.001$ ) immediately after stretches compared with control whereas neither the H-reflex size (normalized to the Mmax that did vary after the fatiguing task) nor the EMG of tibialis anterior changed throughout the experiment. However, the H reflex/Soleus EMG ratio was significantly greater when standing with eyes open compared with eyes closed ( $p < 0.001$ ), and decreased ( $p < 0.05$ ) immediately after the stretches, regardless of the vision condition. Discussion Even though five 60-s passive stretches of the calf muscles did not alter one-leg stance stability, the results show that stronger calf muscle contractions are required to control balance after stretches. Moreover, the reduced H-reflex/soleus EMG ratio immediately after the stretches might suggest a presynaptic modulation of Ia afferents. This study indicates that balance control after repeated passive stretches of the calf muscles requires neural adjustments in leg muscle activation to maintain stability. #### ARE THERE TRADE-OFFS BETWEEN REPEATED SPRINT ABILITY AND OTHER SPEED QUALITIES DURING SOCCER PRE-SEASON?

Patras, K., Tsiaras, V., Siaravas, S., Georgoulis, A.

*Orthopaedic Sports Medicine Center, University of Ioannina*

INTRODUCTION: In professional soccer repeated sprint ability is an important performance factor [1], along with first step quickness, acceleration and maximal speed [2-4]. The purpose of the present study was to establish the interrelationship between repeated sprint ability (RAST test, 6 X 35m interspersed with 10 sec of passive recovery) and first step quickness (5m), acceleration (10m) and maximal speed (30m) in professional soccer players. We hypothesized that repeated sprint ability will be related to maximal speed rather than first step quickness or acceleration. METHODS: Nineteen soccer players were tested during the preseason for repeated sprint ability, first step quickness, acceleration and maximal speed. The magnitude of the relationship ( $r \pm 90\%$  CI) was classified as 0.1-0.3 small, 0.3-0.5 moderate, 0.5-0.7 large, 0.7-0.9 very large, and 0.9-0.99 nearly perfect and classified as practically important where there was a >75% likelihood of the correlation exceeding the smallest practically important (0.1) value, using an Excel spreadsheet [5]. Using the median split technique, players were divided into BEST and WORST groups according to the median RAST mean time [1]. The effect size (ES) was calculated to assess meaningfulness of differences. Effect sizes of 0.8, 0.8-0.5, 0.5-0.2, and <0.2 were considered as large, moderate, small, and trivial, respectively [6]. RESULTS: There was a likely moderate positive relationship between RAST and acceleration ( $r=0.33$ , 90% CI: -0.07 to 0.64) and a very likely large positive relationship between RAST and maximal speed ( $r=0.59$ , 90% CI: 0.26 to 0.80). There was a likely large negative relationship between RAST-BEST and first step quickness ( $r=-0.52$ , 90% CI: -0.85 to 0.09) and a very likely large positive relationship between RAST-WORST and first step quickness ( $r=0.69$ , 90% CI: 0.17 to 0.91). There was a small difference in both first step quickness ( $1.060 \pm 0.054$  vs.  $1.023 \pm 0.091$ ,  $ES=0.5$ ) and maximal speed ( $4.209 \pm 0.104$  vs.  $4.269 \pm 0.144$ ,  $ES=-0.48$ ) between RAST-BEST and RAST-WORST respectively. DISCUSSION: During preseason repeated sprint ability is more related to speed rather than acceleration. Furthermore, although RAST-BEST and RAST-WORST groups differ little in first step quickness, it appears that this quality is related differently to repeated sprint ability. REFERENCES: 1. ## IMPROVEMENT OF THE CRUCIAL PHYSIOLOGICAL CHARACTERISTICS OF PROFESSIONAL SOCCER PLAYERS AFTER COMPETITIONAL SEASON

Olm, T., Baskin, K., Herde, K.

*Tallinn University*

**Introduction** Despite massive research work there are different views on how long and how effectively aerobic endurance can be trained in elite soccer players. The aim of this study was to assess the changes of characteristics of the soccer players after a competition season. **Methods** The subjects were 15 soccer players of the best club of Estonia. Average age was  $22.5 \pm 2.8$  years. The test battery included electro-, echo- and polycardiography, and incremental treadmill test to exhaustion. Anticipation speed and correctness were assessed. Correlation coefficients were calculated. All indices were compared with the identical indices received one year ago from the same players at the same pre-seasonal period. **Results** From 29 compared means six hadn't changed: height ( $181.5 \pm 6.4$  cm), body mass ( $74.7 \pm 3.2$  kg), body fat ( $11.3 \pm 2.1\%$ ), blood pressure ( $123/72$  mmHg), anticipation speed ( $0.574 \pm 0.07$  sec) and anaerobic threshold ( $181.1 \pm 6.0$  beat/min at  $L 4$  mmol/l). Statistically significant improvements were found in four characteristics:  $VO_{2max}$  ( $62.8 \pm 3.8$  ml/kg/min),  $VO_2$  ( $4.6 \pm 0.3$  l/min), maximal ventilation ( $174.6 \pm 19.3$  l/min) and  $maxBLa$  ( $12.4 \pm 2.7$  mmol/l). The remaining indices showed a tendency to improve, but not that strongly. **Discussion** From results we can see that the most changeable characteristics are those which are related to the energy systems.  $VO_{2max}$  increased by 8.5%. A similar increase (by 8.6%) was reported by J. Helgerud et al. (2011). The improvement of  $O_2$  uptake was accompanied by an increase of maximal ventilation by 6.6%. Heart stroke volume, heart mass/volume index increased without a significant difference of the means. The anaerobic threshold was surprisingly stable:  $181.1 \pm 6.0$  versus  $181.6 \pm 6.8$  beat/min a year ago. Similar results were reported by K. McMillan et al. (2012). B. Sterzing et al. (2011), assessing levels of aerobic endurance in young soccer players, found that neither anaerobic thresholds nor velocity at 4 mmol/l lactate differed significantly between the age groups U16, U17 and U19. Only the U23 group showed significant difference to younger age groups. The authors' opinion is that the higher aerobic capacity in U23 players is based on a selection of players. **Conclusion** The results of the study support previous researches indicating that adult professional players, having relatively high-level physiological characteristic, can improve them. We are convinced that as the anaerobic threshold is not a very changeable, involving other characteristics in assessment of aerobic capacity is necessary. **References** Helgerud J, Rodas G, Kemi OJ, Hoff J. ## THE INVESTIGATION OF PHYSICAL FITNESS CHARACTERISTICS OF THE IRANIAN ELITE SOCCER REFEREES AND ASSISTANTS

Saremi, A., Shavandi, N., Javidi Athar, A.

*Arak university, Iran*

**Introduction** Despite the importance of referees' role in soccer, very little scientific literature is available on soccer refereeing, especially compared with that available on players (Castagna et al., 2007). The aim of the present study was to investigate the physical fitness characteristics of Iranian professional soccer league referees and their relation with referees' performance. **Methods** 25 main referees ( $36.1 \pm 5.6$  years,  $181 \pm 5.2$  cm, and  $76.4 \pm 7.7$  kg) and 33 assistant referees ( $35.3 \pm 6.8$  years,  $179 \pm 5.6$  cm, and  $75.5 \pm 6.5$  kg) participated in the study (2010-2011 League). To assess the physical fitness levels, all of the referees were tested using the fitness test battery adopted by FIFA (Bartha et al., 2009; Reilly et al., 2006): endurance ability was measured by a 12-minute run, and speed and anaerobic power were measured using 50 and 200 m sprint runs, respectively. The referees' performance was assessed by calculating the average score which each referee obtained during soccer professional league (2010-2011) which was recorded by refereeing supervisors. Pearson correlations were used to assess the relationships between variables. **Results** In the 50-m, 200-m, and 12-minute run tests the referees scored,  $6.88 \pm 0.08$  seconds,  $29.7 \pm 0.63$  seconds, and  $2951 \pm 276$  m, respectively. In the 50-m, and 12-minute run tests the assistant referees scored,  $6.86 \pm 0.03$  seconds, and  $2940 \pm 238$  m, respectively. In referees, significant positive correlation were found between aerobic fitness (12-minute run test) ( $r=0.58$ ,  $p<0.03$ ) with refereeing performance, while in assistant referees speed performance (50-m run test) showed a significant positive correlation with refereeing performance ( $r=0.57$ ,  $p<0.01$ ). **Discussion** These results suggest that the 12-minute run test and 50-m sprint test are suitable predictors of refereeing performance in main referees and assistant referees, respectively. Furthermore, based on FIFA standards (Bartha et al., 2009; Casajus et al., 2006), Iranian elite referees are considered to be in a high level of aerobic capacity and speed. **References** Castagna C, Abt G, D'Ottavio S. ## FATIGUE AND RAPID HAMSTRING/QUADRICEPS FORCE CAPACITY IN ELITE SOCCER PLAYERS

Greco, C., Silva, W.L., Camarda, S.R., Denadai, B.S.

*Human Performance Laboratory - UNESP*

**Introduction** Muscle fatigue, defined as a reduction in the maximal force exerted by a muscle or a muscle group due to central and/or peripheral mechanisms is frequently found during soccer match, especially towards the end of play. Significant changes in the conventional concentric hamstrings:quadriceps ratio (Hcon:Qcon) and functional eccentric hamstrings:concentric quadriceps ratio (Hecc:Qcon) were also found after both exhaustive laboratory-based soccer-specific exercise and a field test representative of soccer specific movements. Zebis et al. (2011) have recently introduced the rate of force development (RFD) hamstrings:quadriceps strength ratio (RFDH:Q) to assess the potential to stabilize the knee joint during explosive movements of elite soccer players. Thus, the aim of this study was to investigate the effect of fatigue induced by an exhaustive laboratory-based soccer-specific exercise on different hamstrings:quadriceps (H:Q) ratios of soccer players. **Methods** Twenty-two male soccer players ( $23.1 \pm 3.4$  yr.) performed maximal eccentric and concentric contractions for knee extensors (KE) and flexors (KF) at  $60^\circ/s$  and  $180^\circ/s$  to assess Hcon:Qcon and Hecc:Qcon ratios. Additionally, they performed maximal voluntary isometric contractions for KE and KF, from which the maximal muscle strength, RFD and RFDH:Q were extracted. Thereafter, subjects performed an exhaustive laboratory-based soccer-specific exercise and a post-test similar to the pre-test. **Results** There was significant reduction of Hcon:Qcon ( $0.60 \pm 0.06$  vs.  $0.58 \pm 0.06$ ) and Hecc:Qcon ( $1.29 \pm 0.2$  vs.  $1.16 \pm 0.2$ ) after the soccer-specific exercise. However, no significant difference between Pre and Post exercise conditions was found for RFDH:Q at 0-50 ( $0.53 \pm 0.23$  vs.  $0.57 \pm 0.24$ ) and 0-100 ms from the onset of muscle contraction ( $0.53 \pm 0.17$  vs.  $0.55 \pm 0.17$ ). **Discussion** The principal original finding of this study was that the H:Q strength ratios based on peak force values are more affected by fatigue induced by a soccer specific intermittent protocol than rapid H:Q force capacity. The reduction of both Hcon:Qcon and Hecc:Qcon is consistent with previous studies (Rahnama et

al., 2003; Delestrat et al., 2010). RFDH:Q obtained during early contraction phase was not modified after exercise. Thus, fatigue induced by soccer specific intermittent protocol seems not reduce the potential for knee joint stabilization during the initial phase of voluntary muscle contraction. References Zebis MK, Andersen LL, Ellingsgaard H, Aagaard P. (2011). Rapid hamstring/quadriceps force capacity in male vs. female elite soccer players. *J Strength Cond Res*, 25: 1989-1993.

### REPEATED HIGH-INTENSITY RUNNING AND SPRINTING IN WOMEN'S FOOTBALL COMPETITION

Spencer, M.1, Wiig, H.1, Gabbett, T.2,3

*Norwegian School of Sports Sciences*

REPEATED HIGH-INTENSITY RUNNING AND SPRINTING IN WOMEN'S FOOTBALL COMPETITION Spencer, M. 1, Wiig, H. 1, Gabbett, T. 2,3 1: Norwegian Research Centre for Training and Performance, Norwegian School of Sports Sciences, Oslo, Norway, 2: School of Exercise Science, Australian Catholic University, Brisbane, Australia, 3: School of Human Movement Studies, The University of Queensland, Brisbane, Australia Introduction Despite the reported importance of high-intensity running (Mohr et al., 2005) and repeated-sprint ability (Gabbett et al., 2008) to competitive success in football, studies investigating the nature of repeated high-intensity activity in games are limited (Gabbett et al., 2008). To our knowledge, no study has investigated the concurrent repeated, high-intensity (RHIA) and repeated-sprint activity (RSA) of intermittent team sport competition. Therefore, the aim of this study is to describe the nature of RSA and RHIA (e.g. striding and sprinting activities) that involve a high energy cost and are associated with short duration (i.e.  $\leq 20$  seconds) recovery periods. Methods Thirteen elite women football players underwent video-based time-motion analysis on 34 occasions during national and international standard matches, in which all players played 90 min. RSA and RHIA were defined as successive (i.e. 2 or more) sprints, or striding and sprinting efforts that occurred with  $\leq 20$  seconds between efforts. Results The number of RSA and RHIA bouts performed was similar between the first and second half of matches, when analysed as sets of 2, 3, 4, 5 or 6 efforts. Sprinting and striding/sprinting durations tended to remain relatively stable irrespective of the number of efforts in a RSA or RHIA bout, or the period of play. However, the mean recovery duration progressively increased with a greater number of efforts per bout; RSA (sets of 2:  $9.94 \pm 4.73$ ; sets of 6:  $16.57 \pm 2.49$ ; Effect Size (ES) = 1.75, large) and RHIA (sets of 2:  $9.49 \pm 2.60$ ; sets of 6:  $14.74 \pm 2.66$ ; ES = 2.00, large). Furthermore, RSA bouts were associated with moderately greater recovery durations between efforts (ES = 0.67-0.93) for sets of 4 and 5 sprints, in the second half compared to the first half of matches. However, only trivial or small differences (ES = 0.01-0.33) were observed between halves for RHIA bouts. Discussion These findings suggest that first to second half reductions in RHIA and RSA do not occur in elite Women's soccer competition. However, players increase the amount of low-intensity recovery performed between RHIA and RSA efforts, most likely in an attempt to maintain RHIA and RSA performance. These findings are novel and emphasize the importance of repeated-effort ability to elite Women's football, and highlight the importance of training this quality to minimise reductions in performance during competitive match-play. ### EFFECTS OF 16 WEEKS OF STRENGTH AND PLYOMETRIC TRAINING ON PHYSICAL PERFORMANCE IN SEMIPROFESSIONAL SOCCER PLAYERS

Otero-Esquina, C., Pareja-Blanco, F., Rodriguez-Rosell, D., González-Badillo, J.J.

*University Pablo de Olavide*

Effects of 16 weeks of strength and plyometric training on physical performance in semiprofessional soccer players Otero-Esquina, C1. Pareja-Blanco, F1. Rodriguez-Rosell, D1. González-Badillo, JJ1. 1Faculty of Sport, UPO, Seville, Spain Introduction There are several studies which have evaluated the effects of strength training over jump height and acceleration capacity with soccer players using loads  $>85\%$  1RM until failure (1,3). However, to our knowledge there have not been any studies that evaluate the effects of training with lower loads and not to failure in semi-professional soccer players. Therefore, the aim of this study was to analyze the effects of this type of training on physical performance. Method Fifteen soccer players from third Spanish division took part in this study (age  $22.7 \pm 3.4$  years, height  $1.78 \pm 0.06$ m, weight  $75.4 \pm 6.8$ kg). These subjects completed a strength training twice a week for 16 weeks. Subjects performed full squat (4-8 reps 40-60% 1RM), CMJ with and without load, resisted sprint and loaded change of direction. The variables measured were: estimated 1RM full squat (T-Force System), CMJ height and acceleration capacity in 10 and 20m (T10, T20 and T10-20). A related-samples t-test was used to analyse pre-post changes among variables and correlation was determined through Pearson's coefficient correlation. Results Subjects obtained significant improvements in CMJ height (5.5%;  $p < 0.01$ ), T10-20 (0.8%;  $p < 0.05$ ) and estimated 1RM full squat (7.4%;  $p < 0.05$ ) while T10 and T20 showed no significant changes. Pretest values found significant correlations ( $p < 0.05-0.01$ ) between CMJ and T10 ( $r = -0.69$ ), T10-20 ( $r = -0.59$ ), T20 ( $r = -0.74$ ) while RM correlated significantly ( $p < 0.05$ ) with T10 ( $r = -0.53$ ) and T20 ( $r = -0.57$ ). However, post-test showed stronger correlations between CMJ and 1RM ( $r = 0.61$ ), T10 ( $r = -0.75$ ), T10-20 ( $r = -0.72$ ) and T20 ( $r = -0.78$ ). Discussion These results show that plyometric and strength training with light loads (40-60% 1RM) and not to failure (4-8 reps) improve 1RM full squat, CMJ height and T10-20 which are very important for soccer successful (1). These findings show higher gains on performance than other works (3), which did not show changes neither CMJ nor sprint time training with high loads until failure. Therefore, the present study suggests that is not necessary to train with high intensity (% 1RM) to improve soccer players performance. References 1. Hoff, J, and Helgerud, J. ### PHYSICAL PERFORMANCE, TECHNICAL ACTIVITY AND INJURY RISK IN A PROFESSIONAL SOCCER TEAM IN MATCH-PLAY OVER A PROLONGED PERIOD OF FIXTURE CONGESTION

Lago-Penas, C.1, Dellal, A.2, Casais, L.1

1: UVIGO (Pontevedra, Spain), 2: Olympique Lyonnais FC and USS (Strasbourg, France)

Introduction Professional soccer players are often required to play competition matches with only 2-3 days' recovery. However, the effect of a prolonged period of fixture congestion on players' performance is still inconclusive. Therefore, the aim of this study was to investigate recovery via analysis of activity profiles in a professional soccer team over an intense period of matches. Methods A computerized player tracking system (AMISCO Pro, Sport-Universal Process, Nice, France) was used to characterize activity profiles in the reference team. A 1-

way repeated measures ANOVA was used to compare outcome measures in each category of physical and skill-related performance across: 1) 6 consecutive games over the 21-day-period, and; 2) games played during 3 different congested fixture periods in the same season. The methodologies and definitions of injury are similar to those employed in other investigations on elite soccer play (Carling, et al., 2011; Dupont, 2010). Results Across the 6 successive matches, no differences were reported for the overall distance covered ( $p=0.072$ ) or that covered in high-intensity ( $p=0.622$ ), moderate-intensity ( $p=0.277$ ), low-intensity ( $p=0.467$ ) or light-intensity ( $p=0.368$ ) running. No differences were found in the analysis of the technical actions. The incidence of injury across the prolonged periods was similar to that reported in matches played outside the study periods; however, injury rate during training time was significantly lower during congested period to those outside the study period (4.6 vs. 14.6 per 1000 h exposure,  $p<0.001$ ). The comparison of physical performance in matches played across the 3 separate periods (August, September and October) revealed significant increases in the overall distance covered. Discussion This study provided a valuable opportunity to study physical performance, injury risk and severity in match-play over a prolonged period of fixture congestion. Physical performance and injury rates were generally unaffected which shows that coaches, support staff and players in high-performance teams in a professional setting can cope with a congested playing calendar. As a whole, these results also lend support to findings observed other studies (Carling et al., 2011; Lago-Peñas et al., 2011; Odetoynbo et al., 2009). References Carling C, Le Gall F, Dupont G. ### SEVEN WEEKS OF COMBINED STRENGTH AND POWER TRAINING DURING THE COMPETITIVE SEASON IN HIGH-LEVEL AMATEUR SOCCER: A RANDOMIZED-CONTROLLED TRIAL

Faude, O., Roth, R., Di Giovine, D., Donath, L., Zahner, L.

*University of Basel*

Introduction Speed and power abilities are considered important prerequisites for match performance in soccer. Scientific studies addressing specific strength and power training methods are scarce so far, particularly when conducted during the competitive season. We therefore investigated the effects of a 7 weeks combined strength and power training program during the competitive season on various fitness parameters in high-level amateur soccer players. Methods Sixteen male soccer players (age: 22.5 (SD 2.5) y, height: 1.79 (5.3) m, weight: 76.8 (6.1) kg) from one team of the third Swiss league were randomly stratified (strata: one-repetition maximum (1-RM), 10 m sprint time) to either a combined strength training (CST, N = 8) or a control (CON, N = 8) group. The intervention was conducted twice per week within an in-season period of 7 weeks. CST comprised strength exercises (uni- and bilateral half squats and calf raises with additional weights) combined with plyometrics and/or sprints (5 to 10 m). CON performed technical and tactical training during the same time period. Before and after the training period, several physical fitness parameters were assessed: 1-RM (half squat), isometric peak strength and rate of force development (RFD), leg press, uni- and bilateral), vertical jump height (countermovement jump, CMJ (uni- and bilateral); drop jump, DJ), 10 and 30 m sprint times, agility testing with the ball, and intermittent endurance performance (yo-yo intermittent recovery test 1). Results Players attended on average 10.9 (1.1) training sessions during the 7 weeks period. Large significant test x group interactions were found for 1-RM ( $p < 0.001$ , effect size (ES, partial eta squared) = 0.76), bilateral CMJ ( $p < 0.001$ , ES = 0.58), CMJ with the left leg ( $p = 0.003$ , ES = 0.51), and drop jump reactivity index ( $p = 0.003$ , ES = 0.57) with increases after CST (+3 to 18%) and similar or decreased values (+0.6 to -7.7%) in CON. Although not significant ( $0.09 \leq p < 0.40$ ) comparable results were observed in several other parameters (isokinetic peak strength and RFD, CMJ with right leg, DJ, 30 m sprint time, and intermittent endurance) with effect sizes indicating at least medium effects ( $0.06 \leq ES < 0.19$ ). No relevant test x group interaction was observed for agility testing and 10 m sprint. Discussion It is concluded that a 7 weeks combined strength and power training can improve relevant physical prerequisites compared to routine technical and tactical training in high-level amateur soccer players during the competitive season. The medium effects in sprint time, jump heights and intermittent endurance need further verification in randomized-controlled trials with more participants.

### LEG DOMINANCES EFFECT ON BALANCE IN ELITE SOCCER PLAYERS

Fletcher, I., Long, S.

*University of Bedfordshire*

LEG DOMINANCES EFFECT ON BALANCE IN ELITE SOCCER PLAYERS Fletcher, I.I, Long, S.I 1: UoB (Bedford, UK) Introduction Soccer has a high prevalence of lower limb injuries (Gstotner et al., 2009); with non-contact ACL injuries more prevalent within the preferred rather than non-preferred kicking leg (Brophy, 2010). This could suggest that leg asymmetry could be an inherent injury risk factor. Importantly, balance asymmetry has yet to be tested in the elite population. Therefore, this study aimed to compare kicking leg dominances effect on balance in elite players. Methods 15 male elite soccer players (age  $24 \pm 7$  yr, height  $183.86 \pm 5.16$  cm, mass  $79.9 \pm 9.13$  kg) drawn from an English League One soccer team were assessed for balance asymmetry using an RSscan pressure plate (RSscan Ltd, Ipswich, United Kingdom). 1 legged static, dynamic (a one metre hop and hold) and passing action balance tests were assessed by measuring the deviation from the centre of pressure (CoP) in millimetres. Results When the balance tests were compared a main effect was found ( $F=63.721$ ,  $p<0.01$ , effect size=0.907), indicating that the static test was 10.5% ( $p=0.037$ ) worse than the dynamic balance task. Leg dominance across all the balance tests was not linked to significant differences in CoP deviation ( $F=0.476$ ,  $p=0.501$ , effect size=0.033). However, when pairwise comparisons were employed, though the static and dynamic balance tests showed leg symmetry ( $p>0.05$ ), the pass test indicated that the dominant leg exhibited significantly worse dynamic balance than the non-dominant leg (33.3%,  $p=0.05$ ). Discussion This study's results indicate that static balance was significantly better than dynamic test results. This could be important in terms of screening players for injury risk factors. Njorai (2010) states that players are always in motion, therefore balance systems are rarely required to maintain a stable base for more than a few moments. If this is the case than it brings into question the efficacy of static balance tests. Interestingly, Lambert et al., (2006) has shown functional discrepancies between dominant and non-dominant legs. The present results on standard static and dynamic balance tasks do not support this supposition; however the specific kicking task test found a decrease in stability within the dominant kicking leg. It may be that in a highly trained soccer population leg inequalities are more apparent in specific balance tasks; this may mean that balance screening does not just have to be dynamic; it also has to incorporate a specific football task to explore leg discrepancies within players. ### REGULAR PATTERNS OF PLAY IN EFFECTIVENESS OFFENSIVE SEQUENCES OF FC BARCELONA COUNTERATTACK

Sarmiento, H.1,2, Barbosa, A.1, Martins, J.3, Campanico, J.1, Anguera, M.T.2, Leita, J.1

1-UTAD, CIDESD (Vila Real, Portugal); 2-UB (Barcelona, Spain); 3-UTL (Lisboa, Portugal)

While the results of the literature suggest that the increase in transitions (from defense to offence) speed is linked with an increased likelihood of scoring a goal, very few studies have analyzed the transition as a whole. Thus, the aim of the present study is to demonstrate the potential of the software THÈME 5.0, for the detection of behavior temporal patterns (T-pattern) in the football game, more specifically, in the actions of counterattack of the FC Barcelona, accessing to the interaction contexts in which the behaviors are performed. The sample consisted of 12 football games of domestic competitions that were analyzed by systematic observation by using a specific instrument to observe the offensive process (Sarmiento et al., 2010). We used the software THÈME 5.0., and the following criteria were used: the minimum number of events was set at 3 and the level of significance was set at 0.05. The analysis revealed the existence of 787 different T-patterns in the sequences of the counter-attack. The study of these patterns allowed the knowledge of specific regularities in the offensive sequences of this team, particularly regarding the understanding of how these start, develop and end. This analysis helps us to characterize the transitions (defense-attack) that are associated with total effectiveness (goal scored) in this team. In general, in this type of sequences, the recovery of the ball possession is performed through an interception of the ball in zone 6 of the field, in an interaction context characterized by the numerical superiority; then we observe a quick change in the flank of play (right side to the left side), where a player progresses in the field performing short passes and conductions of the ball in situations of numerical equality. These sequences ended in the central zone (zone 11) of the offensive sector, through a shot with goal scored in an interaction context of numerical inferiority. This type of analysis allows us to know and to characterize the regular structures of offensive sequences in football teams. The t-patterns detected in the defense-attack transition of this successful team allowed us to know how that process is developed in an effective way. This information is relevant, on the one hand to the team itself because it makes it possible to conceive training exercises in order to increase this efficiency, on that other hand it allows, for example, that the opposing coaches can develop strategies to prevent that the Barcelona team performed these transitions effectively. Sarmiento, H., Anguera, T.; Campanico, J. & Leita, J. (2010). Development and Validation of a Notational System to Study the Offensive Process in Football. *Medicina (Kaunas)*, 46(6), 401-407.

### RESPONSES OF PEAK OXYGEN UPTAKE, VELOCITY AT LACTATE THRESHOLD AND RUNNING ECONOMY IN PROFESSIONAL SOCCER PLAYERS DURING SEVERAL SEASONS

Krueger, M.1,2, Broich, H.3, Sperlich, B.4, Mester, J.1,2

1:German Sport University Cologne, 2:German Research Center for Elite Sport, Cologne, 3:Bayer 04 Leverkusen Fußball GmbH, Leverkusen, 4:Institute of Training Science, University of Wuppertal

**INTRODUCTION:** Since professional soccer players have to cover distances up to 12 km during a match, endurance performance is one important component of success (di Salvo et al., 2007). VO<sub>2</sub>peak, velocity at lactate threshold (VLT) and running economy (RE) have been described as major factors accounting for variance in aerobic endurance performance (Midgley et al., 2007). Therefore the aims of this case study were 1) to investigate how VO<sub>2</sub>peak, VLT and RE vary within and over several seasons in elite soccer players and 2) to discuss possible practical applications. **METHODS:** VO<sub>2</sub>peak, VLT and RE of 12 professional and international level soccer players (25 ± 3 yrs, 184 ± 7 cm, 79.8 ± 7.5 kg) were measured during eight time points (i.e. July 2006 [0706]; January [0107] and July 2007 [0707]; January [0108], July [0708], September [0908] and December of 2008 [1208] and May 2009 [0509]) before, during and after three soccer seasons using an incremental treadmill protocol (2.8 m/s, increase 0.4 m/s every 5 min). Capillary blood lactate concentration and VO<sub>2</sub> were determined at the end of each stage. RE was defined as VO<sub>2</sub> in mL/kg/min at 3.2 m/s. ACSM-criteria for exertion were met in all tests. **RESULTS:** VO<sub>2</sub>peak expressed as mL/min/kg was significantly elevated in September 08 when compared to the other time points (57.3 ± 2.5 vs. 55.5 ± 3.4 [0706], 55.6 ± 2.7 [0107], 55.4 ± 3.8 [0707], 55.1 ± 3.0 [0108], 55.3 ± 3.6 [0708], 56.3 ± 4.3 [1208], 54.5 ± 4.3 [0509]; best P = .03). VLT expressed as m/s was also significantly elevated in September 08 when compared to the other time points in the same year (3.29 ± 0.12 vs. 3.24 ± 0.07 [0108], 3.24 ± 0.10 [0708], 3.26 ± 0.09 [1208]; best P = .02) while RE remained unaltered from 0706 to 0509 (best P = .17). **CONCLUSION:** This study showed: 1) RE is not influenced by pre- or in-season exercise in elite soccer players. 2) VO<sub>2</sub>peak and VLT elevated from preseason (July 08) to September 08, but declined to December of the same season. This can be explained by an additional endurance block during season preparation, which is no longer possible during the season due to several matches per week. It seems that frequent match play is not sufficient to maintain high levels of VO<sub>2</sub>peak and VLT during an entire season. We therefore suggest 1) to routinely assess all three endurance relevant parameters in professional soccer players and 2) to implement short conditioning blocks (e.g. high intensity interval training) during the season to maintain a high level of physical fitness.

#### 3D RECONSTRUCTIONS OF SKELETAL MUSCLE MITOCHONDRIAL NETWORK AS A TOOL TO ASSESS MITOCHONDRIAL CONTENT AND STRUCTURAL ORGANIZATION

Dahl, R., Larsen, S., Stride, N., Helge, J.W., Dela, F., Prats, C.

University of Copenhagen. Faculty of Health Sciences Center for Healthy Aging

**Introduction** The mitochondria are highly dynamic organelles that continuously adjust to the energetic demands of cells. There is an ongoing debate in the field about the optimal method to assess mitochondrial volume or markers that correlate with mitochondrial volume. Previous studies have shown a strong association between the content of specific mitochondrial proteins and mitochondrial oxidative capacity [1]. However, few studies have validated mitochondrial proteins as markers for mitochondrial volume. The aim of the present study was to develop a technique to assess mitochondrial content and to identify a suitable marker of mitochondrial volume. Furthermore, we use the technique to investigate the structural organization of mitochondria in human muscle fibers. **Methods** Needle

biopsies from the m. vastus lateralis of 7 healthy middle aged subjects were used in this study. Single muscle fibers from each biopsy (n=24 +/-3,8) were co-immunostained against mitochondria and myosin heavy chain type I. Confocal microscopy z-stacks were acquired and 3D reconstructions of mitochondrial networks were performed to measure mitochondrial fractional volume and assess structural complexity. Several biomarkers were measured and their correlation to mitochondrial volume was investigated. Results The mitochondria of the slow-twitch muscle fibers were generally tubular shaped and interconnecting at the I-band of muscle sarcomere as transverse tubular interconnections creating a complex network of mitochondria. Subsarcolemmal and intermyofibrillar interconnected mitochondria were observed. In the fast-twitch fibers the structural organization of mitochondrial network was more diverse; from individual ellipsoid mitochondria to tubular interconnected mitochondrial networks. Interestingly, the different morphological variants could be found within the same muscle fiber. Type I muscle fibers exhibited higher mitochondrial content than type II muscle fibers (p<0,02). Discussion and Conclusions There is extensive debate in the mitochondrial research field whether the subsarcolemmal mitochondria and the intermyofibrillar mitochondria are connected or if they are two structurally distinct populations. Furthermore, there is also extended debate about the optimal marker for mitochondrial volume. We have developed a technique to analyze the 3D structure of mitochondrial networks in human single muscle fibers and measure mitochondrial volume. Using this technique we show evidence that question the existence of these two mitochondria populations, the two pools of mitochondria are physically interconnected. References: 1 - Holloszy et al. JBC1967; 242, 2278.

### EFFECTS OF VOLUNTARY EXERCISE AND CALORIC RESTRICTION ON MRNA EXPRESSIONS OF TLRs IN OBESE ZUCKER RATS

Kitamura, H., Shiroya, Y., Minato, K., Umetsu, Y., Yamauchi, H.

*Wayo Women's University*

EFFECTS OF VOLUNTARY EXERCISE AND CALORIC RESTRICTION ON MRNA EXPRESSIONS OF TLRs IN OBESE ZUCKER RATS Kitamura H.1, Shiroya Y.1, Minato K.1, Umetsu Y.1, Yamauchi H.2 1: Wayo Women's University (Chiba, Japan), 2: Jikei University School of Medicine (Tokyo, Japan) Introduction Regular physical exercise is associated with improvement of obesity. Recently, Toll-like receptor (TLR) 4 has been reported to play an important role in the link among insulin resistance, inflammation, obesity, and type 2 diabetes. Also, TLR2 is a key mediator of insulin resistance. However, it is unclear what effects physical exercise and caloric restriction on TLRs expressions have in obese Zucker rats. In this study, we investigated the effects of voluntary exercise and caloric restriction on mRNA expressions of TLR2 and TLR4 in liver of obese Zucker rats. Methods Obese Zucker rats were divided into three groups (n=7 for each group); ad libitum food intake (OZ), caloric restriction (CR), voluntary exercise plus caloric restriction (CR+Ex). Lean Zucker rats served as controls (n=7, LZ). During 6-week intervention, food intakes in the CR and CR+Ex rats were 70% and 74% of that in the OZ rats. The rats in the CR+Ex group engaged in voluntary wheel running for 6 weeks. Liver tissue sample was collected after the intervention to measure mRNA expression of TLRs by real-time polymerase chain reaction. Results Fasting serum glucose (BG), triglyceride (TG), total cholesterol (TC), insulin, and leptin were higher in the OZ rats, compared with the LZ rats. Caloric restriction reduced body weight and improved insulin resistance, but aggravated fasting serum TC. Voluntary exercise reduced body weight, fasting serum BG and TG, and improved insulin resistance. Suppressed mRNA expression of TLR2 in the OZ rats was observed. In most of CR+Ex rats (n=6), TLR2 mRNA was not detected. OZ and LZ rats had similar mRNA expression of TLR4. TLR4 mRNA tended to be higher in the CR group compared with the LZ group. There was no significant difference between the OZ and CR groups in mRNA expression of TLR4. Discussions Voluntary exercise and caloric restriction improved obesity and insulin resistance. While TLR2 expression blunted in obese Zucker rats, TLR4 was the same as shown in lean Zucker rats. Our results did not correspond to previous studies that TLR4 expression was higher in diet-induced obesity rats than in the controls. Voluntary exercise tended to blunt the expression of TLR2, but not TLR4 in obese Zucker rats. Further studies to evaluate TLRs expression in obesity Zucker rats are required. These results suggest that voluntary exercise and caloric restriction might not affect mRNA expressions of TLRs in liver of obese Zucker rats. References Reyna, SM, et al. ### URINE TOXIC TRACE ELEMENTS IN PRE AND POSTMENOPAUSAL WOMEN: EFFECTS OF AEROBIC EXERCISE.

Robles, M.C.1, Llerena, F.2, Crespo, C.1, Palomo, R.3, Grijota, F.1, Maynar, M.1, Caballero, M.J.2

*University of Extremadura*

Aluminum (Al), mercury (Hg) and lead (Pb) are non-essential elements in the environment that can become toxic to humans. Al has a role in neurodegenerative processes and is associated with the etiology of Alzheimer (Duce and Busch 2010). Pb and Hg are classified as carcinogenic affecting human health (Koedrith and Seo 2011). Purpose: To evaluate the effect of 6 months of aerobic exercise on urinary excretion of toxic elements in pre and postmenopausal women Method: 45 premenopausal (PRE) (37.40±8.80 yr) and 30 postmenopausal (POST) (51.70±3.81yr) women, all sedentary and living in the same geographical area, were studied before and after a 6 months exercise program based on aerobic dance (60-70% maximal heart rate, 60 min/day, 3 days/week). Before and after the program, VO2 max was measured and overnight fasting urines samples were collected and analyzed by inductively coupled plasma mass spectrometry (ICP-MS). The normality of the variables was assessed using the Shapiro-Wilks test. The Wilcoxon test was used to assess the significance of the differences between before and after exercise, and Mann-Whitney test was used to assess the differences between PRE and POST women. Results: Both groups improved their VO2 max after the aerobic exercise program from 33.87±6.26 to 38.72±8.24ml/min/kg p<0.01 in PRE and from 32.63±6.29 to 37.71±6.70ml/min/kg p<0.01 in POST. No differences were observed between urinary concentrations (expressed in µg/g creatinine) of Al, Hg and Pb in pre and postmenopausal women in basal values (Al 42.61±30.67 PRE vs 35.67±20.78 POST; Hg 2.24±2.19 PRE vs 1.56±0.93 POST and Pb 4.47±6.44 PRE vs 4.90±7.42 POST). After the exercise program, changes were observed to decreased urinary levels of Al, Hg and Pb in both groups, although the decline in Hg and Pb only were statistically significant in postmenopausal women: Al 9.90±6.38 in PRE p<0.00; 10.35±15.57 in POST p<0.00; Hg 0.79±1.09 in PRE; 1.01±1.45 in POST p<0.01; and Pb 0.67±0.75 in PRE; 1.40±1.26 in POST p<0.00. Conclusions: These results suggest that menopause and age does not seem to affect urinary levels of these toxic elements. However, there is a decrease in urinary excretion of Al, Hg and Pb as a possible adaptation to aerobic exercise (Llerena et al. 2011). References. 1. Duce JA, Bush AI. ## COMPARISON OF ESSENTIAL TRACE ELEMENTS CONCENTRATIONS IN SERUM OF ATHLETES AND SEDENTARY SUBJECTS

Crespo Coco, C., Llerena Ruiz, F., Maynar Marino, M., Robles Gil, M.C., Grijoa Pérez, F., Calvo, L., Caballero Loscos, M.J.  
UNIVERSITY OF EXTREMADURA

The quality of human life depends on the chemical composition of food and of the surroundings. Recent improvements and new methods in analytical chemistry and increasing fields of environmental investigations have added substantially to our knowledge of the biochemistry of trace elements (Kabata-Pendias and Mukherjee, 2007). Trace elements (zinc, copper, selenium, etc.) are essential for the correct functioning of an organism (Savarino et al, 2001). Purpose: To assess serum levels of essential trace elements in athletes and sedentary people. Method: 23 elite endurance athletes (21.62±4.27 years) and 30 sedentary (23.57±2.53 years) men, all participants lived in the same geographical area. The development of the method and its application in the analysis of serum samples was carried out in an ICP-MS Nexion model 300D (PerkinElmer, Inc., Shelton, CT). Serum samples were stored in 1 mL eppendorf vials at -80 °C. The validity of the methodology was checked by the biological certified reference material. The normality of the variables was assessed using the Shapiro-Wilks test. Student's T test was used to assess the differences between elite athletes and sedentary men. Results: No differences were observed between serum concentrations of Co, Cu and Se. Significant differences were observed in Zn ( $p < 0.001$ ), being higher serum levels in sedentary men than in athletes (645.70±70.84 vs 993.99±100.32 µg/L). Serum levels of Mn ( $p < 0.05$ ), Mo ( $p < 0.05$ ) and V ( $p < 0.01$ ) were higher in athletes than in sedentary men (Mn: 3.766±1.576 vs 1.269±0.358 µg/L; Mo: 0.479±1.548 vs 0.357±0.146 µg/L and V: 0.689±0.507 vs 0.160±0.024 µg/L). Conclusions: These results suggest that physical activity, in particular the high-level training in long distance, does not produce significant changes in serum levels of Co, Cu, and Se (González-Haro et al., 2011). Zn serum levels are lower in athletes than in sedentary, as a possible consequence of the important role of Zn in metabolic processes that occur during exercise. Mn, Mo and V levels are higher in athletes than sedentary men as possibly adaptive consequences. References 1.Kabata-Pendias A, Mukherjee A. ## COMPARISON OF URINE ESSENTIAL TRACE ELEMENTS CONCENTRATIONS IN ATHLETES AND IN SEDENTARY SUBJECTS LIVING IN THE SAME AREA OF EXTREMADURA .

Llerena, F., Robles, M.C.2, Crespo, C.2, Grijoa, F.2, Munoz, D.2, Palomo, R.1, Maynar, M.2, Caballero, M.J.1  
University of Extremadura

Comparison of urine essential trace elements (Co, Cu, Mn, Mo, Se and Zn) concentrations in athletes and in sedentary subjects living in the same area of Extremadura (Spain). Llerena, F.1, Robles MC.2, Crespo C.2, Grijoa, F.2, Muñoz, D.2, Palomo, R.1, Maynar, M.2, Caballero, M.J.1 1: University of Extremadura (Badajoz, Spain), 2: University of Extremadura (Cáceres, Spain). Introduction Trace elements such as cobalt (Co), copper (Cu), manganese (Mn), molybdenum (Mo), selenium (Se), and zinc (Zn) are integral part of important enzymes or coenzymes involved in vital biologic processes. The data about how physical activity affects element metabolism is rather contradictory. It was emphasized that heavy physical exercise led to a redistribution of elements between body stores, blood, and tissues and that the increased losses by sweat and urine in exercise could cause deficiency in some elements pointing out the importance of dietary intake of them (Lukaski et al., 1990, Savas et al., 2007). The present work reports differences in urinary excretion of Co, Cu, Mn, Mo, Se and Zn between athletes with those of age-matched sedentary subjects living in the same geographical area. Methods Middle-distance runners (n=21; age, 21.62±4.3 yr; BMI, 18.25±1.73) and sedentary men (n= 26; age, 22.65±3.6 yr; BMI, 21.81±3.14) participated in this study. Morning midstream urine samples were collected and acidified with 1% (v/v) HNO<sub>3</sub>. Co, Cu, Mn, Mo, Se, and Zn were determined in urine samples using a Perkin-Elmer Elan 9000 inductively coupled plasma mass spectrometry (ICP-MS) with a quadrupole based collision/reaction cell. Creatinine concentrations were measured in all urine samples to take into account the different degree of dilution (Shi et al. 1995). The Mann-Whitney test was performed for statistical analysis. A p value of <0.05 was used to determine statistical significance. Results Concentrations, expressed in µg/g creatinine, of the six trace elements in urine from athletes versus those from sedentary subjects were as follows: Co (0.038±0.08 vs 0.434±0.65  $p < 0.001$ ); Cu (55.180±18.94 vs 19.66±9.93,  $p < 0.001$ ); Mn (2.84±8.99 vs 5.58±10.28,  $p < 0.001$ ); Mo (41.51±20.57 vs 33.14±22.66, not significant (NS)); Se (22.66±5.92 vs 23.49 ±13.54, NS); and Zn (149.9 ±120.8 vs 261.3±214.9, NS). Discussion Urinary Co and Mn concentrations were lower in runners, consistent with the possibility that body attempts to conserve these elements most likely because of organism requirements. The increased excretion of Cu in athletes may be the reason of reported lower serum Cu levels as a result of physical exercise (Savas et al. 2007). ## EFFECTS OF EXERCISE TRAINING ON THE BODY COMPOSITION, LIPID METABOLISM, THYROID HORMONE, AND THYROID STIMULATING HORMONE RECEPTOR MRNA IN RAT HYPOTHYROIDISM

Kim, K.  
Keimyung University

EFFECTS OF EXERCISE TRAINING ON THE BODY COMPOSITION, LIPID METABOLISM, THYROID HORMONE, AND THYROID STIMULATING HORMONE RECEPTOR mRNA IN RAT HYPOTHYROIDISM Kim, K.1, Ko, J.1, Ahn, N.1, Byun, J.1, Park, K.1, Kim, S.1, Kim, H.2, Chang, I.3 1: KMU (Daegu, Korea), 2: KMC (Daegu, Korea), 3: CUD (Daegu, Korea) Introduction Hypothyroidism brings negative effects on energy metabolism. It is reported that possibilities of obesity, diabetes and atherosclerosis increase (Fisher, 1996). This study analyzed the mechanism of the depression of metabolic function through the analysis of blood metabolic markers relation to induced hypothyroidism in rat. And this study examined the effects of treadmill exercise on the changes of blood metabolic markers relation to hypothyroidism in rat. Finally, this study suggested the importance of exercise training for the prevention of hypothyroid induced obesity, diabetes, and atherosclerosis. Methods The markers of hypothyroidism and the effects of exercise interventions on thyroid functions were analyzed to measure the function of hypothyroidism in comparison with pre- and post-results of injections in 6-propyl-2thiouracil (PTU) on rats in the study. Results After injections in PTU, rats showed the negative results of bone mineral contents and body composition. Before exercise intervention,

PTU group showed a significant lower value of serum T4 concentration than control group. and PTU-Ex group showed a significant higher values than PTU-non Ex group. But serum T3 concentration showed no significant difference between PTU-Ex group and PTU-non Ex group. Related blood markers on thyroid function as TC and LDL-C showed a significant elevation after injection of PTU. Especially, PTU group showed significant lower values than control group. Discussion These results imply the hypothyroidism increase the prevalence of metabolic syndrome. Hypothyroidism with 6-propyl-2-thiouracil (PTU) had the negative effects on lipid metabolism and metabolic syndrome. It could be suggested the positive effects of exercise training on hypothyroidism by the changes of serum T4 concentration (Mastorakos & Pavlatou, 2005; Ciloglu et al, 2005). ### **HUMAN MUSCLE PROTEIN FRACTIONAL BREAKDOWN RATE DETERMINED BY THE DISAPPEARANCE RATE OF PROTEIN-BOUND ALANINE PRE-LABELLED WITH 2H VIA INTAKE OF A SINGLE BOLUS OF 2H<sub>2</sub>O**

Holm, L., Reitelseder, S., Dideriksen, K.J., Nielsen, R.H., Doessing, S., Kjaer, M.

*Bispebjerg Hospital*

**Introduction** We here validate the fractional breakdown rate (FBR) method in a human setting and further test whether the approach by pre-labelling proteins via infusion of a labelled amino acid complies with the assumptions. **Methods** Thirteen healthy and sedentary males were enrolled and started at day0 (zero) by drinking a dose of 5.25 mL 2H<sub>2</sub>O•kg<sup>-1</sup> lean body mass. Eight subjects had 15N-phenylalanine (phe) infused on day70 and had bilateral biopsies from vastus lateralis muscle taken at day80 and 94 to calculate the FBR over the 14 days period based on both the water-derived 2H<sub>4</sub>-alanine and the pre-infused 15N-phe. At day94 an infusion of ring-13C<sub>6</sub>-phe was given to determine the fractional synthesis rate (FSR). Five other subjects had bilateral biopsies taken at day80 and 90 (to calculate FBR), where in between they resistance trained one leg 6-7 times. On day90 they received an infusion of 1,2-13C<sub>2</sub>-leucine to determine the FSR in the rested and exercised muscles. **Results** The intake of 2H<sub>2</sub>O and the infusion of 15N-phe resulted in immediate and prolonged plasma enrichments of 2H-alanine and 15N-phe, respectively. However, during the FBR-measurement period (from day80-94) only the plasma 2H-alanine had dropped to non-detectable levels, whereas the 15N-phe was still abundant in plasma. The myofibrillar protein FBR based on 2H-alanine disappearance over 2 weeks was 0.017±0.001 %•hr<sup>-1</sup> with no difference between legs (p<0.05). In comparison the myofibrillar protein FSR over 4 hours measured by the incorporation of ring-13C<sub>6</sub>-phe was 0.082±0.014 %•hr<sup>-1</sup>. Frequent resistance training during a 10-days period only minorly increased the myofibrillar protein turnover rate (FSR: change 0.0080±0.0008 %•hr<sup>-1</sup>, p<0.05, measured by 1,2-13C<sub>2</sub>-leu incorporation and FBR: rest 0.0061±0.0062 %•hr<sup>-1</sup>, p>0.05). **Discussion** The presence of FBR-tracer in the precursor pool during the period of FBR determination results in a re-incorporation of the tracer and thus, the infusion of labelled phe cannot be used in the present setting. In comparison, the 2H<sub>2</sub>O approach does not seem to inherit this risk of tracer recirculation. We could determine a similar level of muscle protein FBR under the same conditions in two separate experiments and report a good inter-subject coefficient of variation (FBR: 22.2 vs. FSR: 46.9%). However, the FBR seems lower than the corresponding FSR, which warrants further investigation. Using the present experimental setting, exercise did neither have any major effect on muscle contractile protein FSR nor FBR.

### **EFFECTS OF OREXINS ON WATER INTAKE AND PLASMA ANTIDIURETIC HORMONE LEVEL**

Molnár, A.H.1, Kis, G.K.2, Daruka, L.2, Orbán, K.1, Szablics, P.1, Balogh, L.1, László, F.1,2, László, F.A.2, Varga, C.2

**Introduction** Orexin-A (OxA) and orexin-B (OxB) play a significant role in the regulation of food intake, energy balance, sleep-wake cycle and muscle tone. Additionally, these anabolic neuropeptides may cause increased water consumption and urinary output (Heinonen et al., 2008). The antidiuretic hormone (ADH) regulates the water balance of the body. It acts on the kidneys, increasing the water permeability of the renal tubules and collecting ducts, leading to increased water reabsorption of water (Wilmore and Costill, 2004). Thus, ADH and indirectly the orexins take part in the regulation of water homeostasis. **Aims** The effects of the centrally administered OxA and OxB on water intake and ADH secretion were investigated. We studied whether there is an interaction between orexins and the effect of ADH on water balance. **Methods** Different doses of orexins (10-30-90 µg/10 µl) and a specific orexin receptor-1 (OX1) antagonist SB 408124 (30 µg/10 µl) were administered intracerebroventricularly (i.c.v.) in male Wistar rats (200-250 g) under anaesthesia. Water consumption was measured for 6 hours. Plasma ADH level elevation was induced by histamine (10 mg/kg) or 2.5% NaCl (10 ml/kg) administered intraperitoneally 15 minutes after OxA or OxB administration. Plasma ADH levels were measured by radioimmunoassay. **Results** Orexins enhanced the water consumption. Most increased water intake was observed after administration of 30 µg/10 µl OxA (11.4±0.86 ml vs. control: 2.73±0.39 ml). OX1 antagonist decreased polydipsia significantly. There were no changes in basal ADH level (5.8±0.45 pg/ml) after administration of orexins. A significant increase in plasma ADH concentration was detected following histamine administration (59.03±1.98 pg/ml) and moderate enhancement was observed after 2.5% NaCl administration (23.65±2.47 pg/ml). I.c.v. OxA (30 µg/10 µl) reduced the histamine- (25.6±0.36 pg/ml) or hyperosmosis-induced (12.5±1.3 pg/ml) increased ADH level. These inhibitory effects were prevented by the specific OX1 antagonist. **Conclusion** We observed that there is an interaction between orexins and the ADH-system. Our results suggest that the effects of the orexins on water consumption or blockade of the histamine and osmotic-induced ADH level increase are mediated by the OX1 receptor. **References** Heinonen MV, Purhonen AK, Makela KA, Herzig KH. 1 UTAD, CIDESD, Vila Real – Portugal; 2 ESDRAM, Rio Maior – Portugal; 3 UTAD, CECAV, Vila Real - Portugal Study financed by FCT (PTDC/DES/121575/2010) **INTRODUCTION** Stress is the result of several factors, such as work demands, fatigue, sleep, diet and others. Psychological stress depends not only on the magnitude and density of the stress factors, but also from subject's perception of his/her own capacities to deal with each situations. Psychological stress has been proposed as an important factor in the pathogenesis and

development of several diseases, and in cancer (1). Oxidative DNA damage has been used to estimate cancer risk, once it causes mutagenesis and carcinogenesis (2). A few studies tried to establish the link between psychological stress, biochemical changes, oxidative stress and DNA oxidative damage. On the other hand, it has been proposed that an active lifestyle is associated with an increased organism protection to oxidative stress, and an increase in the ability to develop psychological strategies of coping with stress events. The aim of the present study was to analyze the influence of daily perceived stress on DNA damage and to verify the possible role of physical activity in reduction of DNA damage and perceived stress. METHODS Thirty healthy men, nonsmokers, above 40 years old, integrated this study. 15 of these subjects had a moderate to vigorous daily physical activity and the remaining ones had sedentary to lower daily physical activity, according to the levels proposed by the ACSM (3). Psychological stress was measured through Perceived stress scale (PSS). Daily physical activity was measured during at least 4 days to 7 days with an accelerometer (ActiGraph). Oxidative DNA damage was quantified by comet assay with FPG enzyme (4). T-test for independent samples were used to analyze differences between groups, and significant level was set at  $p < 0.05$ . RESULTS/DISCUSSION Our results revealed that the most active subjects exhibited lower perception of stress and oxidative damage to DNA. Habitual physical activity induces an increase in endurance capacity, increasing capacity to deal with higher daily workloads and induce hormonal changes associated with an increase in sleep quality and general relaxed state; we believe that higher physical activity contributes to enhance coping abilities to deal with stress events. Moreover, regular physical activity is also related with a decrease of oxidative damage to DNA, possible due to an decrease in oxidant state, but also to the reduction of biochemical changes associated with hormonal changes. ### THE REPRODUCIBILITY OF VO<sub>2</sub> KINETICS DURING WALKING IN PRESCHOOL CHILDREN

Stasiulis, A., Stasiule, L., Capkauskiene, S.

*Lithuanian Academy of Physical Education*

**Introduction** The pulmonary oxygen uptake (pVO<sub>2</sub>) kinetic response at the onset of exercise provides a non invasive method of evaluating aerobic metabolism in muscles during growth and maturation (Armstrong and Barker, 2009). However, to date only limited research has been devoted to investigating the pVO<sub>2</sub> kinetics during exercise in children. Therefore, the aim of this study was to evaluate the reliability of pVO<sub>2</sub> kinetics during six minutes walking on treadmill in preschool children. **Methods** 34 preschool children (19 girls and 15 boys) participated in 2 consecutive treadmill exercise sessions separated by one hour. Their age was 6.7±0.5 years. During each session, pVO<sub>2</sub> was collected at rest and during walking at 6 km per hour and a 4% grade for 6 minutes. The pVO<sub>2</sub> kinetics during exercise was analysed by applying mono exponential function. **Results** No slow component of pVO<sub>2</sub> kinetics was found in any group of children during this mode of exercise. For the two walking sessions VO<sub>2</sub>baseline value was 0,266 ± 0.057 and 0.266± 0.045 L/min., amplitude of pVO<sub>2</sub> response was 0.588 ± 0.072 and 0.577 ± 0.063 L/min., time constant of pVO<sub>2</sub> kinetics was 15.6 ± 3.1 and 16.1 ± 4.2 s, respectively (in all cases  $p > 0.05$ ). **Conclusion** The results of the present study indicate that at least mean values of pVO<sub>2</sub> uptake kinetics may be accurately estimated using two treadmill walking sessions in groups of young preschool children of both genders. **References** Armstrong N, Barker AR. (2009). Oxygen uptake kinetics in children and adolescents: a review. *Pediatr Exerc Sci*, 21(2),130-147.

#### PPAR $\alpha$ GENE VARIANTS AS PREDICTED PERFORMANCE ENHANCING POLYMORPHISMS IN PROFESSIONAL ITALIAN SOCCER PLAYERS

Proia, P.

*University*

Proia, P.I, Saladino, P.I, Schiera, G.I, Contro', V.I, Bianco, A.I, Traina, M.I, Palma, A.I 1: UNIPA (Palermo, Italy) **INTRODUCTION** One of the genes of the health-related fitness phenotype is a PPAR $\alpha$  coding for peroxisome proliferator activator receptor alpha, a central regulator of expression of genes involved in fatty acid metabolism. Several polymorphic sites have been identified within the PPAR $\alpha$  gene; most of them are very uncommon or where functionally silent. **METHODS** Sixty professional soccer players and thirty sedentary volunteers were enrolled in the study. Samples of venous blood were obtained at rest in the morning by conventional clinical procedures and allowed to clot at room temperature for 30 minutes and centrifuges. Serum was collected and total cholesterol, high density lipoprotein cholesterol, low density lipoprotein cholesterol and triglycerides were measured by using a kit in a chintic enzyme analyzer. An aliquote of anticoagulant-treated blood was used to prepare total RNA from mononuclear cells. The polymorphic site in PPAR $\alpha$  intron 7 was scanned by using PCR-RFLP protocol with Taq I enzyme. **RESULTS** We found variations among genotype distribution of PPAR $\alpha$ , lipidic profile variation and professional soccer players versus sedentary volunteers. To enphatized this correlation, we also investigated mRNA levels of PPAR $\alpha$  in mononucleate cells. **DISCUSSION** The aim of this study was analyzed the role of polymorphism of PPAR $\alpha$  gene in performance enhancing in italian soccer players, compare with the results obtained by Maciejewska et al 2011 in polish rowers. Our results evidenced a variation of genotype distribution of PPAR $\alpha$  in accordance with previously studies showing that intron 7 G allele as well as GG genotype, are associated with endurance performance (Ahmetov et al, 2006; Eynon et al, 2009). However, our study shows that PPAR $\alpha$  genotype distribution change among analyzed population with varying genetic background. So PPAR $\alpha$  G allele may be considered an endurance relates allele. We can explain this one because PPAR $\alpha$  is an important factor that regulate the balance between fatty acid and glucose metabolism. Moreover, we analyzed the correlation between PPAR $\alpha$  mRNA expression and athletes lipid profile (Proia et al., 2012; Horowitz et al., 2000). **REFERENCES** Maciejewska A, Sawczuk M, Cieszczyk P. ## THE TIME COURSE FOR CHANGES IN OXIDATIVE STRESS AND DNA IN RESPONSE TO EXERCISING IN A HOT ENVIRONMENT: THE RELATIONSHIP WITH VO2MAX

Knez, W.L., Kelly, K.B.

*Aspetar, Qatar Orthopaedic and Sport Medicine Hospital*

**Introduction** Exercising in a hot environment is associated with cardiovascular alterations such as an increase in core temperature, dehydration and cardiac drift. However, there is minimal research investigating the time course of changes in oxidative stress and DNA in response to exercise and thermal stress. Additionally, it is not known whether there is a critical point in core temperature for the production of oxidative stress or DNA modification, and whether this relationship is associated with an individual's maximal oxygen consumption (VO2max). Therefore, the first aim of this study was to investigate the time course of changes in indirect markers of oxidative stress and DNA modification during and after an aerobic bout of exercise in a hot environment. Secondly, we sought to determine whether there is a relationship between VO2max and the changes in markers of oxidative stress and DNA modification. **Methods** Eight recreational cyclists (age=30.9±2.2yrs; height=177.9±4.1cm; mass=74.5±4.5kg) completed a cycling VO2max in hot conditions (35°C, 70%RH) to determine 60% of peak power output. One week later the participants returned to the laboratory and cycled at this intensity until they reached a core temperature of 38.5°C. Blood was sampled before, during, and after (0, 10, 25, 35, post 10 and post 20 mins) exercise to determine indirect markers of oxidative stress (malondialdehyde; MDA) and DNA (8-hydroxy-2'-deoxyguanosine oxidation; 8-OHdG) modification. Statistical analysis was completed using linear mixed models with a level of significance set at p≤0.05. **Results** Cycling at 60% of peak power output until core temperature reached 38.5°C resulted in an inverse relationship between VO2max and the production of MDA and 8-OHdG (p<0.047; p<0.001). Additionally, after adjusting for VO2max there was a significant increase in oxidative stress over the exercise bout. Data showed that MDA increased during exercise (0-10, 25, 35 min [0 min post]) and decreased from 0-post to post 20 min recovery. After correcting for multiple comparisons there was a tendency towards significance from 0 mins to the completion of the exercise bout. However, no changes were observed in the modification of DNA during exercise or recovery. No relationship was observed between changes in blood markers and core temperature. **Discussion** Research shows that regular exercise protects against exercise-induced changes in oxidative stress and DNA. This research has also shown that this relationship extends to exercising in a hot environment. In this investigation, higher VO2max was associated with a decrease in both oxidative stress and DNA modification. Changes in oxidative stress appeared to be more sensitive to exercise duration than core temperature. Furthermore, these data showed that there was no critical core temperature for the development of oxidative stress. However, the current project was limited to a maximum core temperature of 38.50C. Future research should continue exercise beyond this point with a larger sample to develop a clearer understanding.

## COMPARISON BETWEEN YOUNG AND ADULT TRACK AND FIELD ATHLETES ON OXIDATIVE STRESS MARKERS

Zalavras, A.

*University of Thessaly*

**COMPARISON BETWEEN YOUNG AND ADULT TRACK AND FIELD ATHLETES ON OXIDATIVE STRESS MARKERS** Zalavras, A.1, Theodorou, AA.1, Nikolaidis, MG.2, Paschalis, V.1, Karatrantou, K.1, Oikonomou, D.1, Fatouros, IG. 3, Koutedakis, Y. 1, Jamurtas, AZ.1 1: UTH (Greece) 2: AUTH (Greece) 3: DUTH (Greece). **Introduction** Reports in the literature suggest that glutathione levels might be different between children and adults (Michelet et al. 1995). Furthermore, glutathione levels were positively correlated with regular physical exercise (Michelet et al. 1995). However, studies comparing the redox status between young and adult individuals are scarce. Therefore, the aim of this study was to compare the antioxidant defense system between young and adult track and field athletes and assess whether it responds differently following an acute bout of aerobic exercise. **Methods** Thirteen young athletes (age: 14.2±1.1; weight: 54.2±8.5; height: 165.6±7.4) and 12 adult athletes (age: 25.2±6.9; weight: 66.9±6.1; height: 175.2±4.5) participated in this study. Blood was collected prior to, immediately post and 1h post an acute exercise bout (45 minutes at 70% VO2max). Blood was analyzed for indices of oxidative stress (reduced glutathione) and the antioxidant defense system (total antioxidant capacity). **Results** A 2X3 (group X time) repeated measures ANOVA did not reveal significant differences between groups nor an interaction effect. However there was a significant difference across time. Glutathione levels were significantly lower (p<0.05) for both groups immediately post exercise and total antioxidant capacity was significantly elevated (p<0.05) immediately post and 1h post exercise. **Discussion** These results indicate that there are no differences in the antioxidant defense system between young and adult track and field athletes. Furthermore, the response to an acute stressor as exercise is similar between the two aged groups. **References** Michelet F, Gueguen R, Leroy P, Wellman M, Nicolas A, Siest G. (1995). Blood and plasma glutathione measured in healthy subjects by HPLC: relation to sex, aging, biological variables, and life habits. *Clin Chem.* 41(10):1509-17.

## CREATINE SUPPLEMENTATION IN FIBROMYALGIA: PRELIMINARY DATA FROM A DOUBLE-BLIND RANDOMIZED CONTROLLED TRIAL

Alves, C.R.R., Santiago, B.M., Benatti, F.B., Tritto, A.C., Campos-Ferraz, P.L., Lancha, J.A.H., Otaduy, M.C., Lima, F.R., de Sá Pinto, A.L., Gualano, B.

*University of Sao Paulo*

**Introduction** Recent evidence has suggested that low muscle phosphocreatine (PCr) content could be implicated in pain and muscle weakness seen in fibromyalgia (FM). Moreover, non-controlled studies have suggested a beneficial effect of creatine (Cr) supplementation in this syndrome. However, no randomized controlled trial has been conducted so far. **Purpose** To explore the possible therapeutic effects of Cr supplementation on muscle function, muscle strength and renal function in FM patients. **Methods** This was a 16-week randomized double-blind placebo-controlled trial. Twenty women diagnosed with fibromyalgia were randomly assigned into two groups: i) placebo (Pl; n = 10), and ii) Cr (Cr; n =10). The Cr group received 20 g/day of Cr for 5 days followed by 5g/day for 16 weeks. The Pl group received the same dose of dextrose. At baseline (PRE) and after 16 weeks (POST 16), we assessed: i) PCr concentration in gastrocnemius by in vivo magnetic resonance spectroscopy (MRS); ii) muscle strength by 1-repetition maximum (1-RM) test in the bench press and leg press; iii) muscle function by Timed-Up-and-Go test. Data were expressed as absolute changes (delta) from POST 16 to PRE and tested by Unpaired Student's T test. Effect Sizes (cohen's d) were also calculated. **Results** After 16-weeks of supplementation, PCr concentration was higher in the Cr group versus the Pl group (p = 0.05). Performance in the Bench press and leg press 1-RM and in the Timed-Up-and-Go test were also greater in the Cr group when compared to the Pl group (bench press: Pl = -2.6 ± 1.8, ES = -0.22 vs. Cr = 0.5 ± 2.6, ES = 0.09; p = 0.005; leg Press: Pl = -0.6 ± 7.5 Kg, ES = -0.21 vs. Cr = 4.6 ± 4.9 Kg, ES = 0.31; p = 0.05 and Timed-Up-and-Go test: Pl = 1.0 ±

2.2, ES = -0.69 vs. Cr = -0.12 ± 0.56, ES = 0.11; p = 0.07). Furthermore, albuminuria, proteinuria, serum and urinary creatinine, serum urea, serum and urinary sodium and potassium were not altered following the intervention (p>0.05). Conclusion In a small cohort of FM patients, Cr supplementation increased muscle PCR concentration, resulting in improvements muscle function and muscle strength. No adverse effect of Cr upon renal function was noted. This study will be expanded with a longer-term follow-up, larger sample and additional measurements related to FM symptoms (e.g., pain and quality of life) in order to confirm or not the therapeutic value of Cr in such a condition.

### THE ANABOLIC-ANDROGENIC STEROIDS EXERT DIRECT TOXIC EFFECTS ON NEURON-LIKE CELLS

Proia, P.

*University*

Basile, JR.1,2, Binmadi, NO.3, Zhou, H.1, Yang, Y.1, Proia, P.1,4 1: UMB (Baltimore, USA), 2: GCC (Baltimore, USA), 3: KAU (Saudi Arabia), 4: UNIPA (Palermo, Italy). **INTRODUCTION** Intake of AAS by athletes and others in an attempt to gain muscle strength and improve performance is often associated with toxic effects on the liver, the cardiovascular system, the male and female reproductive systems, and the central nervous system (Trifunovic et al., 1995). In vivo administration of high doses of androgens has been linked to neurobehavioral changes that could be the outward manifestation of neuronal damage. **METHODS** PC12 cells are a cell line that have been widely used as a model in neurobiological investigations (Fujita et al., 1989; Vaudry et al., 2002). Following exposure to nerve growth factor (NGF), PC12 cells differentiate into a sympathetic-like neuron and develop extensive neuritic processes. Differentiated PC12 cultures, were treated with steroid hormones, methandienone and 17- $\alpha$ -methyltestosterone at final concentrations of 75  $\mu$ M in complete medium, for 24 h. After treatment several analysis were performed on total proteins and RNA samples, as well as immunofluorescence analysis and vitality assay. **RESULTS** Genomic effects of AAS treatment, was found. The experimental procedures described above showed that anabolic steroid hormones induced cell death by activation of the apoptotic pathway that include caspase-3 activation, HSP90 cleaved as well as PARP (Santamarina RD et al., 2008). **DISCUSSION** These preliminary experiments demonstrate that AAS cause an alteration of cellular pathways that control cell survival and differentiation. Particularly, we showed that cell extracts prepared from anabolic steroid hormones-treated PC12 cells showed caspase-3 activity and the PARP (the main substrate of protease activity) is cleaved during this death process. In our studies, we also confirmed the cleavage of HSP90 after 24 hours PC12 cells treatment with methandienone and 17- $\alpha$ -methyltestosterone, when we used a suprapharmacological concentrations, that means an activation of the apoptotic pathway. However, we saw a neuritin increases correlated with a loss of neurites. This protein is an important effector of androgen in enhancing peripheral nerve regeneration following injur. This discrepancy could be attributable to the high concentrations of AAS used in our study, which were an attempt to approximate the excessive amounts of steroids used by athletes to enhance performance. **REFERENCES** Trifunovic B, Norton GR, Duffield MJ, Avraam P, Woodiwiss AJ. ### THE EXPRESSION OF FGF21 BY MECHANICAL STRETCHING IN C2C12 MUSCLE CELLS

Tanimura, Y.1, Aoi, W.2, Mizushima, K.1, Naito, Y.1, Yoshikawa, T.1

*1: Kyoto prefectural University of Medicine (Kyoto, Japan), 2: Kyoto prefectural University (Kyoto, Japan)*

**Introduction** Fibroblast growth factor 21 (FGF21) is a novel metabolic regulator and controls glucose and lipid metabolisms (Kharitononkov et al., 2005). We reported that the expression of FGF21 in skeletal muscle is elevated by exercise in mice, and this elevation is associated with phosphorylation of Akt (p-Akt) (ECSS 2011, Liverpool). In this study, we investigated whether mechanical stretching in mouse C2C12 cells induces the expression of FGF21 using an in vitro experimental model. **Methods** Mouse C2C12 myoblasts were cultured in high glucose Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum in a 10-cm<sup>2</sup> elastic silicone chamber precoated with 0.05% porcine type I collagen at 37°C. To induce cell differentiation, the medium was changed to low glucose DMEM supplemented with 2% horse serum for 96 h. To determine the effects of mechanical stretching, the cells were stretched using an NS-200 apparatus driven by a computer-controlled stepping motor. Then, an 8% uniaxial sinusoidal stretch was applied at 1 Hz for 60 min (Nakai et al., 2010). Immediately after the treatments, C2C12 were then scraped and lysed. Cell lysates were prepared for quantitative analysis of FGF21, p-Akt, and Akt. **Results** Mechanical stretching increased the expression of FGF21 in C2C12. Additionally, we could identify the increase of p-Akt in C2C12 by the stretching, although total Akt was not changed. **Discussion** We investigated the effect of mechanical stretching on the expression of FGF21 in C2C12. This treatment increased the expression of FGF21 along with phosphorylation of Akt. These observations supported our previous study, which the increase of p-Akt by acute exercise induced FGF21 in skeletal muscle. In conclusion, the expression of FGF21 in C2C12 depends on the increase of p-Akt via mechanical stretching. **References** Kharitononkov, A., Shiyanova, T. L., Koester, A., Ford, A. **Introduction** The process of skeletal muscle regeneration is due to the activation of satellite cells, which proliferate and differentiate to form new myotubes. In regeneration the key role play hydrogen peroxide, nitric oxide, cytokines and growth factors which may come from many sources like, muscles and/or motor nerves and inflammatory cells. During recovery, most of these molecules have been released and could be useful in assessment of muscle regeneration in athletes (Hawke and Garry, 2001). The purpose of the study was to estimate the regenerative potential of skeletal muscle in elite Greco-Roman wrestlers compared to non-athletes. **Methods** Greco-Roman wrestlers, members of national team were observed during preparatory training period (pre-season January). In blood were measured concentrations of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), nitric oxide (NO), pro-inflammatory cytokines (IL-1 $\beta$ , TNF $\alpha$ ), hepatocyte growth factor (HGF), insulin-like growth factor (IGF-I), platelet-derived growth factor (PDGF-BB) and brain-derived neurotrophic factor (BDNF). Total creatine kinase (CK) activity was determined as a marker of muscle damage. Body composition were estimated using a bioelectrical impedance (Tanita, Japan). Healthy and untrained men made a reference group. **Results** The H<sub>2</sub>O<sub>2</sub> concentration was higher in non-athletes, oppo-

site to NO that was higher in wrestlers. The positive correlations was observed between NO and BDNF ( $r=0.641$ ,  $P<0.001$ ). The level of TNF $\alpha$  was 7-fold higher in wrestlers. Athletes with very high values of IL-1 $\beta$  and TNF $\alpha$  demonstrated the low level of growth factors and delay in regeneration of damaged muscles. IGF-I, PDGF-BB and BDNF was increased in wrestlers, in opposite to HGF that was lower in wrestlers compared to non-athletes. Individual analysis of IGF-I, PDGF-BB and BDNF revealed significant changes in highly qualified wrestlers. The activity of CK in wrestlers was measured for three days after strenuous training. The negative correlation was between percentage changes of CK and IGF-I ( $r=-0.755$ ,  $P<0.001$ ). CK activity was even 4-9-fold elevated in wrestlers. Analysis of body mass showed that wrestlers have lower fat mass (FM) but free fat mass (FFM) was higher than in non-athletes. Discussion We have concluded that wrestling training at high intensity has significant influence on growth factors and increase of hydrogen peroxide and nitric oxide. The release of pro-inflammatory cytokines and growth factors is related to athlete's fitness level, and effects on skeletal muscle regeneration. References Hawke TJ, Garry DJ. (2001). *J Appl Physiol* 91, 534-551. Acknowledgments This study was supported by a grant from National Science Centre Poland: 2011/01/N/NZ7/05282.

### STRESS PROTEIN AND GLUTATHIONE RESPONSES TO 90-MIN INTERMITTENT CYCLING FOLLOWING ALKALOSIS

Peart, D., Kirk, R., Siegler, J., Vince, R.

*University of Hull*

Introduction Inducing a pre-exercise alkalosis with sodium bicarbonate (NaHCO<sub>3</sub>) has been shown to attenuate intra-cellular heat shock protein 72 (HSP72) and lipid peroxidation (TBARS) following a single 4-min bout of anaerobic exercise (Peart et al. 2011). The response of HSP72 is said to be related to exercise duration (Fehrenbach et al. 2005), and the validity of TBARS to examine oxidative stress has been questioned (Powers et al. 2010). Therefore the aim of this study was twofold, firstly to examine whether NaHCO<sub>3</sub> attenuates a more pronounced expression of HSP72 following a longer exercise protocol, and secondly to further examine the effect of NaHCO<sub>3</sub> on oxidative stress by observing glutathione activity and the expression of heme oxygenase-1 (HO-1). Methods Six physically active males ( $23.2 \pm 2.9$  years,  $179.5 \pm 5.5$  cm,  $76.5 \pm 6.8$  kg, and PPO  $315 \pm 36$  W) performed 90-min of intermittent cycling on three occasions. Visit 1 was a familiarisation to the exercise and the following visits were the experimental (SB = 0.3 g.kg.BW<sup>-1</sup> sodium bicarbonate) and placebo (PL = 0.045 g.kg.BW<sup>-1</sup> sodium chloride) trials completed in a blinded and randomised manner. Venous blood for the analysis of HSP72 and HO-1 were taken pre-exercise and the 0-, 45-, 90- and 180-min post-exercise. Both HSP72 and HO-1 were analysed in monocytes via flow cytometry. The percentage of oxidised to total glutathione (GSSG/TGSH) was analysed pre-exercise, and then 0-, 45- and 90-min post-exercise using a commercially available assay kit. Results HSP72 and the percentage of GSSG/TGSH were significantly increased in both conditions from 45-min post-exercise ( $p \leq 0.014$ ), with no differences between trials. HO-1 was also significantly increased in both trials from 45-min post-exercise ( $p \leq 0.016$ ), and the increase was significantly higher in PL compared to SB ( $p = 0.036$ , 183 and 66% respectively). Discussion NaHCO<sub>3</sub> had no effect upon HSP72, contrary to previous research reporting an attenuation following 4-min of high intensity cycling (Peart et al. 2011). Discrepancies between these studies are likely to be due to the differing exercise intensity and duration, and these results may suggest that alkalosis only attenuates HSP72 when there is a sufficient disruption to acid-base balance. Both GSSG/TGSH and HO-1 indicated the presence of oxidative stress, however only HO-1 was attenuated by NaHCO<sub>3</sub>. Differences may be due to the fact that HO-1 has previously been shown to be sensitive to changes in acid-base status (Christou et al. 2005). References Christou et al. ### MUSCLE ATROPHY OCCURS HETEROGENEOUSLY AFTER CAST IMMOBILIZATION IN MOUSE SOLEUS MUSCLE

Sudo, M., Tsubuko, T., Tomiga, Y., Eshima, H., Ando, S., Tanaka, H., Higaki, Y.

*Fukuoka Univ.*

Introduction Skeletal muscle is a highly plastic tissue, and its physiological responses are dependent upon the amount of mechanical load on the tissue. A number of studies have found that physical inactivity induces significant muscle atrophy (e.g., Frimel et al., 2005). However, whether muscle atrophy occurs heterogeneously in a muscle remains to be elucidated. The purpose of this study was to examine the heterogeneity of muscle atrophy induced by cast immobilization for 1 week. Methods Male C57BL/6J mice aged 10 weeks were subjected to unilateral hind limb cast immobilization for 1 week. This study involved three groups ( $n = 5-6$  for each condition): (1) cast immobilization group (Cast), (2) non-cast immobilization in the contralateral hind limb group (N-Cast), and (3) untreated control group (CON). In the Cast group, unilateral ankle joints were stabilized with plaster casts under anesthesia. Ankle joints were fixed in full plantar flexion, and the soleus muscle was immobilized in a shortened position. The soleus muscle was dissected after cast immobilization. Muscle sections were histochemically stained. We measured the cross-sectional area to assess muscle atrophy from the proximal, middle, and distal sections of the soleus muscle. Muscle damage was evaluated from stained cross-sections as the relative number of damaged fibers in relation to intact fibers. Results After 1 week of cast immobilization, the soleus muscle weights were significantly lower in the Cast ( $0.28 \pm 0.04$  mg/body weight) compared with the CON group ( $0.36 \pm 0.03$  mg/body weight) ( $p < 0.01$ ). Muscle atrophy was severe in the middle myofibers ( $693 \pm 182 \mu\text{m}^2$ ) compared with the proximal ( $1127 \pm 336 \mu\text{m}^2$ ) and distal ( $1235 \pm 300 \mu\text{m}^2$ ) portions of the soleus muscle. Myofiber damage frequently occurred in the immobilized mice (Cast,  $2.45\% \pm 3.12\%$ ; N-Cast,  $2.81\% \pm 3.66\%$ ) compared with the CON mice ( $0.18\% \pm 0.18\%$ ). The occurrence of myofiber damage did not differ among the proximal, middle, and distal portions in all groups. Discussion The present findings suggest that the middle portion of the soleus muscle may be more vulnerable to physical inactivity than the proximal and distal portions. A decrease in mechanical load by cast immobilization may heterogeneously lead to muscle atrophy. We conclude that after 1 week of cast immobilization, muscle atrophy was greater in the middle than in the proximal and distal portions of the soleus muscle. ### IN VIVO MUSCLE VOLUME AND PHYSIOLOGICAL CROSS\_SECTIONAL AREA OF HUMAN TRUNK MUSCLES

Ikegawa, S., Okazaki, H., Suzuki, Y., Okabe, N., Kumagawa, D., Takahashi, Y., Tanaka, S., Tsunoda, N.

*Jumoni University*

IN VIVO MUSCLE VOLUME AND PHYSIOLOGICAL CROSS\_SECTIONAL AREA OF HUMAN TRUNK MUSCLES Shigeki Ikegawa 1, Hitomi Okazaki 1, Yukari Susuki 1, Naoko Okabe 1, Daisuke Kumagawa 2, Yusuke Takahashi 3, Shigeharu Tanaka 3, Naoya Tsunoda 3 1:Jumoni University, 2:Japan Institute of Sports Science, 3:Kokushikan University Introduction The structure of muscle is a important factor of its function. Fascicle length determine the excursion of muscle and physiological cross-sectional area(PCSA) determin the force-generating

capacity. Such studies were mainly in the upper and lower limbs. Trunk muscles have valuable task for control of body posture, protect the abdominal area, and suspend the spine. Therefore, the aim of the present study is to determine the muscle volume and physiological cross-sectional area of trunk flexors and extensors using magnetic resonance imaging (MRI). Methods Serial cross-sectional images of the trunk were obtained for nine healthy females by MRI. From the obtained images, anatomical cross-sectional area (ACSA) of Rectus Abdominis (RA), Psoas Major (PM), Quadratus Lumborum (QL, proximal and distal) and Erector Spinae + Multifidus (ST: Spinal Thoracis, LT: Longissimus Thoracis, IL: Iliocostalis Lumborum, M: Multifidus) were measured. Muscle volume of each muscle and muscle group were calculated as sum of ACSA between most proximal to distal images. PCSA was calculated from the muscle volume divided by muscle fiber/muscle length ratio reported by former cadaver studies. Result Mean muscle volume of trunk flexors indicated 165.4 cm<sup>3</sup> for RA and 147.2 cm<sup>3</sup> for SM. Trunk extensor muscle volume were 23.9, 13.1, 18.6, 134.1, 113.8, 133.7 for the QLprox and QLdist and ST and LT and IL and M. Mean fiber length of RA was 29.2 cm. This fiber length was four to eight times longer than other muscles. Mean PCSA of M indicated 23.6 cm<sup>2</sup>, from two to six times larger than other muscles. Discussion Comparing the PCSA data of present study and Delp et al (1991), all the data of present study is larger than previous study. It is considered that shrinkage of the cadaver affect this difference. As reported by Ward et al (2009), the greater PCSA and shorter fiber length suggest that M is structurally designed to generate large forces over narrow range of muscle length. This is due to the valuable task of M to stabilize the spine. On the contrary, RA have longer muscle fiber and smaller PCSA. Comparing the trunk extension, trunk flexion is wide range of motion of body. It is considered that trunk flexor and extensor muscles are purposely-designed structures. #### EFFECT OF HOME EXERCISE PROGRAM ON ISOMETRIC LEG EXTENSOR STRENGTH, POSTURAL STABILITY AND PLANTAR PRESSURE IN WOMEN WITH GONARTHROSIS

Rätsepsoo, M.1,2, Gapeyeva, H.1,2, Sökk, J.1,2, Ereline, J.1,2, Haviko, T.3, Märtson, A.3, Päsuke, M.1,2

*University of Tartu*

Introduction: It has been found that patients with gonarthrosis experience decreased postural stability and muscle strength (Hurley et al., 1997; Hassan et al., 2001) and present weight bearing asymmetry (Christiansen & Stevens-Lapsley, 2010). Aim of this study was to investigate the effect of resistance exercises on isometric strength of leg extensors, postural stability and plantar pressure in women with late stage gonarthrosis. Methods: Ten women with gonarthrosis aged 46-72 years who were scheduled for unilateral total knee arthroplasty (TKA) participated in this study. All patients performed home exercise program (HEP) which included resistance and balance exercises during 2 months. Isometric maximum voluntary contraction (MVC) of leg extensors was measured with custom made leg bench. Postural stability characteristics (30 s bipedal standing, eyes open) were recorded on a dynamographic force plate. Plantar pressure distribution characteristics were measured with a digital biometric images scanning system (Italy). Results: Significant improvement ( $p < 0.01$ ) in unilateral maximum peak torque (MPT) of the involved leg and bilateral MPT ( $p < 0.001$ ) was found after 2 months of HEP. Patients had an increase ( $p < 0.05$ ) in peak torque:body mass (MPT:BM) ratio of the involved leg and bilateral MPT:BM ( $p < 0.001$ ) ratio after 2 months of HEP. MPT and MPT: BM ratio of the involved leg were significantly lower compared to uninvolved leg ( $p < 0.05$ ) before HEP, but not after HEP. Plantar pressure distribution and center of pressure sway characteristics (anteroposterior and mediolateral displacement, trace length and area) did not differ significantly 2 months after HEP. Discussion: After two months of home exercise program isometric strength of leg extensors remarkably increased in women with late stage gonarthrosis; therewith no changes were found in postural stability and plantar pressure distribution characteristics. #### MOVEMENT PATTERN OF THROWING DRAG-FLICK OF THE U-21 FIELD HOCKEY

Antonio, R., López de Subijana, C., Navarro, E.

*Sport Sciences Faculty- Technical University of Madrid- Madrid-Spain*

Introduction In field hockey, the drag-flick is one of the most effective throwing in penalty corner (McLaughlin, 2007; Piñero, 2008). The objectives of this study were to describe the sequence of linear velocities of the kinematic chain during the drag-flick and to determine the throwing patterns of sample players. Methods The sample were three men (19,8 ± 0,9 years-old; 69,9 ± 7,2 Kg.; 177,4 ± 6,8 cm and 5 ± 1 years of experience in the skill) and a woman (18,8 years-old; 71,6 Kg.; 171,3 cm and 6 years of experience in the skill) participated in this study. They were all drag-flickers and members of the under-21 Spanish national team. Each player executed 20 drag-flicks. Six automatic capture Vicon cameras sampling at 250 Hz were used to capture the positions of the reflective markers. For the normality of the distribution a Kolmogorov-Smirnov test was made. Not all variables meet the criteria of normality and a Kruskal-Wallis and Mann-Whitney test were done to determine and to quantify the differences between variables ( $\alpha = 0,05$ ). Later the Bonferroni's correction was applied which placed the significant level at  $\alpha/6 = 0,00833$ . Results and Discussion The results confirmed the existence of a proximal-distal sequence of movements of the kinematics chain of the body segments (Brétigny, Seifert, Leroy & Chollet, 2008; López de Subijana, Juárez, Mallo & Navarro, 2010). The relative timing (TRel) of movement was determined by the instants when the maximal speeds were reached. They provided relevant information about the coordination of this skill. Based on the TRel it has been described different patterns of drag-flick. Conclusions It has been established ranges of time to describe the most effective pattern for these throwers. Acknowledge This study was funded by the Spanish Sport Council (Ref n= P08-1110-338) References Brétigny, P., Seifert, L., Leroy, D., & Chollet, D. (2008). ### DYNAMICS OF CG DURING ACCELERATION OF MAXIMAL SPRINT

Nagahara, R.1,2, Matsuo, A.3, Matsubayashi, T.3, Zushi, K.1

1: University of Tsukuba (Tsukuba, Japan), 2: JSPS Research Fellow, 3: Japan Institute of Sports Sciences (Tokyo, Japan)

DYNAMICS OF CG DURING ACCELERATION OF MAXIMAL SPRINT Nagahara, R.1,2, Matsuo, A.3, Matsubayashi, T.3, Zushi, K.1 1: University of Tsukuba (Tsukuba, Japan), 2: JSPS Research Fellow, 3: Japan Institute of Sports Sciences (Tokyo, Japan) Introduction Running speed of maximal sprint is usually approximated by exponential equation (Chelly and Denis, 2001; Volkov and Lapin, 1979). This approximation is based on the idea which the acceleration of sprinters gradually becomes small. On the other hand, it is generally thought that the height of whole body centre of gravity (CG) during acceleration of maximal sprint becomes high with increasing running speed. However, a previous study showed that the increasing running speed during maximal sprint changed like a cubic curve (Nagahara, 2009). Moreover, in practical side, the acceleration of maximal sprint is divided into two or three sections. Thus, the purpose of this study was to clarify whether the running speed and height of CG during acceleration of maximal sprint gradually increase or not. Methods Twelve male sprinters (age  $21.6 \pm 2.6$  yr, stature  $1.74 \pm 0.04$  m, body mass  $68.1 \pm 4.1$  kg and the best time of 100 m race  $10.71 \pm 0.33$  s) participated in this study. The subjects performed 60 m sprint twice with maximal effort started by crouch position as used in 100 m race. The time of 60 m sprint was measured using photocell connected starting gun and VICON motion-capture system. Whole running motion from start to 50 m mark was recorded using VICON system consisted by sixty cameras (250Hz). The coordinates of segment endpoints were obtained by filtering and CG were calculated. Results and Discussion Time of 60 m sprint was  $7.24 \pm 0.16$  s. As a typical result, the height of CG increased to the 11th step, and then leveled off to the 18th step, and gradually decreased thereafter while the running speed still increased. At the same spot, the 11th step, the acceleration shifted to constant and decreased again thereafter. These are novel and unexpected results and suggest that the sprinters accelerate with unsteady change of running speed and height of CG. References Chelly SM, Denis C. (2001). *Med. ### EFFECT OF PROPHYLACTIC TRAINING ON A POTENTIAL RISK FACTOR FOR FUTURE ACL INJURY; A RANDOMIZED CONTROLLED TRIAL

Petersen, M.B.1, Bencke, J.1, Lauridsen, H.B.1, Curtis, D.1, Bandholm, T.1, Thorborg, K.2, Hölmich, P.2, Andersen, L.L.3, Myklebust, G.4, Aagaard, P.5, Zebis, M.K.5,1

1 Copenhagen University Hospital, Hvidovre, Denmark, 2 Copenhagen University Hospital, Amager, Denmark, 3 NRCWE, Denmark, 4 Oslo Sport Trauma Research Center, Norway, 5 University of Southern Denmark

Introduction Young female soccer and handball players are at highest risk of sustaining an ACL-injury (Lind et al. 2009). Most non-contact ACL-injuries occur during sidecut manoeuvres (Olsen et al. 2004). A potential risk factor during sidecutting is a high vastus lateralis (VL) and low semitendinosus (ST) neuromuscular activity just before foot strike (Zebis et al. 2009). The present study examined the effect of 12 weeks of prophylactic training on the VL-ST pre-activity difference in young female athletes. Methods Forty young female soccer and handball players (age  $15.7 \pm 0.5$  years, weight  $63.7 \pm 10.8$  kg, height  $168 \pm 5.6$  cm) were randomized to prophylactic neuromuscular training (NMT, n=20) or control group (Con, n=20). In the NMT-group, 12 weeks of prophylactic training (Olsen et al. 2005) was implemented 3/week while the Con-group continued their regular warm up exercises. VL and ST muscle activity (EMG) was measured during a sidecutting manoeuvre in the 50 ms time interval prior to foot strike on a force plate (AMTI). EMG activity was normalized to peak EMG amplitude recorded during MVC. A per protocol analysis was performed on players who remained uninjured and who had undergone at least 10 weeks of full training and match play, (NMT, n=15) and (Con, n=10). Results In the Con-group neuromuscular pre-activity of the ST was significantly lowered ( $P=0.011$ ) and the VL-ST pre-activity difference significantly increased ( $P=0.046$ ) compared with the NMT-group. In the Con-group, seven players suffered an injury in the lower extremity compared to one player in the NMT-group ( $P=0.04$ ). Discussion Twelve weeks of prophylactic training prevented a decrease in the neuromuscular activity of the ACL-agonist ST in young female soccer and handball players. Further, the increase in VL-ST pre-activity difference in the Con-group implies a reduced capacity for knee joint stabilization during high-risk movements like the sidecut manoeuvre. References 1. ### ANKLE SPRAINS ON SOCCERS AND BIOMECHANICAL REPERCUSSIONS

Leiras, J., Villas-Boas, J.P., Sousa, F.

FADEUP

ANKLE SPRAINS ON SOCCERS AND BIOMECHANICAL REPERCUSSIONS Leiras, J.1, Villas-Boas, J. P.1,2, Sousa, F.1,2 1 CIF2D, Faculty of Sports, University of Porto, Porto, Portugal 2 Porto Biomechanics Laboratory (LABIOMEPI), University of Porto, Porto, Portugal Soccer is considered by F.I.F.A. the most popular sport in the world. Increasing the volume and intensity of games and practices the incidence of the injuries also increases. The ankle injuries are very common, since takes several functions of mobility and stability associated with jumping, running and sudden changes in movement direction. The ankle sprain is an acute effect of soft tissue, and occurs more often in the ligaments of the ankle joint complex. Regarding the mechanism of injury, most ankle sprains occur in inversion movements (Giza et al. 2003), many of which prove highly disabling for sports and conditioning of the load support. The main objective of this study was to determine the incidence, severity and biomechanical effects of ankle sprains in soccer players of the Portuguese League. Forty six soccer players aged  $27.1 (\pm 4.3)$  years, of  $178.8$  cm ( $\pm 5.4$ ) height and  $79.0$  kg ( $\pm 6.42$ ) body mass, were evaluated. A first observational and exploratory podiatric analysis was conducted, which included a static evaluation of body composition, morphology of the foot and lower extremity alignment. A Podoscope, a Goniometer, a Perthes ruler, a Pelvimeter, a Pedigraph, and Footscan plate, was used. The registration of all injuries occurred during two sportive seasons was done, including: type of injury, mechanism and treatment. Of the players assessed, twelve (26%) suffered ankle sprains by inversion, predominantly in the support foot, mainly of grade II, with an average duration of treatment of 2-4 weeks. About 40% of subjects had two or more sprains, which shows a high recurrence rate, occurring more commonly in the competitive period (65%). The gait of the individuals who suffered sprains had specific features to highlight: less time of total contact of

the foot, and difficulty in sustaining balance. A larger pressure displacement from lateral to medial was found at the initial contact stage and at the support phase of the forefoot, and lower lateral displacement of the pressure at the digital elevation stage. They was also decreased the range of motion of extension of the 1st metatarso-phalangeal joint, which hinders the ability to accommodate the load and motion control, and the contact on the 1st metatarsal was anticipated. However, the maximum peak pressure occurred in the 1st ray, which is related to a radius hypermobile in individuals with sprains by inversion. It should also be noted that the sprains occur mostly in the mid-field players. This study allowed us to conclude that sprains trigger specific biomechanical changes, both at the time of full contact of the foot, and on the ability to maintain balance and a proper distribution of plantar pressures. ## BIOMECHANICAL ANALYSIS OF THE BASIC BODY MOVEMENT IN AIKIDO

furutani, o., horita, t.

*Univ. of kokushikan.*

Biomechanical analysis of the basic body movement (irimi) in Aikido O.Furutani<sup>1</sup>, T.Horita<sup>2</sup>, <sup>1</sup>Kokushikan University, Tokyo, Japan, <sup>2</sup>University of Toyama, Toyama, Japan INTRODUCTION Aikido is one of the martial system derived from the many martial arts traditions of Japan (M.Ueshiba.2005). Aikido practice is performed by barefoot using a sliding step (suri ashi). The basic movement in Aikido is called "irimi" (entering). The motion of irimi is characterized as follows, the performer moves laterally using a sliding step against the opponent's attack, and then moves closely to the opponent's "dead (blind) angle". The aim of irimi is to render the opponent's attack ineffectively. This entering to the side of an attack with a sliding step and placing oneself in the opponent's dead angle is called "one step irimi" (M.Ueshiba.2005). Irimi represents the characteristics of budo as manifested in martial technique (K.Ueshiba.1984). The motion of Irimi is based on the circular rotation of the body in keeping with a stable position of the center of gravity (K.Ueshiba.1984). The purpose of the present study was to investigate the biomechanical characteristic of the basic body movement (irimi) in Aikido. METHODS Eight skilled(5-6 grade) male experts (61.4±11.5yr;63.8±6.5kg;169.5±4.2cm) and 5 unskilled male (19.6±1.5yr;61.3±5.6kg;168.1±2.5cm) subjects participated in this study. The subjects performed irimi on the two force plates (KISTLER, Type2986A). The motion of the subjects was recorded by two video cameras (30 f.p.s.). Three-dimensional (3D) analysis was performed by a computerized motion analysis system (FRAME DIASIV, DKH, JAPAN). Center of gravity of the body (CG) and lower limb joint kinematic variables were analyzed. RESULTS AND DISCUSSION The differences were found in the path of CG and lower limb joint kinematics between skilled and unskilled subjects in irimi. The skilled subjects showed small change (92.4±0.9cm) in horizontally frontal displacement of CG during movement as compared to unskilled subjects (98.8±2.2cm). The skilled subjects showed small change (11.5±0.3cm) in horizontally lateral displacement of CG during movement as compared to unskilled subjects (16.8±0.7cm). Skilled subjects showed shorter movement time (1.36±0.04s) as compared to the unskilled subjects (1.66±0.08s, P<0.05). In addition, force impulse of the skilled subjects were lower (9.93±0.27Ns/Kg) than the unskilled subjects (10.89±0.98Ns/kg, P<0.05). Therefore it has been considered that Aikido experts possess well-coordinated and economical movement. REFERENCES K. Ueshiba, *The Spirit of Aikido*, 41, 1984, Kodansha, Tokyo, Japan. M. ## POWER PRODUCTION DURING THE INITIAL PHASES IN LUGING: A PRELIMINARY STUDY

Fedotova, V.1, Pilipiv, V.2

*1: Riga Technical University (Riga, Latvia), 2: Latvian Olympic Team (Riga, Latvia)*

Introduction In winter sport of lugging the first phases of the start are known to have a leading role for the successful start performance (Lembert et al., 2011). Kinetics of this highly demanding sport is seldom evaluated. The aim of this study was to assess power output of lugers during the initial start phases, as a possible performance predictor. Methods Experienced lugers (4 female and 4 male) gave an informed consent for their routine training start attempts on the ramp to be videotaped and analysed. For each athlete the best out of 3 attempts was processed. Average power output during the start spurt phase (Ps), average power to reach maximal positive velocity in the spurt phase (Pmax), and average power to reach maximal backward velocity (Pback) were calculated as in (Bezodis et al., 2008). Sled velocity was estimated from 100 fps video records using Simi Motion analysis software. 2 start interval times – time to clear 3 m (t1) and 15 m (t2) distance on the slope – were used as performance criteria. Results For all athletes Pmax had the largest values among all power parameters; it ranged from 3104 to 3875 W in male group, and from 1584 to 2458 W in female group. Other power parameters showed larger relative differences within groups: Ps ranged from 334 to 867 in male, and from 187 to 394 W in female group; Pback 505 to 1293 for male, and 295 to 600 W in female group. From all measured variables only maximal velocity (Vmax) during the start spurt correlated with performance criteria (in male group only). Discussion From the preliminary study all calculated power parameters appear to be poor performance predictors. This is also true for values normalized to body mass. Vmax correlation with start time in male group is in accordance with Platzer et al. (2009) data; however, in female group correlation was not obvious. Average Pmax values normalized to body mass for both groups are comparable to values in snatch pull in weightlifting according to previously published data; absolute values tend to exceed the ones reported for weightlifters (Garhanner, 1991; Zebas et al., 2000). Given an emphasis is put on strength training in lugging, power output assessment might provide additional information for coaches and athletes. Nevertheless, using power output as a performance predictor is not justified so far. References Bezodis NE, Trewartha G, Salo A. (2008). 26th ISBS Conf Proc, 498-501. Garhanner J. ## PROPOSAL OF A NEW EVALUATION INDEX OF BICYCLE PEDALING SKILL. - USING WIRELESS MULTI-AXIS ACCELERATION AND ANGULAR VELOCITY SENSORS -

KITAWAKI, T., OKA, H.

*Okayama University*

Introduction: In order to evaluate bicycle pedaling skills, it is important to know how bicycle crank are rotate. Several previous studies, crank angle were measured on a road cycle via a potentiometer (Hull and Davis, 1981) or photo encoder (Chapman et al., 2006). Alternatively, it is possible to use a motion capture device to measure the rotation state of the crank (Trumbower and Faghri, 2004); however, this necessitates the use of a large-scale system in order to measure angles precisely. In this study, we propose a simple measurement system for the technical evaluation of bicycle pedaling for beginner or novice class cyclists. The system consists of small wireless sensor

units, and can simultaneously record the rotational state of the bicycle crank. Method: A wireless multi-axis sensor unit (9-axis motion sensor: Logical Products) was used for data acquisition. This unit was fixed to the bicycle crank in order to obtain the rotational state of the bicycle crank's acceleration and angular velocity data. Twenty-four male test subjects pedaled the road cycle which was attached to a bicycle trainer (Power Beam Pro: CycleOps) with a fixed rear-axis at 70, 100 rpm and preferred revolution. Wireless multi-axis sensor data was acquired for 25 seconds at a sampling rate of 1 kHz, and data recording was controlled by a soft-ware application (Logical Products). Results: In this study, several results have been obtained as follows: (1) Using wireless multi-axis acceleration and angular velocity sensors, the rotational state of the bicycle crank can be measured at a high accuracy and frequency. By averaging, the angular velocity for each crank angle is provided more precisely. (2) We propose an 'Angular Velocity Irregularity Index (AVII)' that is averaged root-mean-square error of the crank angular velocity per revolution. AVII depends on power and the number of revolutions. Additionally, the AVII has a tendency to be lower for an expert cyclist, and to be higher for beginners. (3) However, there are several beginner or intermediate cyclists having a low AVII. This shows the possibility that the AVII can become an evaluation index of the pedaling skill from the viewpoint of pedaling efficiency. Acknowledgments: This study was subsidized by JKA through its promotion funds from KEIRIN RACE. References: Chapman AR, Vicenzino B, Blanch P, Knox JJ, Hodges PW (2006). *J Sport Sci*, 24, 115-124. ## THE RELATIONSHIP BETWEEN THE KICK START AND LOWER-LIMBS MUSCLE STRENGTH IN SWIMMING

Suito, H.1, Nunome, H.2, Ikegami, Y.2

1:Aich Gakuin University (Nisshin, Japan), 2:Nagoya University(Nagoya, Japan)

Introduction Recently, the competing swimming was introduced the new start block with starting block. The start is one of the most important factors for swimming performance. The kick start using the new start block was reported significant improves start time than the traditional start (Ozeki et al., 2011). The kick start is like track start but uses a starting block by backward leg. The purpose of this study was to investigate the relationship between the start time and maximal isometric strengths of forward and backward legs. Methods Subjects in this study were 5 males Japanese competitive swimmers (Age = 20.4 ± 0.5 years, Height = 175.6 ± 7.0 cm, Weight = 65.7 ± 6.1 kg, freestyle(n=3), breaststroke(n=1), butterfly(n=1)). The start time of the subjects was measured by digital camera operating at 30 Hz in the transit time of head of 5 m from takeoff of foot during race of the national intercollege competition swimming. Maximal isometric strengths of knee extension were determined as peak torques using an isokinetic dynamometer. Results The average time of start at 5 m was 0.75 ± 0.04 s. The average maximal isometric strength of forward leg was 196.0 ± 42.1 Nm. The average maximal isometric strength of backward leg was 202.6 ± 67.4 Nm. Moreover, a significant correlation was obtained between the start time to 5 m and maximal isometric strength of forward leg ( $r = -0.911$ ,  $P < 0.05$ ). However, there was no significant correlation between the maximal isometric strength of backward leg and the start time to 5 m. Discussion From these results, it is suggested that isometric maximal strength of the forward knee extension influence the kick start. On the other hand, isometric maximal strength of the backward knee extension has an insignificant effect on the kick start. Therefore, it is possible that develop muscle strength of the forward knee extension was effective to improve of the kick start performance in competitive swimming. ## DIFFERENCES IN EMG ACTIVITY WHEN EXERCISING ON A STATIC AND MOVING ROWING MACHINE

Baca, A., Schöllauf, V., Kornfeind, P.

Institute of Sports Science, University of Vienna

Introduction Rowing machines are used for land-based training in periods of bad weather conditions. Two main modes of operation can be distinguished. In the static mode, the foot stretcher is stationary and the rower moves relative to the static rowing simulator. If the simulator itself rolls back and forth during the rowing stroke, a motion more similar to outdoor rowing may be expected (Elliott et al., 2002). Whereas comparisons of kinematics and reaction forces between the two modes have been reported (Kleshnev, 2005; Baca et al., 2006; Colloud et al., 2006), no such studies for EMG activity can be found. Methods Seven Austrian female and male subjects (21.0 ± 2.5 yr) with international competition experience participated in the study. A Concept2 (Concept2, Vermont, USA) rowing machine was operated both in the static mode and on slides (a construction that is attached to the legs), enabling rolling back and forth. The subjects exercised with 18 and 30 strokes per minute (SR18, SR30). EMG signals were derived from the m. biceps brachii (BB), m. triceps brachii (TB), m. deltoideus posterior (DP), m. teres major (TM), m. erector spinae (ES), m. vastus lateralis (VL), m. biceps femoris (BF) and m. gastrocnemius medialis (GM) with a wireless Delsys system (Bagnoli DesktopEMG) on the right side of the body. Results Significant differences (Wilcoxon,  $p < 0.05$ ) could be found for the pre-activation (ratio of the EMG amplitude at the beginning of the pulling phase and the maximum amplitude) of VL (SR18), BF (SR18) and GM (SR18, SR30), the maximum of the EMG-signals of BB (SR18, SR30), TB (SR30), DP (SR18, SR30), TM (SR18, SR30), ES (SR30) and VL (SR18, SR30), which was normalized to the average power during the pulling phase, the integral of the thus normalized EMG-data during the pulling phase of BB (SR18, SR30), DP (SR18, SR30), ES (SR30) and VL (SR18, SR30) as well as the duration from the beginning of the pulling phase until the maximum EMG-amplitude for DP (SR 30), TM (SR30) and GM (SR30). Discussion The present study suggests that the choice of the rowing machine influences muscular adaptation and affects the rowers' motor control pattern. Differences (in particular between pre-activation and the maximum amplitudes) are supposed due to different masses (rowing machine vs. body mass of subject) having to be accelerated/decelerated at the beginning of the pulling phase. Comparative studies in on-water rowing are required in order to draw further conclusions regarding the advantage of a specific rowing simulator modality. **EFFECTS OF WEIGHT TRAINING AND MARTIAL ARTS IN ANTHROPOMETRIC AND STRENGTH CHARACTERISTICS IN ADOLESCENT BOYS**

Ferunaj, P., Mara, F., Kavaĳa, G., Kuvarati, S., Skenderi, D.H., Erindi, A.

*University of Sports of Tirana*

**Introduction** Many adolescent boys are highly concerned about their body image perception and combined martial arts and weight training are preferred by them to improve muscle strength. Pubescent boys have presented a higher arm and thigh circumference in relation to prepubescent boys, and this fact may be explained due to the higher increase on the muscular mass in this maturational stage(1). However, there are controversial data determining the ratio of predominant factor for this change, growth age or physical training. **Methods** In the study 9 volunteer adolescents (mean age  $17 \pm 0.23$ ) undertook the 3 days per week, 1.5 hour per session, 16 weeks of mixed training, combination of taekwondo (45 minutes) and progressive weight training (45 minutes). We have measured the body mass, anthropometric traits (Chest, biceps, leg girth) and body fat percentage (%BF) via skinfold thickness (SKF) method (2). The maximal and endurance strength for major muscle groups was measured before and after training using 1 RM and 75% of 1RM, respectively. **Results** Body mass was increased from  $73.77 \pm 13.28$  kg to  $77.43 \pm 13.98$  kg and interestingly, body fat decreased from 18.43 % to 16.75 %. The decrease in body fat was parallel combined with anthropometric changes. Thus, pectoralis girth increased from  $87.8 \pm 4.32$  cm to  $90.35 \pm 5.82$  cm, biceps girth from  $30.2 \pm 2.45$  cm to  $32.17 \pm 2.61$  cm, leg girth from  $56.92 \pm 7.07$  cm to  $59.25 \pm 7.86$  cm. Maximal strength in back squat, dead lift and bench press was increased 23 %, 26 % and 18 %, respectively, whereas endurance strength 19 %, 22 % and 17 %. **Discussion** The major finding of this study was that martial arts and weight training was effective to improve maximal strength and anthropometric traits in adolescent boys. However, data from our study suggest that body weight status is not influenced by concurrent training. But despite of high intensity training, there was no decrease in body mass. Although we did not measure muscle mass, considering the increase in body mass and other anthropometric traits let us conclude that dominant factor for this change is the physical training and not age status. Furthermore, strength is clearly more closed to muscle size (3). However, the weak point of our study is the lack of control group. **References** 1. Hansen L, Bangsbo J, Twisk J, Klausen K. 1999. **THE EFFECT OF THROWING MOVEMENT IN VARIOUS RUN-UP SPEEDS FOR JAVELIN THROWERS**

Aoyama, S.1, Kanazawa, N.1, Aoyama, T.2, Tsunoda, N.2

*1: Kokushikan University. 2: Graduate School of Sport System, Kokushikan University.*

**Introduction** The javelin throw involves complex movements that run-up and throwing also run-up is an integral part of the javelin throw. Most studies of javelin throwing performance are final phase such as release parameters. However, no study has focused on between run-up and movement speed of javelin throw. Therefore the purpose of this study was to clarify the effect of throwing movement speeds in various run-up speeds for javelin throw. **Methods** The subjects were seven male right-handed javelin throwers (age:  $21.3 \pm 2.1$  yrs, height:  $174.9 \pm 5.9$  cm, body weight:  $80.6 \pm 6.0$  kg, PB:  $66.97 \pm 3.95$  m). All the subjects performed for total 6 throws. Details were two throw which same run-up speed as competition (CT), two 80% of CT (80%) and two 60% of CT (60%) for recorded best throw from each throw. The run-up speed was measured using by Speed meter (VINE, Japan) with attached to the waist. Throwing movement velocities of during the run-up were measured from the front and right side of the throwing area by video cameras operating at 60 frames per seconds and set at 1/250s shutter speed. It was used in DLT to 3-D coordinates of the digitized body and javelin parts (movement velocity of javelin: JV, movement velocity of right wrist: WV, movement velocity of right elbow: EV, movement velocity of right shoulder: SV). **Results** The results of this study were: CT was significantly higher than 80% and 60%. A significant correlation was observed between various run-up speed and javelin throw performance in all the throws ( $r=0.534$ ,  $p<0.05$ ). Also, CT of javelin throw performance was significantly higher than 60% of javelin throw performance. However, no significant differences in JV were observed between CT and 80% and 60%. Moreover, there were no significant differences between various run-up speed and WV, EV, SV. **Discussion** The run-up speed is one of the important contributions to javelin throw. In this study, there were no differences between movement velocity of JV, WV, EV and SV in various run-up speeds. In addition, there were no significant between various run-up speed and JV, WV, EV, SV. This means that it does not need to throw run-up of maximum speed to daily training of javelin throw technique. Therefore, run-up speed of 80% and 60% are good way to develop the correct movement and skill of javelin throw training. From these results, it was suggested that it is important factor to consideration for prevented injury of shoulder, elbow and wrist that can be expectation of better javelin throw technique and performance. **References** Mero A, Komi P.V., Korjus T, Navarro E, Gregor R.G. **BIOLOGICAL MATURITY INFLUENCES MATCH RUNNING PERFORMANCE IN JUNIOR FOOTBALL**

Gastin, P., Bennett, G.

*Deakin University*

**Introduction** Children and adolescents mature at different rates (Jackowski et al. 2011) such that individuals competing in the same competition may differ in physical and biological maturity despite being of similar chronological age. Despite the attempt to provide equitable junior competition through age group categories, early maturing adolescents are likely to have an advantage over their late maturing peers (Armstrong & Welsman 2005). Outcomes related to differences in physical and biological maturity may include selection bias, physical fitness, skill, drop-out and injury (Burgess & Naughton 2010). Whether differences translate into on-field performance in competition is relatively unknown. The purpose of this study was to investigate the influence of biological maturity on match running performance

in junior Australian football (AF). Methods Eighty seven players from an under 15 AF junior competition were categorised into early ( $n = 20$ ), average ( $n = 45$ ) and late ( $n = 22$ ) maturity groups based on self-reported assessment of biological maturity (Tanner 1978). Biological development was also assessed objectively from anthropometric measurements to estimate years from peak height velocity (PHV) (Mirwald et al. 2002). Running movements during competition were collected using GPS technology (SPI Pro, 5 Hz, GPSports, Australia), including measures of total distance, peak speed, high-intensity running distance (HIR;  $>14.4$  km/h), number of high-intensity efforts (HIE;  $>14.4$  km/h) and number of sprints ( $> 23$  km/h). Results On average, there was a 0.9 year difference in the timing of PHV between the early and late maturers, although the range spanned a period of 2.7 years. Early maturers were significantly ( $p < 0.05$ ) heavier and taller than all other boys, with longer upper and lower bodies. Running distance, HIR and HIE were significantly greater in the early maturers compared to both average and late maturers. No differences were observed between groups in the number of sprints or the peak speed obtained during competition. Discussion Individuals within the same chronological age group varying considerably in physical and biological maturity. This translates into enhanced running performance during match competition in early maturing boys, placing them at a performance advantage to their less mature peers. Holistic models of talent development that acknowledge these differences and in particular cater for late developing players should be encouraged. References Armstrong N, Welsman J. ### 'ON YOUR MARKS': LAST CHANCE FOR NEUROMUSCULAR ACTIVATION

Smirniotou, A., Katsikas, C., Zacharogiannis, E., Dallas, G., Paradisis, G.

*Kapodistrian University of Athens*

Introduction Starting action in sprinting, as this is defined by RT and initial acceleration after block clearance, is a complex motor action which critically affects sprint performance. It requires high neuromuscular activation and explosive force production exerted on the blocks. The purpose of this study was to explore the effectiveness of specific dynamic actions usually performed by athletes using their body weight as well as mechanical stimuli - vibration, in order to produce neuromuscular activation the 'very last moment' just behind the blocks. Methods 16 male PE students with no starting experience participated in this preliminary study. After the 'On your marks' signal, all subjects, replicating the usual dynamic actions executed by athletes behind the blocks as supplementary 'last moment' neuromuscular activation, underwent the following conditions, in a random order, for 3 sec each : 1. No action behind the block 2. Tuck jumps 3. Power lunges. 4. Activation on vibration platform (Power Plate – 30Hz, 2.5mm). Before testing, all subjects followed a 30 min specific warm up protocol comprised of sub maximal running, dynamic stretching and sprint specific dynamic activities (Behm and Chaouachi, 2011). Afterwards, they performed three 5 m sprints from blocks for each condition. Each condition was tested in a separate day. Reaction times (RT) were recorded (ReacTime-Lynx) as well as times at 2.5m and 5m from the blocks (photocells - Polifemo, Microgate). The best 5m performance was used in the statistical analysis. Results ANOVA with repeated measures was used to compare performance after each condition. Where appropriate, post hoc analysis was carried out (Bonferroni). The level of significance was set at  $P < 0.05$ . Significantly better performance was found in RT ( $P = 0.01$ ) and 2.5m ( $P = 0.027$ ) only for the vibration condition. Discussion In the present study, the 'last moment' very short duration dynamic stretches (lunges) and activities (tuck jumps) did not enhance performance. The vibration condition though did have a positive effect in block clearance. A possible explanation could be that the mechanical stimuli caused by vibration enhances motor neural activation leading to powerful muscle contractions (Bosco, 1998). Since practically is not possible to use vibration platform before starting, further research could explore if acute and 'quick' stimulating activities just behind blocks (e.g quick feet skipping) could possibly be more effective than lunges or jumps. ### THE EFFECT OF DIFFERENT FREQUENCY OF WHOLE BODY VIBRATION IN DIVERS' FLEXIBILITY AND EXPLOSIVE STRENGTH OF LOWER LIMBS

Dallas, G., Paradisis, G., Tsiganos, G., Argeitaki, P., Smirniotou, A.

*KAPODISTRIAN UNIVERSITY OF ATHENS*

Introduction Flexibility and explosive strength of lower limbs are significant factors in diving. The purpose of this study was to examine the acute effect of different Whole Body Vibration (WBV) frequencies on diver's flexibility and explosive strength of lower limb. Methods Eighteen male and female competitive divers (Mage  $15.00 \pm 4.47$  years, body mass  $48.61 \pm 14.97$  Kg, Height  $159.38 \pm 13.36$  cm and Body fat %  $14.15 \pm 5.31$ ) volunteered to participate in this study. The sample was assessed under different intervention programs a) vibration program with low frequency (30 Hz) and amplitude (2 mm) (LFA) b) vibration program with high frequency (50 Hz) and amplitude (4 mm) (HFA) and c) Non Vibration program (NVP). Each intervention program consisted of a single repeated bouts session lasting for 2 minutes. The following tests were done before-pre and after-post each intervention program: a) flexibility (sit & reach test), and b) explosive strength of lower limbs under 3 different tests a) Squat Jump (SJ), b) Counter Movement Jump (CMJ), c) Single Leg Jump for the Right (RL) and Left Leg (LL). Results A two-way ANOVA (day\*trials) with repeated measures on both factors was used. Univariate analysis with Bonferroni adjustments (.05/3) were selected as post hoc tests. There was significant interaction between day \* trials with respect to: a) sit & reach ( $p = .001$ ), b) SJ ( $p = .004$ ), c) RL ( $p = .017$ ). However, no interaction effect between day \* trials was found with respect to a) CMJ and LL ( $p > .05$ ). Discussion The results support that both vibration intervention programs showed a great percentage of improvement on flexibility compared to NVP. Further, vibration programs is an effective method to maintain the gain in explosive strength of lower limbs immediately after, whereas NVP failed to maintain the initial values in this test. The athletes underwent the vibration programs showed an improvement on flexibility and explosive strength, while the athletes of NVP showed no significant effect between pre and post sessions. Further, the improvement through vibration programs was significant higher than the NVP. References Bazett-Jones DM, Finch HW, Dugan EL. (2008). ## THE EFFECT OF NAP ON MOTOR LEARNING: DOES AN ADVANTAGE OF NAP AFTER MOTOR LEARNING CONTINUE IN THE FOLLOWING DAY?

Morita, Y.1,2, Ogawa, K.3,4, Uchida, S.1,4

1 Waseda University, 2 Research Fellow of Japan Society for the Promotion of Science, 3 Hiroshima University, 4 Future Institute for Sport Sciences

**INTRODUCTION:** Past studies have presented that beneficial role of sleep in motor memory consolidation. In our previous study, we revealed that motor performance was improved by 2-hour nap after motor learning compared to staying awake. However, a question arises whether the effect of nap reflects on the following day's performance after a nocturnal sleep. Regardless of taking a nap after motor learning or not, if following day's performance could be improved equally, it is useless to use a nap in a practical sense. The purpose of this study is to examine whether an advantage of nap after motor learning continues in the following day. An additional purpose of this study is to examine whether the less than 2 hour nap facilitate performance. **METHODS:** Subjects were 12 college students. They were divided into nap group and control group. All subject practiced three-ball cascade juggling for 15min, and juggling technique was evaluated at 1030h (test). After the test, nap group took a 70min nap from 1400h while control group stayed awake. Both groups retested juggling at 1730h (retest 1). The following day, both groups retested again at 1030h (retest 2). Juggling performance was quantified as the catching number. Analysis carried out using two-way ANOVA (group: nap, control  $\times$  time: test, retest). **RESULTS:** The mean number of catches in nap group was  $4.76 \pm 1.43$  (mean  $\pm$  SD), and in control group was  $4.01 \pm 2.48$ . There were no differences of juggling performance between nap group and control group in the test. In the retest 1, mean number of catches in nap group was  $8.39 \pm 2.20$ , whereas in control group was  $5.23 \pm 3.49$ . In the retest 2, mean number of catches in nap group was  $14.52 \pm 6.57$ , whereas in control group was  $7.24 \pm 4.44$ . There was a main effect of test time ( $p < 0.001$ ), and significant group  $\times$  time interaction ( $p < 0.05$ ). The result of simple main effect test, in nap group, the mean number of catches was significantly increased from test to retest 1 ( $p < .001$ ). Similarly, the mean number of catches increased significant from test to retest 2 ( $p < .001$ ), and from retest 1 to retest 2 ( $p < .005$ ) in nap group. Furthermore, in the retest 2, the mean number of catches in nap group was significantly large compared to the control group ( $p < .05$ ). **DISCUSSION:** Data from juggling performance, when it took a nap after motor learning, it was shown that the performance in the following day improved more greatly. This result indicated that an advantage of nap after motor learning continued in the following day through the nocturnal sleep. It showed that performance was facilitated by 70min nap shorter than 2 hours.

## ARE PHYSICAL ACTIVITY AND FUNDAMENTAL MOTOR SKILLS RELATED AT THE AGE OF FOUR?

Iivonen, S.1, Mehtälä, A.2, Sääkslahti, A.1, Tammelin, T.3, Kulmala, J.3, Villberg, J.2, Poskiparta, M.2

1:University of Jyväskylä, 2:University of Jyväskylä, 3: LIKES Research Center for Sport and Health Sciences

**ARE PHYSICAL ACTIVITY AND FUNDAMENTAL MOTOR SKILLS RELATED AT AGE FOUR?** Iivonen, S.1, Mehtälä, A.2, Sääkslahti, A.1, Tammelin, T.3, Kulmala, J.3, Villberg, J.2, Poskiparta, M.2 1: Department of Sport Sciences, 2: Research Centre for Health Promotion, University of Jyväskylä, 3: LIKES Research Center for Sport and Health Sciences, Jyväskylä, Finland **INTRODUCTION** Research lacks knowledge regarding the intensity of physical activity (PA) that preschool children need for the sufficient fundamental motor skills (FMS) necessary to be physically active (Stodden et al. 2008). This study aims at determining if different intensities of PA and FMS are related at the age of four. **METHODS** The data was collected during autumn 2011 from 26 boys and 32 girls (mean age  $4.12 \pm 0.33$  years). PA was measured objectively for 5 consecutive days (for at least 2 weekdays and 1 weekend day) using the ActiGraph GT3X accelerometer and FMS by APM Inventory (Numminen 1995). The FMS measures were 1) right- and left- foot static balance, 2) dynamic balance, 3) standing broad jump, 4) sliding and galloping, 5) throwing and catching combination, 6) throwing at a 2m target, 7) kicking a ball at a target and 8) sum score of manipulative skills (5–7). PA was classified by intensity cut-points established by Van Cauwenberghe et al. (2010). The Mann-Whitney U-test and the Pearson correlation coefficients analyzed the differences between the two genders and the relationships between average weekday and weekend-day PA and FMS. PA was categorized as total (counts per min.), light (373–584), moderate (585–880) and vigorous ( $\geq 881$ ) and combined categories of LMVPA ( $\geq 373$ ) and MVPA ( $\geq 585$ ). **RESULTS** Boys had more moderate PA during weekdays than girls ( $p = 0.035$ ). Among girls, several significant ( $p \leq 0.05$ ) positive correlations ( $R = 0.42$ – $0.48$ ) were observed between PA and FMS. The significant relationship was observed between throwing and the 2 categories of moderate and LMVPA for weekdays, and the 5 categories of light, moderate, vigorous, LMVPA and MVPA for weekend days. The similar correlations were found between manipulative skills and light PA for weekdays, and light and moderate PA for weekend days. The highest correlations were observed between throwing and light PA for weekdays ( $R = 0.52$ ), manipulative skills and light PA for weekend days ( $R = 0.55$ ) and manipulative skills and MVPA for weekend days ( $R = 0.53$ ). PA was not related to FMS among boys. **DISCUSSION** Boys were more physically active than girls during weekdays at the age of four. PA was related to FMS among girls, but not among boys. Even light PA was positively related to girls' manipulative skills, both during weekdays and weekend days. One reason for this might be that the nervous system in girls developed earlier than in boys. **REFERENCES** Numminen, P. 1995. APM-Inventory. Jyväskylä: LIKES. ## EFFECT OF PHYSICAL EXERCISE ON ATTENTIONAL FUNCTIONING IN YOUNG ADULTS

Moratal, C., López-Ramón, M.F., Monleón, C., Pablos, A., Blasco, E., Lupiáñez, J., Huertas, F.

Universidad Católica de Valencia

**Introduction** Many authors have shown the benefits of regular physical exercise on physical and psychological abilities in all ages (Bouchard et al., 1990; McMorris et al., 2009). According to Posner and Petersen (1990), attention modulates perception and action by three different attentional networks: alertness, orienting and executive control. The ANTI-Vigilance (ANTI-V) is a new version of the ANTI (Callejas et al., 2004) that measures vigilance in addition to the above mentioned attentional functions and their interactions. In other previous studies performed by our group, we described the influence of physical exercise and sports practice on children's cognitive functioning. The present research aims to study whether practice of physical exercise (systematic or unsystematic) improves perceptual-motor performance in general, and more specifically, in young adults attentional networks functioning. **Methods** A sample of university students performed the ANTI-V. Reaction Time (RT) and accuracy were registered. Moreover, participants completed a questionnaire to collect data about their physical activity profile (systematic practice / unsystematic practice / no practice, and modality: open vs. close tasks, and hours of practice /week). **Results** Results showed a reduction in alertness and an increased in orienting on practitioners of systematic physical activity compared to non-practitioners or practitioners of unsystematic physical activity. Also, those participants who exercised regularly for more hours a week had a positive impact on attentional performance compared to those who less exercised. No interaction between

executive control functioning and physical exercise related variables were found. Discussion Results seems to indicate that systematic practice of physical activity improves cognitive processing as demonstrated by previous studies (BrainWork, 2002). The practice of physical exercise is associated with segregation of IGF-1 by muscle that stimulates the production of BDNF (Brain-derived neurotrophic factor), a neurotrophin related to nerve growth factor, located mainly in the hippocampus and in the cerebral cortex. This might be the mechanism by which physical exercise helps to improve cognitive and sensory functioning of the brain. These evidences would justify the need of promoting physical activity programs in young adults who are one of the populations that usually abandon the practice of sports and physical activity. ### THE EFFECT OF WATER IMMERSION ON SHORT AND LONG AFFERENT INHIBITION, SHORT INTRA CORTICAL INHIBITION AND INTRA CORTICAL FACILITATION IN HUMAN

Sato, D., Yamashiro, K., Yoshida, T., Onishi, H., Shimoyama, Y., Maruyama, A.

*Niigata University of Health and Welfare*

**Introduction** Water immersion can alter numerous physiological parameters depending on physical characteristics like buoyancy, hydrostatic pressure, and temperature. We have examined the effects of water immersion on cerebral cortical activities, and proposed that water immersion influences the cortical processing of somatosensory inputs (Sato et al., 2012). This result might imply that water immersion affect the sensorimotor processing. Therefore, the aim of the present study was to investigate the effect of water immersion on short and long afferent inhibition (SAI and LAI), short intra cortical inhibition and intra cortical facilitation (SICI and ICF). **Methods** Motor evoked potentials (MEPs), SAI, LAI, SICI and ICF were measured for seven healthy males at rest before, during and after the 15-minute water immersion. SAI and LAI were evaluated by transcranial magnetic stimulation (TMS) protocol based on coupling peripheral nerve stimulus with TMS of the motor cortex. MEPs induced with TMS were conditioned by painless electrical stimuli applied to right median nerve at interstimulus intervals (ISIs) of 20 and 200ms. The intensity of the stimulus was fixed at about three times the sensory threshold. SICI and ICF were tested using the paired-pulse TMS paradigm. MEP was recorded from first dorsal interosseous (FDI) muscle. The water level was allowed to reach the axillary level, and during the experiment, room and water temperatures were maintained at 30°C. **Results** SAI and LAI were reduced during water immersion (101.4±12.9% and 64.4±10.1%) compared with before and after water immersion (before: 67.5±9.7% and 41.2±14.9%, after: 63.4±10.0% and 40.4±13.1%). SICI and ICF were not significantly different among three conditions (before, during and after water immersion). **Discussion** Water immersion decrease short and long afferent inhibition in human. Tamburin et al. (2001) have suggested that increased sensory receptive field might induce summation of the SAI due to 'centripetal gating' mechanism or a 'floor effect'. Our previous research have clarified that water immersion to the axillary level has a centripetal gating effect on short-latency somatosensory evoked potentials (SEPs) (Sato et al., 2012) and increases the amplitudes of long-latency SEPs. Therefore, the present data suggested that the change in sensory input induced decreasing SAI and LAI during water immersion. **References** Tamburin S, Manganotti P, Zanette G, Fiaschi A. #### THE SUPPORT OF PARENTS WHEN CHILDREN CHOOSE THE SPORT DURING THEIR LEISURE TIME. CASE STUDY IN SCHOOL PIA BALMES

Franco-Sola, M., Sebastiani, E.M., Figueras, S., Guerra, M.

*Universitat Ramon Llull*

**INTRODUCTION** The aim of this study was to identify the influence of parents in decision making when children from 8 to 12 years old choose a sport. This study is part of a single case study conducted during 2010-2011 school year, in the School Pia Balmes (Barcelona, Spain), about the perceptions of school sports activities for students. **METHODOLOGY** Case Study of School Pia Balmes. The study sample was 204 children, 111 boys and 93 girls, aged 8-12 years and, therefore, corresponds to 3rd until 6th Primary. The instrument was a questionnaire related to the amount of sport played and motivation to practice these sports in school. We used SPSS (v15.0.1) for data processing. A descriptive statistical analysis was prepared by knowing the frequency of the different variables raised. **RESULTS** Our results show that as children grow, there is less influence of parents in deciding which sports they will practice. The 46.5% in 3rd Primary ensure their chose sport with the help of their parents. And when they get to 6th grades, the 80% of children says that they chose the sport alone, without the help of their parents. **DISCUSSIONS AND CONCLUSIONS** The autonomy of children in the choice of sport is increasing in size as they get older. Parents also advise the younger students. Therefore, we conclude that it is important that the families should not be separated from their child meanwhile practicing sport, in order not to crash the motivation and, consequently, the sport during adolescence. **REFERENCES** - Blázquez, D. **SELF-ESTEEM AND POSTURE: AN INNOVATIVE PROGRAM OF PEDAGOGIC AND POSTURAL TRAINING**

Bellafiore, M., Battaglia, G., Caramazza, G., Storniolo, F., Costantino, D., Bianco, A., Palma, A.

*University of Palermo*

SELF-ESTEEM AND POSTURE: AN INNOVATIVE PROGRAM OF PEDAGOGIC AND POSTURAL TRAINING Bellafiore, M.1,3, Battaglia, G.1,3, Caramazza, G.2,3, Storniolo, F.1, Costantino, D.3, Bianco, A.1,3, Palma, A.1,3. 1: DISMOT (Palermo, Italy), 2: PhD in "Human Diet and Nutrition" (Palermo, Italy), 3: Regional Sport School of Sicily CONI (Olympic National Italian Committee, Italy). Introduction It is known that exists a strong interaction between psycho-emotional aspects and postural system. A deficit in self-esteem can be associated with an altered conception of own body image which reflects itself in the behavior and posture of the person. The aim of this study was to evaluate the influence of a program of body pedagogy and postural recovery on thoracic hyperciphosis and low level of self-esteem in adolescents. Methods Ten female subjects (age:  $15.5 \pm 1.4$  years; weight:  $56.0 \pm 5.1$  kg; height:  $160 \pm 3.0$  cm; BMI:  $21.9 \pm 1.8$ ) and ten male subjects (age:  $15.3 \pm 1.8$  years; weight:  $67.3 \pm 5.8$  kg; height:  $170 \pm 4.0$  cm; BMI:  $21.9 \pm 1.8$ ) with thoracic hyperciphosis (Cobb angle:  $45-55^\circ$ ) and low level of self-esteem (PSDQ index  $< 2$ ) were selected from a center of global postural re-education and recruited to participate in a 6-month training program for 1 hour 6 times per week. In particular, 3 hours/week were addressed to treatment of postural alteration through the application of Pilates, Mezieres and RPG methods; while the other 3 hours/week were aimed at the body education using Feldenkrais and Gendlin methods. Before, during (3 months) and after 6 months of training program, ciphotic curve and self-esteem level were assessed measuring Cobb angle and with Physical Self-Description Questionnaire (PSDQ) respectively (Marsh, 1996). One-way ANOVA test with Bonferroni's correction was used to analyze significant differences ( $p < 0.05$ ). Results After 3 and 6 months of body education and postural recovery, we found a significant reduction in Cobb angle in both genders ( $p < 0.001$ ), who did not show any difference between them ( $p > 0.05$ ). This structural modification was associated with an increase in the self-esteem level in both groups; however, the growth trend was significantly different between the two genders. In particular, we noticed that self-esteem was higher in female than male adolescents after 3 months ( $p < 0.001$ ); while in men increased more in the 3-6 month period ( $p < 0.05$ ). Discussion The results of our study indicate that there is a similar response to our program of body pedagogy and postural recovery by two genders as concern to the morphological features but different in the psycho-emotional aspects. This program can be a helpful method for reducing either postural alterations in brief time and the risk of relapses in adolescents because it has positive effects on self-esteem, one of the factors contributing to postural habits. **CONTEXTUAL INFLUENCES ON YOUTH ATHLETES' DEVELOPMENT AND ENJOYMENT**

Santos, A.1, Diogo, F.1, Goncalves, C.E.1

*University of Coimbra - NIF 501617582*

Introduction The youth in development suffer influences from the context were is inserted (Bronfenbrenner, 1999), having the sport programs a potential to promote positive youth development (Urban, Lewin-Bizan, & Lerner, 2009). For adhesion and maintenance in sport the enjoyment is consider a major factor (Scanlan, Carpenter, Lobel, & Simons, 1993). The purpose of this study is to verify the influences of different contexts, type of organization and demographic, in youth sport enjoyment and positive development. Method Three Portuguese soccer clubs of different contexts (one professional club (PC) and two amateur – one of rural area (RAC), other of urban area (UAC) were selected. And the athletes ( $n=225$ ), with ages between 12 and 18 ( $15.06 \pm 1.64$ ), respond to the Sources of Enjoyment in Youth Sport Questionnaire, Sport Attitudes Questionnaire and Development Assets Profile. To select the professional club it was used the criteria of being on the Portuguese Professional Soccer League. For the amateur ones, it was a district competition level, and the case of urban and rural, the demography, accessibilities and local economy base. For the data analyses it was performed a MANOVA and LSD post-hoc test. Results The dependent variables are influenced by club context (25%,  $p=.000$ ) and the age echelon (15%,  $p=.001$ ). The groups showed significant differences by club and echelon in the peers affiliation ( $p=.009$ ;  $p=.001$ ), convention ( $p=.000$ ), effort ( $p=.000$ ,  $p=.002$ ), support ( $p=.002$ ,  $p=.034$ ), learning commitment ( $p=.010$ ,  $p=.045$ ) and familiar ( $p=.006$ ,  $p=.008$ ), having the RAC athletes register the lower scores. Conclusions This shows that the athletes practice context influences some variables of the sports attitudes, the sources of enjoyment and the development assets. Also, the PC and UAC athletes' characteristics are more similar between themselves than with RAC. The RAC context appears a disadvantage factor for positive developmental, maybe due to organizational or local context. References Bronfenbrenner, U. (1999). **THE EFFECT OF THE SOCCER CLASS TAKING INTO ACCOUNT IMPROVEMENT IN PHYSICAL FITNESS : FOCUSING ON THE GAMES WITH CHANGING PITCH AREA PER PLAYER**

Tsuda, R., Inoue, A., Suzuki, K., Marutani, Y.

*Kanazawa Medical University*

THE EFFECT OF THE SOCCER CLASS TAKING INTO ACCOUNT IMPROVEMENT IN PHYSICAL FITNESS : FOCUSING ON THE GAMES WITH CHANGING PITCH AREA PER PLAYER Ryosuke T. 1, Akihiro I. 2, Koya S. 3 and Yasuhiko M. 4 1 : KMU (Ishikawa, Japan), 2 : KSU (Ishikawa, Japan), 3 : TGU (Miyagi, Japan), 4 : UJH (Ishikawa, Japan) Introduction It has been suggested that small-sided games in football enable players to improve their physical fitness if conditions for the games, such as the court area per player and player number, are adjusted appropriately (Hill-Hass et al., 2011). However, no study based on this knowledge has yet been conducted in PE classes. The purpose of this study was to examine the effect of playing small-sided games of soccer with changing pitch area per player in PE classes. Methods Two types of small-sided games, "pitch area per player was smaller", and "pitch area per player was larger", were played by two first year junior high school PE classes. 20 students participated in the game with pitch area per player was smaller (S group), and 20 students participated in the game with pitch area per player was larger (L group). Before and after classes, a skill test (ball lifting), a fitness test (150m sprint with changing direction ;  $25m \times 6$ times, rest interval 30s), and a test game were conducted. In addition, students' formative evaluation was conducted after each class. Results and Discussion The result of the first set of 150m sprint with changing direction was improved significantly after class in the S group. This result suggests that improvement of anaerobic power could be obtained in use of small-sided game, pitch area per player was smaller. On the other hand, the mean time for 6 sprints was improved significantly after class in both groups. This result suggests that improvement of aerobic capacity could be obtained regardless of whether they played the

game with pitch area per player was smaller or larger. The distance covered and heart rate during the game were increased significantly after classes in L group. In addition, the score in students' formative evaluation tended to increase as class progressed in L group. Conclusion These results suggest that improvement of energy-related physical fitness could be obtained without compromising students' interest and volition in use of small-sided game, pitch area per player was larger. ### **MOTIVATIONAL CLIMATE IN PHYSICAL EDUCATION: A COMPARISON BETWEEN THE PERCEPTIONS OF STUDENTS FROM CLASSES OF BEGINNING TEACHERS AND EXPERIENCED TEACHERS.**

Martins, J.1, Marques, A.1, Sarmiento, H.2, Carreiro da Costa, F.1,3

1: CIPER, Faculty of Human Kinetics, Technical University of Lisbon; 2: University of Trás-os-Montes and Alto Douro; 3: Lusophone University of Humanities and Technologies

Introduction: Motivational climate (MC) plays an important role on students' physical activity (PA) participation. Therefore, it is important to investigate whether beginning teachers were trained in promoting a proper MC. This study aimed to examine the MC prevailing in physical education (PE) classes as well as to compare the perceptions on MC between students of beginning teachers and those of experienced teachers. Methods: A total of 423 students, aged from 15 to 18, participated in the study. They attended 8 public schools, from 10th to 12th grade. One hundred and eighty nine beginning teachers' students (44.7%, age 15.9±1.1, 98 boys, 91 girls) and 234 experienced teachers' students (55.3%, age 16.3±0.9, 92 boys, 142 girls) were assessed using Papaioannou et al.'s questionnaire (2007), validated for the Portuguese population. The students' perceptions were measured with emphasis on mastery, performance-approach and performance-avoidance goals. Individual (and not class) was considered as the unit of analysis. Experienced teachers had more than five years of teaching. Results were compared by using student's t-test. Results: Ranging on a scale from 1 to 5, the mean levels of beginning teachers' students perceptions of mastery-involving climate were high (3.8±1) and did not differ significantly (p=0.259) from those reported by experienced teachers' students (3.7±0.9). However, these results suggest that a mastery climate could be even more emphasized by both types of teachers. According to student's views, beginning teachers emphasized significantly higher values of performance-approach goals than experienced teachers (3±1 vs. 2.8±1; p<0.05). Finally, beginning teachers' students also perceived a higher performance-avoidance environment (2.1±1) than experienced teachers' students (1.79±0.8), and significant differences were observed (p<0.05). A tight control of all aspects of decision-making by beginning teachers, as well as interventions emphasizing normative comparison, might explain these results. Discussion: Beginning PE teachers emphasised performance-approach and performance-avoidance goals more than experienced teachers. More challenging tasks and a positive evaluation for personal improvement should be delivered to all PE participants. Future research concerning affective, behavioral, and cognitive learning outcomes is needed to provide a holistic perspective to help teachers implement methods that will enhance student participation in lifetime PA. ### **PRELIMINARY STUDY AIMING TO IDENTIFY THE CONDITIONS OF IMPLEMENTATION OF A PROJECT INTEGRATING PHYSICAL ACTIVITY FOR 10-16 YEAR-OLD CHILDREN WITH CANCER IN A HOSPITAL CONTEXT**

Cloes, M.1, Del Guidice, A.2

University of Liege

Introduction Today, it is considered that, in children with serious illnesses such as cancer, physical activity during treatment has beneficial effects (physical and mental well-being, self-confidence and self-esteem ...)(INSERM, 2008). However, it is important to notice that physical activity has to be appropriate according to the circumstances (Herbinet, 2002). If some programs begin now to be offered in some hospitals, a lack of resources suitable for children and adolescents appears to be the norm. This study aimed to identify needs and resources for the implementation of a project like this in the department of Hematology Oncology at a hospital in the region of Wallonia, Belgium). Methods In this perspective, we interviewed various members of the medical and paramedical staff (n = 20), young patients (n = 8) and their parents (n = 5). This triangulation process aimed to guarantee the validity of the data. The semi-structured interviews were focused on the representations of these subjects about physical activity at the hospital in young people with cancer (definition of physical activity, opportunities and habits of the young patients to exercise, benefits and risks of being active) as well as about their opinions about the characteristics of the actions to implement (type of activities, recommendations, needed resources and conditions). Respecting the principles of the qualitative research, a content analysis of the answers has been conducted. Results Most of the subjects supported this type of project. Five categories of activities have been identified (adapted ball games, soft gymnastics, group fitness classes, relaxation activities, outdoor activities). A daily medical monitoring has been emphasized while precautionary measures have been listed, as well as the resources of the human, material, organizational and financial aspects that would be needed. Discussion Our findings show that hospitalized children no longer practice physical activity and that availability of specialized physical educators would encourage them to meet their expectations to be more active. Adults recognize that the implementation of these activities would have many physical and psychological benefits for children. They emphasize that individualization is at the center of the intervention. This would require the development of multidisciplinary collaboration. The funds seem less relevant than the presence of a promoter. References Herbinet, A. ### **MOTIVATION TO GO INTO SPORTS OF LATVIA YOUNG PEOPLE**

Porozovs, J., Porozova, D.

Riga Teacher Training and Educational Management Academy

Introduction Sport pedagogues must turn great attention for rousing interest of young people to physical activities. Perceived competence, self-determination and self-motivation are important factors in promoting of lifelong physical activity and development of talent in children (Collins et al, 2010). Methods The questionnaire of 15-18 years old Latvia young people actively participating in sport exercises was carried out. 289 young people were questionnaire. Results The results of investigation showed that 33% of questionnaire young people attend sport exercises in order to reach high results in competitions and become high-class sportsmen, 28% - in order to rise physical condition

and keep good health, 24% in order to acquire new skills, 9% to enjoy sport exercises, 3% in order to meet friends, 2% to keep family traditions etc. 94% of questionnaire young people are fond of sport exercises. As negative factors which hamper participating in sport exercises young people mention lack of time (28%), bad level of sport equipment (10%), difficulties in training process (9%), disagreements with coach (7%), disagreements with other sportsmen (7%), problems with health (6%), etc. The motivation to go into sports is very closely connected with the fact that majority of questionnaire young people have accepted sports as part of their life and also with motivation to reach high results. The main reasons for leaving sports of Latvia young people are following: other interests not connected with sports (16%), injuries and traumas (13%), inability to reach high results in sports (12%), interest about other branches of sports (11%), high level of competition (11%), disagreements with coach (7%), disagreements with other sportsmen from group (6%), hard training exercises (4%) etc. The majority of young people started their sport activities by their own decision (62%) or by advice of parents (14%). Only 7% of young people started to attend sport exercises as a result of suggestion of sport pedagogues. 61% of questionnaire young people consider that they train during sport exercises accordingly their abilities but 39% admit that they could do it harder. Discussion Sport pedagogues must pay more attention to problem of motivation of young people to go into sports. The personality of sport pedagogue has great role in forming motivation to go into sports and reaching high results of young people. If coach knows the main motivations of sportsmen he or she could use it for reaching of the goals. Instead of early specialization all-round sport activities are suitable for children moreover pleasure and enjoyment are especially important. References 1. Collins, D., Martindale, R., Button, A., Sowerby, K. Building a physically active and talent rich culture: An educationally sound approach. ### **RUN TEST AFTER FIVE YEARS: DATA ON A POPULATION OF URBAN SEDENTARY STUDENTS**

Frattini, G., Vago, P., Casolo, F., Bruseghini, P., Merati, M., Lovecchio, N.

*Catholic University of Milan, Italy*

Introduction Urban environment may effect the physical practice, of the student population. Many sporting facilities are present in a city but sedentary approach is more typical in a city than in a rural environment. Often, in a large city (like Milano) students play sport or engage in physical activity only during physical education classes (1). The purpose of this study was to compare the same physical performance after five years: during the first and last years of high school course. Material and methods During the first month of high school (September 2005) the Physical Education teacher assessed the 1000m run test to their student. After five years (September 2011) 196 students (108 male and 88 female) repeated the test. All phases of the test were carried-out by the same teacher in the same path (out-door). All students were sedentary and lived in the city since their birth. Results In the first session boys spent 5min ( $\pm 28$ s) to cover the path while girls used 42s ( $\pm 43$ sec) more than male (340 s). No girls used less than 300 sec while only one boy run 1000m more than 360sec. After 5 years the 70% of boys increase the performance using, on average, 42s less to cover the run distance. The girls showed a poor improvement: only 55% of them decrease the time. Mean speed of the girls was 2,96m/sec. Both boys and girls decrease the mean variation: boys from 37 to 34sec; girls from 43 to 30sec. The best gaps between the two tests were 60sec and 94sec for females and males respectively. No significant correlations were found between time spent and anthropometric characteristics. Also, after five years, the performance did not correlate with weight and height:  $r=0,006$ ;  $r=0,21$  and  $r=0,28$ ;  $r=0,19$  within male and female respectively. Discussion The current data show population's characteristics that seem specific of a city environment. Indeed only the sedentary students who play games and perform physical activity during Physical Education classes showed improved running performance (2). The boys obtained better results than the girls both in terms of the number of students showing an improved performance as well as in the magnitude of the improvement. Therefore the Physical Education courses, in an urban context, are a precious element to contrast the sedentary life style (3) and to reduce the drop-out. References 1. Ozdirenç et al. ### **SPORTS AND EXERCISE SAFETY IN FINLAND : A NATIONWIDE IMPLEMENTATION CASE TO TEACHERS AND COACHES**

Jussila, A.M., Oksanen, R., Pasanen, K., Parkkari, J.

*UKK Institute for Health Promotion Research*

Introduction Sports activities are considered to be beneficial to health. On the other hand, participating in sports can also be dangerous by increasing the risk of acute and overuse injuries. Number of sports injuries has increased considerably in Finland during the past decades. Today sports injuries are the most common injury type in our country. Treating of these injuries is often difficult, expensive, and time consuming. The purpose of The Sports and Exercise Safety in Finland program (LiVE) is to increase physical activity in general and safety of sports and exercise in a nationwide setting. Methods LiVE research projects focus on sports-specific injury incidence, risk factors, mechanisms and prevention strategies. Study findings are delivered to the field by communication and education. Implementation of injury prevention is conducted in two nationwide campaigns, Healthy Athlete (2006-) and Safety in School Sports (2010-). The main target groups are young athletes (age 12-20) and their coaches and parents but also elementary school pupils (grades 7 to 9) and their teachers. LiVE programs main communication and education channels are websites: [www.terveurheilija.fi](http://www.terveurheilija.fi) and [www.tervekoululainen.fi](http://www.tervekoululainen.fi). Results Two large randomized controlled studies have been carried out, one among female athletes (Pasanen et al. 2008) and another among army recruits (Parkkari et al. 2011). Also, numerous original studies of injury epidemiology in different sports have been published. The findings of these studies have indicated that sports injuries are true public health problem in Finland. However, a remarkable part of these injuries can be prevented by enhancing awareness of injury risks, increasing quality and contents of training and drills, and taking care of safety environment and equipment in sports. During 2006-2011 LiVE program has educated 70 LiVE-tutors (LiVE education lasts for 1-year) who work in different organisations (e.g. Finnish Ice Hockey Association, Finnish Gymnastic Federation and Judo Federation). In addition, LiVE program has appeared annually in about 30 different events (e.g. European Youth Olympic Summer Festival 2009, Power Mover 2011, Floorball World Championship 2010, PE teachers seminars 2010, 2011 and 2012) and organized several education sessions to improve safety in sports. LiVE websites (in Finnish) have attracted 3000-6000 visitors and 50 000-80 000 hits per month. Discussion Successful development and implementation of preventive strategies against sports and exercise related injuries are likely to result in large reduction in the absolute number of health problems, a reduction in work and school absenteeism, and decrease in medical costs. The true effects of the preventive measures and programmes of the LiVE will be seen within five to ten years. Program is financially supported by the Finnish Ministry of Social Affairs and Health and the Finnish Ministry of Education and Culture. References Pasanen K et al. ## STATUS LABOUR OF TEACHERS OF EXTRACURRICULAR SPORTS ACTIVITIES IN SCHOOLS ACCORDING TO HIS INITIAL QUALIFICATION

González, M.D.1, Campos, A.2, Pablos, C.3, Pablos, A.3

1: Alcalá University (Alcalá de Henares, Spain), 2: Polytechnic University of Madrid (Madrid, España), 3: Catholic University of Valencia (Valencia, Spain)

**Introduction** Most people working in sport and physical activity in Spain have unstable employment and low income according to the jobs (Campos, 2010). Specifically, in the extracurricular sports activities in schools there are few studies about the employment situation of these teachers in Spain. Therefore, the objective of this study is to analyse the status labour of teachers of extracurricular sport activities in the Primary schools of the Autonomous Community of Madrid according to his initial training. **Methods** We have used a quantitative methodology of descriptive cut. For this target the sectional survey through personal interview have been applied to people who is working teaching extracurricular sports activities in Primary Centers of Madrid (300 teachers). To catch the relevant information for the study we have used a structured interview. **Results** The results showed that 93% of the teachers who have a sports qualification have a temporary contract and part-time, only 7% of them do have permanent contracts. The teachers who have not a sports qualification have a percentage between 45% and 88%. According hours worked, earnings are highly diversified, the teachers who have sports qualification earn between 9.01 and 18 euros per hour. The monitors that have not sports qualification show more diversification in their earnings. According to monthly earnings, 48% the teachers who have not sports qualification earn less than 150 euros a month and 38% between 150 and 300 euros. The teachers that have a sports qualification, the monthly income are very diverse, between 150 euros and 1953 euros a month, although this income is not more than 10%. **Discussion** Most teachers, regardless of their sport qualification, have temporary contracts and part-time and there is no logical connection between the incomes and training. Comparing these results with other studies of people working in the labor market of physical activity and sport (Augustin, 2003; Campos, 2010), in this job there are higher situations of precarious employment. It is therefore necessary to improve the employment status of teachers of extracurricular sport activities, to ensure adequate education of students and practice healthy physical sports. **References** Augustin, J.P. #### EFFECTS OF GENDER AND SPORT ON DUAL CAREER OF ITALIAN STUDENT ATHLETES

Guidotti, F., Minganti, C., Cortis, C., Piacentini, M.F., Tessitore, A., Capranica, L.

*University of Rome Foro Italico*

**Introduction** This study aimed to examine the effects of gender, competition level (i.e., county, regional, national), and type of sport (i.e., Individual sports and team sports) on motivations toward academic, athletic and sport careers in Italian student athletes enrolled in Sport Science degree. **Methods** Italian Sport Science student athletes (n=293; gender: 35.49% female and 64.51% male; age: 21.36±2.55 yrs; competition level: 24.91% county, 41.98% regional and 33.11% national; type of sport: 29% individual sports and 71% team sports) completed the Harmonized Italian version of the SAMSAQ (H-SAMSAQ; Guidotti et al., 2012). A multivariate analysis of variance (MANOVA) was applied (p<0.05) to Academic Motivation (AM), Sport Motivation (SM), Sport Career as Athlete (SCA), and Sport Career as Operator (SCO) scores in relation to gender (male and female), competition level (county, regional, and national), and type of sport (Individual and Team). **Results** No difference emerged for gender, AM and CSA. For CSA a main effect emerged for competition level (p<0.0001; National=5.4±1.2pt, Regional=4.6±1.2pt, County= 4.1±1.1pt) and for type of sport (p<0.0187; Team=5.0±1.4pt, Individual=4.6±1.2pt). For SM, a difference (p=0.0134) emerged only for competition level, with National athletes showing a higher value (5.9±0.8pt) with respect to Regional (5.6±0.7pt) and County (5.5±0.7pt) levels. **Discussion** As expected, competition level and type of sport affect CSA, being national athletes are more motivated to be professional sportspersons, and team-sport athletes having more opportunities to emerge in professional sport. The lack of gender differences should encourage the cooperation between Education and Sport Bodies to promote equal opportunities for athletes in sport careers. **References** Gaston-Gayles J. #### MEDIA DISCOURSE ABOUT DOPING IN SPORT – CONTENT ANALYSIS OF THE COVERAGE IN DIFFERENT GERMAN NEWSPAPERS

Schirm, J.

*German Sport University Cologne*

**Introduction** Based on the assumption that everything we know about our society – and, for that matter, about the world we live in – we know through mass media, coverage plays a great role in the education and the formation of culture. Particularly the discourses about doping in sport give reason to think about the responsibilities and the ethic standards in media coverage. There is almost no theoretically informed empirical data about the coverage of doping in mass media. The focus of this paper is the doping discourse in mass media, i.e. the way in which doping is presented as a phenomenon of elite sport and the kind of interpretative frames that inform the discourses. The research is based on assumptions derived from the theoretical work on elite sports as a social system and from concepts of framing in media. **Main questions and theoretical background** The general questions that are put forward in the paper are what kind of interpretative schemes are referred to in the media discourses about doping and are there any differences between the discourses in different German newspapers? The main assumption in this paper will be the proposition of individualised coverage. It is expected that there is no discerning media coverage about doping, i.e. that there is no broad view on the causal factors of doping but on the contrary, that journalists are likely to support individualisation of the (mass) phenomenon of doping, thus focusing on individual cases, individual offenders

or victims. This proposition is derived from the fact that sport, mass media and economy are highly interconnected and have a common interest that 'the show must go on' and should not be irritated by reports on responsibilities and liabilities of diverse agents. These (and further) national peculiarities (e.g. political/financial support of elite sport; anti-doping law; national (identity) sports) are expected to have an impact on the mass media system and their way to observe, select, process and disseminate information to the public. Methods The media discourses is analysed on the basis of a content analysis of a representative sample of articles on doping during the year 2012 in six broad sheet papers in Germany (Frankfurter Allgemeine Zeitung, Süddeutsche Zeitung, Die Welt, Frankfurter Rundschau, Die Tageszeitung, Bild). The content analysis includes formalities (e.g. placement, size, author of articles) and qualitative aspects about the discourses (e.g. frame of reference, foci of report). Findings The findings will be discussed within the theoretical frame of agency based action theory. References Philipp M. (2002). Die Konstruktion des medialen Dopingdiskurses. Wiesbaden: Universitätsverlag. Schirm J, Hartmann-Tews I. (2011). Impulse – scientific magazine of the German Sport University Cologne. 02/ 2011, 36-43.

### **BODY CONSTRUCTION AND ANABOLIC STEROIDS USE: 'A MAD THING TO TAKE!'**

Santos, A.M., Serejo, O., Hoenisch, J.

*Universidade Federal da Bahia, Instituto de Saúde Coletiva*

Introduction: Anabolic androgenic steroids (AAS) and other drugs are used to enhance athletic performance and appearance (Bahrke & Yesalis, 2004). However, a comparable synthesis of nonclinical studies has not been made (Clark & Henderson, 2003). The aim of the present study was to investigate the body construction and appearance and performance enhancing drugs (APEDs) use among young male Brazilian bodybuilders. Methods: Employing an ethnographic approach, with in-depth interviews, we qualitatively investigated body image construction among 7 bodybuilders (20-30 yrs of age) in a gym Northeast of Brazil. We used the Discourse of the Collective Subject (DCS) (Lefèvre and Lefèvre, 2003) in order to tabulate and organize the qualitative data obtained during the semi-structured interviews. Adhering to the Theory of Social Representation, this technique permits synthesis of individual narratives – written in the singular, first person – into "one voice" in order to express 'community thought'. In other words, the discourse of seven individuals becomes one. Results: The DCS interpretations for these themes are: 'I saw the guys 'very big' in the gym and I began to take as a mad; I take this (ASS) very hard; I take many kinds of things as testosterone cypionate, nandrolone decanoate, ADE, stanazolol, Greek Deca Durabolin, ADE (injection source of vitamins A, D, and E for animals); I did not get big naturally; I take so much creatine'. Discussion: Men's body image problems may manifest as an unhealthy drive for muscularity and propensity to use anabolic-androgenic steroids (AAS). Based on our results, this group of bodybuilders – with the apparent purpose just 'to look big' (Santos, da Rocha & da Silva, 2011). Conversely, stereotypically male body image disturbance is anchored in a "drive for muscularity". Body image importance and sociocultural pressures predicted increasing muscle bulk for normal and overweight young male (McCabe, Ricciardelli & Holt 2010). And the most commonly cited behavior associated with body image disturbance (BID) in men is illegal APED (Hildebrandt, Alfano & Langenbucher, 2010). Future research on male BID should account for this structure in order to better define relevant diagnostic categories and evaluate the nonclinical significance of BID. ### **DESIGNING EVIDENCE POLICIES FOR ENHANCING SPORT PARTICIPATION**

Breedveld, K.

*WJH Mulier Institute*

Designing evidence based sportspolicies in the Netherlands: lessons learnt Breedveld, K. 1; Van der Poel 1; Collard, D 1; De Jong, M. 1 1 Mulier Institute Introduction In the Netherlands, in 2005 the national government issued a new policy program called A new policy, 'Time for Sports'. The program had three main objectives: enhancing health through sports, enhancing participation in and through sports, and improving performance in elite sports. On all three policy-areas, concrete goals (quantitative indicators) were formulated and policy-programs were issued. Time for sports were a major effort to develop a transparent sportpolicy, that would allow for in depth monitoring and evaluation. Method In this paper, we will go into the results of the Time for Sports program. For this, we draw on an intensive study of policy documents, interview with 20 experts, secondary analyses of the most relevant sportstatistics, and membership data for 500 sportclubs for over 4 years. Results The outcome of the evaluation are that the program largely reached its 'throughput' and 'output', yet failed to reach many of its 'outcome goals': physical activity levels did not rise that much in the 2005-2010 period, and the program failed to reach many other of the other goals that were set out at the start of the program. Yet the program can not be labeled unsuccessful, though it is hard to proof the effectiveness of the program by merely looking at 'objective' outcome measures. Discussion Taking all this in consideration, and taking into account how the policy was first formed in 2005 and how its goals came into being, we will deliver a theory on why the Time for Sports program did not deliver fully what it set out to do at the beginning. The theory has important implications for sportspolicies, but also for sportsresearch aiming to support such policies with data and research-findings.

### **THE OLYMPIC GAMES IN LONDON 2012 FROM A SWEDISH MEDIA PERSPECTIVE**

Hedenborg, S.

*Malmö University*

The aim of this paper is to map out and study Swedish media coverage of the Olympic Games in London 2012 from 6th July 2012 (when London was chosen as the host of the Olympic Games 2012) up until the Games are finished (Olympic games 27 July to 12 August and Paralympics 29 August to 9 September ) in order to discuss how the Olympic Games are presented for the Swedish audience. Four themes will be focused: sustainability, gender, body and ethnicity/nationality. One daily newspaper (Dagens Nyheter) and one tabloid (Aftonbladet) will be used as source material. This study will be published together with other studies with similar aims in an international anthology.

**MEASURING QUALITY OF LIFE IN HANDBALL PLAYERS: A DESCRIPTIVE STUDY.**

Santos, A.

*University of São Paulo and FAPESP*

**INTRODUCTION:** There are few data on quality of life in sports. Studies that measure quality of life can map several factors that make up the index of quality of life and allow the analysis of satisfaction and importance regarding aspects of the lives of athletes related to health and functioning, family, socioeconomic conditions, the psychological and spiritual. **OBJECTIVE:** The purpose of this research is to investigate the quality of life in handball athletes through a descriptive study. **SUBJECT & METHOD:** The instrument used to investigate the quality of life of the athletes was the Quality of Life Index created by Ferrans and Powers. The instrument consists of two parts with thirty four factors each part. The first part measures the satisfaction with various aspects of life, and the second part measures the importance of these aspects for the individual life. The instrument results in values between 0 (worst QLI) and 30 (best QLI). Study participants were members of the handball federation. The athletes had over 18 years of both genders, and they participated in official competitions. This research respected all the ethical procedures. The sample comprised 67 subjects, 25 men and 42 women, mean age 23.6 years (SD=4.3). **RESULT:** The sample presented total QLI with a minimum of 4.3 and maximum 28.8, mean 22.2 (SD=4.2). The QLI health and functioning domain reached the minimum value of 4.5 and maximum 28.5, mean 21.7 (SD=4.6). The family domain got minimum value of 6.6 and the maximum value of 30, average 20.7 (SD=4.4). The socioeconomic domain reached minimum value of 5.6 and maximum 23.6, mean 16.1 (SD=3.5). The spiritual and psychological domain obtained minimum value of 0 and maximum of 30.0, average 23.7 (SD=5.6). Among the factors that resulted in lower values are the intensity of pain, stress and worry. Among the factors that present higher values are satisfaction with their children and faith in God. **DISCUSSION:** High levels of quality of life for athletes can have a positive impact on the efficiency of training and athletic performance. On the other hand, problems outside of sports can take the focus on work and disrupt the dedication of the athletes in daily training. The study presents evidence of the need to improve the quality of life for athletes, especially in the socioeconomic field. In addition to data on quality of life, the results indicate the areas of the lives of athletes in need of further investigation and possible interventions. **REFERENCES** Ferrans CE, Powers MJ. **NEGLIGENCE, CHILDREN AND SPORT 2: AVOIDING LIABILITY.**

Greenfield, S., Osborn, G.

*University of Westminster*

This paper considers how Governing Bodies in sport have reacted to avoid being held liable in negligence. There are two aspects to this strategy. First the construction of the rules under which youth sport is played and how individual differences in size and ability can be encompassed. Both Rugby Union and Cricket have introduced protective measures to ensure children are not exposed to undue risk. The three areas cover; the requirement for protective equipment, protecting the child from 'over playing', and from 'unfair' or 'unequal' competition. Different sports require specific protective equipment and there is the question as to whether the wearing of such equipment is voluntary, compulsory or subject to parental waiver. Overplaying acts to limit what a child may do in terms of playing time or activity such as a restriction on the number of overs a young cricketer may bowl. Similarly scrummages in Rugby Union are subject to strict regulation with the potential for uncontested scrums. Such regulations are primarily based around age groups with a progressive increase in physical activity according to date of birth. The application and effectiveness of these measures is reviewed. Secondly the judgment exercised by the organizers, coaches and referees and how potentially dangerous situations are prevented. The essence of this is both the interpretation of the rules under which the game is played and how reasonable care is exercised. This encompasses the identification and application of professional practices and guidance in the selection and management of teams and the adjudication of matches. The paper analyses how such judgment interacts with liability for negligence

**APPLYING THE DEVELOPMENTAL MODEL IN INVESTIGATING THE CAREER DEVELOPMENT OF FLEMISH FORMER ELITE ATHLETES**

Reints, A.

*Vrije Universiteit Brussel*

**Introduction** While the athletic career may seem continuous in nature, sport psychology research has revealed that it consisted of within-career transitions. Wylleman and Lavallee (2004) developed a developmental model reflecting the developmental and interactive nature of transitions at athletic, psychological, psychosocial and academic/vocational level. The aim of this study was to explore athletes' career development, career experiences and challenges as perceived by former elite athletes in their (post-) athletic career. Methods Face-to-face interviews were performed with 24 Flemish former elite athletes (M = 36.79 years old, SD = 5.19), including 12 female athletes (M = 34.25, SD = 5.55) and 12 male athletes (M = 39.33, SD = 3.39); 13 former athletes from individual sports (M = 35.92, SD = 4.48) (e.g., cycling, track and field, triathlon, sailing, swimming, fencing, judo), and 11 participants from team sports (M = 38.18, SD = 5.42) (e.g., soccer, basketball, korfbal, volleyball). The participants retired from elite sport between 1 and 6 years ago, on average 2.9 years ago. Directed content analysis combining a deductive and inductive approach, was used. Results Participants clearly described their athletic career as having experienced several different stages and transitions. Results confirmed the existence of the four levels within the developmental model (i.e., athletic, psychological, psychosocial, academic/vocational level) and also revealed the presence of several within-career transitions not included in the model (e.g., during the mastery and discontinuation stage). Second, data analysis led to the identification of two developmental levels, which were not included in the model, namely the (a) financial level of development, and (b) physical level of development. Discussion By suggesting two stages within the mastery stage, five stages within the discontinuation stage, and stages, transitions and experiences at physical and financial level, current study results broadens the conceptualisation of the normative transitions (former) athletes may face. In this way, it enables to envisage transitions which might overlap and lead athletes to more and/or extensive coping. More specifically, this study leads to a better understanding of the developmental model's capacities and more fully describes athletes' career development. References Wylleman, P, Lavallee D (2004). Developmental sport and exercise psychology: A lifespan perspective, 507-527. FIT, Morgantown.

**INCREASING PHYSICAL ACTIVITY USING Pedometer AND WEB-BASED INCENTIVES**

Allen, M.

*London South Bank University*

Introduction There is now compelling evidence that at least 30 minutes of moderate intensity physical activity five times a week has beneficial outcomes. Despite this consistent finding it is often difficult to motivate people to incorporate physical activity into their daily lives. Pedometers which provide daily step counts have recently been shown to help people increase their levels of physical activity. This study explores how effective a new web based service called Activity4Charity is at increasing physical activity levels. It combines using pedometers and downloading the data onto a web based system with the incentive of raising money for charity. Methods 72 healthy adults (24 men, 48 women) participated in the study. They had a mean age of 41.71 years (sd = 11.87) and a mean Body Mass Index of 26.77 (sd = 7.37). Participants were randomly assigned to one of four groups: 1) collecting money for charity and participating alone, 2) collecting money for charity and participating in a group, 3) not collecting money for charity and participating alone, 4) not collecting money for charity and participating in a group. Following a two week baseline, participants completed a 6 week trial. They were required to wear their pedometer at all times during the day, and they were required to regularly download their data onto the Activity4Charity website. Before and after the 6 week trial participants completed questionnaire measures of health and wellbeing. Performance data (average daily steps and total steps) were downloaded from the Activity4Charity website and compared across conditions. Health data were also compared before and after the trial and between conditions. Results There was a significant difference in the daily average steps taken between baseline (mean = 8,987.73) and trial (mean = 9,832.39) conditions,  $t(61) = 2.88, p = .005$ . Also, participants in the charity condition performed better than those in the non-charity condition, with greater daily average steps,  $t(48) = 2.36, p = .022$ , and total steps,  $t(48) = 2.60, p = .012$ . There was no significant difference for daily average steps,  $t(70) = 1.15, p = .255$ , or total steps,  $t(70) = 1.52, p = .132$ , between those taking part in groups and those taking part individually. There was also some evidence that levels of depression were lower after the intervention than before the intervention,  $t(18) = 1.84, p = .083$ . Conclusion This study demonstrates that a 6 week web-based physical activity (pedometer) intervention can increase physical activity levels and benefit mental health particularly when raising money for charity.

**COMPARISON BETWEEN SELF-PERCEPTION AND ACCELEROMETER MEASURED PHYSICAL ACTIVITY PATTERNS IN COLLEGE STUDENTS.**

Van Hoomissen, J., Downs, A., Julka, D., Lafrenz, A.

*University of Portland*

Participation in physical activity on a regular basis is important for maintaining health, yet many people do not meet the levels recommended by scientific and health organizations. Physical activity behavior during the late adolescence/early college period in life is of particular importance as behaviors adopted during this time frame may carry over into adulthood. Previous research indicates that between 40-50% of college students are physically inactive, thus putting their health at risk (1,2,3). The purpose of this study, therefore, was to measure physical activity levels in college students, utilizing both objective, quantitative data (accelerometers) as well as more traditional self-report measures (International Physical Activity Questionnaire). In addition, we examined the relationship between these two different forms of measurement and common mental health constructs associated with physical activity levels such as depression, anxiety, stress, self-efficacy, self-esteem, and happiness. Forty nine male and female college aged subjects were recruited from a private, liberal arts university during both the fall and spring semesters. Students completed a series of mental health questionnaires and fitness tests prior to measurement of physical activity behavior, which was assessed over a two week period using two different forms of measurement: 1) IPAQ and 2) Accelerometer (Actigraph). Subjects tended to overestimate their time spent in all categories of physical activity (light, moderate, and vigorous), and underestimate their time spent in sedentary behavior indicating a discrepancy in self-perception of actual physical activity behavior. There were significant positive correlations between average minutes per day spent in moderate/vigorous activity and happiness, self-efficacy, and self-esteem. In addition, higher physical activity levels were associated with lower levels of anxiety and stress. These results are consistent with previous research showing significant correlations between physical activity and aspects of mental health. This study remains one of the more extensive college population studies that matches objectively measured physical activity using accelerometers and mediators of mental health. One of the major findings is the discrepancy in perceived time spent in moderate and vigorous activity and the actual time spent in moderate and vigorous activity. The benefits of exercise are well known to this population but there remains a low level of participation. Further research will focus on interventional studies based on feedback to individuals in the college population with regards to what constitutes moderate and vigorous physical activity. **COMMUNICATION AND PHYSICAL ACTIVITY BEHAVIOR**

Pfeffer, I.

*University of Leipzig*

Introduction Effective health communication is an important aspect of health behavior change (Noar et al., 2007). Based on the Regulatory Focus Theory (RFT; Higgins, 2000) it was examined whether the regulatory fit between the chronic regulatory focus of a person (promotion vs. prevention) and the arguments used in a physical activity promotion message (promotion-goals vs. prevention-goals) enhances physical activity motivation in contrast to non-fit messages. Method In a randomized design with two experimental conditions chronic regulatory focus (promotion vs. prevention) was measured of N = 98 participants (44 female; age M = 41.2 years, SD = 10.18; physical activity M = 157.20 minutes/week, SD = 162.30). Subsequently, participants were allocated at random to one of two conditions (message

with promotion-goals vs. prevention-goals). Participants were asked to read the respective message and to fill in a standardized questionnaire including measures of the value derived from fit variables (Latimer et al., 2008). Internal consistencies of the scales were satisfactory to good. Results Hierarchical multiple regression analyses controlling for physical activity behavior re-vealed significant interaction effects Condition x Regulatory Focus for intention to perform the behavior,  $\Delta R^2 = .043$ ,  $\Delta F(1,93) = 4.81$ ,  $p < .05$ ;  $f^2 = .04$ , prospective feelings,  $\Delta R^2 = .061$ ,  $\Delta F(1,93) = 7.45$ ,  $p < .01$ ;  $f^2 = .06$ , and retrospective feelings associated with the behavior,  $\Delta R^2 = .043$ ,  $\Delta F(1,93) = 5.32$ ,  $p < .05$ ,  $f^2 = .05$ . No effects were found for inclination towards the message and perceived goal value. Mediation analyses revealed prospective and retrospective feelings to mediate the effect of regulatory fit on intention to perform the behavior. Discussion Creating regulatory fit between the chronic regulatory focus of a person and the arguments used in a physical activity promotion message produces more positive feelings associated with the behavior and enhances physical activity motivation in contrast to non-fit conditions. It is therefore an effective strategy to improve message persuasiveness. However, it is not clear if regulatory fit also would have influenced physical activity behavior itself. ### MOTIVATIONAL PREDICTORS OF PHYSICAL SELF-CONCEPT AND PHYSICAL ACTIVITY IN SCHOOL AND LEISURE-TIME ACROSS THE PRIMARY-SECONDARY SCHOOL TRANSITION

Taylor, I.M., Spray, C.M., Pearson, N.

*Loughborough University*

Introduction: A significant life-event that occurs at the onset of developmental declines in physical activity (PA) is the transition from primary to secondary school physical education. With this in mind, we adopted self-determination theory (Deci & Ryan, 2000) to longitudinally explore children's motivation in primary school PE as a predictor of change in physical activity behaviour in school and leisure time across this transition. In addition, children's physical self-concept was explored as an important component of their global sense of well-being which may be vulnerable to potential declines across the primary-secondary school transition. Methods: 348 10- and 11-year old school children (52% male) took part in the study by completing a multi-section questionnaire exploring the study variables at the end of primary school and three months into secondary school (approximately five months later due to the summer vacation). Results: Paired samples t-tests revealed that children's physical self-concept, school PA, and leisure-time PA significantly declined over the primary-secondary school transition (all  $p < .05$ ). Further, intrinsic motivation in primary school PE positively predicted change in physical self-concept and school PA ( $\beta = .12$  and  $\beta = .13$ , respectively; both  $p < .05$ ), whereas external regulation in primary school PE negatively predicted change in leisure-time PA ( $\beta = -.10$ ,  $p < .05$ ). Children's identified regulation and introjected regulation did not predict change in the outcome variables. Conclusions: Evidence is provided that children's physical activity and physical self-concept decline over the transition from primary to secondary school. Moreover, children's enjoyment and interest (i.e., intrinsic motivation) in primary school PE, as well as their experiences of pressure and coercion (i.e., external regulation) may partially explain these worrying declines. ### VALIDATION OF THE GREEK VERSION OF THE EXERCISE SELF-EFFICACY SCALE

Theodoropoulou, E., Karteroliotis, K.

*National and Kapodistrian University of Athens*

Introduction The exercise self-efficacy scale has been established to have sound psychometric properties (Marcus et al., 1992). However, no validity or reliability data of this scale are available in the Greek language, hence prompting the present study. Therefore, the aims of the current study were to examine the factorial validity and reliability of the Greek version of the exercise self-efficacy scale (Marcus et al., 1992). Methods Participants were 340 volunteers that attended the physical education classes at the University of Athens. To test the factorial validity, two samples were used. The first sample (N=150) were 77 men and 73 women (24.28±6.32 yrs), whereas the second sample consisted of 86 men and 64 women (22.85±5.64 yrs). An Exploratory Factor Analysis (EFA) was conducted with the first sample. The extraction method employed was principal axis factor followed by promax rotation (Russell, 2002). A Confirmatory Factor Analysis (CFA) (maximum likelihood method) was performed with the second sample to confirm the goodness of fit of the model found in EFA. The CFA was conducted using the AMOS 16.0 statistical software (Arbuckle, 2007). Assessment of model fit was based on  $\chi^2$ ,  $\chi^2/df$ , CFI, GFI, IFI, TLI and RMSEA indices (Kline, 2005). To test the internal consistency, the Cronbach's alpha ( $\alpha$ ) coefficient was used. To examine the test-retest reliability, 40 students, 21 men and 19 women (28.78±5.647 yrs), completed this scale twice with an interval of 15 days between the two assessments. Results The Kaiser-Meyer-Olkin (KMO) was 0.831 and the Bartlett Test of Sphericity was statistically significant ( $\chi^2=263.56$ ,  $df=10$ ,  $p=0.00$ ). EFA yielded one factor accounted for 59.54% of the variance of the model. The item factor loadings ranged from 0.48 to 0.82 ( $\alpha=0.83$ ). Similarly, CFA showed that this model presented a good fit ( $\chi^2=9.487$ ,  $df=5$ ,  $p=0.091$ ,  $\chi^2/df=1.897$ , CFI=0.988, GFI=0.974, IFI=0.988, TLI=0.976, RMSEA=0.078,  $\alpha=0.87$ ). The item factor loadings ranged from 0.56 to 0.84. The test-retest reliability coefficient was 0.92. Discussion The results indicated that the exercise self-efficacy scale was a valid and reliable instrument. These findings show that it is a useful tool for studies focusing on exercise and self-efficacy topics. Future studies are proposed in other Greek samples in order to increase the knowledge about the validity and reliability of the exercise self-efficacy scale. References Arbuckle JL. ### SATISFACTION WITH LIFE IN UNIVERSITY STUDENTS: THE ROLE OF SPORT PRACTICE

Figueiras, T., Martins, C., Santana, P.

*Instituto Superior da Maia*

Introduction The most recent researches on Positive Psychology show the increasing importance of subjective well-being (SWB) as one of the main indicators of well-being in western societies. SWB concerns each individual's judgment of his own life, considering personal experiences and the general assessment of such experiences. Satisfaction with life (LS) is the SWB cognitive component and is considered crucial for assessing the individual's quality of life. SWB is understood as the outcome of the personality and the experiences and life

circumstances (like gender and age), but also as the result of the voluntary control of individuals, through intentional activities such as practicing sports, that can cause lasting changes in SWB and LS. We wonder if, as a vehicle of positive psychology, a close relationship with sport can be assumed as able to promote and contribute to sustainable increase in individuals SWB and LS. In this sense, the objective of this study was: i) to assess the level of LS of university students, and ii) determine whether there were gender differences and between practitioners and non-practitioners and also between physical education and sport students (PES) and other courses students. Methods The sample was formed by 204 university students (116 girls and 86 boys) from the Instituto Superior da Maia (115 practitioners and 87 non-practitioners; 96 PES students and 106 of other courses). To evaluate the students' personal judgment on their LS we use a version translated and adapted to the Portuguese reality of the Satisfaction With Life Scale (SWLSp) of Diener, Emmons, Larsen and Griffin (1985). Results The whole sample ( $3.69 \pm 0.6$ ), boys ( $3.73 \pm 0.56$ ) and girls ( $3.65 \pm 0.62$ ) revealed LS above the mean value of the scale, which is usual in western societies. Boys practitioners showed higher rates of LS than the girls practitioners ( $3.73 \pm 0.52$  vs  $3.62 \pm 0.69$ ;  $p = .018$ ). There were no statistical differences between practitioners and non-practitioners, both boys ( $p = 0.12$ ) and girls ( $p = 0.09$ ). Also we didn't find statistical differences between PES students and other courses students – total sample ( $p = 0.87$ ); boys ( $p = 0.31$ ); girls ( $p = 0.42$ ). Discussion These results show the LS influence of multifactor, highlighting the prevalence of some factors, such as in this case the university, at certain stages of life, and therefore could not only be the result of exercise training. ## PREDICTING CHANGES IN STUDENT'S AMOTIVATION IN PHYSICAL EDUCATION

Jackson, R., Spray, C.

*LOUGHBOROUGH UNIVERSITY*

Abstract text Introduction In Physical Education (PE) amotivation is evident when individuals lack the intention and willingness to participate in the compulsory activities (Deci and Ryan, 1985). Therefore, the aim of this study was to investigate relationships between the four dimensions of amotivation (ability beliefs, value of the task, effort beliefs and task characteristics), physical self-concept and a student's effort, and to explore potential predictors of change in amotivation. This study also aimed to investigate whether a teacher satisfies a students' three needs of satisfaction; autonomy, competence and relatedness and whether satisfying these needs predicts changes in amotivation. Method A total of 179 students (male, mean age = 14 years) participated in the study by completing a questionnaire during their scheduled PE lesson. Participants completed the same questionnaire at the end of every PE lesson over three different time points during a five week unit of work. Measures included an adapted version of a recently devised academic amotivation scale and a physical self-concept scale. In addition students' perceptions of teachers need support (NS) were measured using a scale adapted by Standage, Duda and Ntoumanis (2005). Teachers rated student's effort on a rating scale of motivated behaviour. Results Multilevel regression analyses showed that at Time 1, all three needs of satisfaction negatively predicted the amotivation dimension; task characteristics. Competence NS and relatedness NS negatively predicted value of the task and task characteristics, but there was no significant relationship between need support and effort beliefs. The amotivation dimensions did not significantly predict physical self-concept and there was no significant rate of change over time. Value of the task, effort beliefs and task characteristics significantly predicted teacher ratings of effort and there were significant decreases in amotivation over time. Ability beliefs was the only amotivation dimension that did not significantly predict teacher ratings of student effort over time. Student's perceptions of need support did not predict changes in physical self-concept or teacher ratings of effort. Conclusions Overall the findings suggest that the three needs of satisfaction have an influence on levels of amotivation. Students who perceived their teacher as failing to support their need for autonomy, competence or relatedness, may find the task itself less interesting, be deficient in their ability beliefs and fail to see the value of the task, causing a decrease in amotivation over time. Moreover, student effort grades may be able to predict whether a student is lacking in motivation in Physical Education, and as a result may have important implications for how teachers assess their students in schools. References Deci, E.L and Ryan, R.M. (1985). *New York: Plenum*. Standage, M; Duda, J and Ntoumanis, N. (2005). *British Journal of Educational Psychology*, 75, p. 411-433.

## HEALTHY LIFE AND PERSONAL RESPONSIBILITY: STUDY ABOUT BELIEFS OF BRAZILIAN PHYSICAL EDUCATION STUDENTS

Vaisberg, T.M.J.A., Ambrosio, F.F., Fialho, A.A.

*Pontifícia Universidade Católica de Campinas- Brasil*

Considering that practice of health workers depends not only on scientific knowledge but also in beliefs sometimes unconscious, we investigated the collective imaginary of physical education students, that nowadays are recognized as important agents of health promotion. Methodology: Twenty-seven subjects participated in a collective interview organized with the use of the "Thematic Drawings and Stories Procedure". According to this method, we asked the subjects to imagine and draw a healthy person. Hereafter, we asked them to create and write a story about the figure drawn. Results: These physical education students believe that health depends on exercise practice, appropriate diet, contact with nature, church attendance, friendship and satisfactory love and sex life. They don't refer to social and environmental public policies. Discussion: These beliefs may be interpreted as result of a vision of health as a personal responsibility that depends only on individual actions. We conclude that the students have a positive attitude valuing self-care, but the lack of perception of the importance about social and environmental public policies can mean that health is not viewed as a right of the citizens.

## BODY IMAGE DISSATISFACTION IN PORTUGUESE YOUTH: THE ROLE OF OBESITY, GENDER AND PHYSICAL ACTIVITY

Coelho, E., Gomes, M., Rodrigues, V., Fonseca, S., Mourao, I.

*University of Trás-os-Montes and Alto Douro*

Introduction: Many studies have shown variability in body image dissatisfaction among children and adolescents based on weight status, gender and physical activity. The aim of this study was to compare body dissatisfaction according to obesity, gender and physical activity in Portuguese youths. Methods: The sample was composed by 331 youths, aged 10-16 years (176 boys and 155 girls). Body image was assessed using Collins's (1991) body shape silhouettes and participants were asked to identify the silhouette that most accurately represented their body size (real) and the ideal body image. Body dissatisfaction was calculated by the difference between the real and ideal body image. Height and weight were measured to calculate BMI and Cole et al. (2000) cutoffs were used to define obesity. The chi-square test was used to compare groups. Results: The prevalence of obesity was 30.1% in boys and 30.1% in girls. The prevalence of body dissatisfaction was 54.7%; 37.1% wants to be thinner while 17.6% wants to be fatter. According to physical activity level, 81% practise

regularly. The body weight dissatisfaction varied according to weight status ( $p=.000$ ). The obese youth were more dissatisfied with their body image than the normal weight youth (80.6% vs. 44.5%). Girls are more dissatisfied with body weight than boys (59.5% vs. 50.3%), and the majority want to lose weight (40.9%), but the differences were not statistically significant ( $p=.223$ ). The prevalence of body dissatisfaction was similar (50%), when we compared the youth with different levels of physical activity ( $p=.896$ ). Discussion: The present study identified that body weight dissatisfaction varied according to obesity prevalence. In disagreement with other investigations, physical activity and gender did not discriminate the body image dissatisfaction. We suggested the inclusion in future investigations of other important variables, like, socio-economic status and age. References: Collins, E. (1991). Body figure perceptions and preferences among preadolescent children. *International Journal of Eating Disorders*, 10 (2), 199-208. Cole T, Bellizzi M, Flegal M, Dietz W, (2000). ### **A SYSTEMATIC REVIEW OF THE CORRELATES OF SOCIAL COMPARISON IN PHYSICAL EDUCATION**

Barnes, J., Spray, C.M.

*Loughborough University*

Purpose: To identify and review the associations between social comparison and behavioural, affective and cognitive outcomes in physical education (PE). The review collates and critiques the findings of included studies highlighting the limitations of these in addition to providing recommendations for future research. Design: A systematic review including a narrative synthesis. Five papers all published in the English-language were identified using electronic searches of seven databases and by manually searching reference lists and personal files. Peer reviewed research involving children (aged 0 – 18 years), a grounding in social comparison and an outcome variable were included. Results: Physical-self concept was negatively related to class average ability. Boys reported higher self-evaluations of ability in PE than girls and higher levels of physical self-concept. Negative associations between comparative evaluations of ability within the class and free time physical activity level were also identified. Different associations with the dependent variables were found depending on the frame of reference in question (i.e. the class had a negative relationship, but a small group had a positive relationship). Conclusions: Children are influenced simultaneously by multiple frames of reference, however, how these associations effect one another is unknown. There is clearly a dearth of knowledge in this area demonstrated through the small number of studies identified and included. Additionally, the review highlights the need for future research assessing other dependent variables and the simultaneous effects of comparisons with multiple frames of reference in addition to the need to develop measures of social comparison.

### **CONSISTENCY OF THE ENVIRONMENTAL DIMENSIONS OF AN OBSERVATIONAL INSTRUMENT ASSESSING COACH INITIATED MOTIVATIONAL CLIMATE.**

Tzioumakis, Y., Papaioannou, A., Digelidis, N., Zourbanos, N., Krommidas, H., Keramidis, P.

*University of Thessaly*

CONSISTENCY OF THE ENVIRONMENTAL DIMENSIONS OF AN OBSERVATIONAL INSTRUMENT ASSESSING COACH INITIATED MOTIVATIONAL CLIMATE. Tzioumakis, Y.I, Papaioannou, A.I, Digelidis, N.I, Zourbanos, N.I, Krommidas, H.I, Keramidis, P.I. 1: DPES (Trikala, Greece) Introduction Motivational climate in physical education and sport settings had been traditionally assessed via self-report scales. Grounded to the Achievement Goal (AGT) and Self Determination Theories (SDT) an observational approach has been developed (Tessier, Tzioumakis, Smith, Sarrazin, Digelidis, Papaioannou, Quested & Duda, 2011) as part of a European based project (PAPA Project), for the objective assessment of the coach-created motivational climate, aiming to identify the empowering and disempowering features of coach-initiated motivational environments. Methods A series of 10 video recordings, of approximately 60 minutes each, were analyzed according to the instrument's empowering and disempowering dimensions. After acceptable interobserver reliability ( $k=.75$ ) was established, state lag sequential analysis using Observer XT® 7.0 software was conducted to examine the consistency of each of the seven environmental dimensions of the instrument. Results As the results revealed across all codings, the Autonomy support dimension was most often rated very low (0 in a 0-3 scale, while probability rate was .71 in a scale 0-1), the Controlling dimension was usually rated high = 2 (probability rate was .57), the Task-involving dimension was most often rated low = 1 (.70), the Ego-Involving dimension was usually rated low = 1 (.48), while Relatedness Support was most often rated very low = 0 (.73), Relatedness Thwarting was usually rated low = 1 (.59), and finally the Structure dimension was most often rated low = 1 (.74). Discussion Observers' ratings revealed discrete behavioral patterns in terms of coach-created motivational climate across the instrument's environmental dimensions, also adding to the reliability of the observational measure. As results showed, coaches created an environment that lacked autonomy support, while on the other hand they engaged in behaviors that emphasized control. Furthermore, empowering features of the climate as relatedness support and task involvement were low. Similarly, coaches placed weak emphasis on disempowering motivational dimensions as ego involvement and relatedness thwarting as well as in structure. Coaches might use the current observation system for self-monitoring and goal setting to enhance the empowering climate in their teams. References Tessier D, Tzioumakis Y, Smith N, Sarrazin P, Digelidis N, Papaioannou A, Quested E, Duda J. L. (2011). ### **EFFECT OF PHYSICAL ACTIVITY AND CARDIORESPIRATORY FITNESS ON ATTENTIONAL VARIABLES**

Luque, A., Zabala, M., Morales, E., Sanabria, D.

*University of Granada*

Introduction Several studies indicate that chronic exercise provides positive effects on cognitive performance (Themanson & Hillman, 2006). The effect of training seems to be robust, but may selectively benefit cognitive performance. The aim of this study was to show the relationship between physical fitness and their effects on attentional performance in different task conditions. Methods There were two groups of participants (athletes and sedentary). Both groups completed three experimental conditions: rest, incremental exercise test and anaerobic power test. Three cognitive tasks involving attention and temporal processing were performed at rest (Psychomotor Vigilance Task "PVT", temporal orienting and time duration discrimination). In the other two experimental conditions, participants performed the PVT immediately after an acute bout of exercise. We used a SRM lab ergometer, a FirstBeat Bodyguard and a Lactate Pro Meter Set to determine the fitness level. Results The results showed a significant main effect of Group only in the PVT task. Reaction times were faster for the trained cyclists as compared to the sedentary group. This difference disappeared after performing acute exercise. In addition, both groups increased reaction times after exercise. No significant differences between groups were found in the temporal orienting task or in the time duration discrimination task. Discussion Our results support previous studies showing that the effect of training seems to have

selective benefits in cognitive performance (Colcombe & Kramer, 2003). The main benefit was obtained in the PVT that was designed to measure sustained attention. This benefit appeared only in the resting condition. This supports other research showing a decrease in brain activity in temporal processing after physical effort. Also, it suggests that the decrease in vigilance may appear only after strenuous exercise (Smit, Eling, Hopman, & Coenen, 2005). We conclude that a good physical fitness selectively improves sustained attention, while it does not modulate attentional temporal orienting or fine temporal discrimination. #### PREDICTING MUSCLE INJURIES WITH ISOKINETIC AND BODY COMPOSITION

Martínez-Ruiz, E.1, Esparza-Ros, F.1, Martínez-Pardo, E.2, Rubio-Arias, J.A.2, Alcaraz, P.E.2

*Catholic University of San Antonio*

**Introduction** The muscle injuries are characterized by high injury and re-injury rate. Therefore, a better understanding of morphology, mechanism and function muscles, could provide a basic for improving current rehabilitation strategies and predicting re-injury. So, the aim of this study was correlate muscle strength isokinetic and body composition variables with the severity grades of muscle injuries in semi-professional soccer players. **Methods** Twenty-four male soccer players were tested at the same day, in January (mid-season). Firstly, was assessed body composition with a dual energy X-ray absorptiometer, obtaining fat free mass, fat mass, segmental and total regions, and bone mineral content. Thereafter, was measured an isokinetic concentric test flex/extension knee at angular velocity of 60°/s, 180°/s and 270°/s, obtaining the peak torque (Nm), hamstring/quadriceps ratio (H:Q ratio), acceleration time (m/s) and power (W). Finally, the grade of injury was calculated following the methodology proposed Kujala et al. (1997). This data was analyzed with the Pearson's correlation coefficients (r) the priori level of statistical significance was set at  $p \leq 0.05$ . **Results** Body composition was not correlated with the grade of injury. However, significant correlation was found between the grade of injury and power knee flexion at 180°/s ( $r = 0.447$ ,  $p \leq 0.05$ ), power knee flexion at 270°/s ( $r = 0.428$ ,  $p \leq 0.05$ ) and with acceleration time for knee flexion at 180°/s ( $r = -0.452$ ,  $p \leq 0.05$ ). **Discussion** Our result suggest that the peak torque concentric, and specially the H:Q ratio, no appear to be relevant in the more or less grade of muscle injury. However, other variables as the muscle power, identified also by Henderson et al. (2010), and acceleration time, related to an altered neuromuscular control of hamstrings, specially at long muscle lengths (Sole et al., 2011), could show a better risk of injury. In summary, the isokinetic variables such as power muscle and acceleration time for knee flexion was correlated with the grade of muscle injury; and body composition variables not interacted with the risk of injury. **References** Henderson, G., Barnes, C. #### DEVELOPMENT OF A SKELETAL MUSCLE INJURY MODEL IN THE RAT AND IN VIVO EVALUATION OF THE USE OF HUMAN MESENCHYMAL STEM CELLS FROM THE UMBILICAL CORD MATRIX IN MYECTOMY INJURY TREATMENT

Pereira, T.1,2, Gärtner, A.1,2, Amorim, I.1, Ribeiro, J.1,2, Franca, M.1,2, Armada-da-Silva, P.A.S.3,4, Luís, A.L.1,2, Maurício, A.C.1,2

**Introduction** Muscle injuries are common in athletes and it is important to develop new methods to improve muscle regeneration. Muscle has good regenerative ability, but the extent of muscle injury might prevent full regeneration. We developed a novel experimental muscle injury in the tibialis anterior muscle of the rat by using a biopsy punch to create a standardized myectomy lesion. Using this model we tested the use of a cellular therapy by application of HMSCs from human umbilical cord matrix. **Methods** We tested chemical (collagenase), mechanical (crush) and surgical (myectomy) lesions and assessed different times of muscle collection for histological analysis (3 to 60 days after lesion) in order to develop an optimal in vivo muscular lesion model. HMSC from Wharton's jelly umbilical cord matrix were cultured. Sasco Sprague male rats with 250-300g were used. After a standardized 5 mm-diameter myectomy lesion of the tibialis anterior muscle, we tested different treatment combinations (HMSCs and conditioned media) and vehicles (FloSeal and thrombin). After 15 days, animals were sacrificed and the anterior tibial muscles were collected and fixed in formaldehyde for qualitative histological analysis of myotubes and inflammatory cells presence. **Results** The myectomy model proved to be the most appropriate for a comprehensive and standard evaluation of the rat skeletal muscular regeneration ability. The transplanted HMSCs presented normal morphology and immunocytochemistry markers for MSCs. Myotubes were present in peripheral borders of the created injury whereas the center of the injury was occupied by an extensive and hypercellular inflammatory infiltrate. Injuries treated with HMSCs presented several ectopic calcifications that probably were caused by the Floseal vehicle since they were present in all these groups. **Discussion** At 15 days muscle regeneration was not complete after our myectomy injury suggesting the possibility of permanent changes in normal muscle architecture after such extensive muscle injury. The use of HMSCs did not prove to help regeneration but this could be explained by the vehicle (FloSeal) tested. The choice of proper vehicle seems to be critical for local application of stem cells in muscle injuries. Thrombin is an alternative vehicle that is currently being tested. **Acknowledgements** This work was supported by grant PTDC/DES/104036/2008 from Fundação para a Ciência e a Tecnologia, Portugal.

### DIFFERENCES IN INJURY RATES BETWEEN SOCCER CLUBS: A PROSPECTIVE STUDY

Stubbe, J., Stege, J., Verhagen, E., Van Mechelen, W.

*TNO: Netherlands Organisation for Applied Scientific Research*

Differences in Injury Rates between Soccer Clubs: A Prospective Study JH Stubbe (1,2), JP Stege (1,2), EALM Verhagen (2,3), W van Mechelen (2,3) 1) TNO, Leiden, The Netherlands 2) Body@Work TNO VUmc, VU University Medical Center, Amsterdam, The Netherlands 3) Department of Public & Occupational Health/EMGO+ Institute, VU University Medical Center, Amsterdam, The Netherlands In professional soccer, where large salaries are paid, the absence of players due to injuries leads to high costs. However, it is unclear whether there are large differences between soccer clubs in injury rate. PURPOSE: To study the injury rate in Dutch professional soccer players and investigate whether there are differences in injury rates between soccer clubs. METHOD: During the 2009-2010 season, the medical staff of 16 professional soccer clubs registered the injuries and recoveries according to the consensus statement established by the FIFA Medical Assessment and Research Centre (F-MARC). They provided information on the training and match exposure of each player per week. Players who sustained an injury were registered by the club (para)medic. RESULTS: In total 457 professional soccer players were registered of which 318 (67.7%) sustained one or more injuries. In total 679 injuries were reported, with 11.8% being reported as a re-injury. Significant differences between soccer clubs were found in the percentage of players that sustained an injury during the soccer season (lowest percentage = 41%; highest percentage = 92%) and in injury incidences (number of injuries per 1000 hours of training and matches). CONCLUSION: This study shows that the rate of injuries among professional Dutch soccer players is high. There are significant differences between clubs regarding the percentage of players that sustained an injury during the soccer season and injury incidences.

### EFFECTS OF A SINGLE SESSION OF WHOLE-BODY CRYOTHERAPY <-110 °C> ON MUSCULAR PERFORMANCE

Ferreira Júnior, J.B.

*University of Brasilia*

Ferreira-Junior, J.B.1,2, Vieira, C.1, Soares, S.1, Guedes, R.1, Rocha-Junior, V.A.1, Brown, L.E.3, Bottaro, M.1 1: UnB (Brasilia, Brazil), 2: IFTM (Paracatu, Brazil), 3: CSU, (Fullerton, USA) Introduction It has been shown that body cooling may decrease the performance of muscles. Whole-body cryotherapy (WBC) is a mode of cold therapy, in which patients are repeatedly exposed to very cold air (-110 to -140 °C). WBC has been used in sports medicine and to enhance recovery in athletes following heavy periods of training. However, the effect of a single session of WBC on muscle performance has not been documented. Therefore, the aim of this study was to evaluate the effects of a single WBC bout on strength in healthy subjects. Methods Fourteen young men (21.1 ± 2.3 yrs) were randomly exposed to two different conditions separated by a minimum of 72 hours: 1) WBC (Subjects were exposed to 3 min of WBC at -110 °C); 2) Control no-WBC (NWBC; subjects stayed in the WBC chamber for 3 min at 21 °C). All subjects were tested for maximal isokinetic elbow flexion at 60°.s<sup>-1</sup> before and after each condition. Statistical evaluation of the data was performed using a 2 x 2 repeated measures ANOVA [condition x time]. The significance level was set at  $p < 0.05$ . Results The peak torque of WBC was 65.54 ± 9.23 N.m in the pretest and 63.98 ± 9.39 N.m in the posttest. The NWBC group obtained 66.30 ± 9.25 N.m and 64.74 ± 10.14 N.m in the pretest and posttest, respectively. The total work performed by WBC in the pretest was 455.96 ± 68.85 J and in the posttest was 447.90 ± 70.22 J. For the NWBC the scores of total work were 450.95 ± 61.25 J in the pretest and 445.13 ± 64.08 J in the posttest. There were no significant differences in peak torque or total work between conditions or between pretest and posttest. Discussion The results indicate that a single 3-min session of WBC (-110 °C) did not decrease muscle torque production or work capacity. These findings were in disagreement with results previously reported. Westerlund et al. (2009) observed a decrease in the drop-jump flight time after a single WBC exposure. In the other hand, Fricke et al. (1999) found that the isokinetic torque of the knee flexors and extensors improved after a single WBC bout (2 min) in untrained healthy subjects. The differences between the present investigation's results and previous reports may be due to a difference in body segments analyzed in each study. Upper body and lower extremities may respond differently to the WBC. Further studies should test this hypothesis. However, the present findings suggest that coaches and physical therapists can use WBC before training and rehabilitation without compromising the performance of upper-body muscles. ### BODY COMPOSITION ANALYSIS IN SUBJECT WITH DIFFERENT PATTERN OF PHYSICAL ACTIVITY

Rilova, N.1,2, Mustafina, L.1, Ahmetov, I.1

*1. Volga Region State Academy of Physical Culture, Sport and Tourism (Kazan, Russia), 2. Kazan State Medical University, Department of pediatrics (Kazan, Russia).*

Introduction Human body has a multi-component structure and can be studied by bioelectrical impedance analyzers at the tissue and molecular level. Body composition can vary between individuals depending on various factors such as gender, age, nutritional state and pattern of physical activity (Heyward and Wagner, 2004). Currently, measurement of bioelectrical impedance is actively used in many countries (Fornetti et al., 1999). Bioelectrical impedance measures the level of resistance of electrical current through the body. Since water conducts electrical current well, those tissues with higher water levels (muscle) conduct electricity better than those with lower levels (fat) (Kushner, 1992). Athletes tend to have greater lean mass (composed of metabolically active tissues, such as muscles and organs), while unfit subjects have an excess of fat mass (composed of visceral and subcutaneous adipose tissue). The aim of the study was to analyze body composition in subjects with different pattern of physical activity. Methods One hundred and twenty two subjects were recruited for the study. Body composition parameters (percentage of fat and muscle mass, visceral fat, body water, metabolic age, etc.) were assessed by bioelectrical impedance analyzer "Tanita MC 980" (Japan). Physical activity pattern was determined by a questionnaire. Subjects were first divided into several groups depending on their physical activity. Next, two groups at opposing extremities of physical activity pattern (16 sedentary men (age 24.8 (2.2) yr, weight 76.8 (4.3) kg) reported no regular physical activity (S group); 17 physically active men (age 22.9 (3.6) yr, weight 77.8 (12.5) kg) regularly participated in high intensity physical activity of more than 12 hours per week (A group)) were compared. Results We found that the percentage of body fat (9.5 vs. 19.1%;  $p < 0.01$ ), visceral fat mass (1.5 (0.5) kg vs. 4.3 (1.1) kg;  $p < 0.01$ ) and metabolic age (13 (2.8) yr vs. 26.7 (3.1) yr;  $p < 0.05$ ) were significantly lower in A group compared with the S group. In contrast, subjects from A group had a higher muscle mass (66.6 (8.9) kg vs. 58.8 (1.8);  $p < 0.02$ ), total body water (65.1 (4.2)% vs. 58.4 (3.5)%;  $p < 0.027$ ) at the expense of intracellular water (33.7 (4.7) vs. 26.8 (1.3);  $p < 0.03$ ). Conclusions Thus, men with high physical activity had a reduced fat mass, a lower risk of obesity and an increased muscle mass than sedentary men. We have demonstrated that significant changes in morphological and metabolic characteristics are formed under the influence of regular physical activity. References Kushner RF. ## MEDICAL ATTENDANCE REQUIREMENTS OF HIGH PERFORMANCE ATHLETES

Porcar, C.1,2, Guerra, M.2

*1.Consorci Sanitari de Terrassa; 2 FPCEE-Blanquerna. University Ramon Llull*

Introduction Nowadays, to prevent injuries, it is important to know which kinds of injuries are more frequent. Some research has been done with an American high school population (Darrow, C J., Collins, C L., Yard, E E., Comstock, D., 2009). Through medical visits, we have studied athletes belonging to an Olympic Training Center and their epidemiologic characteristics to know the requirements for a medical attendance. Methods Informatics Clinical histories of medical attendance were obtained and analyzed determining the number of visits done by the physician in charge of these athletes, as well as the variables associated to these visits. 16925 visits were analyzed during 45 months, in 16 Olympic sports. Variables were the following: Acute disease, Chronic disease, Chronic injury, Acute Injury, Recidivated injury, Sequel of injury, Injury's circumstances (training, competition, non sportive), Topography of injury, Tissue structure damaged and Kind of injury. Results Respiratory Diseases were the most frequent (52 % of the total number of medical visits). Headache was the second more frequent (12 %), Digestive system problems (9 %), dermatological diseases (12 %) and ORL (8 %). In relation to muscle-skeletal system, 90 % of all the injuries appeared during training. Acute were the most frequent (75 %) and only an 18 % were chronic injuries. In relation to affected tissue, the muscle was the most affected (27 %), followed by bone (16 %), tendon (13 %) and ligament (12 %). The most injured sports were tennis and gymnastic (16% each of them), track and field (12 %) and swimming and Tae-Kwon-Do (12 % each of them). Topography of injury showed that knee (17%), ankle (12%), foot (11%) and low back (10%) were the most frequent. Discussion High performance athletes present peculiar epidemiologic characteristics (Spence, L., 2007; Alonso, J M., Tscholl, P M., 2010) that need to be studied to optimized the health service that they receive. More research is needed to determine the characteristics that differ from a general population as well to determine the kind of injury related to the kind of sport (Hootman, J M., Dick, R., Agel, J., 2007). ## POST EXERCISE RESPONSE OF STROKE PATIENTS TO AEROBIC REHABILITATION PROGRAMME.

Oladipo, O., Orege, A.

*University of Ibadan; Ibadan, Nigeria.*

Abstract Objective: To investigate the effect of Aerobic Training programme on the cardiorespiratory responses, aerobic fitness and exercise programme in the patients with chronic cerebrovascular injury. Design: Randomized pre-test, post-test experimental design. Setting: Exercise physiology laboratory, university of Ibadan, Nigeria. Main outcome: Maximum oxygen uptake, vital capacity, forced vital capacity, peak expiratory flow, maximum ventilatory volume were determined by spirometry measurements while exercise time was determined by the time spent on the bicycle ergometer by participants on reaching their volitional stoppage, blood pressure and heart rate were also determined before and after each training session. Result: The exercise intensity ranged from 50% to 80% heart reserve. Exercise duration was between 30 to 40 minutes for three days a week. The total number of participants included in the study was 30. A participant was disqualified due to his irregular systolic blood pressure on the second week of training and continuous right hamstring pain. A significant trend of improvement was found in all aerobic and cardiovascular parameters. Statistical analysis of one way anova revealed a significant improvement in favour of aerobic training to improve maximum oxygen uptake. (Vo2max) (95% confidence interval, 16.963-18.995; p<0.005), and exercise performance time (1614.069-1847.095, p<0.005). Improvement in sensory motor function was significantly related to aerobic capacity. Conclusion: We concluded that patients with chronic attack of stroke may improve their aerobic capacity, sub-maximal exercise systolic blood pressure and improve their functional abilities with aerobic training.

## EFFECTS OF PHYSICAL EXERCISE AN ANIMAL MODEL OF RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENT

Esteves, A.M.1, Frussa-Filho, R.2, Lopes, C.1, Cavagnoli, D.A.1, Frank, M.K.1, Arida, R.M.3, Tufik, S.1, de Mello, M.T.1

*Universidade Federal de São Paulo*

Introduction Epidemiologic data have been increasingly attesting to the negative impact of restless legs syndrome (RLS) upon health. Treatment for idiopathic RLS is most commonly pharmacological. Notwithstanding, the beneficial influence of physical exercise on RLS symptoms and periodic leg movement (PLM) has also been the subject of clinical research. The purpose of the present study was to verify the influence of physical exercise on a experimental animal model (6-OHDA – induced lesion of A11 dopaminergic nuclei) of RLS and PLM. Methods In the first experiment (physical exercise post lesion of A11), control, SHAM operated and rats submitted a A11 lesion were submitted to baseline sleep recording and to a second sleep recording after the last session of a 4 week physical exercise program. In Experiment 2 (physical exercise pre- and post lesion of A11) a 2 week physical exercise was conducted before A11 lesion. Seven days after surgery the first (baseline) sleep recording session was performed and subsequently, a 4 week physical exercise program was conducted. After the last training session second sleep recording session was performed. The sleep analyses were realized in 24h and in 6 blocks of 4h (7-11am, 11am-3pm, 3-7pm, 7-11pm, 11pm-3am and 3-7am). Results The results demonstrated that A11 lesion produced and increased percent of wakefulness in the last block of the dark period (3-7am) and a significant enhancement of the number of limb movements (LM) through out the day. Chronic physical exercise (conducted before and /or after A11 lesion) counteracted both the sleep pattern alterations (decreased of percent of wakefulness) and the increase in the number of LM produced by 6-OHDA-induced A11 Lesion. Discussion While there is considerable experimental evidence linking physical exercise and an enhancement of dopaminergic function<sup>2,3</sup>, clinical studies have reported beneficial effects of this non pharmacological approach in RLS/PLM<sup>4,5</sup>. These findings extend the validation of 6-OHDA-induced A11 lesion as an animal model of RLS/PLM and strengthen the notion that physical exercise can produce beneficial effects on their symptoms. 1. **FREQUENCY OF POLYMORPHISM TRP64ARG IN BRAZILIAN ADOLESCENTS OBESE WITH METABOLIC SYNDROME**

Leite, N., Milano, G.E., Tiiski, A.C.T., Milano, G., Carvalho, H.M., Radominski, R.B., Coelho-e-Silva, M.J., Alle, L.F.

*Federal University of Paraná*

**Introduction** The  $\beta$ 3-adrenergic receptor ( $\beta$ 3-AR) gene polymorphism of the human  $\beta$ 3-AR gene has been reported to be positively associated with obesity (Kim-Motoyama et al., 1997) and obesity-related metabolic syndrome (Knowler, 1996). The  $\beta$ -adrenoceptors play important roles in energy expenditure and control body weight (Iwashita; Tanida; Terui, 2002), however there are also reports that showed no significant correlation of 64Arg allele with body weight gain and metabolic disorders (Matsushita et al., 2003). The aim of the present study was evaluate the frequency of polymorphism Trp64Arg in ADBR3 in obese adolescents with metabolic syndrome (MS). **Methods** The study included 114 obese with MS, classified as having MS if they met three or more criteria for age and sex according the Adult Treatment Panel III (ATP III). Systolic (SBP) and diastolic blood pressure (DBP), waist circumference (WC), BMI Score Z, glucose and lipid profile were determined. The Trp64Arg genotype of the ADBR3 gene was examined in peripheral blond leukocyte DNA. Student's t test was performed with a significance level of 0.05. **Results** Participated in the study 114 (50 girls and 62 boys) obese with MS. The frequency of polymorphism in the ADBR3 gene was 19% in this sample (n=22), consisting of 19 showed genotyping Trp/Arg and 3 Arg/Arg. Comparing the MS groups: G1 = without ADBR3 gene polymorphism group (Trp/Trp) and G2 = with ADBR3 gene polymorphism group (Trp/Arg and Arg/Arg), we observed similar results in both groups for age (G1= 12.73 $\pm$ 1.88 years vs G2= 12.58  $\pm$  1.52 years, p=0.26), BMI Score Z (G1= 3.45  $\pm$  0.13 vs G2= 3.71  $\pm$  1.12, p=0.23), WC (G1= 100.11  $\pm$  13.41 cm vs G2= 102.38  $\pm$  11.16 cm, p=0.37), SBP (G1= 110.39  $\pm$  14.93 mmHg vs G2= 110.53  $\pm$  16.15 mmHg, p=0.85), DBP (G1= 71.28  $\pm$  11.55 mmHg vs G2= 73.57  $\pm$  9.63 mmHg, p=0.32), HDL-c (G1= 42.14  $\pm$  7.33 mg/dL vs G2= 41.66  $\pm$  8.78 mg/dL, p=0.29), TG (G1= 135.04  $\pm$  60.74 mg/dL vs G2= 155.9  $\pm$  86.2 mg/dL, p=0.80) and glucose (G1= 90.46  $\pm$  9.05 mg/dL vs G2= 89.1  $\pm$  1.82 mg/dL, p=0.50). **Discussion** In this sample, the frequency of polymorphism in the ADBR3 gene in MS group was higher than obese group in study of Ochoa et al. (2004). When comparing MS groups with or without polymorphism in the ADBR3 gene were not found differences in variables related to MS. However, Tahara et al. (2011) found higher blood glucose values in the Trp64Arg polymorphism group. We suggest further studies with larger samples and different age groups. **References** Kim-Motoyama H, Yasuda K, Yamaguchi T, Yamada N, Katkura T, Shuldiner AR. (1997). *Diabetologia*, 40, 469-72. **13:45 - 14:45****Poster presentations****PP-PM38 Nutrition 3****IMPACT OF AN ESSENTIAL AMINO ACID RICH IN LEUCINE/CARBOHYDRATE SUPPLEMENTATION ON MUSCLE MASS FOLLOWING RESISTANCE TRAINING IN YOUNG MEN**

Stragier, S., Vieillevoye, S., Poortmans, J., Carpentier, A.

*Université Libre de Bruxelles*

**Impact of an essential amino acid rich in leucine/carbohydrate supplementation on muscle mass following resistance training in young men** Stragier, S., Vieillevoye, S., Poortmans, J., Carpentier, A. *Université Libre de Bruxelles, Belgium* **Introduction** Recent studies indicated that orally administered leucine (leu) appears as a stimulus of the muscle protein synthesis in rats (Anthony et al, 2000) and humans (Dreyer et al, 2008). The aim of this study was to investigate the impact of oral essential amino acid (EAA) supplementation rich in leu on muscle mass in combination with resistance training. **Methods** Twenty height young males performed two sessions of resistance training per week during 12 weeks. They were divided into two groups, one group received placebo (30g carbohydrate; PL) and the other group received an EAA+leu (15g)/carbohydrate (15g) supply (S). Each exercise was performed at 70-85 % of the subject's one repetition maximum and consisted of about 50 repetitions subdivided in several sets. Dietary supplementations were consumed twice a day, with breakfast and immediately after the training session on the exercise days (and with dinner the others days). Maximal strength during squat and bench press exercise were tested on an isokinetic ergometer (Ariel CS 6000) before and after training programme. Skeletal muscle mass (SMM) was assessed by anthropometric measurements (Lee et al, 2000). **Results** Training resulted in an increase in SMM in both PL (2.3 $\pm$ 2.2%, p<0.01) and S groups (4.0 $\pm$ 2.4%; p<0.01). Concentric strength increased for the bench press and squat exercises by 9.9 $\pm$ 8.8% (p<0.01) and 11.7 $\pm$ 8.7% (p<0.001), respectively in S group and an increase was shown only for the bench exercise in PL group (12.6 $\pm$ 11.4%; p<0.001). After normalization of the initial strength with the initial SMM, a negative linear regression between this ratio and the increase in muscular strength after training was found in S group (r<sup>2</sup> = 0.47, p<0.01). **Discussion** Our results confirm that a combined EAA drink did not result in greater improvement in SMM and strength following a 3 months strength training programme. However, our data indicate that a daily intake of 10.5g of leu enhances SMM and strength, but did not provide greater gains in muscle mass, strength and power in young male compared to an intake of 5.7g/day (Vieillevoye et al., 2010). **In conclusion**, EAA/carbohydrate supplementation is effective to provide additional gains in SMM and muscle strength when combined with resistance training on subjects who had a lower initial muscle strength. **References** Anthony J, Yoshizawa F, Anthony T, Vary T, Jefferson L, Kimball S (2000). *J Nutr* 130:2413-2419 Dreyer H, Drummond M, Pennings B, Fujita S, Glynn E, Chinkes D, Dhanani S, Volpi E Rasmussen B (2008). *Am J Physiol Endocrinol Metab* 294:392-400 Lee R, Wang Z, Heo M, Ross R, Janssen I, Heymsfield S (2000). *Am J Clin Nutr* 72: 796-803 Vieillevoye S, Poortmans J, Duchateau J, Carpentier A (2010). *Eur J Appl Physiol* 110:479-488

## EFFECTS OF L-ARGININE SUPPLEMENTATION ON PLASMA LACTATE AND AMMONIA REMOVAL IN HIGHLY TRAINED RUNNERS

Alvares, T., Marques, A., Batista, D., Conte-Junior, C., Silva, J., Paschoalin, V.

*Federal University of Rio de Janeiro*

**EFFECTS OF L-ARGININE SUPPLEMENTATION ON PLASMA LACTATE AND AMMONIA REMOVAL IN HIGHLY TRAINED RUNNERS** Alvares, T.1; Marques, A.2; Batista, D.1; Conte-Junior, C.1; Silva, J.1; Paschoalin, V.1. 1: DBq-IQ-UFRJ (Rio de Janeiro, Brazil). 2: SPEED sports advisory group (Rio de Janeiro, Brazil). Introduction L-arginine has been used to promote an increase in blood perfusion in the active muscle, and supposedly increasing the removal of metabolites, such as lactate and ammonia, which are related to exercise fatigue during intense physical exercise. Therefore, the aim of this study was to analyze changes on plasma lactate and ammonia concentrations in response to exercise after L-arginine supplementation. Methods 15 highly trained runners (4 females) were randomly divided in ARG (6 g of L-arginine) and PLA (6 g of corn starch) groups. At the first, the runners took the supplementation and rested for 20 min. Afterwards, the subjects performed two bouts of a 5 km time-trial running test with a 10-min rest period. Blood samples were drawn before supplementation (T0), immediately after the first 5 km time-trial running test (T1), immediately after the second 5 km time-trial running test (T2) and after 20 min of rest (T3). Plasma lactate and ammonia were detected (in duplicate) by spectrophotometry at 450 and 570 nm, respectively. Two-way ANOVA with repeated measures was performed in order to identify differences between groups in plasma lactate and ammonia concentrations on the four time point in which measurements were taken. Results Significant increases in plasma lactate and ammonia from T0 to T1 and T2 ( $P < 0.01$ ) in both ARG and PLA groups with no significant change between the groups. However, a significant reduction ( $P < 0.01$ ) on plasma lactate and ammonia were observed from T2 ( $1.78 \pm 0.57$  mM lactate;  $179.1 \pm 101.0$   $\mu\text{mol/L}$  ammonia) to T3 ( $0.80 \pm 0.21$  mM lactate;  $79.73 \pm 78.14$   $\mu\text{mol/L}$  ammonia) only in ARG group. Discussion In both ARG and PLA groups, lactate and ammonia increased significantly in response to exercise. However, during the recovery period of the 5 km time-trial running test, the removal of lactate and ammonia were higher only in ARG. Previous evidence (Denis et al., 1991) has shown positive effect of L-arginine in reducing the exercise-induced hyperammonemia after 15 min of cycle ergometer exercise. Furthermore, the significant decreases on plasma lactate and ammonia in ARG group may be related with the possible effect of L-arginine on increasing blood perfusion as show by early evidence (Alvares et al., 2012). Although increases in the removal of plasma lactate and ammonia on ARG group were detected, they were not significantly different from PLA group. ## ACUTE EFFECTS OF ENERGY RESTRICTION DURING ENDURANCE TRAINING ON PHYSICAL PERFORMANCE

Pilger, N., Koehler, K., Zinner, C., Braun, H., Mester, J., Schaezner, W.

*German Sport University*

**Introduction** Many athletes, especially participants in endurance and aesthetic sports and weight category sports, are chronically energy deficient (Loucks, 2004). The effects of energy restriction on body composition, hormone levels and metabolism are well described, but little is known about the effects on physical performance capacity. Hence, our study was aimed on the effects of energy restriction combined with endurance training on physical performance parameters. **Method** Four male athletes ( $26 \pm 3$  y,  $79 \pm 8$  kg) underwent a randomized, cross-over-design intervention. Dietary energy intake was designed to reach either a normal energy availability of 40 kcal/kg FFM (control group = CG) or a low energy availability of 15 kcal/kg FFM (energy restriction group = ERG). Each intervention went for four consecutive days and daily endurance training sessions were performed at 60% of the maximal oxygen uptake. Training energy expenditure was 15 kcal/kg FFM. Energy intake was adapted to the subjects' typical diet, which was assessed with a diet history. Pre and post tests were performed to assess body weight, body composition, submaximal cycling performance, maximal power output during a Wingate test and isometric strength tests (leg curl, leg extensions and bench press). **Results** There was a significant reduction in body weight between CG and ERG of  $2.5 \pm 1.9$  kg ( $p < 0.01$ ). Body fat was reduced by  $2.2 \pm 1.1$  kg (ERG) vs.  $0.3 \pm 1.1$  kg (CG), without statistical significance. maximal isometric strength in bench press, leg curl and leg extension and maximal power output during the Wingate test did not change significantly. During the submaximal cycling test, heart rate was elevated during energy restriction ( $p < 0.05$ ). **Discussion** The results show that an acute energy restriction combined with training has no significant effects on several parameters of physical performance. Maximal anaerobic capacity measured with the Wingate test and strength tests showed no significant differences. Only in the submaximal cycling test, heart rate was significantly lower in the CG compared to ERG. If an acute energy restriction takes place in combination with training, athletes may loose weight but maximal performance capacity seems to be unaffected significantly. **References** Loucks AB. (2004). J Sports Sci, 22, 1-14.

## NUTRITIONAL INTAKE OF ELITE MALE AND FEMALE HIGH JUMPERS DURING THE GENERAL PREPARATION PHASE

VELIGEKAS, P., BOGDANIS, G.C., CHRISTOFI, E.

*University of Athens, GREECE*

**Introduction** The importance of physique in high jump is demonstrated by the prevalence of tall and extremely lean somatotypes among elite male and female high jumpers who also have a high muscle power to body mass ratio (O'Connor et al., 2007). Nutrition plays a key role in maintaining optimal body weight and body composition and also supports the requirements of heavy training (Stellingwerf et al., 2011). However, only a few studies have assessed the nutritional intake of high jumpers (Houtkooper et al., 2007). Therefore, the aim of this study was to investigate and compare the nutritional intake of elite male and female high jumpers during the general preparation phase of their annual training plan. **Methods** Fifteen elite male and female high jumpers took part in the study (7 males:  $1.86 \pm 0.08$  m,  $75.4 \pm 4.4$  kg, personal best:  $2.07 \pm 0.21$  m and 8 females:  $1.76 \pm 0.06$  m,  $59.4 \pm 5.6$  kg, personal best:  $1.67 \pm 0.15$  m). Participants weighed and recorded their diet for 3 days (2 weekdays and 1 weekend day), during the general preparation phase. Nutrient intake was analyzed using custom-made software based on a standard nutritional database (Food Standards Agency, 2002). Statistical comparisons between male and female jumpers were made using independent t-test ( $p < 0.05$ ). **Results** Average daily energy intake for male and female jumpers was  $11.3 \pm 1.8$  and  $7.9 \pm 1.0$  ( $p = 0.12$ ), respectively and was derived from carbohydrate by  $40 \pm 3\%$ , from fat by  $41 \pm 2\%$ , from protein by  $18 \pm 2\%$ , while alcohol represented less than 1%. Macronutrient intake per kg body mass did not differ between male and female jumpers and was  $3.6 \pm 0.8$  and  $3.3 \pm 0.5$  g/kg for carbohydrate,  $1.6 \pm 0.1$  and  $1.3 \pm 0.1$  g/kg for protein and  $1.6 \pm 0.3$  and  $1.5 \pm 0.2$  g/kg for fat. **Discussion** The main finding of this study was that both male and female elite high jumpers followed a diet that was inadequate to support their daily training and recovery needs in terms of carbohydrate intake (Houtkooper et al., 2007). Although total energy intake was moderate to

low, fat intake was in excess of what is recommended, while protein intake was within the range proposed to support intense training (Stellingwerff et al. 2011). The low energy and carbohydrate intake of elite high jumpers may be related with their perception that a low body weight is of paramount importance for success, but this may lead to sub-optimal training adaptations by affecting both duration and quality of training. ### **AEROBIC EXERCISE TRAINING REDUCES SERUM CONCENTRATION OF LEPTIN BUT DOES NOT CHANGE THE TNF- $\alpha$ AND IL-10**

Matos-Neto, E.M.1, Trindade, M.C.C.1, Torres-Leal, F.L.1, Pantaleao, L.C.1, Fonseca-Alaniz, M.H.2, Rogero, M.M.1, Tirapegui, J.1

1: USP (São Paulo, Brazil), 2: INCOR (São Paulo, Brazil)

**Introduction** - The anti-inflammatory effect of exercise training (ET) is due, at least in part, to changes in the body composition, in the dietary intake, and in the synthesis and release of pro- and anti-inflammatory adipocytokines from the white adipose tissue (GLEESON et al., 2011). Therefore, the aim of this study was to investigate the effect of aerobic ET on body composition, dietary intake and serum concentrations of adipocytokines related to inflammation. **Methods** - For this study, we used 15 male Wistar rats with eight weeks of age. The animals were distributed in two groups: sedentary (SG, n=7) and trained group (TG, n=8). The TG animals were submitted to ET on a treadmill for eight weeks. Both groups were fed ad libitum AIN 93-M. The following parameters were analyzed: chemical composition of the carcass, weight of the fat pads and serum leptin, TNF- $\alpha$  and IL-10 through immunoassay multiplex method. **Results** - There was a significant difference in final body weight (SG: 426.7  $\pm$  11.3 and TG: 390.7  $\pm$  5.88). There was no statistical difference in the food intake of animals (SG: 54.07  $\pm$  2.61 and TG: 53.42  $\pm$  4.74). The ET significantly reduced the mass of subcutaneous (SG: 12.72  $\pm$  3.35 and TG: 4.81  $\pm$  0.22), periepididymal (SG: 14.51  $\pm$  2.51 and TG: 7.35  $\pm$  0.58) and retroperitoneal adipose tissues (SG: 10.96  $\pm$  1.57 and TG: 5.28  $\pm$  0.45). Also, ET increased the fat-free mass (SG: 82.57  $\pm$  3.62 and TG: 91.60  $\pm$  0.57) and significantly reduced the body fat percentage (SG: 17.43  $\pm$  3.62 and TG: 8.40  $\pm$  0.57), which was followed by a reduction in the serum concentration of leptin (SG: 19.02  $\pm$  2.03, TG: 8.68  $\pm$  0.78). Serum concentrations of both TNF- $\alpha$  and IL-10 did not change significantly between the groups (GS: 2.35  $\pm$  0.30, TG: 1.89  $\pm$  0.01 and GS: 101.5  $\pm$  21.35; GT: 91.51  $\pm$  16.61, respectively). **Discussion** - Confirming previous studies, we found that the reduction of body fat promoted by ET was accompanied by a reduction in serum leptin, an adipokine often related with anorexia, but also with infectious and inflammatory processes (OTERO et al., 2005), demonstrating that ET exerted an anti-inflammatory effect. However, when analyzing serum concentrations of TNF- $\alpha$  and IL-10, there were no significant changes between the groups. Therefore, the results presented here indicate that the aerobic ET anti-inflammatory action is independent of food intake (GAREKANI et al., 2011). ### **EFFECT OF 8 WEEKS OF AEROBIC TRAINING ON INFLAMMATION IN SPRAGUE DAWLEY RATS**

Pedroso, J.A.B., Nishimura, L.S., Matos-Neto, E.M., Moreira, R.L.L., Azevedo, L.B., Gimenis, D.P., Tirapegui, J.

University of São Paulo

**Introduction** Several studies have shown the effect of exercise in reducing the risk of developing chronic degenerative diseases and cardiovascular diseases. Although it is unclear in the literature, several authors suggest that this benefit is due to changes in the inflammatory responses caused by exercise. Thus, the objective of this study was to investigate the effect of endurance exercise training on inflammatory proteins. **Methods** Fourteen (14) adult male Sprague Dawley rats were assigned into two groups: sedentary (SED) (n = 6) and trained group (Training) (n = 8), which was subjected to 1-hour training per day on a treadmill for 8 weeks, 50 -70% VO<sub>2</sub>max. Cytokine levels were measured by multiplex immunoassay using rat serum adipokine (panel kit 7 LINCplex) for simultaneous measurement of TNF- $\alpha$ , IL-1 $\alpha$ , IL-6, MCP1 and leptin, in the automatic Lincplex 200. **Results** Trained group showed a higher concentration of IL-6 (880.36  $\pm$  276.09 pg / ml and 194.31  $\pm$  76.97 pg / ml) and IL-1 $\alpha$  (203.47  $\pm$  49.16 pg / ml, 31, 29  $\pm$  4.7 pg / ml) compared to SED group (p <0.05). There was no statistically significant difference on MCP1 and TNF- $\alpha$  levels between groups. We observed a higher leptin concentration in SED group (17.03  $\pm$  4.46 ng / ml) compared to trained group (6.44  $\pm$  1.06 ng / ml) (p <0.05). **Discussion** The results suggest that eight weeks of aerobic training was able to alter the production of some inflammatory proteins, exerting anti-inflammatory effects, and can provide several metabolic and hormonal improvements in different tissues, thus providing a powerful tool to control and / or reduce the risk of developing chronic degenerative disorders. ### **RELATION OF MACRONUTRIENTS CONSUMPTION AND MENARCHE IN ADOLESCENTS**

Leite, N., Mascarenhas, L.P.G., Titski, A.C.T., Moser, D., Rodrigues, A.M., Coelho-e-Silva, M.J., Boguszewski, M.C.S.

Federal University of Paraná - CAPES - Brazil

**Introduction** In several populations has been observed the decrease in age at menarche and the lack of scientific agreement about the factors that can stimulate increasingly early puberty (CABANES et al., 2009). The aim of this study was to identify the relationship between macronutrient intake and age at menarche in adolescents. **Methods** We evaluated 400 girls divided into two groups according to the intake of saturated fat acid (SFA) from food: Group G1  $\geq$  10% of saturated fat acid ingestion and Group G2 <10% of saturated fat acid ingestion. The height, weight, waist circumference (WC) and BMI were measured following the usual anthropometrics procedures. The menarche age was obtained by self-report. To assess the nutritional intake of young participants, the questionnaire of food frequency (FFQ) was applied. Student's t test and stepwise linear regression were performed with a significance level of 0.05. **Results** In the Groups Characteristics, there were no significant differences in age (G1= 14.06  $\pm$  2,13 years vs G2 =14.55  $\pm$  2,94 years; p= 0.37), weight (G1= 50,55  $\pm$  10,74 kg vs G2= 52, 02  $\pm$  14,73 kg; p= 0.28), height (G1= 156  $\pm$  0,8 cm vs G2= 154  $\pm$  0,8 cm; p= 0.15) and BMI (G1= 20,53  $\pm$  3,49 kg/m<sup>2</sup> vs G2= 21,42  $\pm$  4,85 kg/m<sup>2</sup>; p= 0.10). The G2, group with low saturated fat acid consumption has lower age of menarche than G1 (G1= 11.97  $\pm$  1,16 years vs G2= 11.60  $\pm$  1,26 years; p=0.03), calories intake (G1= 2755.40  $\pm$  806,58 kcal vs G2= 2399,35 $\pm$ 887,93 kcal; p=0.001), proteins (G1= 101,88  $\pm$  32,66 g vs G2= 81,93  $\pm$  31,08 g; p=0.001), total fat (G1= 98,04  $\pm$  37,81g vs G2= 60,84  $\pm$  32,24 g; p=0.001), and cholesterol (G1= 365,65  $\pm$  252,41 mg vs G2= 201,93  $\pm$  206,63 mg; p=0.001). By linear regression analyzes was observed that the consumption of saturated fatty acid can explain menarche age with R =0.232 and R<sup>2</sup> =0.05. **Discussion** In this study saturated fatty acids

were significantly associated with age at menarche. Others authors also found that high consumption of saturated fat acid is associated with postpone of menarche (MACLURE et al., 1991; GALLO et al. 2010). We suggest further studies with larger samples and longitudinal groups. References Cabanes A, Ascunze N, Vidal E, Ederra M, Barcos A, Erdozain N, Lope V, Pollám M. (2009). BMC Public Health, 9, 449. THE EVOLUTION ONTOGENESIS OF THE ANTHROPOMETRIC INDICES AND MOTOR CAPACITY COMPONENTS OF THE CHILDREN WITH INTELLECTUAL DISABILITIES DURING THE SECONDARY LEVEL CYCLE Suta, V.E.N.1;2, Marinescu, Gh.2, Salgau, S.3, Chirila, D.2, Tranca, S.2, Crangus, N.2, Petrisor, L.2, Paunescu, M.2, Oancea, C.2, Suta, L.1 1:Special School no 11 (Bucharest, Romania), 2:NUFES (Bucharest, Romania), 3:UVA (Bacau, Romania) Introduction The purpose of the research was highlight the evolution of the somatic indices and the development of the motor skills in ontogenesis of the students with severe mental deficiency, during the entire secondary level cycle. Methods During the study, there were used bibliographic research, the test method and statistical mathematical methods of data processing. The standardized biometric tests used to evaluate the 60 students with intellectual disabilities, divided in to 4 groups where the following: The Brockport Test Battery, The Romanian Biomotor Potential of the School Population, The Matorin Test and the Flamingo Balance Test of Euroit Test Battery. To process the recorded data there was used a statistical mathematical program called SPSS 16 before Windows, U Mann-Whitney Test being applied or two independent groups. The significance level taken as point of reference was  $p < 0,05$ . Results After comparing the group of the girls with mental disabilities from the 5th grade having 11-12 years and the group of girls with intellectual disabilities from the 8th grade, aged 15-16 years, there were recorded statistically significant differences at the level of waist, bust, weight, chest, muscle strength and the force of the bilateral flexors. There were recorded no significant statistically differences at the level of thoracic elasticity, running speed, hand and leg coordination, body mass index, shank plicae tricipital and subscapular, upper limb muscle strength and at the level of abdominal muscles, spine mobility, shoulder and hip joints, general coordination and balance. The comparisons made between the groups of boys with intellectual disabilities having the same age as the girls revealed additional significant differences at the level of the body mass index and hip joint mobility. Discussion The values of the anthropometric indices of the students with mental deficiency are statistically significant increasing between 11 and 15 years, while in terms of motor capacity components values there are no major differences in ontogenesis during the secondary level cycle. #### COMPARISON BETWEEN REAL AND VIRTUAL ENVIRONMENTS IN AN ADAPTED TABLE TENNIS TASK

Silva, E., Teruya, T.T., Mochizuki, L., Silva, T.D., Guimaraes, E.A., Santos, B.S., Santos, L.C., Neiva, J.F.O., Monteiro, C.B.M.

University of São Paulo

Introduction The use of training for the physically disabled in a virtual environment is highly questioned (Deutsch et al, 2011; Shih et al, 2012). The aim of this study was to compare the stroke performance of individuals with physical disabilities in the real and virtual conditions. Methods 19 wheelchair athlete performed the strokes with a table tennis robot and playing a tennis table video game (Wii Sport Resort, Nintendo). Each trial was 30 s long. A triaxial accelerometer was attached to the table tennis paddle and to the video game remote control. The sampling rate was 1 kHz. The analysis of variance was ran to test the effect of practice condition (real and virtual) in the peak acceleration of the table tennis racket and Nintendo Wii remote controller on the transversal, longitudinal and perpendicular axes. Results There was no effect on the type of practice in the maximum acceleration in the transversal ( $F(1,36)=0.2, p=0.29$ ) and longitudinal axes ( $F(1,36)=0.07, p=0.79$ ), but had effect on the perpendicular axis ( $F(1,36)=25.1, p<0.001$ ). For the perpendicular acceleration to the paddle or remote control, the post-hoc Tukey HSD test showed that the practice in the real environment had the highest peak acceleration. Discussion Currently, different studies are assessing the use and application of virtual games in performance improvement of the physically disabled (Shih, 2012). The results showed differences in peak acceleration of movement in the ball return in table tennis when practiced in a real environment. The perpendicular acceleration is the highest for the table tennis stroke in a real condition; because the participants did not hit the ball with so much effort during the virtual table tennis as they did for the real condition. ### MOTOR LEARNING THROUGH VIDEO GAMING IN CEREBRAL PALSY

Silva, E., Silva, T.D., Guimaraes, E.A., Santos, B.S., Santos, L.C., Neiva, J.F.O., Monteiro, C.B.M.

*University of São Paulo*

**Introduction** Cerebral Palsy describes a group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to non-progressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, perception, cognition, communication, and behavior, by epilepsy, and by secondary musculoskeletal problems (Rosenbaum et al, 2007). An option of physical activity and sport that uses current technological advances are virtual video consoles. The objective of this study is to verify the occurrence of motor learning in a video game task in individuals with cerebral palsy. **Methods** Participating in the intervention were five children (2 girls, 3 boys) diagnosed with cerebral palsy, aged between eight and twelve years. Task execution consisted of playing a bowling game on a Nintendo Wii video game console. To verify the occurrence of motor learning, 10 attempts were held to throw the bowling ball a distance of 2 meters in the television in the acquisition stage; 5 attempts in the retention phase and 5 in the immediate transfer phase, which was held at a distance of 3 meters. To organize the results and data comparison, we chose to display the value of means of pins knocked down in each phase of the task. **Results** The following are data of the phases evaluated through the mean of the last attempt of each phase: acquisition 1(3.8), acquisition 2 (5.3), retention (4.2) and transfer (4.2). **Discussion** There is a growing use in the practice of virtual games used by individuals who have a physical disability (Silvia and Howe, 2012), and to consider motor learning when analyzing the results in the acquisition phase, the occurrence of better performance can be deduced due to participants showing an improvement in scores when compared to the starting point to a point later in time (acquisition 1 with respect to acquisition 2). However, the maintaining of values was not observed in the phases of retention and transfer, determining that more practice is perhaps necessary in the release task of the bowling ball in the virtual environment, providing improved performance in all phases that characterize motor learning. **References** Rosenbaum P, Paneth N, Leviton A, Goldstein M, Bax M. ### EFFECTS OF POSTURE ON INTEGRATED EMG IN RESPIRATORY MUSCLES ACTIVITY DURING SPORT BLOWGUN

Hayashi, S., Arakane, K., Takahara, T., Yamaguchi, H., Imai, H., Onodera, S.

*Kwasaki University of Medical Welfare*

**Introduction:** Sport Blowgun is used as a disabled sport. The same rules are applied for non-disable person and disabled person in a competition. Wheelchair users play a game with the sitting posture. It is able to estimate the different pattern of muscle activities between sitting and standing posture. The purpose of this study was to compare to respiratory muscle activities and flying distance of arrow between standing condition and sitting condition. **Methods:** Six healthy young male subjects (age, 22.7±1.2 yr; height, 171.3±6.1 cm; weight, 67.7±5.8 kg) volunteered to participate in this study (mean ± SD). All participants underwent measurement in standing and sitting conditions. None had medical history with respiratory system. Respiratory function tests were performed with a spirometer. The forced vital capacity and first second forced expiratory volume were recorded. Electromyography (EMG) was used to measure expiratory muscle activity. The external oblique, rectus abdominis, and external intercostal were chosen as target muscle. After the full-wave rectified, integrated EMG of pre and post 50msec from expiratory commenced was calculated. Flying distance of arrow was also recorded. **Results:** The respiratory function did not have a significant difference between standing condition and sitting condition. Different posture did not affect the respiratory function. However, flying distance of arrow and the pattern of activity of the different muscle was distinct. Flying distance of arrow in standing condition was longer than sitting condition ( $p < 0.05$ ). Rectus abdominis activity did not have significant difference between each condition. External oblique and external intercostal activity of the standing condition was higher than sitting condition ( $p < 0.05$ ). **Discussion:** It is considered that the decline of stimulation for the brainstem reticular formation from lower limb suppressed expiratory muscular strength according to practice in sitting condition. Previous studies reported that external oblique muscle activity was large in forced expiratory (Hodges P.W et al. 1997). Flying distance of arrow is reflected the activity of external oblique. It suggests that the activity of external oblique and external intercostal contributed to the increase of flying distance of arrow. In conclusion, the muscular activities of wheelchair were significantly lower than that of standing posture.

### CHANGES IN HEART RATE, BLOOD PRESSURE, AND RATING OF PERCEIVED EXERTION DURING 200M-CRAWL SWIMMING IN SINGLE-HANDED WITH ELBOW JOINT FIXED CONDITION

WADA, T.1, SAITO, T.1, TAKAGI, Y.1,2, ARAKANE, K.1, ONODERA, S.3

1: GRADUATE SCHOOL, KAWASAKI UNIVERSITY OF MEDICAL WELFARE, 2: RESEARCH FELLOW OF THE JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, 3: KAWASAKI UNIVERSITY OF MEDICAL WELFARE

**Purpose:** The purpose of this study was to investigate the relationship of the heart rate, blood pressure, and rating of perceived exertion during swimming in single-handed with elbow joint fixed condition in normal person. **Methods:** Eight Japanese males (age: 21.4 ± 0.9 years, weight: 60.3 ± 7.7 kg, height: 166.8 ± 6.5 cm) volunteered to this study. We got an informed consent from subjects. We conducted this study in indoor pool at K University, 2011. This study consisted of two experimental conditions; Crawl swimming in normal condition (NC) and single-handed with elbow joint fixed condition (SC). Subjects participated in both conditions. After 200 meters swimming, they sat down for 15 minutes. Measurement items were heart rate, blood pressure (SBP: Systolic Blood Pressure / DBP: Diastolic Blood Pressure), rating of perceived exertion (RPE) and Frontal projected area. These were measured at rest time, 5 (Rec5) · 10 (Rec10) · 15 (Rec15) minutes after swimming. The water temperature was 30 degrees Celsius. **Results:** Heart rate at Rec5 (106 ± 6 bpm), Rec10 (102 ± 7 bpm) and Rec15 (98 ± 7 bpm) in SC was higher than that of NC ( $p < 0.05$ ). RPE at Rec5 (14 ± 2) and Rec10 (12 ± 2) in SC was higher than that of NC ( $p < 0.05$ ). SBP at Rec15 (115 ± 7 mmHg) in SC was higher than that of NC ( $p < 0.05$ ). Frontal projected area in SC was larger than that of NC ( $p < 0.05$ ). **Discussion:** There was significantly difference between SC and NC. Increase of frontal projected area by elbow joint fixed increased viscosity resistance in water to SC. In addition, the pull turnover of person with short upper limb in SC increases more than NC. Therefore, it was considered that heart rate and RPE in SC were higher than that of NC. **Conclusion:** Heart rate and RPE in single-handed with elbow joint fixed condition were higher than that of normal condition in 200M-crawl swimming. **References:** Kanai S. ### THE GYNECOPATHY RISK FACTORS ASSOCIATED WITH HIGH PHYSICAL ACTIVITY IN SPORT

Kovalenko, T., Shklyarenko, A., Ulyanov, D., Tkachenko, L.

*Volgograd State University*

THE GYNECOPATHY RISK FACTORS ASSOCIATED WITH HIGH PHYSICAL ACTIVITY IN SPORT Russia, Volgograd State University T.Kovalenko, A. Shklyarenko, D.Ulyanov, L.Tkachenko Introduction Despite the high adaptability of the female body, according to statistics there is a steady increase in female reproductive function abnormality in the last decade. Many researchers such as Serov and others, 2002; Vikhlyaeva and others 2003; Kulakov 2005; Prilepskaya and others 2009) have revealed that the frequency of infertile marriages in Russia is about 18-20% and there is no reduction tendency. Methods We used dynamic medical and educational techniques as well as methods of evolution of the functional status (rheography). Results The anamnesis revealed numerous gynecological diseases (retroflexion, retroversion of uterus) in young girls associated with high physical activity in sport. Such sports as heavy athletics (stress and straining efforts), artistic gymnastics (dismounts from apparatus gymnastics), wrestling, track-and-field athletics: high jumps, long jumps (concussion and shaking of the body), etc can provoke abnormal uterine version (retroversion) and flexio uteri (retroflexio). We developed therapeutic exercise techniques based on specially selected and measured methods aimed at gynecological pathology treatment. They have stress on loads on the pelvic floor muscles, abdominal and internal surface muscles. The developed exercise techniques has a restorative effect as well as rehabilitation of correct position of the uterus thanks to the right choice of preparatory position and the special exercises that rehabilitate and fix the uterus to its normal position. Discussion 1. The major risk factors for female reproductive function and infertility were revealed. 2. Our research showed the frequency of complications during pregnancy and childbirth among the former athletes which is up to 32%. 3. The most vulnerable were athletes whose out-of-season activity took place during the menstrual cycle when the uterus is filled with blood, heavy, and it changed its position easily. Whereas concussion and shaking of the body increased intra-abdominal pressure, stress and straining efforts lead to pathology. 4. The developed method has reduced the gynecopathy risks and contributed to disease prevention.

### THE COMPARISON OF MOTOR ABILITIES BETWEEN ATHLETE AND NON-ATHLETE DOWN SYNDROMES

Sabbaghian Rad, L.

*Sharif University of Technology*

Background & Aim: The main purpose of this research was to study and compare the gross motor and fine motor skills of athletes and non-athletes with Down syndrome. Methods: All of the participants have mild intellectual disability and educable. They were between 24-33 years old from Iran. There were two groups in this study. Athletes group and non-athletes group (10 males, and 10 females in each group). Athletes groups had trained for an average of 4 hrs/week and they were members of Iranian Special Olympics. Non-athletes groups didn't have the regular physical activity. The short form of Bruininks-Oseretsky test was used to assess gross motor and fine motor skills (Test of Motor Proficiency= BOTMP).It has 8 subtests and 14 tests and take 10-15 minutes. Results: Regarding the scores, a significant difference was found in scores of fine skills and gross skills. The gross and fine motor skills scores of non-athletes were also significantly lower than athletes with Down syndrome. Conclusion: The findings in this study illustrate a clear relation between the fine and gross motor skills and physical activity and it also showed that physical activity improved fine skills and gross skills in Down syndrome.

### THE FUNCTIONAL FITNESS CAPACITY OF ADULTS WITH DOWN SYNDROME IN SOUTH AFRICA

Boer, P., Terblanche, E.

*Stellenbosch University*

Introduction Considering all the health related problems that Down syndrome (DS) individuals are born with, their tendency to live sedentary lifestyles and a high likelihood of obesity, it is imperative that functional capacity is maintained in order to perform activities of daily living with as much independency as possible. To date, there is no information available on the amount of physical activity that DS individuals engage in, and their functional capacity has not been quantified yet. This information is important when one needs to consider how much exercise and what type of exercise should be prescribed for DS individuals in order for them to maintain or improve their functional capacity. The purpose of the study was to establish the functional fitness capacity of adults with DS in South Africa. Methods Data was collected at various intellectual disability centres and private homes in 7 provinces of South Africa. 371 DS individuals (199 male and 172 female) from 18-66 years were tested. Thirteen tests consisting of balance (2), flexibility (2), coordination (2), muscular strength and endurance (5), agility (1), and one maximal cardiovascular test (1) were analysed. Descriptive statistics were expressed as means and standard deviations. Four age groups (18-25, 26-35, 36-45, and older than 46) were constructed. Multiple analyses of variance and Tukey post-hoc tests were calculated to determine age- and gender related differences in variables amongst the DS adults. Trend analysis will also be performed to examine changes in fitness with age. A p value <0.05 will be considered statistically significant. Results DS men performed significantly better on all but two tests compared to the DS women (P<0.05). DS women performed better on the sit-and-reach flexibility item and the chair stand test however, differences were not statistically significant. Significant differences across age groups were also measured for 9 of the 13 functional fitness tests (p<0.05). Conclusions This study confirms that adults with DS have low functional capacities which deteriorate even more with increasing age. This has serious implications for these adults to maintain their ability to function independently as they grow older.

### ANALYZING THE EFFECTS OF PHYSICAL ACTIVITY LEVEL ON SENSE OF PAIN IN SOME PHYSIOTHERAPY APPLICATIONS

Taskin, G.

*Başkent University Hospital*

The aim of this study is to determine the effect of existing physical activity levels of people between the ages of 35-65 on sense of pain in classical physiotherapy applications used in clinics. 250 cases between the ages of 35 and 65 diagnosed with such musculoskeletal system diseases as cervical spondylosis, lomber spondylosis, carpal tunnel syndrome, cervical herniation nucleus pulposus (CHNP), lomber herniation nucleus pulposus (LHNP) and gonarthrosis; applied to Başkent University Hospital, Department of Physical Medicine and Rehabilitation and having some physiotherapy programs were participated in the study. Existing physical activity level, sex, BMI, age, income level, education level, occupation, diagnosis and whether taking physiotherapy beforehand and pain level before and after the treatment of cases were evaluated. Questions were applied to evaluate the socio-demographic features of cases, visual analog scale (VAS) was applied for pain evaluation and physical activity evaluation survey (PAES) was applied to evaluate the level of physical activity.

Information was given to the participant subjects and their written consent was taken. Data collected were made with the help of SPSS 16.0 statistics program. T-test and ANOVA (single direction variance analysis) were used in the evaluation of data. Our results show that women consume more energy in house works and men in workplace and sports. A significant difference wasn't found between sex, BMI, age, occupation variables and pain. There is a statistically significant difference between the diagnosis and pre-treatment pain. It has been ascertained that income level doesn't affect the physical activity level and pain level. It has been observed that the more education level increases, the more MET value increases. When the relation between the occupation of cases and their PAES values, it can be said that being a housewife and retirement are a risk factor for physical inactivity. It has been determined that there isn't a statistically significant relation between the physical activity levels of cases and PAES values. This result indicates that physical activity level doesn't have any effect on pain in physiotherapy patients.

### EFFECTS OF WEIGHT LOSS ON THE CHANGES IN DYNAMICAL MARKS OF CENTRE OF GRAVITY

Szablics, P.1, Szabó, S.1, Dvorák, M.1, Orbán, K.1, Balogh, L.1, Molnár, A.H.1, László, F.1,2, Varga, Cs.2

*University of Szeged*

EFFECTS OF WEIGHT LOSS ON THE CHANGES IN DYNAMICAL MARKS OF CENTRE OF GRAVITY Szablics, P.1, Szabó, S.1, Dvorák, M.1, Orbán, K.1, Balogh, L.1, Molnár, A.H.1, László, F.1,2, Varga, Cs.2 <sup>1</sup>Institute of Physical Education and Sport Sciences <sup>2</sup>Department of Physiology, Anatomy and Neuroscience University of Szeged (Szeged, Hungary) Introduction: The quality and dynamical marks of movement deteriorate due to obesity and overweight. Several studies suggest that body weight begins to normalise and the health status improves resulting from submaximal, aerobic training. Based on these data the movement dynamics is also improved by recreational training (Katzmarzyk and Lear, 2012). Aims: We investigated the changes in dynamical marks of centre of gravity (CG) after weight loss in case of simple movements like crouch and jump. Methods: 93 participants (age: 11-70 years, mean BMI: 26.9±0.57) took part in our study. They did 60 minute long recreation trainings two times a week for 3 months on 60 percent of maximal heart rate. APAS 3D system was used for movement analysis. The examination was performed in the beginning and at the end of training program in 2 dimensions with 4 reference points and 11 joint points (ankles, knees, hips, shoulders, elbows and forehead). Participants crouched and jumped in front of a camera. The speed of video record was 30 frames per second. We analysed the position, velocity and acceleration of CG. Changes of body weight, fat and muscle mass were determined by InBody230. Participants were divided into the following five age groups: gr. I: 11-18 years, gr. II: 19-29 years, gr. III: 30-45 years, gr. IV: 46-60 years, gr. V: 61-70 years. Results: Significant decrease of body weight was detected in gr. II (-1.17±0.6kg), gr. III (-4.83±1.5kg), gr. IV (-1.15±0.6kg) and gr. V (-1.19±0.3kg). The fat mass was reduced in gr. II (-1.65±0.8kg) and gr. III (-3.9±1.3kg). We observed significant increase in lifting of CG in case of jump in gr. III (+2.6±1.3cm) and gr. V (+2.2±1.1cm). The increase of CG velocity was significant in gr. IV (+47.5±17.5cm/s) and gr. V (+25.75±8.7cm/s). In case of crouch the extent of sinking and the velocity of CG were enhanced significantly in gr. IV (-5.09±2.7cm and +85.37±43.9cm/s). We did not detect any significant changes in acceleration of CG in neither group. Conclusion: Our results suggest that low intensity recreational training optimizes the body composition and the dynamics of movement. Weight loss mends the position and velocity of CG in case of crouch and jump. Our training program was the most effective among 30-60 year-old people. Reference: Katzmarzyk PT and Lear SA. (2012). Obesity Reviews, 13(2), 95-105. Support: SROP 4.2.2-08/1-2008-0006; SROP 4.2.1/B-09-1/KNOV-210-0005

### PHYSICAL ACTIVITY IN SPORT SCHOOL CHILDREN FROM AGE 10 TO 12, A LONGITUDINAL STUDY

Uvacsek, M.1, Tóth, M.1, Ridgers, N.D.2

*Semmelweis University: 1: SU (Budapest, Hungary), 2: DU (Melbourne, Australia)*

Introduction There is a lack of information about objectively measured physical activity levels of primary school children in Hungary (Hamar 2009). The aim of this study was to investigate the differences in physical activity levels of children attending a sport school between 2008 and 2010. Methods Fifty-two children took part in the first investigation in 2008, with 35 (19 boys, 16 girls) providing follow-up data at 18 months (67% retention rate). Physical activity (PA) was quantified every 5-seconds using uni-axial accelerometry for 3 (baseline) and 5 (follow-up) consecutive school days. The accelerometer was worn on the right hip using a fitted elastic belt during all waking hours except for water-based activities. Time spent in sedentary, light (LPA), moderate (MPA), and vigorous physical activity (VPA) during school days was determined using existing age-appropriate cut-points (Riddoch 2007). Children who did not have complete data for 2 week-days (480 minutes wear time per day) were excluded from the analyses. Thirty-two children provided complete data over both testing occasions. Differences in body dimensions (BF% and BMI) and PA were assessed using dependent samples t-tests. Statistical analyses were conducted using Statistica for Windows 8.0. Statistical significance was set at  $p < 0.05$ . Results The prevalence of overweight, according to BMI cut-points for children (Cole 2000), decreased from 16% to 13%. Time spent being sedentary increased significantly (477.7 ± 63.1 min/day to 555.4 ± 66.4 min/day), whilst MVPA decreased significantly (148.4 ± 45.1 min/day to 116.2 ± 22.8 min/day). Discussion All the children met the 60 minutes per day international recommendation, though decreases in MVPA were evident over 18 months. The relatively high average of MVPA during weekdays may be explained by the daily physical education lessons and participation in afternoon clubs in schools, though further research is needed to determine why increases in sedentary time and decreases in MVPA were observed. **POST EXERCISE ORAL CONJUGATED LINOLEIC ACID SUPPLEMENTATION CANNOT IMPROVE SUBSEQUENCE ENDURANCE PERFORMANCE**

Cheng, I.S.1, Tsao, J.P.2, Chen, H.W.1

1: NTCU (Taichung, Taiwan), 2: NTUPES (Taichung, Taiwan)

**Introduction** Conjugated linoleic acids (CLA) is refers to a group of polyunsaturated fatty acid with two double bonds (Evans et al., 2002). Previous studies showed that CLA had advantages for reducing body fat mass in human study (Blankson et al., 2000). Little study is regarding to whether CLA administration is expected to cause metabolic consequence in exercised human and resulted in improvement of endurance performance. The purpose of this study was to demonstrate the effect of post-exercise CLA supplementation on subsequenced endurance performance. **Methods** This study was a double-blind, crossover design and eight healthy male subjects participated in two treatments which included placebo or CLA supplementation after cycling at 70% VO<sub>2</sub> peak oxygen consumption for 60 mins, separated at least 7 days. When the subjects consumed carbohydrate meal with 4.0 g mixed-isomer CLA supplementation after exercise, immediately performed endurance exercise performance on a cycle ergometer of 70% VO<sub>2</sub> peak until voluntary fatigue. The blood samples were measured for glucose, insulin, NEFA and glycerol concentrations. The gas parameters were measured for respiratory exchange ratio (RER), CHO oxidation rate and fat oxidation rate. **Results** All parameters which included blood glucose, NEFA, glycerol and serum insulin concentrations or RER, carbohydrate oxidation rate and fat oxidation rate were no significantly different between CLA and placebo trials. No significant differences in subsequenced endurance performance were shown between CLA and placebo supplementation immediately after a single bout of exercise (CLA: 37.3 ± 3.1 mins ; Placebo: 38.4 ± 1.8 mins). **Discussion** The present study cannot support the evidences in animal study that dietary conjugated linoleic acid increases endurance capacity (Mizunoya et al., 2005), as evidenced by no significant improvement in endurance performance after post-exercise CLA supplementation. In human study, the concentration of CLA in chylomicrons reached peak level at 4 h after CLA supplementation (Ferne et al., 2004). The suggestion in our study is commended, to examine the endurance performance over 4 hours after CLA supplementation. However, the present results of this study will not positively benefit to athletes, who are training for competitions. **References** Blankson J A, Stakkestad J A, Fagerun H, Thom E, Wadstein J, Gudmundsen O. **ANAEROBIC PERFORMANCE DURING MODERATE ALTITUDE EXPOSURE UNDER ACID OR ALKALINE FORMING NUTRITION**

Limmer, M., Platen, P.

*Ruhr-University Bochum*

**Introduction** The present pilot study was conducted to examine the effects of moderate altitude exposure in combination with acid or alkaline forming nutrition on parameters of the anaerobic energy metabolism and on acid-base blood parameters in moderately trained sport students. **Methods** 12 healthy physical education students (n=10 males; n=2 females) were randomized into 2 groups according to the acid/alkaline load of their nutrition: the alkaline forming (ALK; n=6) and acid forming (ACID; n=6) group. 7 days of moderate hypobaric altitude exposure (MA) were obtained in the European Alps while living and hiking at an altitude level of 2434 m to 3772 m. During MA, ALK mainly consumed alkaline forming nutrients while ACID mainly consumed acid forming nutrients. To assess anaerobic power subjects performed a 15 s skipping test to maximum exertion prior to MA, during MA (on days 2, 5 and 7), and 1 day after returning to sea level. Anaerobic performance related parameters (maximal lactate production rate (VLamax) and blood bicarbonate concentration (HCO<sub>3</sub><sup>-</sup>) were determined in pre- and post-exercise capillary blood samples taken from the earlobe. All parameters were analysed directly after sampling. Data were analysed with repeated measures ANOVA. **Results** VLamax, and HCO<sub>3</sub><sup>-</sup> decreased continuously (p<0.01) during MA in the collective group and did not reach the pre-MA level after 1 day at sea level (VLamax (mmol/l/min): 0.76±0.10, 0.68±0.12, 0.67±0.15, 0.60±0.12, 0.64±0.16; HCO<sub>3</sub><sup>-</sup> (pre-exercise, mmol/l): 26.6±3.6, 24.1±2.4, 23.1±2.3, 22.1±1.0, 24.8±1.6; HCO<sub>3</sub><sup>-</sup> (post-exercise, mmol/l): 23.5±2.7, 20.9±2.4, 19.0±2.4, 18.7±2.0, 20.2±2.5; values are listed for the tests prior to MA, during days 2, 5 and 7, and after MA, respectively). ALK or ACID did not have any significant influence on VLamax and HCO<sub>3</sub><sup>-</sup>, although VLamax and HCO<sub>3</sub><sup>-</sup> declined less during MA in some subjects of the ALK group. **Discussion** The results clearly indicate that moderate altitude exposure negatively affects VLamax and HCO<sub>3</sub><sup>-</sup> in moderately trained sport students. Nutritional acid/alkaline load does not clearly influence anaerobic performance related parameters during MA. Further studies with longer or higher altitude exposure are needed to demonstrate possible chronic effects of nutritional acid or alkaline loads on anaerobic metabolism.

**NITRATE SUPPLEMENTATION AND HIGH-INTENSITY CYCLING PERFORMANCE**

Hoon, M.H.1, Burke, L.B.2, Jones, A.M.3, Hopkins, W.G.4, Johnson, N.J.1, Halson, S.L.1, Martin, D.T.1, West, N.P.5, Bartram, J.1

1: *University Of Sydney*, 2: *Australian Institute Of Sport*, 3: *University Of Exeter*, 4: *Auckland University Of Technology*

**Introduction** Recent studies have demonstrated that consumption of inorganic nitrate enhances endurance performance, most likely via the conversion of nitrate to nitric oxide. Most of the research has been conducted on recreationally trained subjects, but in athletes cardiovascular adaptations to exercise training may blunt the response to nitric oxide. **Aim** To investigate the effect of nitrate supplementation in national-level cyclists on performance of two 4-minute cycling time trials, separated by 75 min. The effect of the timing of nitrate ingestion was also investigated. **Methods** In a randomised cross-over design, 26 cyclists performed the time trials on Wattbike cycle ergometers under four conditions, each separated by a seven-day washout: consumption of 75 ml of nitrate-rich beetroot juice either 150 min or 75 min before the first time trial, consumption of a 30-ml top-up dose following the first time trial in the 150-min condition, and consump-

tion of a placebo. Plasma nitrite was sampled at five time points. A linear mixed model with adjustments for learning effects and athlete fitness (peak incremental power) was used to estimate and express mean power in each time trial of each nitrate condition as percent change from that in the placebo condition, with probabilistic inferences based on a smallest effect of 1.0%. Results Plasma nitrite concentration rose to a peak of ~50% above baseline by ~75 min after consumption of nitrate. Collectively, there was an unclear mean effect on average power in each of the nitrate conditions in the first time trial (1.1%, 90% confidence limits  $\pm 1.7\%$ ) and a possibly harmful effect on the second time trial (-0.5%,  $\pm 1.6\%$ ). For the fitter cyclists (+1SD), the effect of nitrate supplementation was possibly harmful in both time trials (-0.6%,  $\pm 2.8\%$ ; -1.7%,  $\pm 2.7\%$ ). Conclusion On the basis of these results, acute nitrate supplementation in the form of beetroot juice cannot be recommended for high-intensity performance in highly trained cyclists.

### **EFFECT OF A SPORT DRINK WITH ELECTROLYTE AND ISOMALTULOSE ON TIME TO EXHAUSTION AT AN INTENSITY ABOVE ANEROBIC THRESHOLD**

De Angelis, M., Spinozzi, M., Chiavaroli, S.

*University of L'Aquila*

**EFFECT OF A SPORT DRINK WITH ELECTROLYTE AND ISOMALTULOSE ON TIME TO EXHAUSTION AT AN INTENSITY ABOVE ANEROBIC THRESHOLD** De Angelis, M.1, Spinozzi M.2, Chiavaroli S.1 1: BST dept. (L'Aquila, Italy), 2: Sport Science Faculty (L'Aquila, Italy) Introduction Sports drinks are formulated to provide fluid, facilitating drinking, essential electrolytes and carbohydrate replacement for an optimal thermoregulation and to maximize exercise performance. Isomaltulose, for its slow rate of hydrolysis and low glycaemic index (Lina et al., 2002), and for the characteristics of fructose, its component, with increased fluid and solute absorption in the small intestine and increased exogenous oxidation (Johnson and Murray, 2010), could improve the duration of exercise. The aim of this study was to test, with a trial to exhaustion, one commercial sport drink with these elements. Methods Twenty young subjects performed, not knowing the aim of the test and not seeing the clock, two separate trials at exhaustion on a cycle ergometer, at a fixed power 10% higher than their Lactate Threshold, during which they could drink ad libitum, in a random order, plain water or a commercial sport beverage (H3OPro®), with electrolytes, isomaltulose, vitamins B and C. Heart rate, blood lactate, time to exhaustion and drunk fluid were measured at the end of the trial. Paired Student-t test were performed. Results When subjects could drink H3OPro® they drank more (505 vs 361ml;  $p=0.031$ ), cycled longer (40'24" vs 32'57";  $p=0.005$ ) and reached a lower blood lactate (4.9 vs 5.5mM) than with plain water. Discussion A beverage, like the one tested, that helps drinking more fluid can maintain euhydration and, therefore, optimal thermoregulation. A moderate and balanced concentration in the ingested fluid of essential electrolytes enhances both water absorption and retention (Wendt et al. 2007). A sound carbohydrate formulation provides useful fuel for muscles but, according to blood lactate values, and differently from other studies (Achten et al., 2007), fat oxidation seemed to be higher and carbohydrate oxidation lower with H3OPro® than with water. This could be probably due to the presence of isomaltulose that, as previously showed (West et al. 2011; Achten et al. 2007), can lower carbohydrate and enhance lipid oxidation rates during the later stages of exercise. Consuming a well balanced sport beverage can significantly improve duration of exercise in cycling. References Achten J, Jentjens RL, Brouns F, Jeukendrup AE. (2007). *J Nutr*, 137(5), 1143-8. ### **EFFECTS OF BETA-ALANINE COMBINED WITH SODIUM BICARBONATE ON FREESTYLE SWIMMING PERFORMANCE**

Coelho, D.

*University de São Paulo*

Coelho, DF.1, de Salles Painelli, V.1, Campos, PL.1, Artioli, GG.1, de Jesus, F.1, Galves, VF.1, de Oliveira, N.1, do Carmo, CA.1, Solis, MY.1, Benatti, FB.1, Roschel, H.1, Sale, C.2, Harris, RC.3, Gualano, B.1, Lancha Junior, AH.1. 1: USP (São Paulo, Brazil), 2: NTU (Nottingham, United Kingdom), 3: UCC (Chichester, United Kingdom). Introduction Muscle acidosis is a major cause of fatigue during high-intensity exercise. Anaerobic contribution to simulated swimming bouts of 100 and 200 yd is known to be high. Few nutritional aids are able to reduce intramuscular H<sup>+</sup> accumulation, namely sodium bicarbonate (SB) and beta-alanine (BA) supplementation. Two studies were conducted to investigate the effect of BA supplementation alone (study A) and the combined effect of BA plus SB on 100-m and 200-m swimming performance (study B). Methods In Study A, 16 trained swimmers received either BA (3.2 g/d for 1 week plus 6.4 g/d for 4 weeks) or placebo (PL). At baseline and after 5 weeks, the athletes completed simulated 100-m and 200-m freestyle swimming races. In Study B, 14 trained swimmers received either BA (3.2 g/d for 1 week plus 6.4 g/d for 3 weeks) or PL. Swimming time trials were performed at baseline, after 4 weeks and following 4 days of combined SB and PL supplementation, in a crossover fashion. Blood lactate was assessed in both studies. Results Study A: BA supplementation significantly improved performance in the 200-m race by 2.0% (-2.8 seconds,  $p=0.01$ ). Study B, both BA and SB alone improved 200-m time trial performance when compared to PL (BA-SB: 2.11%, PL-SB: 1.43%; BA-PL: 1.2%,  $p<0.05$ ). The co-ingestion of BA plus SB provided no further benefit in comparison to BA or SB alone ( $p=0.78$  and  $p=0.53$ , respectively). BA, with or without SB, had no significant effect on 100-m time trial performance. Blood lactate concentration increased, as a function of exercise trials. However, SB led to greater lactate accumulation when compared with other conditions. Discussion BA supplementation effectively improved the 200-m freestyle swimming performance. Our additional results indicated that BA and SB were equally capable of improving swimmers performance; the co-ingestion of both supplements promoted a further non-significant improvement. SB resulted in higher blood lactate concentration after the exercise, probably caused by an SB-induced increased activity of monocarboxylate transporter-1 (Requena et al., 2005). Neither BA nor SB promoted a significant improvement in 100-m time-trial performance, which is in line with other studies (Webster et al., 1993; Derave et al., 2007). ### **EFFECT OF LEUCINE AND ARGININE SUPPLEMENTATION ON RESISTANCE EXERCISE PERFORMANCE AND BODY COMPOSITION IN HEALTHY MALE SUBJECTS**

Rosa, F., Dacar, M., Donatto, F., Seelaender, M.

*University of São Paulo*

Effect of leucine and arginine supplementation on resistance exercise performance and body composition in healthy male subjects Dacar, M1, Rosa, FO1, Donatto, FF1, Seelaender, M.C.L1 1:University of São Paulo (São Paulo, Brazil) Introduction: The anabolic effect of

leucine on protein synthesis is of great interest both in the prevention of reduction of lean body mass in various diseases, and in the maintenance/enhancement of lean body mass in healthy individuals. Arginine is employed by athletes for increasing lean muscle mass, by inducing vasodilation. Therefore, the aim of this study was to determine whether chronic leucine or arginine supplementation may, in fact, improve strength exercise performance, and anthropometric characteristics in healthy young individuals. Methods: Fourteen male (aged 19-37 yr old), supplemented with leucine (LEU, n=6), arginine (ARG, n=6) and valine (VAL, n=6), experienced weightlifters with at least 1 year or more experience in strength training, and with body mass index (BMI) between 21 and 26 kg/m<sup>2</sup>, except by one subject (33 kg/m<sup>2</sup>) were submitted a progressive resistance training program after all baseline assessment and which was performed 4 times a week for 6 weeks (~22 training days), analyses strength was assessed by Strength Testing (1 RM), Body Composition (Body mass index as kg/m<sup>2</sup>) and whole lean and fat mass were determined by hydrostatic weighing, according to the equations described by (Siri, 1961). Results: There were no significant changes in fat mass for all three groups over time. Significantly higher (P < 0.01) lean mass gain was observed in group LEU (mean 2.93 kg) in relation to ARG (mean 1.22 kg) and VAL (mean 0.08 Kg). The LEU(0.48 ± 0.12 - 0.55 ± 0.13Kg) group had significantly improved effects (P < 0.001) performance in barbell bench press, when compared to VAL(0.55 ± 0.07 - 0.60 ± 0.06Kg) and ARG (0.56 ± 0.18 - 0.60 ± 0.16Kg) groups. Discussion: Resistance exercise increases muscle protein synthesis through changes in muscle cell signaling. In particular, it appears to elicit its effects by signal transduction through the mammalian target of rapamycin (mTOR) pathway leading to phosphorylation and activation of its downstream target proteins. Not all amino acids have the same potency in stimulating protein synthesis, and studies shown that BCAA, particularly leucine, seem to be the most potent among all amino acids with regard to promoters skeletal muscle protein synthesis. In conclusion, we demonstrated that the combination of resistance exercise training and leucine supplementation conferred greater gain in lean body mass and improved performance during training sessions in healthy male athletes strength.

### EFFECTS OF BIOLOGICAL MATURITY ON HYDRATION STATUS AND SWEAT RESPONSES TO MATCH PLAY IN HIGHLY-TRAINED YOUNG SOCCER PLAYERS

Gurr, S.1, Al Haddad, H.2, Mendez Villanueva, J.A.2

*1)Aspetar Sports Medicine Hospital 2)Aspire Academy of Sports Excellence*

Introduction Empirical field based data on the hydration status and sweat response of highly trained young soccer players during competitive matches is scarce (Da Silva et al., 2012). Laboratory based studies that have examined the thermoregulatory response in children and adolescents during continuous exercise modes have found post-pubertal children sweat more than pre-pubertal children when exercising at the same relative intensity (Araki et al., 1979; Falk et al., 1992). However, it is not clear whether the results of these studies are readily applicable to the intermittent nature of soccer played outdoors. The aim of this study was to compare the pre-match hydration status and sweat response of highly-trained adolescent soccer players differing in biological maturity during competitive soccer matches played in warm conditions. Methods Thirty nine players (Age: 14.7 ± 1.4 yrs; body mass: 49.1 ± 9.2 kg; Height: 165.4 ± 8.9 cm) from the same football academy were monitored for hydration status and sweat response during eleven games lasting 70-90 minutes. Urine samples were collected before the game and analyzed for osmolality. Sweat loss was assessed from the change in body mass after correction for fluid intake and urine losses. Heat Index (HI) was used as a marker of environmental conditions. Players were later subdivided into three non-overlapped maturational groups based on their age of predicted height velocity (APHV): 1) Pre-APHV <-1.1 yrs to PHV (n=11), around the estimated APHV (Circum-APHV >-1yrs to PHV to <+1 yrs) (n=18) and post-APHV (>1 PHV) (n=10). Differences in the mean values were assessed using a one-way ANOVA. Bonferroni's post hoc tests was applied when a significant interaction was found. Results There was no significant difference in the environmental conditions (HI-33.2 ± 2.5°C pre-APHV; 35.2 ± 3.7°C circum-APHV; 34.6 ± 1.9°C post-APHV; p=0.25) or in the pre-match hydration status (699 ± 311 mOsm/kg pre-APHV; 884 ± 217 mOsm/kg circum-APHV; 673 ± 377 mOsm/kg post-APHV; p=0.12) between the groups. There were significant differences between all groups for percentage change in body mass (Pre-APHV vs. Post-APHV (0.8 ± 0.6 vs. 2.3 ± 0.8; p < 0.001); Circum-APHV vs. Post-APHV (1.5 ± 0.7 vs. 2.3 ± 0.8; p = 0.022); Pre-APHV vs. Circum-APHV (0.8 ± 0.6 vs 1.5 ± 0.7; p=0.045). Corrected for differences in body mass, a significant difference in sweat losses was only observed between Pre-APHV and Post-APHV groups (19.6 ± 4.4 vs. 25.9 ± 4.5 ml/kg/hr; p= 0.017). Discussion This study supports previous laboratory-based findings that pre-pubertal adolescents rely less on evaporative sweat loss than post-pubertal adolescents when exercising in the heat. The large variability sweat rates within groups reinforces the need to individualise hydration advice for players. References Da Silva RP, T. Mundel T, et al. (2012). *J Sports Sci*, 30(1), 37-42. ### DYNAMICS OF EXERCISE PERFORMANCE AND AEROBIC CAPACITY OF ATHLETES IN THE CONDITIONS OF COMBINED HYPOXIA AT INTAKE OF MIXTURE OF BAS

Sukhov, S., Ivanov, A.

*National Research and Practical Centre of Physical Culture*

Introduction At coaching and contesting in mountain terrain, athletes are exposed to combined hypoxia. To minimize its negative effect on athletes, there was developed a mixture of biologically active supplements (BAS) characterized with antihypoxic action. The goal of the study was to test its effect on exercise performance and aerobic capacity of athletes in the conditions of combined hypoxia. Methods Forty-five elite judoists (22 athletes – experimental group, 23 athletes – control group) have been examined. Both groups were coached with the same program and catered in the same canteen. Athletes in the experimental group received BAS mixture for 8 weeks. Duplicate testing of athletes, at an 8-week interval, was made at breathing with hypoxic mixture with oxygen content 14% that corresponds to altitude 3300 m above sea level. There was assessed the physical performance on bicycle ergometer at a three-step discrete small, submaximal and maximal aerobic load, maximum oxygen consumption (VO<sub>2</sub>max) and oxygen pulse. Results At the second testing of the experimental group, the physical performance at heart rates 130, 150, 170 bpm and maximal heart rate has increased, as compared with the first test. In the control group, at heart rates 130 and 150 bpm, the physical performance at the second test was lower, as compared with the first examination, while at heart rates 170 bpm and maximal rate it remained on the same level. Overall volume of work in the experimental group has increased at the second testing from 220±5.0 to 231±5.5 kgm•kg<sup>-1</sup>, while in the control group it has slightly decreased from 209.5±5.8 to 202.6±4.0 kgm•kg<sup>-1</sup>. Prior to administration of BAS, in the experimental group the VO<sub>2</sub>max was 2524±98 ml•min<sup>-1</sup> (37.72±1.27 ml•kg<sup>-1</sup>•min<sup>-1</sup>), while after the intake it reached 2598±90 ml•min<sup>-1</sup> (38.95±1.25ml•kg<sup>-1</sup>•min<sup>-1</sup>). In the control group, at the first test the VO<sub>2</sub>max was equal to 2547±97 ml•min<sup>-1</sup> (36.12±1.06 ml•kg<sup>-1</sup>•min<sup>-1</sup>), and at the second test it reached 2493±95 ml•min<sup>-1</sup> (35.41±1.24 ml•kg<sup>-1</sup>•min<sup>-1</sup>). Oxygen pulse in the experimental group did not change at rest and tended to increase at loads of different aerobic capacity, while the control group has demonstrated an opposite trend. Conclusion The tested BAS mixture has

demonstrated a positive effect on the physical performance, VO<sub>2</sub>max and oxygen pulse of athletes in the conditions of combined hypoxia.

### **CARBOHYDRATE GEL INGESTION SIGNIFICANTLY IMPROVES THE INTERMITTENT ENDURANCE CAPACITY OF ADOLESCENT TEAM GAMES PLAYERS DURING PROLONGED INTERMITTENT SHUTTLE RUNNING**

Phillips, S.M.<sup>1</sup>, Turner, A.P.<sup>2</sup>, Sanderson, M.F.<sup>2</sup>, Sproule, J.<sup>2</sup>

*1: University of Abertay Dundee, Scotland; 2: University of Edinburgh, Scotland*

**Introduction** In recent years, ingestion of carbohydrate (CHO) in the form of a gel has become more prevalent, due in part to the ability to manipulate CHO and fluid intake independently and to ingest greater amounts of CHO in gel compared with solution form. Carbohydrate gel ingestion has been demonstrated to significantly enhance intermittent endurance capacity in adults (Patterson & Gray, 2007). However, its efficacy has not been studied in young people. The aim of this study was to investigate the influence of ingesting a CHO gel on the intermittent endurance capacity, sprint performance, and physiological response of adolescent team games players during prolonged intermittent, high-intensity running. **Methods** Eleven participants (mean age 13.5 ± 0.7 years, height 1.72 ± 0.08 m, body mass (BM) 62.1 ± 9.4 kg) performed two trials. In each trial, they completed four 15 min periods of part A of the Loughborough Intermittent Shuttle Test (LIST), followed by an intermittent run to exhaustion (part B). In the 5 min pre-exercise, participants consumed 0.8 ml.kg BM of a CHO or a non-CHO placebo gel, and a further 0.3 ml.kg BM every 15 min during part A of the LIST (38.0 ± 5.5 g CHO.h in the CHO trial). **Results** Intermittent endurance capacity was increased by 21.1% during part B when the CHO gel was ingested (4.6 ± 2.0 vs. 3.8 ± 2.4 min, P < 0.05, r = 0.67), with distance covered in part B significantly greater in the CHO trial (787 ± 319 vs. 669 ± 424 m, P < 0.05, r = 0.57). Gel ingestion did not significantly influence mean 15 m sprint time (P = 0.33, r = 0.31), peak sprint time (P = 0.81, r = 0.08), heart rate (P = 0.66, r = 0.16), gut fullness (P = 0.09, r = 0.51) or gastric discomfort (P = 0.72, r = 0.11) ratings during exercise. **Discussion** Pre-pubertal children are able to oxidise more exogenous CHO than adults (Timmons et al., 2007), and adolescents may also have this ability, although exogenous oxidation rates decline throughout puberty (Timmons et al., 2007). Greater exogenous CHO use may enable greater sparing of muscle glycogen and therefore increased intermittent endurance capacity in adolescents. The lack of influence of CHO supplementation on mean sprint duration and physiological responses throughout the LIST is in line with previous adult work (Nicholas et al., 1995; 1999). **References** Nicholas CW, Williams C, Lakomy HKA, Phillips G, Nowitz A. ### **THE EFFECTS OF CREATINE SUPPLEMENTATION ON FATIGUE AND RECOVERY AFTER RESISTANCE EXERCISE IN FEMALES**

Touba, M., Altareki, N.

*Alfateh University*

**ABSTRACT** The objective was to quantify the effect of creatine (Cr) supplementation on muscular strength and biochemical responses to resistance exercise in female subjects. The methodological studies described in the pilot and main studies were used to create the protocols to reliably assess MVC and RFD. Subjects undertook a resistance exercise session at an intensity corresponding to 80% of 1-RM. They were required to consume 20g of creatine monohydrate or placebo in a double-blind experimental design for 5 days before being tested. Blood samples were taken before each session of tests, and analyzed for blood biochemical variables which included: creatine kinase (CK), Growth hormone (GH), Myoglobin (MYO). A significant effect of Cr was found on MVC and RFD recovery (P<0.01). Body mass was not significantly different between sessions (P= 0.14) but there was a slight increase following Cr supplementation session (1.0 kg) compared to other conditions. The CK and MYO, data revealed no significant main effect on time and conditions (P>0.05). It was concluded that short-term creatine supplementation does not alter the responses of creatine kinase, and myoglobin to a single bout of fatigue and recovery on heavy resistance exercise but were greater on growth hormone with Cr condition. These data suggest that oral creatine supplementation does not reduce muscle damage but enhances recovery following a resistance exercise challenge. These partially explain the increases in strength and improvements in exercise performance following oral creatine ingestion and has strong support as a nutritional strategy for females.

### **THE EFFECTIVENESS OF A NUTRITIONAL INTERVENTION ON THE ATHLETIC PERFORMANCE OF NON-PROFESSIONAL MALE BOXERS.**

Veniamakis, E., Giovani, D., Nikolaidis, P.

*Technological Education Institute of Crete*

**Abstract Background:** The purpose of this study was to assess the effectiveness of a nutritional intervention on athletic performance of male non-professional boxers. **Methods:** Eight non-professional male boxers (29,4±3,2 age, 77,6±8,6 kg, 39,3±7,5 VO<sub>2</sub>max) participated in the study, in which they were randomly divided into two groups of four (control group and intervention group). The control group continued their eating habits, as they were until before the study, whereas the intervention group followed a diet for three weeks according to their needs in energy, micro- and macronutrients in combination with the needs of boxing training in order to maintain their current weight. Before and right after the nutritional intervention, anthropometric (weight, height, body composition and body type) and fitness assessment measurements (flexibility, sub-maximal aerobic test (W170), maximal aerobic test (VO<sub>2</sub>max), speed force test for upper and lower extremities, upper extremities strength test, body core strength test, body core-lower extremities strength test and Wingate test) were conducted to the athletes. For the data analysis a paired-samples t-test and an independent-samples t-test were used. **Results:** The intervention group showed an increase in VO<sub>2</sub>max, upper extremities strength, and free-fat mass, with a simultaneous decrease in % body fat. **Conclusions:** This study showed that the nutritional intervention can improve the athletic performance of non-professional male boxers. More research is needed on this area, as the period of the nutritional intervention was short and also a follow up study is necessary.

**ATTITUDES TOWARDS DOPING IN PARTICIPANTS OF A POPULAR LONG-DISTANCE ROAD CYCLING EVENT ACCORDING TO THEIR PERFORMANCE**

Zabala, M.1,3, Freire, C.1, Ramírez-Lechuga, J.2, Morente-Sánchez, J.1

*1 Faculty of Sport Sciences, University of Granada (Spain); 2 Faculty of Sport, University Pablo Olavide (Seville-Spain); 3 Spanish Cycling Federation, Madrid (Spain)*

**Introduction** Social science researchers strive to better understand psycho-social variables of doping (attitudes or beliefs) that may be salient in educational programs directed towards the prevention of such behavior (Gucciardi et al. 2011). The purpose of this study was to know the attitudes towards doping of participants of a popular long-distance road cycling event according to their performance. **Methods** A sample of 2022 amateur cyclists (40.95±9.42 years) who participated in a long-distance (205 km) Spanish road cyclist event called "Quebrantahuesos" (UCI Golden Bike), was divided into groups according to their performance (<6 hours -G1-, 6-7 hours -G2-, 7-8 hours -G3-, 8-9 hours -G4-, 9-10 hours -G5-, >10 hours -G6-). Sample size for each group was: G1=321; G2=495; G3=618; G4=365; G5=157; G6=66). Descriptive design was carried out by means of a validated questionnaire (Petroczi & Aidman, 2009) of 17 questions using a Likert scale from 1 (Strongly Disagree) to 6 (Strongly Agree) for different statements that supported the use of doping in sport. Mean value ± Standard Deviation was obtained for each item and Mann Whitney test for independent variables with Bonferroni post hoc was carried out. **Results** Analyzing the total sample, the overall score was 41.61±12.51 (from 17 to 102) and the mean score was 2.45±0.74 (2=Through Disagree). In addition, the lowest score was observed for the item "Doping is not cheating since everyone does it" with 1.40±1.11, and the highest for "Athletes are pressured to take performance-enhancing substances" with 4.17±1.63 (4=Slightly Agree; 5=Agree). For the mean score and the overall score significant differences were observed in G1 vs G2 (p<0.001), and G1 vs G3 (p<0.002), respectively. Furthermore, there were significant differences for certain items in different groups: legalizing performance-enhancing substances would be beneficial for sports (G1 vs G2, p<0.002); The media blows the doping issue out of proportion (G1 vs G2 & G2 vs G5, p<0.001; G2 vs G4, p<0.002); Media should talk less about doping (G2 vs, G1, G4, G5. P<0.001). **Discussion** The G1 (<6 hours), which should be composed by the best cyclists, showed the lowest values regarding attitudes towards doping. Despite of having the best performance, G1 showed the highest disagreement towards doping. In addition, media is considered as one of the responsible agents of spreading the phenomenon of doping. **References** 1. Gucciardi, D., Jalleh, G. Donovan, R. (2011). **STRESS AND BURNOUT SYNDROME VS. PERFORMANCE OF REFEREES IN BASKETBALL**

Antic, T., Curcic, D., Dikic, N., Radivojevic, N., Vukasinovic-Vesic, M., Andjelkovic, M., Baralic, I.

*Sports Medicine Association of Serbia*

**Introduction** In this study we evaluated the level of stress in basketball referees and their performance in the court in terms of how much time they spent in running, walking and standing during the games. We used these parameters to evaluate correlation between performance during the game and level of stress and burnout syndrome among referees. **Methods** This study included 30 referees on FIBA Eurochallenge men and FIBA Euroleague women competition. **Methodology** of this study included two inventories: Self-assessment scale for stress level and Maslach Burnout Inventory (MBI) adapted for workers in the sport. MBI scale consists of three subscales: Emotional Exhaustion (sense of emotional overload), Depersonalization (sense of alienation, loss of empathy and idealism in the work) and Personal Accomplishment subscale (perceptions of their own professional efficiency). The other part of this study visualized and analyzed the referee's movements in the court. This was possible thanks to the use of ESpor (E-analyze) Software (Ankara Technology Development) that generates data of the position of the referees during the basketball match. We calculated how much time referees spent in running, walking and standing during the basketball games. **Results** The obtained parameters showed intermediate level of stress in referees. Six referees had moderate and one referee had high level of emotional exhaustion. On Depersonalization subscale 15 referees had moderate level and even 8 referees had high level of depersonalization. We noticed that referees with higher level of depersonalization were performing at a lower level during the game (they spent less time in running compare to other referees in a particular match). We used Independent sample T test and found statistically significant difference in level of depersonalization among referees who had highest and lowest level of running (p=0,012). There was no statistically significant difference in level of stress among referees in terms of running during the game. **Discussion and conclusions** Referees who had higher level of stress did not run less than referees who were not under stress at all, which could be explained by the fact that many people are relieving from the stress by engaging in high intensity physical activity. Since depersonalization is defined as sense of alienation, loss of empathy and idealism in the work it can be concluded that this mental condition can affect performance in the court in terms of less running during the game. **References** Kate Goodger et al. Burnout in Sport: A Systematic Review *The Sport Psychologist*. 2007, 21, 127-151

**DIETARY HABITS AMONG POLISH AMATEUR RUNNERS**

Szygula, Z.1, Kossak-Machno, D.2, Schlegel-Zawadzka, M.2

*1: University School of Physical Education (Krakow, Poland), 2: Jagiellonian University Medical College, (Krakow, Poland)*

**Introduction** Numbers of different studies confirm the importance of physical activity in civilization disease prevention. One of the groups of free time physical activity practitioners are amateur runners. They start running in different ages, taking part in group races of 10-42 km distance. **Aim** Assessment of nutritional habits and physical activity undertaken amongst the Polish amateur runners taking part in mass races. **Methods** The study was conducted on a group of 53 amateur runners (34 men and 19 women) aged 40,1±11,8 (20-67 years) within the Krakow region. The questionnaire was used to collect data and was conducted individually during the tournaments. **Questionnaire**

included questions on life-style, free-time physical activity level (Baecke Questionnaire on Regular Physical Activity), and nutritional habits. Moreover, the height and body mass were assessed (BMI and waist-to-hip ratio were calculated). Energetic expenditure during one-hour training session was calculated from heart rate assessed using telemetry system POLAR S120 (Polar Electro OY, Finlandia). To calculate statistic differences  $\alpha=0.05$  was assumed. Results Women ran mainly to keep their silhouette (73.7%). Both sexes indicated health and shape as the main reason for running (69.8% and 71.7%). 90% of the group consumed meals in a regular way, amongst them 45% consumed 4 and 34% consumed 3 meals per day. Runners (50%) ingested mainly fruits between main meals. Fish intake was on the low level as 66% consumed it less than once a week. Nutriment for athletes were taken by 35.8% of all runners, while majority did not consult their intake with specialist. 73.7% of runners had proper BMI (20-24.9kg/m<sup>2</sup>), 11.3% were obese (BMI 25-29.9 kg/m<sup>2</sup>, only men) and 15.0% underweight (BMI <20kg/m<sup>2</sup>, only women). Waist-to-hip ratio was proper in majority of runners (<0.8 women – 63.2%, <1.0 men 91.2%). Around 3.4±0.9 hours a week, which gives one month during the year, are spent on running. During one-hour training session runners use-up approximately 720.6±186.0 kcal (361-1020 kcal). Conclusions Amateur running influences physique and prevents obesity. Not all nutritional habits (especially amongst men) were assessed as proper, which may be caused by the lack of knowledge within this subject.

### IS THE DOPING FIGHT LOST: AN EMPIRICAL ANALYSIS OF THE DRUG ABUSE IN FITNESS GYMS IN THE NORTH OF GERMANY

Schulz, T., Pukowski, P., Peters, C., Oberhoffer, R.

*Technical University Munich*

Introduction The abuse of prohibited substances according to the world antidoping code is not only a problem of elite athletes (Bahrke and Yesalis 2004). It is also an important public health problem of leisure time and fitness sports. Several international studies indicate that doping substances are used widely, ranging from 3–31% among gym users (Wiefferink et al. 2008). In Germany on an average 7 million people trained in fitness gyms in 2009. Therefore, the purpose of this investigation was to determine the substances used and the attitudes towards doping of leisure time fitness athletes in the area of Greifswald in the northern part of Germany. Methods A 12-page questionnaire was designed to determine the drug abuse, the knowledge about the used doping substances and the motivation for the fitness training. The questionnaire was divided into seven parts: 1. body perception, 2. training, 3. motivation to fitness training, 4. body development, 5. knowledge of doping substances, 6. abuse of doping substances 7. personal data. Altogether the questionnaire contained 43 questions with 160 items. We received the filled-in questionnaires from 184 athletes: 153 from fitness athletes of normal gyms and 31 from athletes of a real bodybuilder gym. Results Altogether 21,3% of the athletes used performance enhancing doping substances. Subdivided in normal gyms and bodybuilder gyms we found only 15,2% users for the normal gyms and 48,4% for the bodybuilder gym. 21,2% of the athletes in normal gyms and 51,5% of the bodybuilders used stimulants. 9,3% of the athletes in normal gyms used anabolic-androgenic steroids (AAS) whereas 48,4% of the bodybuilder gym already abused AAS. The age of the abusers was between 17 and 34 years. Knowing that the abuses of prohibited substances had no biomedical side effects, 27,9% of normal gym athletes and 64,5% of the bodybuilder gym would use doping substances. Normally, the abusers obtain their drugs from friends or acquaintances. All in all, the knowledge about side effects of doping in both groups was rare, especially in the group of the normal gym athletes. 59,3% of all athletes believed that the abuse of doping substances under control of a medical doctor is not dangerous. Discussion/Conclusion In summary our results showed that doping in leisure time sports especially in fitness gyms is a common problem in the group of young adults of an average age of 29 years in Germany. Reasons for the abuse were in most cases the promotion of a body shaping. On the basis of these results effective prevention programs to counteract doping in fitness gyms have to focus on the improvement of the knowledge about the biomedical side of the athletes. ### RELATIONSHIP BETWEEN INSULIN RESISTANCE AND INFLAMMATORY MARKER WITH MEASUREMENTS OF FATNESS AND FITNESS AMONG PORTUGUESE ADOLESCENTS

Moreira, C., Santos, R., Santos, P.C., Abreu, S., Vale, S., Mota, J.

*Faculty of Sport, University of Porto*

Introduction: Obesity is increasingly among children and adolescents worldwide. This is alarming because childhood obesity is associated with several risk factors of cardio-metabolic diseases. Insulin resistance is a key component in the development of metabolic syndrome and low-grade inflammation may provide a mechanism linking obesity with cardio-metabolic diseases and it is also related to cardio-respiratory fitness (CRF). Therefore, the aim of this study was to determine if fatness and fitness is related to insulin resistance and inflammation during adolescence. Methods: A cross-sectional school-based study was conducted on 517 adolescents aged 15-18, from the Azorean Islands, Portugal. Intravenous blood samples were taken after an overnight fast to determine insulin resistance (HOMA-IR) and for high sensitivity C-reactive protein (hs-CRP). The percentage of body fatness (BF) was assessed using the Bioelectric Impedance Analysis. CRF was measured with the 20-m-shuttle-run-test from Fitnessgram battery test as number of laps. Results: Girls had higher percentage of BF than boys (25.5 vs 14.4%  $p<0.001$ ). No differences in HOMA-IR and hs-CRP were observed between sexes. HOMA-IR and hs-CRP were positive and significantly correlate with BF ( $r=0.34$  vs  $r=0.23$   $p<0.001$ ) while the correlation between HOMA-IR and hs-CRP and CRF were negative and significant ( $r=-0.22$  vs  $r=-0.15$ ,  $p<0.001$ ). Linear regression, controlling for age, sex and pubertal stage, showed that HOMA-IR and hs-CRP increased with BF percentage ( $B=1.7$  vs  $B=0.2$ ,  $p<0.05$ ), whereas only HOMA-IR declined with CRF level ( $B=-2.8$ ,  $p<0.001$ ). Conclusions: Our findings emphasize the importance of promoting and increasing CRF levels and decrease fatness among adolescents in order to prevent cardiovascular diseases in the upcoming adult population. Funding: This study was supported by FCT-MCTES grants: BD/44422/2008; BPD/65180/2009; BSAB/1025/2010, PTDC/DES/098309/2008 and by the Azorean Government.

### ATTITUDES TOWARDS DOPING IN PARTICIPANTS OF A POPULAR LONG-DISTANCE ROAD CYCLING EVENT ACCORDING TO COMPETING CATEGORY

Zabala, M.1,3, Freire, C.1, Ramírez-Lechuga, J.2, Morente-Sánchez, J.1

*1 Faculty of Sport Sciences, University of Granada (Spain); 2 Faculty of Sport, University Pablo Olavide (Seville-Spain); 3 Spanish Cycling Federation, Madrid (Spain)*

Introduction The aim of this study was to know the attitudes towards doping of non-professional cyclists taking account their competing category (Junior, U23, Elite, Master, Cycle-tourist, One-day License). Methods A sample of 2022 amateur cyclists (40.95±9.42 years) who

participated in a long-distance (205 km) Spanish road cyclist event called "Quebrantahuesos" (UCI Golden Bike), was divided into groups according to the competing category (30 Junior -G1-, 9 U23 -G2-, 32 elite -G3-, 546 Master -G4-, 1013 Cycle-tourist -G5-, 392 One-day License -G6-). Descriptive design was carried out by means of a validated questionnaire (Petroczi & Aidman, 2009) of 17 questions using a Likert scale from 1 (Strongly Disagree) to 6 (Strongly Agree) for different statements that supported the use of doping in sport. Mean value  $\pm$  Standard Deviation was obtained for each item and Mann Whitney test for independent variables with Bonferroni post hoc was carried out. Results The lowest overall score was observed for G6 ( $39.46 \pm 11.62$ ) and G1 ( $40.07 \pm 11.61$ ), and the highest was showed by G3 ( $49.06 \pm 14.10$ ). For the mean score and overall score were observed significant differences between G6 vs G3, G4, G5 ( $p < 0.001$ ). For certain items there were significant differences between different groups: The risks related to doping are exaggerated (G3 vs G6,  $p < 0.001$ ); Athletes should not feel guilty about breaking the rules and taking performance enhancing drugs (G3 vs G6,  $p < 0.001$ ; G4 vs G6,  $p < 0.002$ ; G3 vs G5,  $p < 0.003$ ); Health problems related to rigorous training and injuries are just as bad as from doping (G3 vs G4 & G5 vs G6,  $p < 0.001$ ; G3 vs G5,  $p < 0.002$ ); The media blows the doping issue out of proportion (G3 vs G5 & G4 vs G5,  $p < 0.001$ ; G4 vs G6,  $p < 0.002$ ); Media should talk less about doping (G5 vs G1, G3, G4, G5,  $P < 0.001$ ). Just for one item ("Doping is not cheating since everyone does it") significant differences ( $P < 0.001$ ) were found between G1 ( $1.03 \pm 0.18$ ) and G3 ( $1.84 \pm 1.35$ ). Despite of not having significant differences, mean scores of G1, G2 and G3 were  $2.36 \pm 0.69$ ,  $2.54 \pm 0.61$  and  $2.89 \pm 0.83$ , increasing respectively. Discussion This results contrast with others studies (Morente-Sánchez et al. 2011) which also used PEAS and where a sample of elite cyclists (Spanish cycling national team) showed a lower mean score ( $2.06 \pm 0.39$ ). So, it seems that the higher age, the higher score. Due to the fact that overall scores are lower in Junior and U23 than elite, we consider that a psychosocial intervention since the earliest ages is needed to keep attitudinal levels. References 1. ### PROTEIN SUPPLEMENT USE AMONG NETSURFERS VISITING HEALTH AND FITNESS COMMUNITY: FINDINGS FROM AN INTERNET-BASED SURVEY

Caramazza, G.2,3, Battaglia, G.1,2, Bianco, A.1,2, Bellafiore, M.1,2, Palma, A.1,2

*University of Palermo*

Introduction It is largely known that protein supplement (PS) use is a widespread and accepted practice by athletes and people who attend commercial gyms (Bianco et al., 2011). However, only few studies have been carried out in order to investigate supplement use and lifestyle in netsurfers of health and fitness community. For this reason the purpose of this preliminary study was to investigate the use of PS, age and lifestyle of people who visited a specific Italian sporting website: [www.fitnessa360.com](http://www.fitnessa360.com). Methods 273 subjects netsurfing in the [www.fitnessa360.com](http://www.fitnessa360.com) completed the 6-item online-questionnaire about age, gender, daily cigarette consumption, protein supplement use, information source about use of PS and sitting time per day. All data were analyzed by a preliminary descriptive statistical analysis. Results The survey showed that subjects, of which 170 males and 103 females, declared an age of 15-20 years (11%), 21-30 years (8%), 31-40 years (72%), 41-50 years (4%), 51-60 years (3%), 61-70 years (0%), 71-80 years (0%), 81-90 years (2%). When examining the daily cigarette consumption, we found that the majority of the subjects claimed not to smoke (66.0%) and to take SP (62%). Moreover, 60% of participants did not specify the information source about use of SP. Only 37% of sample declared to use SP. Moreover, examined data showed that 15%, 40%, 30%, 12% and 2% of subjects spent sitting time per day 1-3 h, 3-5 h, 5-8, 8-10, >10 h respectively. Discussion This preliminary analysis showed that netsurfers of the used health and fitness Italian community mainly appear to be office workers with healthy lifestyle. Indeed in agreement with Nagaya et al. (2007), that showed a coexistence between smoking and sedentary lifestyle, we found that the majority of participants (66%) did not to smoke. Moreover, protein supplementation does not appear to interest the netsurfers of the used sporting website heavily. An online survey can be a low-cost, efficient, and confidential modality to investigate the netsurfers' lifestyle of sporting websites. However only by a dissemination strategy of this questionnaire from other Italian sporting websites we could investigate the lifestyle of their netsurfers. ### EFFECTS OF THE SUMO EXERCISE ON ALLEVIATING LOWER BACK PAIN.

Nigorikawa, T., Endo, S., Shintani, K., Kato, H., Ishiwata, T., Kanou, H., Hirono, M., Yasukawa, M., Oishi, K.

*Rikkyo University \*Chuo University*

Introduction Lower back pain (LBP) among Japanese people has become a serious social problem. Previous researches indicate that certain types of exercise are effective for alleviating and preventing LBP, including findings that suggest that the basic movements of the traditional Japanese sport of 'sumo wrestling' may be helpful. However, there have been few empirical studies on this topic, and it is hoped that further studies will be conducted. Accordingly, this study was conducted to examine whether "sumo exercise" were effective in alleviating LBP compared to the other types of conventional lower back exercises. . Methods The subjects of the study consisted of 119 adults (47 men and 72 women). They were interviewed to determine the presence or absence of LBP by using JOA( Japanese Orthopaedic Association) back pain evaluation questionnaire (JOA). JOA can be used to measure several items which related to LBP, namely the degree of LBP, psychological disorders, walking impairment, disability of social life and so on. Moreover, the subjects were divided into three groups and assigned tasks consisting of 'the sumo exercises', 'conventional lower back exercises', and 'no exercises', which were performed for 10 months respectively. A comparative study was then made of the preventive and ameliorative effects demonstrated by these exercises. Results According to the survey of JOA, the sumo exercise group showed a significant improvement in the two items which were degree of LBP and disability of social life. In contrast, the conventional exercise group showed a significant improvement also in the two items which were disability of social life and psychological disorders. As far as the no exercise group, there was no significant change in any item. Discussion Improvement of QOL by betterment of LBP has become an important theme in Japanese society. Several findings suggested that basic movement of the sumo wrestling represented by "shiko" was effective for alleviating and preventing LBP. Results of this study showed that the sumo exercise, in the sense of improving the degree of LBP, was more effective than conventional exercise. In the future, if customarily done this kind of exercise among the Japanese, it might be able to reduce the problem of LBP in Japan.

## DIET AND EXERCISE ADHERENCES CORRELATIONS BY SEXES IN WEIGHT LOSS PROGRAMS

Rojo-Tirado, M.A.1, Peinado, A.B.1, Benito, P.J.1

*Facultad de Ciencias de la Actividad Física y del Deporte (INEF), Universidad Politécnica de Madrid, Spain*

**Introduction** Physical activity in conjunction with moderate dietary energy restriction and behavior modification has been promoted as an important component of a successful weight-loss regimen (1-3). Low-energy diets and physical activity are important for weight loss, defining successful efficacy (4, 5). Therefore, the aim of this study was to compare the diet and exercise adherences by sex, and know if both adherences have any kind of correlation. **Methods** One hundred eighty overweight and obese people (Body Mass Index: 25-34.9 kg•m<sup>-2</sup>), aged from 18 to 50 years, participated in the study (84 males, 96 females) during 6 months. Four types of treatments were randomly assigned: strength training (S, n=43), endurance training (E, n=51), combined S and E training (SE, n=46), and diet and physical recommendations (C, n=40). All participants followed a 25% calorie restriction diet. Adherence to diet was calculated as the estimated Kcal of the diet divided by the real Kcal intake in percentage, representing the major adherence the value 100%. Higher values mean a higher restriction and on the contrary. Adherence to exercise was calculated by the number of sessions developed from the total. A MANOVA was used to determine differences between sexes in diet and exercise adherences. The Pearson's correlation coefficients were used to analyze the relationship between both adherences. Probability level for statistical significance was set at  $\alpha=0.05$ . **Results** The weight loss was lower in women than in men (-7.56±4.05 vs. -9.56±4.58 kg, respectively,  $p=0.02$ ). Women were more adherent to diet program (104.03±22.46%) than men (116.33±35.42%) ( $p=0.017$ ). However, for exercise program women and men had the same adherence (88.9±7.25 vs. 88.85±7.63%, respectively,  $p=0.967$ ). No correlations were found between diet and exercise adherences, since for women it was obtained  $r=-0.006$  ( $p=0.96$ ) and for men  $r=-0.117$  ( $p=0.379$ ). **Discussion** Although women had a higher adherence to diet than men (near to 100 %), men followed a more restrictive diet what might explain the greater weight loss. In a weight loss program, exercise adherence is equal for women and men, so physicians should pay more attention to diet fidelity. As no significant correlations between adherences have been found, it is not possible to conclude that people who was more adherent to diet, was more adherent to exercise too. **References** 1. ## ARTERIAL STIFFNESS AND PHYSICAL FITNESS IN PUBERTY

Matsumoto, N.1, Yoshioka, A.2, Takahara, T.3, Nose, Y.4, Takagi, Y.5, Saito, T.4, Arakane, K.4, Yamaguchi, H.6, Iemitsu, M.7, Takahashi, K.8, Miyachi, M.9, Onodera, S.3

*1)Shujitsu Junior College, 2)Kagawa Univ, 3)KUMMW, 4)Graduate School, KUMMW, 5)JSPS Reserch Fellow, 6)KIBI International Univ, 7)Ritsumeikan Univ, 8)TAU, 9)National Institute of Health and Nutrition.*

**PURPOSE:** Arterial stiffness progressively increases with aging. The high level of arterial stiffness is an independent risk factor of cardiovascular diseases. Higher levels of physical fitness, especially cardiorespiratory fitness are associated with delay of age-related arterial stiffening in adults. Yamamoto et al. recently reported that arterial stiffness was significantly correlated with flexibility in middle-aged and elderly people, but there was no such correlation in young people. The purpose of the present study was to clarify the correlation between arterial stiffness and fitness (muscular strength and flexibility) in puberty. **METHODS:** 72 Japanese adolescents participated in this study (40 boys and 32 girls). We measured their height, body weight, blood pressures, arterial stiffness, muscular strength (handgrip test) and flexibility (sit-and-reach test). The arterial stiffness was measured by the pulse wave velocity between brachial and ankle arteries (baPWV). We examined the relationship between fitness and baPWV. **RESULTS:** The handgrip strength of boys indicated a significant positive correlation with their height, weight and systolic blood pressure. However, there was no relationship between handgrip strength and baPWV. In girls, there were no relationships at all. The flexibility in both of boys and girls indicated significant positive correlation with their height. However, there was no relationship between flexibility and baPWV. **DISCUSSION:** The handgrip strength in boys was associated with systolic blood pressure. It is possible that the relationship between handgrip strength and blood pressure is associated with an increase in muscle mass, blood volume and sex hormone secretion with growth development. We speculate that the flexibility and baPWV were unconcerned because artery in pubertal child were distensible enough. In conclusion, the present results indicate that arterial stiffness is not associated with muscular strength and flexibility in puberty. ## PHYSIOLOGICAL RESPONSE, ENJOYMENT AND RATE OF PERCEIVED EXERTION FOLLOWING A BOUT OF INTERACTIVE GAME CYCLING AND CONVENTIONAL CYCLING IN ADULTS

Monedero, J., Collins, N., Torris, L., O'Gorman, D.J.

*Dublin City University*

**Introduction** Physical inactivity is the fourth leading risk factor for global mortality (WHO, 2010). Though sedentary behaviour is a modifiable risk factor for a myriad of chronic diseases, adult physical activity levels remain low. Innovative approaches are required to reverse these behaviours and increase daily energy expenditure. Interactive video games have become popular in recent years but it is not clear how they compare with conventional exercise. The purpose of this study was to compare cardiovascular, metabolic, perceptual and enjoyment responses between one bout of conventional cycling and one bout of interactive game cycling at a matched workload. **Methods** Thirty four healthy subjects (sixteen women and eighteen men) volunteered for this study. Peak oxygen uptake (VO<sub>2</sub>peak) was measured using an incremental cycling test and subjects were familiarised with the cycling game prior to testing. Subjects carried out a 30 min interactive cycling trial and a 30 min conventional cycling trial at 55% of peak power output, in random order, with at least 2-days between trials. During the trials, VO<sub>2</sub> was measured using a metabolic system (Innovision Ltd, Odense) and heart Rate (HR) was measured by radiotelemetry. These measures were used to calculate heart rate reserve (HRR), VO<sub>2</sub> Reserve (VO<sub>2</sub>R), the rate of energy expenditure (REE) and MET's. Rate of Perceived Exertion (RPE) and enjoyment was measured every 10 minutes with Borg scale and a modified PACES scale. **Results** Interactive cycling resulted in a significantly greater VO<sub>2</sub>R (68.31% ± 10.12% vs 64.9% ± 9.6%), REE (8.8 ± 1.9 vs 8.47 ± 2 kcal/min), MET (7.1 ± 1 vs 6.8 ± 1.1) and enjoyment (27.2 ± 6.1 vs 17.1 ± 5.7),  $p<0.05$ . No significant differences between interactive cycling and conventional cycling were found for HRR (72.5 ± 10.4 vs 71.4 ± 10.1%) and RPE (13.1 ± 1.8 vs 13.2 ± 1.7). **Discussion** The main finding of this study was that interactive cycling resulted in significantly higher metabolic responses and energy expenditure. Interactive game cycling did not result in higher perceptual ratings of effort and was deemed more enjoyable. Interactive cycling games can be a valid alternative to conventional exercise since they result in a higher intensity of effort and have higher enjoyment ratings. **References** 1. War-

#### RUNNING DEMANDS AND HEART RATE RESPONSES IN RUGBY SEVENS REFEREES

Suarez moreno arrones, I.

*Faculty of sport*

Running Demands and Heart Rate Responses In Rugby Sevens Referees Suarez-Arrones, L.1, Portillo, J.2, Calvo-Lluch, A.1 and Mendez-Villanueva, A.3 1:Pablo de Olavide University,Seville.2:University of Castilla la Mancha.3:ASPIRE, Qatar. Introduction To date, only very limited information exists on the physiological and running demands associated to match play in rugby refereeing, and no data are available yet on rugby sevens. Accordingly, the aim of this study was to examine for the first time the match running demands and exercise intensity associated with men rugby sevens refereeing. Methods Time-motion analysis of running activity was collected from 12 elite male rugby referees. Match analyses were performed 2–4 times on each referee during a total of 38 matches played during two international rugby sevens tournaments. Portable global position system (GPS) technology and heart rate (HR) responses were used to assess match running demands and exercise intensity, respectively. GPS data were recorded at 15 Hz frequency. Results Referees covered an average distance of 1665.2 m per game. Over this distance, 22.3% (371.8 m) was spent standing and walking, 25.9% (431.2 m) jogging, 12.4% (206.5 m) cruising, 23.8% (395.6 m) striding, 8% (133.3 m) high-intensity running, and 7.6% (126.7 m) sprinting. The average maximal distance of sprints, the number of sprints and the mean sprint distance over the game were: 31.3±13.4 m, 5.76±3.6 sprints, and 19.9±7.8 m respectively. The referee's work-to-rest ratio was 3.5:1, and the average heart rate in the second half was higher ( $P<0.05$ ) than the heart rate recorded in the first half. Discussion The referees evaluated in the present study were exposed to a higher running demands than their counterparts refereeing other rugby codes (Kay and Gill, 2003; Martin et al., 2001). Compared with video data collected in rugby league (Kay and Gill, 2003) and union (Martin et al., 2001) referees, the current group of rugby sevens referees covered substantial greater total distance per min (110 m.min<sup>-1</sup>) in comparison with ~79 m.min<sup>-1</sup> in rugby league and 101 m.min<sup>-1</sup> in rugby union. The average heart rate of the referees in this study was slightly lower than the estimated HRmax reported in rugby league referees (Kay and Gill, 2004) and the HRmax obtained in male rugby sevens players (Suarez-Arrones et al., 2011). #### THE IMPORTANCE OF LEAN MASS IN PROFESSIONAL AUSTRALIAN FOOTBALL PLAYERS: SEASONAL CHANGES AND RELATIONSHIPS WITH PHYSICAL PERFORMANCE

Bilsborough, J.C.1,2, Greenway, K.1, Livingstone, S.1, Hocking, J.1, Sullivan, C.1,2, Cordy, J.1, Coutts, A.J.1,2

*1. Carlton Football Club (Melbourne, Australia). 2. UTS (Sydney, Australia)*

Introduction Most studies show muscular strength and power are reduced during the competition season in team sports, with these changes often being attributed to reduced training volume, accumulated fatigue, and altered body composition. Whilst it is likely that losses in lean mass (LM) underpin these changes, to date no studies have examined the importance of LM in highly trained team sport athletes. Therefore, the purpose of this investigation were; 1) to examine the relationships between LM and various components of physical performance in professional Australian Football players, and 2) to examine if changes in LM during the competition phase of the season are related to changes in muscular strength and power. Methods Forty one professional players from an Australian Football League (AFL) team (age, 22.6±3.3 y; height, 189±7 cm; mass, 88.2±8.1 kg; mean ±SD) were assessed for muscular strength (1-RM bench press, deadlift and squat), lower body power (weighted CMJ30) and unweighted counter movement jumps (CMJ)), speed (20 m sprint), Yo-Yo intermittent recovery test (Yo-YoIR2) performance, and DEXA-derived LM and fat mass (FM), immediately prior to-, midway, and at the completion of the 24 week AFL competition season. In addition, match activity profiles (i.e. m/min and distance travelled higher speed running (>14.4 km/h) were collected using 10-Hz GPS during the season. Pearson's correlations (•90% confidence intervals) were used to determine strength of associations of changes in anthropometry, physical performance characteristics. One-way ANOVA was used to examine differences between the pre-mid and post-season anthropometry and performance measures. Results Significant relationships between LM and strength (deadlift: 0.58,•0.21, bench press: 0.46,•0.23), power (CMJ: 0.67,•0.15, CMJ30: 0.70,•0.14), YoYoIR2 (-0.38,•0.27) and match activity profiles (m/min: -0.48,•0.18, HSR: -0.64,•0.18) were observed. Relative LM (LM%) was moderately related to YoYoIR2 (0.33,•0.29). FM was correlated with strength (deadlift: 0.37,•0.27), power (CMJ: 0.40,•0.23, CMJ30: 0.34,•0.24), YoYoIR2 (-0.40,•0.27) and match activity profiles (m/min: -0.37,•0.26, HSR: -0.46,•0.18). Mass and LM, remained stable at the mid-point of the season; however, BF increased at the end of the season ( $P<0.05$ ). The small changes in LM during the season were related to changes in strength (0.49,•0.36) and power (0.37,•0.43). Discussion and Conclusions Increased LM is related to improved strength and power performance; however, increased LM was associated with poorer YoYoIR2 scores and lower match activity profiles. The negative associations with match activity profiles are most likely due to positional roles within AF. Nonetheless, small changes in LM during the season may be important as these were associated with poorer strength and power. To ensure consistent physical performance toward the end of the season, strategies should be implemented to protect the loss of LM and prevent increases in FM during the competition season.

## PHYSICAL PERFORMANCE AND EVIDENCE OF FATIGUE IN RUGBY SEVENS REFEREES

Portillo Yábar, L.

*Universidad Castilla La Mancha*

PHYSICAL PERFORMANCE AND EVIDENCE OF FATIGUE IN RUGBY SEVENS REFEREES Portillo, L. J.1, Suárez-Arrones, L.2., Sánchez M.1, Sánchez, F.1, Nuñez, F.J.2, García J.M.1 1: UCLM (Toledo, Spain), 2:UPO (Sevilla, Spain) INTRODUCTION The aims of this study was to examine changes in running demands and effects of fatigue in elite referees during the competition of rugby sevens tournament. METHODS A prospective and observational study design was used to assess physical demands of 7 elite referees in 21 competition matches. Time-motion analysis of running activity was collected using Global Positioning System (GPS, SPI Pro X 15Hz) and HR monitors. RESULTS Mean total distance ( $\pm$  SD) covered over the whole match by referees was  $108.5 \pm 9.5$  m $\cdot$ min<sup>-1</sup>. The number of sprint during the match was  $6.1 \pm 3.1$  with rank from 1 to 13 sprints. The distance of high-speed zone ( $> 20$  km.h<sup>-1</sup>) was  $18.6 \pm 6.5$  m. with rank from 7 to 74.4 m. The referees spent most of their match time at HR intensities between 81- 90% HRmax with significant differences ( $P < 0.05$ ). The fatigue in matches have been analyzed considering information by quarters. Whole match is divided in four quarters and therefore each half has two. There was a significantly reduction in traveled distance between first quarter and second quarter of both halves ( $P < 0.01$ ). When the three tournament matches were analyzed total distance decreased significantly between first and last match ( $P < 0.01$ ). Distance of sprinting decreased significantly ( $P < 0.05$ ). Also the peak of maximum speed decreased between first and last match ( $P > 0.05$ ). DISCUSSION There are substantial differences around the development of the physical demands of referees during the matches in rugby sevens tournament. Running demands of referees investigated in this study are higher than other types of rugby (Kay & Gill, 2003; Martin et al., 2001) and similar to the rugby sevens players (Suarez-Arrones et al., 2011a ; 2011b). This study has reported running demands in rugby sevens referee. Running speed is higher than other modalities such as rugby union. Study findings can be used as a reference value to adapt specific training programs for rugby sevens referees. REFERENCES Kay, B.; Gill, ND. ## DIFFERENCES IN PHYSICAL DEMANDS BETWEEN INTERNATIONAL AND NATIONAL FEMALE RUGBY SEVENS PLAYERS

Portillo Yábar, L.

*Universidad Castilla La Mancha*

DIFFERENCES IN PHYSICAL DEMANDS BETWEEN INTERNATIONAL AND NATIONAL FEMALE RUGBY SEVENS PLAYERS Portillo, L. J.1, Suárez-Arrones, L.2., Sánchez M.1, Sánchez, F.1 García J.M.1 1: UCLM (Toledo, Spain), 2:UPO (Sevilla, Spain) INTRODUCTION In this study, the physiological demands of an international and national women's rugby 7s were investigated during competition. Obtaining measures of physiological demands between different level of performance in rugby 7s female players during the competition match enabled us to determine how these athletes responded to a competition and if exists differences between physiological and movement patterns. METHODS Variables were measured by means of GPS receivers and HR monitors. In order to determine whether there were physiological changes in these aspects, participants were tested during international and national tournament. The data used in the study was gathered from 20 players (10 international and 10 national players) during four matches in both levels of competition. RESULTS The results of this study show that, during a Rugby 7s match, there are differences in the physiological profile of international and national female rugby sevens players. Mean total distance ( $\pm$  SD) covered over the whole match by international players was  $1642 \pm 171.20$  m. and national players was  $1363.45 \pm 221.87$ . The number of sprints during the match by international players was  $6.18 \pm 3.13$  and national players was  $1.97 \pm 1.49$ . The distance of high-speed zone ( $> 20$  km.h<sup>-1</sup>) was  $62.01 \pm 37.80$  m. and  $21.10 \pm 24.50$  m. The average speed obtained throughout the game was  $6.06 \pm 0.33$  km.h<sup>-1</sup> and  $5.29 \pm 0.63$  km.h<sup>-1</sup>. The international players spent at HR intensities ( $> 95\%$ ) expressed as percentage of HRmax,  $26.55 \pm 16.09\%$  and national players was  $13.28 \pm 10.60\%$ . In general, physical demands were significantly greater ( $p < 0.01-0.001$ ) by international players. DISCUSSION The results of this study are similar to those obtained by (Suárez-Arrones L. et al., 2011) in the physiological profile of international female rugby sevens player. The data of studies (Anita C. Sirotić et al., 2009; Cameron Brewer A et al., 2010; D. G. Higham et al., 2011) examine differences in physical performance between elite and semi-elite games findings significantly differences. Collectively, these findings provide important information that can be used in the training process for improve specific qualities of female rugby 7s. REFERENCES Anita C. Sirotić, Aaron J. ## THE PHYSICAL FITNESS PARAMETERS OF SENIOR SOCCER PLAYERS

Polat, C., Cerrah, A.O., Ertan, H.

*Anadolu University*

Introduction Talent identification in soccer starts from the early ages. There have been some soccer abilities that are need to be evaluated at that ages. So, the purpose of the current study was to compare the natural talent selection method with physical parameters to identify 11-12 years old senior soccer players across a number of primary school teams. Material & Methods A group of soccer coach has visited the primary schools and contact with the PE teachers to organize small-scale tournaments. A written consent has been achieved from the parents of each senior boy to participate the study. After preliminary natural selection with expert observation, the soccer coaches and PE teachers have selected a school team. A total number of 217 senior boys have been selected to participate in a tournament. The whole group (n=217) has participated to a test session to determine the motor abilities, flexibility, agility, explosive power, and general balance (Table 1). After a tournament, total number of players has been decreased to 35 by the votes of soccer experts. In order to compare result, unpaired t-tests were applied. Results The comparison of selected and non-selected senior soccer players by natural talent identification has been applied. According to results, all of the performance parameters were higher in selected group than that of non-selected (Table 1). However, statistical significant differences ( $p < 0.05$ ) occurred only in weight, sit-up and 20 m sprint tests. Table 1: Physical fitness parameters of soccer players Selected Non-Selected (n=35) (n=182) Parameters Mean $\pm$ SD Mean $\pm$ SD Age 11.02 $\pm$ 0.74 10.93 $\pm$ 0.77 Height (cm) 140.6 $\pm$ 5.71 143.4 $\pm$ 7.56 Weight (kg) 33.87 $\pm$  4.19 38.07 $\pm$ 9.22\* Sit and Reach (cm) 22.38 $\pm$ 5.19 22.22 $\pm$ 5.98 Sit-up 19.20 $\pm$  3.07\*\* 17.51  $\pm$  3.05

Squat Jump (cm) 21.27±5.13 19.61±4.62 CMJ (km/s) 24.74±3.90 23.02±4.30 10m sprint (sec) 2.02±0.32 2.06±0.12 20m sprint (sec) 3.69±0.29\* 3.83±0.29 Flamingo Balance 7.68± 3.22 7.64±2.78 Medicine Ball Perfor. 2.94±1.91 2.67±0.72 Standing B J (cm) 1.46±0.18 1.46±0.69 Bent-arm hang 14.78±7.52 12.26±9.99 \* p<0.05 ; \*\* p<0.01 Discussion & Conclusion In conclusion, the findings from this study suggest that successfully selected players showed consistent performance across all tests in comparison to non-selected players who performed well in one or two tests. On the other hand, the chosen performance parameters are important and decisive to determine the successful soccer players. Findings obtained from this study have a similarity with the results of the researches made by Gravina, et. al (2000); Reilly, et. al (2005). References: 1. Gravina L, Gil SM, Ruiz F, Zubero J, Gil J, Irazusta J. Sports Sci. 18(9):669-83, 2000 2. Reilly T, Bangsbo J, Franks A. Sports Med. 35(6):501-36, 2005

### THE ROLE OF CONDITIONING ON PERFORMANCE IN PROFESSIONAL SOCCER

Reer, R., Stein, D., Wellmann, K., Braumann, K.M.

*University of Hamburg*

Introduction Expert suggest that since 1990's there has been a steady increase in performance demand as well as performance level in professional soccer players. The endurance conditioning level of the German national players in the 1990's is similar to the conditioning of the 3rd division players today. In contrast to endurance performance, the sprint performance level of the national players in the 1990's is achieved only in the 1st professional soccer division today. Therefore, the aim of this study was, based on multiyear record keeping, data collection, and observations, to investigate how the sport specific endurance, speed, and strength that are prerequisites for successful professional soccer players can be improved, maintained, and enhanced. Methods We conducted numerous seasonal tests with a group of professional soccer players. The tests were soccer specific endurance, sprints, jumps and strength training of specific muscle groups. In addition to soccer specific demands, we designed and implemented individually tailored strength and interval training. This type of training was conducted 3-4 hours per week. Results There were statistically significant improvements in soccer specific endurance from the beginning of the 3rd division 4.11±0.19 m/s to 4.26±0.2 (p<0.01) at entry to 2nd division and improved to 4.62±0.25 m/s (p<0.001) at the start of the 1st division. Similar results were observed for 30m sprints. They improved their sprint performance time from the beginning of the 3rd division to 2nd division from 4.27±0.23s to 4.1±0.14s (p<0.01). At entry to 1st division they improved their sprint time to 4.0±0.15s (p<0.001). However, there was no significant difference for counter movement jumps (38.0±3.5cm to 39.2±4.2cm). Discussion The performance of a professional soccer team depends on multitude of factors. The results suggest that systematic and individualized improvements in soccer specific endurance and sprint performance greatly contribute to the success in professional soccer. In addition, our results suggest that players possess physiological abilities that can be harvested and thus can greatly benefit individually and collectively from training methods employed in this investigation. *Pablo de Olavide University*

EVOLUTION OF PHYSICAL PROPERTIES IN DIFFERENT PERFORMANCE LEVELS IN SOCCER PLAYERS. Rodríguez-Rosell, D.1, Franco-Márquez, F.1, Pareja-Blanco, F.1, González-Badillo, J.J.1 1Pablo de Olavide University, Seville, Spain Introduction During a soccer game, endurance plays an important role on performance. Nevertheless, the most conclusive actions are realized at maximum intensity and short periods of time (2). Several works have analyzed correlations among different variables (1RM half squat, sprint and jumping height) in elite soccer players (3). However, to our knowledge there has been no study to analyze the correlation between strength and endurance variables throughout a soccer player's life. Methods One hundred forty-eight male soccer players belonging to the same football club took part in this study. The subjects were divided into seven different teams according to age and category (T1: 11.9±0.2, T2: 12.6±0.5, T3: 13.8±0.5, T4: 14.6±0.5, T5: 16.2±0.5, T6: 17.3±0.6, T7: 24.4±4.5 years). The evaluation was done at the beginning of the season and the variables measured were: countermovement jump (CMJ), full squat 1RM (T-Force System, Ergotech, Spain), acceleration capacity in 10, 20 m (T10, T20, T10-20), maximal aerobic speed (MAS) and maximal throw velocity (MTV). One-way ANOVA was used to detect differences between groups of subjects. The correlation between variables was determined through Pearson's coefficient correlation taking as the control variable age of subjects. Results Every variable measured displayed high reliability (CCI: 0.914-0.997; CV: 1.94-2.61%). As a result we obtained that every physical qualities measured (1RM, CMJ, T10, T20, T10-20, MAS and MTV) improved progressively with age, reaching statistically significant differences (p<0.05) between each category in most cases. Furthermore, we found statistically significant correlations (p<0.01) between each performance analyzed variables (0.36-0.95). Discussion This study indicates that with increasing age of soccer players, those variables that can be explained through improvement of strength (CMJ, 1RM full squat, T10, T20, T10-20 and MTV) show more gains than those variables that depend on endurance (MAS), which do not show improvements after 14 years. These findings could indicate that factors which explain soccer performance would be more related with explosive-type actions (changes of direction, jumps, sprints, tackles) (1) where a high production of strength, power and rate of force development have a more determinant role than MAS. **14:45 - 15:45****Poster presentations****PP-PM43 Physiology 11****EXERCISE TRAINING ENHANCES BUT DOES NOT RESTORE INSULIN SENSITIVITY AND SIGNALLING IN OBESE WOMEN WITH PCOS**

Cassar, S.1, Stepto, N.K.1,2,3, Hutchison, S.K.3, Harrison, C.L.3, Teede, H.J.3

*1 School Sport and Exercise Science, Victoria University, Melbourne, Australia. 2 ISEAL, Victoria University, Melbourne, Australia. 3 Jean Hailes Research Group, Monash University, Clayton, Australia*

Introduction Polycystic Ovary Syndrome (PCOS) is a complex disorder comprising metabolic, endocrine and reproductive dysfunctions, affecting 18% of reproductive aged women (March et al., 2010). Insulin resistance (IR) is recognised as a key aetiological feature of PCOS (Teede et al., 2007). The mechanisms underlying insulin resistance in PCOS remain elusive but may be attributed to impaired insulin signalling within skeletal muscle (Corbould et al., 2005). Methods 8 obese PCOS and 8 control women were recruited. PCOS was diagnosed according to NIH criteria (Harrison et al., 2011). Insulin sensitivity was determined from glucose infusion rate [GIR] during an euglycaemic hyperinsulinaemic clamp. Muscle biopsies were taken for assessment of insulin signalling (p-Akt ser473). Body composition, VO<sub>2</sub>peak, GIR and insulin signalling were analysed before and following 12-weeks of intensified exercise training. Results Body composition did not change over the duration of the study. VO<sub>2</sub>peak improved by 23 (4%) [mean (SEM)] in PCOS vs. 16 (2%) in Control (P<0.05). Insulin sensitivity (GIR) improved by 17 (3%) vs. 23 (4%) (PCOS vs. Control; P<0.05). Changes in insulin sensitivity were accompanied by increases of p-Akt ser473 of 1.3 (0.1) and 2.0 (0.2) fold in PCOS vs. 1.8 (0.2) to 2.3 (0.2) fold in Control pre and post training respectively (time-effect P<0.001). These similar fold changes occurred despite the lower overall insulin stimulated p-Akt ser473 expression in PCOS women (P<0.01, group, time & group x time). Discussion IR was improved following intense exercise in women with PCOS. Akt ser473 phosphorylation was increased, but not normalized in the PCOS group. This may be related to intrinsic aberrant IRS, PP2A and/or PTEN signalling. References Corbould, A., Kim, Y.B., Youngren, J.F. et al. (2005). *Am J Physiol Endocrinol Metab*, 288, E1047–E1054. **EFFECTS OF ENDURANCE TRAINING ON PLASMA CONCENTRATION OF VISFATIN AND INSULIN RESISTANCE AT REST IN RESPONSE TO ACUTE ENDURANCE EXERCISE IN DIABETIC RATS**

Fallah omran, S.1, Kordi, M.2, Ahmadizad, S.3, Mojtahedi, S.4

*Faculty of Physical Education and Sports Sciences*

In this study, we have investigated the effect of endurance training on plasma concentration of visfatin and insulin resistance at rest in response to acute endurance exercise in diabetic rats. Methods : Sixty diabetic wistar rats were randomly divided into sedentary diabetic control (n = 29) and trained diabetic groups (n = 31). Diabetes was induced by single intravenous injection of streptozotocin (STZ; 50 mg/kg BW). The exercise training protocol consisted of treadmill running, 5 times/week for 8 weeks, after 8 weeks one single bout acute exercise consisted of treadmill running with the velocity of 20m/min, 30 min, %5 inflation. Rats were sacrificed 48 h after the last training period and the blood samples were collected. Plasma circulating levels of glucose, insulin, visfatin were assessed. To specify the effect of endurance training on blood factors, the pair t-test was used. Additionally, response to acute endurance exercise was determined by using the repetitive variance analysis (2\*2). Results: plasma visfatin level were decreased after endurance training (p < 0.895, t = 0.037) and this level were significantly reduced (p < 0.001) in response to acute exercise. Insulin resistance was decreased after 8 weeks endurance training and in response to acute exercise. Discussion: There was a significant reduction in plasma visfatin levels in response to acute exercise in diabetic rats. The decrease of visfatin after 8 weeks exercise suggests that other factors than glucose metabolism, body weight, or the lipid profile may be responsible for this finding (Frydelund- Larsen et al 2007, Haider 2007). Although the molecular mechanism underlying attenuated glucose-stimulated insulin secretion in Namp1+/- islets is still unclear, alterations in NAD levels could alter activities of important enzymes in metabolic pathways such as glycolysis or fatty acid oxidation in pancreatic  $\beta$  cells (Revollo et al 2007). **EFFECTS OF EXERCISE TRAINING AND ENERGY-RESTRICTED DIET ON FATTY LIVER IN ZUCKER FATTY RATS.**

Shiroya, Y., Umetsu, Y., Kitamura, H., Minato, K., Yamauchi, H.

*Wayo Women's University*

Backgrounds Both energy-restricted diet and physical exercise have been used for the improvement of obesity. In particular, daily physical exercise has beneficial effects on lipid metabolism. We have found that voluntary running training with energy-restricted diet improved fatty pancreas in Zucker Fatty rats, but not energy-restricted diet treatment only. Aim The purpose of the present study was to investigate whether voluntary running training and/or energy-restricted diet improves fatty liver in Zucker Fatty rats. Methods Male Zucker Lean rats were used as control (LC). Male Zucker Fatty rats were divided into 3 groups; Obese (OB), Energy-restricted diet (ERD), and Trained (TR) groups. The LC and the OB rats had free access to food, the ERD and TR rats had food intake restricted to 69% and 74% of the OB group level, respectively. The TR rats were exercised voluntarily on the wheel ergometer with a load of 30% on their body weight every day. After 6 weeks, all rats were prepared for experiment. The liver was excised and weighed. Hepatic tissue was prepared for transmission electron microscopy. Results Body weight in the LC group was significantly lower than in the Fatty groups. Body weight in the OB

group was greater than in the ERD and the TR groups. Final body weight was matched between the ERD and the TR groups. Serum triglyceride and total-cholesterol concentrations in the OB and the ERD groups were higher than in the LC and the TR groups. Liver weights in the OB and the ERD groups were significantly greater than in the LC group. Liver weight in the TR group was significantly lower than in the OB and the ERD groups. Electron micrographs of the hepatocytes in both OB and ERD groups revealed accumulation of lipid droplets and degeneration of mitochondria. In contrast, the hepatocytes from TR group showed reduction of lipid droplets and increase of mitochondria content. Discussion The main finding in the present study was that training combined with energy-restricted diet obviously decreased lipids in serum and tissues of the liver in Zucker Fatty rats, but not in the energy-restricted diet group. Training accelerates lipolysis in the adipocyte and utilization of fatty acids in the muscle and the other cells, not only exercise period but also resting period, energy-restricted diet alone may decrease resting-metabolic-rate and inhibit these lipid metabolism to the contrary. The findings in the present study suggest that physical exercise combined with energy-restricted diet may improve lipid metabolism in Zucker Fatty rats, while energy-restricted diet alone may not.

### **NEW MECHANISMS FOR ENDURANCE TRAINING ON GLUCOSE HOMEOSTASIS: REDUCED INSULIN CLEARANCE AND LIVER INSULIN DEGRADING ENZYME EXPRESSION**

Costa, J.M.1, Ferreira, S.M.1, Rezende, L.1, Zoppi, C.1, Protzek, A.O.1, Oliveira, C.A.M.2, Santos, G.J.1, Boschero, A.C.1, Carneiro, E.M.1

1: State University of Campinas ; 2: Federal University of São Paulo State

Introduction It is well established that endurance training improves peripheral insulin sensitivity in liver and skeletal muscle, but the mechanism for this effect is poorly understood. Moreover, it has been recently proposed that insulin clearance plays a major role in both glucose homeostasis and insulin sensitivity. Therefore, our goal was to assess the mechanism by which endurance training improves insulin sensitivity and how it controls insulin clearance in mice. Material and Methods Swiss mice were separated in sedentary (S) and trained (T) groups. At the end of 4 weeks training, mice achieved a treadmill speed of 0.27 m/s  $VO_2$  máx for 60'. We evaluated glucose tolerance by ipGTT, insulin resistance by ipITT and kITT tests and insulin clearance. After tests, mice were killed for liver, skeletal muscle, and adipose tissues analysis. Proteins phosphorylation and expression were assessed by Western-Blot. Results Trained mice showed increased max  $VO_2$ , time to exhaustion and reduced fat pads, evidencing training effectiveness. Those mice presented lower plasmatic insulin and glucose, both in fasted and non-fasted states. Also, trained mice were more glucose tolerant, as evidenced by lower ipGTT and AUC of ipGTT, and more insulin sensitive, as evidenced by ipITT, kITT and AUC of ipITT. Endurance training also reduced insulin removal from plasma, as evidenced by insulin clearance test. Liver from trained mice had increased phosphorylation of Insulin receptor and AKT (insulin canonical pathway), as well as increased phosphorylation of CaMKII, AMPK and ACC. In skeletal muscle, on the other hand, there is no activation of insulin canonical pathway (Insulin receptor and AKT), but a marked increase in CaMKII, AMPK and ACC phosphorylation. The lower insulin clearance observed in trained mice could be attributed to reduced expression of Insulin degrading Enzyme (IDE) in liver. Discussion Taken together, our results show that endurance training improves glucose homeostasis not only by increasing peripheral insulin sensitivity, but also by reducing insulin clearance through reduced IDE expression in liver. Moreover, we found that endurance training improved insulin action on skeletal muscle and liver through increased activation of the CaMKII-AMPK pathway, which allows us to propose that this is an alternative signalling pathway for the long-term action of physical exercise. Financial Support: FAPESP/CNPq

### **THE ANTI-INFLAMMATORY EFFECT OF THE WHOLE BODY CRYOSTIMULATION IN OBESE MEN**

Ziemann, E., Olek, R.A., Grzywacz, T., Kasprovicz, K., Antosiewicz, J., Laskowski, R.

University of Physical Education and Sport

Introduction The increasing number of obese people was recorded in recently published report (Ruesten et al. 2011). Elevation of adipose tissue is the crucial factor in the regulation of many pathological processes. Certain cytokines produced by this tissue are thought to provide an important link between the obesity and related inflammatory disorders (Tigl 2006) The method, which may effectively exert the anti-inflammatory response is exposure to cold. Therefore, the aim of this study was to investigate the effect of the whole body cryostimulation on secretion of the cytokines in obese men Methods Seven obese men (BMI >30 kg/m<sup>2</sup>) participated in the study. Body composition was assessed using a multi-frequency bioelectrical impedance analysis (In Body 720, Biospace). Additionally maximal oxygen capacity was determined on an electromagnetically braked cycle ergometer (ER 900 Jaeger, Germany/Viasys Health Care). The subjects were exposed to the series of 10 sessions in a cryogenic chamber (ones a day at 9:30, for 3 min, at temperature -120°C). Blood samples were collected prior to the first cryostimulation and after finishing the last one. Results The series of 10 whole body cryostimulation sessions triggered the alteration in blood cytokines profile. Concentration of pro-inflammatory adipocytokines decreased by 6.8 % and 7.4% in resistin and visfatin, respectively. At the same time no change in adiponectin and leptin was observed. Moreover, the cold exposure induced 22% elevation of the anti-inflammatory cytokine IL-10. Furthermore, TNF $\alpha$  was 4.3 fold lower to the baseline, and IL-6 decreased by 19%. No changes of hematological parameters were noted. Discussion The investigation revealed that series of 10 whole body cryostimulations resulted in a significant decrease of pro-inflammatory and increase anti-inflammatory cytokines in obese men. It is important to note that concentrations of pro-inflammatory cytokines were above normal level in all subjects. This suggests that they experienced low- grade systemic inflammation and cryotherapy could be the strategy to reduce it. Our recently published data (Ziemann et al. in press), where cold exposure-induced drop of TNF $\alpha$  concentration in professional sportsmen could be supporting this conclusion. ### **EFFECT OF NEUROPEPTIDE W ON FEEDING ACTION WITH VOLUNTARY EXERCISE**

Takenoya, F.1,2, Kageyama, H.3, Yamamoto, N.4, Ryushi, T.5, Shioda, S.2

1:Hoshi Univ. 2: Showa Univ. 3: Kiryu Univ. 4:Japanese Red Cross Hokkaido College of Nursing. 5:Daito Bunka Univ.

Introduction Neuropeptide W (NPW), isolated from the porcine hypothalamus, was identified as the endogenous ligand for both GPR7 (NPBWR1) and GPR8 (NPBWR2) that belong to the orphan G protein-coupled receptors (GPCRs) family [1]. NPB/NPW is reported to be widely distributed in brain including the hypothalamus [2], pituitary and adrenal glands, suggesting that NPB/NPW may have important roles in modulating neuroendocrine functions [3]. Central (icv) infusion of NPW is known to decrease food intake in rodents [4]. Several types of stress are reported to suppress feeding behavior through the hypothalamus-pituitary-adrenal gland (HPA) axis. NPW may pro-

mote to secrete CRF (corticotropin-releasing factor), adrenocorticotropin hormone (ACTH) and corticosterone. It is generally accepted that voluntary wheel running reduces the activation of HPA axis to stimuli. Therefore, we studied to clarify the effect of infusion of NPW on feeding action with voluntary exercise in mouse. Methods Male C57BL/6J and DIO (Diet-induced obesity) mouse were icv infused with the vehicle (saline) and NPW (2 nM) once a day. Body weight, food intake, water intake and locomotor activity were measured 24 hours after infusion of NPW. The animals were used which adapted themselves to running wheel for 5 days, afterwards the mouse moved voluntarily. Then, the animals were sacrificed and then the brain sections of control and exercise group were immunostained with c-Fos antibody to look at the light microscope. Results DIO mouse did not change body weight, food intake, water intake and locomotor activity by voluntary exercise with NPW icv infusion. The voluntary wheel running canceled the NPW-induced anorexia and c-Fos expression was decreased in the paraventricular nucleus of the hypothalamus. Discussion These results suggest that the voluntary exercise stimulates the HPA axis and to influence feeding regulation in mice. References [1] Shimomura Y, Harada M, et al. ## ADHERENCE TO DIET AND DAILY ACTUAL KILOCALORIE DISCREPANCY BETWEEN GROUPS IN WEIGHT LOSS PROGRAMS

García-Hortal, M.I, Rojo-Tirado, M.A.I, Peinado, A.B.I, Benito, P.J.I

*Facultad de Ciencias de la Actividad Física y del Deporte - INEF, UPM*

**Introduction** Physical activity in conjunction with moderate dietary energy restriction and behavior modification has been promoted as an important component of a successful weight-loss regimen (1-3). Low-energy diets and physical activity are important for weight loss, defining successful efficacy (4, 5). Therefore, the aim of this study was to evaluate the dietary adherence and daily kilocalorie discrepancy between different treatments, in order to know which program has a higher level of adherence. **Methods** Eighty-four overweight people (Body Mass Index: 25-29.9 kg•m<sup>-2</sup>), aged from 18 to 50 years, participated in the study (36 males, 48 females) during 6 months. Four types of treatments were randomly assigned: strength training (S, n=19), endurance training (E, n=25), combined S and E training (SE, n=22), and diet and physical recommendations (C, n=18). All participants followed a 25% calorie restriction diet. Adherence to diet was calculated as the estimated Kcal of the diet divided by the real Kcal intake in percentage, and daily kilocalorie discrepancy was calculated through food diaries records. Two-way ANOVA (treatment and time) with repeated measures was used to determine differences between treatments and months. Multiple comparisons were made with the Bonferroni post hoc test. Probability level for statistical significance was set at  $\alpha=0.05$ . Results No significant differences were found between treatments and months for adherence to diet. Only one difference was revealed in month 4 between treatments E and SE (100.39±3.83 vs. 105.05±12.78%, respectively;  $p=0.030$ ). No significant differences were found between months, except for C treatment between months 2 and 4 (109.84±18.79% vs. 102.13±5.42, respectively;  $p=0.035$ ). When the daily kilocalorie discrepancy was analyzed no significant differences were discovered between months and groups. Only a significant difference was found for group E among months 1 and 4 (-51.56±138.98 vs. 8.54±77.6 kcal/day, respectively;  $p=0.013$ ). **Discussion** The four types of treatments have the same adherence to diet and no differences exist between daily kilocalorie discrepancies. In this way, the treatment selected in any weight loss program similar to us, would not be an important factor to determine the adherence to diet and daily kilocalorie discrepancy. References 1. ## EFFECTS OF GLYCEROL INGESTION AND SUBSEQUENT PLASMA AND BLOOD VOLUME EXPANSION ON VO2MAX

Aphamis, G., Maughan, R.J.

*Loughborough University*

**Introduction** Glycerol ingestion acutely increases serum osmolality attracting and retaining water in the vascular space, with potentially some tissue dehydration, including muscle (Gleeson et al., 1986). A moderate increase in circulating blood volume induced by dextran infusion is known to increase stroke volume, VO<sub>2</sub>max and time to fatigue (Coyle et al., 1990), but reduced muscle hydration could have a different effect on exercise. The aim of this study was to investigate potential effects of glycerol ingestion on body water distribution, VO<sub>2</sub>max and exercise performance. **Methods** Eight healthy males (Mean ± SD age 23 ± 3 y) performed an incremental VO<sub>2</sub>max test on a cycle ergometer on two occasions, 30 min after ingestion of 6 ml•kg<sup>-1</sup> body mass of either a lemon-flavoured glycerol (1 g•kg<sup>-1</sup> body mass) solution or lemon-flavoured water. Percentage changes in blood and plasma volume were estimated from haemoglobin and haematocrit values (Dill & Costill, 1974). Results Glycerol ingestion increased resting serum osmolality from 288 ± 3 mosmol•kg<sup>-1</sup> to 299 ± 5 mosmol•kg<sup>-1</sup>, which was higher ( $P < 0.001$ ) than on the water trial (286 ± 3 mosmol•kg<sup>-1</sup>). Hyperosmolality resulted in 5.4% increase in blood volume ( $P = 0.05$ ) secondary to a 7.7% ( $P = 0.03$ ) increase in plasma volume, potentially due to a watershift from the intracellular to the extracellular space. Water ingestion had no effect on resting blood and plasma volumes. There was no difference between the two trials in VO<sub>2</sub>max (glycerol trial 50.5 ± 10.4 ml•kg<sup>-1</sup>•min<sup>-1</sup>; water trial 51.2 ± 8.1 ml•kg<sup>-1</sup>•min<sup>-1</sup>) or maximum heart rate (glycerol trial 178 ± 12 bpm; water trial 185 ± 8 bpm). Total exercise time on the glycerol trial (904 ± 167 s) was less by 33 s (4.4%) ( $P = 0.04$ ) than on the water trial (937 ± 179 s). Blood lactate at fatigue was similar on both trials (glycerol trial 12.9 ± 3.5 mmol•l<sup>-1</sup>; water trial 13.3 ± 3.6 mmol•l<sup>-1</sup>). **Discussion** Glycerol ingestion increased blood volume, as muscle water potentially decreased. Hyperosmotic blood volume increase did not improve VO<sub>2</sub>max. Blood lactate was similar on both trials, but the shorter exercise time on the glycerol trial indicated an accelerated lactate efflux. Muscle dehydration may be an important limiting factor for exercise performance during an incremental test. References Dill, D.B., & Costill, D.L. (1974). ## OXYGEN UPTAKE KINETICS AND ENDURANCE TRAINING

Da Boit, M.1, Tam, E.1,2, Pogliaghi, S.2, Squatrito, S.1, Capelli, C.2

*Alma Mater Studiorum University of Bologna and University of Verona*

**Introduction** Previous studies have shown faster pulmonary oxygen uptake ( $\dot{V}O_2A$ ) kinetics after endurance training (1). It has been postulated that muscular  $\dot{V}O_2$  kinetics ( $\dot{V}O_{2m}$ ), whose  $\dot{V}O_2A$  kinetics is a reliable proxy, is regulated by muscular mechanisms during moderate intensity exercise in young adults. We investigated  $\dot{V}O_2$  and cardiac output ( $Q'$ ) kinetics during rest to moderate-intensity exercise transitions in young adults at different times of an endurance training (ET) program. Should the adaptation of  $\dot{V}O_{2m}$  kinetics be dissociated from that of  $Q'$ , the peripheral origin of the mechanisms affecting  $\dot{V}O_2$  kinetics during moderate intensity exercise would be confirmed. **Methods** 10 moderately active subjects (males and females) ( $25 \pm 4.8$  years,  $175 \pm 9.0$ ,  $70.6 \pm 11.9$  kg,  $\dot{V}O_{2max}$   $41.1 \pm 6.74$  mL/kg min) performed 3 step transitions of cycling exercise (0 to 100 W) separated by 6 minutes of recovery. Experiments were carried out every week during a 6-week period of aerobic training.  $\dot{V}O_{2max}$  and ventilatory threshold (VT) were assessed (2) at the beginning and at the end of ET that consisted in 45 minutes of cycling exercise performed 3 times a week at an intensity of about 65% of  $\dot{V}O_{2max}$ . Breath-by-breath  $\dot{V}O_2A$  and beat-by-beat  $Q'$  were measured during the tests.  $\dot{V}O_2$  and  $Q'$  values of each single experiment were 1-s normalised, aligned and overlapped to obtain a single time series for. Responses were fitted by using bi-exponential models. Results The time constant ( $\tau$ ) of the fundamental phase of  $\dot{V}O_2$  kinetics became faster during ET (22%) with an absolute rate of decrease of  $1.21s/week$  (before  $27.5 \pm 4.7$  after  $21.4 \pm 4.0$  s,  $P < 0.05$ ).  $Q'$  kinetics did not change significantly.  $\dot{V}O_{2max}$  and VT significantly improved by 7.5% and by 19%, respectively. The weekly rate of decrease of  $\tau$  was related to VT absolute variation:  $y = -0.0024x - 0.4603$   $R^2 = 0.8479$ ), whereas no significant relationship was described between the weekly rate of adjustment of  $\tau$  and the increase of  $\dot{V}O_{2max}$ . **Discussion**  $\tau$  of  $\dot{V}O_2$  kinetics modifies rapidly during endurance training, in agreement with previous results (3). The progressive acceleration of  $\dot{V}O_2$  kinetics was not paralleled by the acceleration of  $Q'$  response as  $\tau$  of  $Q'$  kinetics was not affected by ET. The weekly rate of change of  $\tau$  was significantly correlated with the increase of VT. This suggests that the modifications of  $\tau$  induced by ET are of peripheral origin. **References** (1) J.A. Zoladz, et al. (2006) *J Physiol Pharmacol* 57, suppl 10, 67.84 (2) H. B. ## RECOVERY FROM AN EXHAUSTIVE INTERMITTENT EXERCISE IS NOT ENHANCED BY CARBOHYDRATE-PROTEIN VS. ISOENERGETIC CARBOHYDRATE SUPPLEMENTATION

Denuziller, J.

*UFR STAPS*

**Recovery from an exhaustive intermittent exercise is not enhanced by carbohydrate-protein vs. isoenergetic carbohydrate supplementation** DENUZILLER J, BABAULT N, DELEY G Centre d'Expertise de la Performance Gilles Cometti, Faculté des Sciences du Sport, Dijon, France **Introduction** In many sports, such as combat sports, athletes are required to compete repeatedly on the same day. Fights, i.e. high-intensity intermittent exercises, are separated by recovery periods lasting 40 to 60 minutes, necessitating rapid repletion of muscle glycogen stores. Over years, lots of studies tested nutritional strategies to maximize glycogen resynthesis following exercise and showed that consumption of carbohydrate beverage (CHO) within 30 min after exercise was the most beneficial (Ivy et al. 1988). Several studies also suggested that the addition of proteins in CHO beverage (CHO + P) might improve muscle glycogen resynthesis, particularly if the supplement is limited in time (Berardi et al. 2006). The present study therefore aimed to assess the effects of CHO and CHO + P recovery drinks after high-intensity intermittent exercises separated by 45 minutes. **Methods** Twelve young healthy male subjects physically active participated in this study. The study was composed of three testing sessions separated by at least seven days. Each session corresponded to a different beverage intake: (i) Carbohydrate beverage (CHO), (ii) Carbohydrate + protein beverage (CHO + P), and (iii) Water. Each session was composed of three high-intensity intermittent exercises separated by 45 minutes of passive rest. Each of the three exercises consisted in four Wingate Anaerobic Test (WAnT) separated by 30 seconds of passive rest. Measures in countermovement jump and blood lactate concentration were repeated immediately before and after each of the three high-intensity intermittent exercise. Peak power and mean power developed during each WAnT were also recorded. Results Whatever the beverage, jump height and lactate concentration were still altered at the beginning of the second and third intermittent exercises in comparison with pre values ( $P < 0.05$ ). However, the consumption of CHO+P permitted a greater recovery for the counter-movement jump ( $P < 0.05$ ). The average peak power and mean power calculated for the three intermittent exercises were not modified by beverages consumption. **Discussion** Performances decreases suggest a great fatigue, mainly attributable to peripheral alterations as shown by lactate concentration. Although, CHO+P intake allowed a greater recovery of vertical jump performances between the first and the second exercise, values measured after 45 minutes of passive rest were still depressed in comparison with pre values. None of the beverage enhanced lactate elimination. In association with the depressed performance, this result suggests that when fatigue is too important, the consumption of recovery beverages is not helpful. **References** Berardi JM et al. ## OPTIMAL Q FACTOR AND LABORATORY TIME TRIAL PERFORMANCE

Disley, B.X., Li, F.X.

*University of Birmingham*

**Introduction:** The manipulation of the horizontal distance between the cranks on a bicycle (Q Factor) has received little attention in scientific research, compared with other variables such as crank arm length and saddle height. A standard Q Factor is approximately 150mm for a road bicycle. Optimisation of Q Factor for the individual cyclist is critical for improved performance. Wider Q Factors ( $\geq 150$ mm) have been shown to be less efficient than narrower Q Factors ( $\leq 120$ mm) during submaximal pedalling at 60%  $\dot{V}O_2$  max (Disley & Li, 2011), however the effect of manipulating Q Factor during a maximal time trial (TT) is unclear. **Aims:** The aim of the study was to determine whether 24min laboratory time trial performance was affected by a change in Q Factor. It was hypothesised that the best performance would be reached at a Q Factor  $< 150$ mm, and that deviation from the optimal Q Factor would result in a decrease in performance. **Methods:** 10 trained cyclists performed four maximal 24min TTs on an adjustable bicycle which allowed a change in Q Factor. 4 Q Factors were used: 90, 120, 150 and 180mm. The order of trials was randomised and participants instructed to complete the TTs at maximal intensity. **Results:** No general effect for Q Factor on average power output during the TTs was found ( $p = .470$ ). However, when normalised to individual best TT performance, power output decreased at both higher and lower Q Factors resulting in an inverted U shape ( $R^2 = 0.710$ ), where the best performance occurred at  $144.0 \pm 8.7$ mm. A change in Q Factor of 22.3mm results in a drop in power of 3.6%. **Conclusions:** The Q Factor that resulted in best TT performance differed between participants, suggesting that there is an optimum Q

Factor for every cyclist. Deviation from optimal Q Factor cost the athlete 13.1w on average in the present study. It is therefore important to identify individual's optimum Q Factor for maximum performance. ##### EXERCISE DOES NOT INCREASE HSP72B'

Ruell, P.A.1, Simar, D.2, Periard, J.D.1, Best, S.1, Caillaud, C.1, Thompson, M.W.1

*1 The University of Sydney, 2 The University of NSW*

**Introduction** Hsp70B' is a basic variant of heat shock protein 72 (Hsp72) that is found in human but not rodent cells and tissues. It is the product of a separate gene to Hsp72 and is highly inducible with low or no basal expression under unstressed conditions. Hsp72 is a member of the heat shock protein family found in all organisms and characterized by its cytoprotective role. In the serum Hsp72 appears to function as a danger signal to the cell, initiating an inflammatory response. While it is well known that plasma Hsp72 increases during exercise (2), the response of Hsp70B' has not been determined. **Methods** Seven physically active males aged  $32 \pm 3$  years with a body-weight of  $75.5 \pm 3.4$  kg undertook an incremental treadmill running test to determine their maximum oxygen uptake (VO<sub>2</sub>max). Approximately one week following the determination of VO<sub>2</sub>max subjects ran on the treadmill at 72% VO<sub>2</sub> max in warm conditions (30°C, 40% relative humidity) for 1 hour. Rectal temperature was measured on a portable data logger. Blood samples were collected before, after 60min of running and 1 hour post-exercise and serum was analyzed for Hsp70B' using a commercial Elisa kit. Results Rectal temperature increased from  $36.81 \pm 0.11^\circ\text{C}$  to  $39.39 \pm 0.17^\circ\text{C}$  ( $p < 0.001$ , before vs immediately post). Serum Hsp70B' did not change over time ( $0.71 \pm 0.16$ ,  $0.80 \pm 0.17$  and  $0.80 \pm 0.16$  ng/ml at pre, immediately and 1h post). **Discussion** These findings are in agreement with gene studies which found that Hsp70B' mRNA was not increased in leucocytes by exercise (1). While Hsp72 and Hsp70B' have similar genes (77% sequence identity), the protein product appears to respond differently to exercise stress in humans. ##### THE EFFECTS OF EXERCISE ON BETA ENDORPHIN AND ALCOHOL URGES IN ALCOHOLIC PATIENTS

Jamurtas, A.Z., Zourbanos, N., Georgoulas, P., Mouzas, O., Bletsou, A., Souliou, S., Psifos, V., Oikonomou, D., Theodorakis, Y.

*University of Thessaly*

**Introduction** The consumption of alcohol was considered since ancient time a pleasant and socially acceptable habit. Euphoric feelings due to alcohol consumption are associated with the release of opioids (Giannoulakis). However, alcohol abuse can have many medical consequences which can be harmful for both physical and mental health and can have detrimental effects in social, professional and personal life of the abuser. At the same time alcohol abuse is responsible for increases in criminal behavior and the higher incidence of accidents. Furthermore, alcohol is believed to be responsible for the majority of deaths caused by drugs. **Methods** The purpose of the present study was to examine the effects that physical exercise has on beta endorphin levels and on the urge for alcohol on individuals which participate on rehabilitation programmes. Nine participants (8 men and 1 woman) volunteered to participate in an exercise session on a cycle ergometer. The intensity of the exercise was low (50-60% of maximum heart rate) and the duration lasted 30 minutes. Prior to and following exercise the participants filled out questionnaires indicating their urge towards alcohol consumption and blood was drawn for beta-endorphin assessment. **Results** The results from the present study showed that exercise resulted in significant ( $p < 0.001$ ) increases in the levels of beta-endorphin (pre:  $1.57 + 0.39$  pmol/L, post:  $4.8 + 1.6$  pmol/L) with a trend towards significant decrease in alcohol urge following the exercise. **Discussion** In conclusion, the results from the present study do not support a decrease in alcohol urge following an exercise bout of low to mild intensity. However, the trend towards lower alcohol urge is important and further studies need examine whether there is a link between exercise and prevention of alcohol abuse. References Giannoulakis, C. (2004). Endogenous opioids and addiction to alcohol and other drugs of abuse. *Current Topics in Medical Chemistry*, 4(1), 39-50.

##### THE EFFECTS OF SUPPLEMENTATION WITH OMEGA-3 FATTY ACIDS ON REDOX STATE OF YOUNG FOOTBALL PLAYERS

Djordjevic, D.1, Nestic, M.1, Barudzic, N.1, Vuletic, M.1, Zivkovic, V.1, Puzovic, V.1, Cubrilo, D.1, Jakovljevic, V.1

*Department of Physiology, Faculty of Medicine, University of Kragujevac, Serbia*

**Introduction** Recent investigations in the field of exercise physiology pay special attention to finding and understanding the mechanisms of the inflammatory response, oxidative stress and their mutual effects (1). It was shown that supplementation with omega-3 fatty acids, eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) may be important factor of antiinflammatory response to intensive exercise (2). Despite the many antiatherosclerotic benefits of n-3 fatty acids, there remains a theoretical concern that these fatty acids may increase the fatty acid unsaturation index, consequent to the incorporation of EPA and DHA into membranes and lipoproteins, leading to increased lipid peroxidation (3). Thus the aim of our study was to assess the changes in redox state of young football players after two months of supplementation with either n3- or n6- polyunsaturated fatty acids (PUFA). **Methods** Forty-eight young football players (age  $18.7 \pm 1.1$ ) were subjected to venous blood sampling after an overnight post before and after experimental period of two months (preparatory period) during which players took supplementation with either n3-PUFA, n6-PUFA or placebo and performed their regular football training. Redox state analysis included measurement of levels of: superoxide anion radical, hydrogen peroxide, nitrites as markers of nitric oxide, thiobarbituric acid reactive substances as index of lipid peroxidation, reduced glutathione, superoxide dismutase and catalase activity. **Results** Analysis of data using the two way ANOVA repeated measures (within subjects factor „time“ and

between subjects factor „supplementation”) showed that two months after the beginning of the study players had significantly lower levels of superoxide anion radical, hydrogen peroxide and glutathione, while activities of superoxide dismutase and catalase were higher („time”:  $P < 0.05$ ). However, those differences were not dependent on kind of supplementation that they have taken („time\*supplementation”:  $P > 0.05$ ). Discussion Since observed changes in redox state of football players were not dependent on kind of supplementation they have consumed, we hypothesize that players' improved redox state was a consequence of well programmed football training during preparatory period. The absence of changes in the levels of lipid peroxidation suggests that supplementation with omega-3 fatty acids does not induce oxidative stress. References Pedersen BK and Hoffman-Goetz L. ### THE EFFECTS OF HORMONE ON AMPK-ACTIVATED PROTEIN KINASE IN H460 LUNG CANCER CELLS

Su, M.Y., Hsieh, S.Y., Chang, J.M.

*Development Center for Biotechnology*

**Introduction** For improving the cancer disease, exercise has been widely accepted with its benefit, but the mechanism of action between exercise and cancer has not been elucidated yet. AMP-activated protein kinase (AMPK) is a key regulator in energy homeostasis, and increased AMPK activity by exercise is speculated as key role between exercise and cancer. Our pervious study has appeared the different profiles on AMPK activity following serum stimulation compared with glucose stimulation in H460 lung cancer cells. Accordingly, we used different hormones, which are secreted during exercise, as stimulator in cell culture to elucidate the relationship among hormone, AMPK and lung cancer cell for investigating whether exercise influences cancer development through alteration of AMPK activity. Methods H460 lung cancer cells were incubated with DMEM medium containing 10 % serum, and then epinephrine, growth hormone, insulin and glucagon were added to H460 cell culture, respectively, for analyzing the cell viability, AMPK activity and AMPK protein amount at 3, 6, 12, 24, 48 h. Results Epinephrine and growth hormone significantly increased cell viability about 7 % at 3 h and 24 h, respectively ( $p < .05$ ). Insulin significantly increased cell viability ranging from 7 to 11 % at 3, 12, 24 and 48 h ( $p < .05$ ). Glucagon significantly increased cell viability 8 % and 5% at 3 and 12 h, respectively ( $p < .05$ ). Furthermore, each hormones used in this study suppressed AMPK activity between 26 to 50 % at first 3 h, and elevated AMPK activity between 57 to 148 % at later 48 h. Discussion According to the signaling role of AMPK, many studies has established the regulatory effects of AMPK that were induced by hormone in various tissues (Lim et al., 2010; Dzamko and Steinberg, 2009), but it remains unclear in cancer cells. In this study, we found that AMPK activity induced by each hormones was observed as a biphasic response, in which was not consistent with the change of cell viability. The similar tendency of AMPK activity induced by different hormones implied that AMPK could be stimulated with the same mechanism. It was not apparent time-dependant manner in cell growth for hormones stimulation, but each hormones used in this study induced significant increase in cell growth at different time points. The increase of cell growth by hormone stimulation is coincident with the results of other studies (Wong et al., 2011; Thaker et al., 2006), but it should be notice the influence of AMPK activity. We demonstrated that the cell growth was affected by hormone and this effect might be deduced through the regulation of AMPK. References Lim CT, Kola B, Korbonits M. ### INFLAMMATION AND LOSS OF MUSCLE FUNCTION IN ELDERLY

Ostapiuk-Karolczuk, J., Kasperska, A., Zurek, P., Dziubek-Rogowska, W., Dabrowska, G., Rynkiewicz, M., Rynkiewicz, T., Zembron-Lacny, A.

*Faculty of Physical Culture Gorzow Wlkp. University of Physical Education Poznan*

**INFLAMMATION AND LOSS OF MUSCLE FUNCTION IN ELDERLY** Ostapiuk-Karolczuk J.1, Kasperska A.1, Zurek P.1, Dziubek-Rogowska W.2, Dabrowska G.2 Rynkiewicz M.1, Rynkiewicz T.1, Zembron-Lacny A.1 1. FPC Gorzow Wlkp. USPE (Poznan Poland), 2. USPE (Wroclaw, Poland). **Introduction** One of the most serious consequence of aging is the loss of skeletal muscle mass and strength. This degradation called sarcopenia leads to decreasing the functional status and impairing mobility causing increased risk of musculoskeletal injuries and loss of independence. The underlying cellular changes involve increased level of pro-inflammatory cytokines responsible for activation of processes in consequence leading to muscle cell degradation and apoptosis (Francheschi et al.,2007).The purpose of the study was to investigate whether high level of IL-1 $\beta$  and TNF $\alpha$  are associated with loss of muscle mass and function in the elderly. **Methods** Participants: 16 well-functioning males over 60 years old and 20 healthy, non-smoking and untrained males aged 20-22 years. Body composition were estimated using a bioelectrical impedance floor scale (Tanita, Japan). Measurements of muscular strength, power and work were obtained at 60o/s and 180o/s using Biodex Unit (Biodex Medical System Inc.). In blood serum levels of pro-inflammatory cytokines IL-1 $\beta$  and TNF $\alpha$  were measured. Results Significant changes in the body composition were concerned particularly the percentage of fat content (FAT%) and fat mass (FM). Free fat mass (FFM) was on similar level in both investigated groups. The level of both pro-inflammatory cytokines was significantly higher in elderly compared to the young men. Results also demonstrate considerably higher knee extension and flexion peak torque, work and power in young males compared to the elderly. Discussion It has been estimated that only 25% persons under age of 70 and 40% of those aged 80 or older may suffer sarcopenia (Marzetti and Leeuwenburgh, 2006). Our results have shown that there were no significant differences between body weight and FFM between young and older males however, there were strong differences in total strength, average power and total work between investigated groups. Muscles of elderly are clearly weaker. This may be a result of higher level of IL-1 $\beta$  and TNF $\alpha$  which increase the risk of muscle strength loss through their catabolic effects (Schaap et al., 2006). Higher level of pro-inflammatory markers is often observed in healthy older person and it is responsible for occurrence of chronic low-grade inflammation which is termed “inflamm-aging” (Francheschi et. al., 2007). Furthermore, this phenomenon may be related to an age-related disabilities to generate higher knee extensor and flexor torque. ## SENSORY-PERCEPTION AND CONTROL OF DISPLACEMENT DURING SWIMMING AND WALKING IN BLIND SUBJECTS

Scurati, R., Michielon, G., Longo, S., Invernizzi, P.L.

*Faculty of Exercise Sciences - University of Milan*

**Introduction** In blindness, in place of visual information, alternative feedbacks are needed to supply the control of the movement, such as sensory-perception. In swimming, specific sensory-perception abilities are crucial to build the "feeling the water" and to reduce drag. They can be evaluated by gliding test (Invernizzi et al., 2010). Visual feedback is closely related to balance and to the control of direction during displacement (Danion et al., 2000). This study aimed to relate the sensory-perception abilities, measured by gliding test, to the control of the displacement during swimming and walking, in blind subjects. **Methods** Ten blind subjects (28.4±12.9 years, 65.5±10.1 kg, 166±10 cm, 23.6±3.5 kg/m<sup>2</sup>) volunteered to participate in the study. The deviation from the displacement along the straight direction was assessed (scoring from -5 to 5) during 25m front crawl (FC) and during 25m backstroke swimming (BA). In a gymnasium set, the deviations from the straight direction during 25m of free walking were scored (from -5 to 5). Finally, the length of the swimming glide in a streamline position, pushing-off from the wall, was measured. Three trials for all test have been performed. The sum of the absolute values of the deviations and the mean of the measures of gliding have been considered. **Results** The deviation from the straight direction was higher in BA than in FC swimming ( $p < 0.05$ ,  $11.20 \pm 2.10$  vs,  $9.70 \pm 1.49$ , AU±SD). Significant correlation was found between FC and BA ( $r = -0.76$ ,  $p < 0.05$ ), between gliding and FC deviation ( $r = -0.70$ ,  $p < 0.05$ ) and between gliding and BA deviation ( $r = -0.74$ ,  $p < 0.05$ ). Gliding did not correlate with walking deviation ( $r = 0.27$ ,  $p > 0.05$ ). **Discussion** Blind subjects managed the swimming direction worse in BA than in FC, as previously found in swimmers (Invernizzi et al., 2010). Being not high-level swimmers, the subjects of this study moved their arms with an outer trajectory, making it more difficult in BA than in FC the control of the direction and deviating opposite to the dominant arm. Gliding, such as expected, correlates with swimming, supporting the relationship between the sensory-perception and the ability in governing the swimming. On the contrary, even if more than 6% of subjects walked perfectly straight, other feedbacks would be more crucial during walking than in gliding, such as balance and acoustic feedbacks. **References** Danion F, Boyadjian A, Marin L (2000). ## YO-YO INTERMITTENT RECOVERY TEST LEVEL 1 AND FIELD TESTS FOR WHEELCHAIR BASKETBALL PLAYERS

Yoda, T., Sorimachi, M., Kawanishi, M., Yasumatsu, M., Kobayashi, K., Iso, S.

*Dokkyo University*

**YO-YO INTERMITTENT RECOVERY TEST LEVEL 1 AND FIELD TESTS FOR WHEELCHAIR BASKETBALL PLAYERS** Yoda, T.1, Sorimachi, M.2, Kawanishi, M.3, Yasumatsu, M.3, Kobayashi, K.2, Iso, S.2 1:Dokkyo Univ (Soka, Japan), 2:Waseda Univ (Tokorozawa, Japan), 3:Rikkyo Univ (Niiza, Japan) **Introduction** Wheelchair basketball players have to take high aerobic and anaerobic fitness because they have to perform to push and pull the wheel hard, to stop completely, to turn quickly, and to maneuver the ball repeatedly (Molik et al., 2010). An individual's ability to repeatedly perform high-intensity exercise in able-bodied players is widely measured with the Yo-Yo intermittent recovery test level 1 (YYIR1) (Bangsbo et al., 2008). We tried to apply the YYIR1 to wheelchair basketball players and describe their physical fitness required for the game. **Methods** Ten male wheelchair basketball players participated in this study. We used the YYIR1 and its modification to wheelchair basketball players (YYIR1-WB). YYIR1 consists of 2 x 20 m shuttle run with increasing speed with a 10-second period of active recovery between each run. In the YYIR1-WB the distance for the test was shortened (15 m). We also measured the time of the short sprint with or without dribbling a ball, distance of medicine ball throw, and the time for moving along the plus shape (+) or triangle to check the ability of quick direction change. **Results** Most of subjects could not follow the test speed of normal YYIR1, even at the lowest one, and the longest distance achieved was only 280 m. On the other hand, in YYIR1-WB, the longest distance was 1560 m and the average distance was  $933 \pm 469$  m. The average time of short sprint was  $4.55 \pm 0.26$  s without dribble and  $4.68 \pm 0.36$  s with dribble. The average distances of medicine ball throw was  $8.71 \pm 0.7$  m. In the tests of direction change, all subjects showed better results in pulling the wheel without turn than in pushing the wheel with turn. According to the Player Classification System, players are classified (Class I, II, III, and IV) based upon the players' functional capacity to play (Class I is the most disabled). The score of present measurements were higher for the Class III and IV than the Class I and II. **Discussion** For setting up the workout menus in training, the level of player's physical ability should be well recognized by team staffs. Therefore, at first we did YYIR1 that was developed for the test in the normal players. However, the present subjects could not follow the test speed, and we modified it by shortening the distance so that the subjects could follow the test. The score of the modified test was well correlated with their physical condition. Therefore, the test could be used for the evaluation of physical fitness in wheelchair basketball players. **References** Bangsbo J, Iaia FM, Krstrup P. (2008). *Sports Med*, 38(1), 37-51. ## PREDICTED VO<sub>2</sub> ON 6 MINUTES WALK TEST FOR FAP LIVER TRANSPLANTED PATIENTS

Tomás, M.T., Santa-Clara, H., Bruno, P.M., Monteiro, E., Barroso, E., Sardinha, L.

*Faculty of Human Kinetics; Lisbon Higher School of Health Technologies; Lisbon Hepatobiliopancreatic and Transplantation centre*

**Introduction** Physical function is limited post-liver transplantation and exercise training can improve exercise capacity following transplantation but previously assessment of functional capacity is necessary. The 6 minute walk test (6MWT) is routinely used for studying patient's exercise capacity and is less expensive and time consuming than a Cardiopulmonary Exercise Test (CPXT). There have been some studies looking at the relationship between 6MWT and peak VO<sub>2</sub> in patients but few presented an adequate equation for predicted peak VO<sub>2</sub> from 6MWT to transplanted patients and none for Familial Amyloidotic Polyneuropathy (FAP) liver transplanted patients (FAPTx). The aim of this study was to compare the validity of 6 equations as predictors of VO<sub>2</sub> from the 6MWT and compare it with directly measured VO<sub>2</sub> in patients FAPTx. **Methods** Patients were recruited to participate in this study if they were FAPTx between 2-12 months post-transplant. Forty-eight patients (28 men and 20 women;  $34 \pm 7$  yr; body mass index  $21.9 \pm 3.9$ ;  $4.2 \pm 2.1$  months post transplant) gave their informed consent and participated in this study. All subjects had superficial sensory alterations (tactile, thermal, and painful) of the lower limbs, especially of the feet, had a permanent pacemaker and were sedentary. This study protocol was approved by the Hepatobiliopancreatic and Transplantation Centre of Curry Cabral Hospital at Lisbon and by the Faculty of Human Kinetics Institutional Review Board. Patients performed the 6MWT according to American Thoracic Society guidelines and VO<sub>2</sub> was measured in field using a portable gas analyzer (K4 b2, Cosmed, Rome, Italy). Intraclass Correlation Coefficient (ICC) was used to evaluate absolute agreement among measured values and previously reported peak VO<sub>2</sub> predictive equations. **Results** The results of 6MWT showed a VO<sub>2</sub> measurement of  $17.7 \pm 4.0$  ml/kg/min (highest VO<sub>2</sub> on the last 2 min) for a walked distance of  $512.2 \pm 136.4$  m. The highest value for heart rate on 6MWT was  $124 \pm 15$  bpm. ICC

between directly measured values and the VO<sub>2</sub> predicted from reported equations was between 0.332 and 0.667 ( $p < 0.001$ ). Discussion None of the equations that predicted VO<sub>2</sub> through 6MWT showed to be suitable for FAPT<sub>x</sub> with differences between measured and predicted VO<sub>2</sub> ranging from -7.86 ml/kg/min to 10.38ml/kg/min. All equations, except one, underestimated VO<sub>2</sub> with FAPT<sub>x</sub> patients. It is important to continue studies with this population with more patients to find a new equation that can predict VO<sub>2</sub> from 6MWT specifically for FAPT<sub>x</sub> population.

### **A COMMON INDIRECT SUBMAXIMAL TEST FAIL TO ESTIMATE THE MHC ISOFORM IN LATISSIMUS DORSI MUSCLE FIBERS.**

Moro, T., Pacelli, F.Q., Toniolo, L., Canato, M., Cancellara, P., D'Alpaos, E., Reggiani, C., Paoli, A.  
*University of Padova*

**Introduction** It is well known that there are three major muscle fiber types and corresponding Myosin Heavy Chain (MHC) isoforms (ie, MHC I, IIa, and IIx) in human skeletal muscles (Schiaffino & Reggiani 2011). For athletes may be useful knowing the predominance of fiber's type in muscles to optimize training stimulus. Charles Poliquin hypothesized that the number of repetitions at 85% of 1RM is correlated with fibers distribution; in particular Poliquin stated that if the number of repetition was less than 5 reps the prevalence of fibers was IIx, if it was equal to 5 the prevalence of fibers was IIa and if the repetition was more than 5 muscle contained more I (Poliquin C. 1997). This kind of test is widely diffuse among body builders and athletes. The aim of this study was to validate Poliquin's theory. **Methods** Eighteen healthy volunteers participated in 8-week progressive resistance training for upper limbs muscles. Pre and posttraining, one repetition maximal test and the maximal number of repetitions at 85% of 1RM were assessed; muscle samples from latissimus dorsi were obtained with a fine needle biopsy technique (Paoli et al. 2010) The composition in MHC isoforms of bundles of muscle fibers or single muscle fibers was determined on 8% polyacrylamide slab gels after denaturation in SDS (SDS-PAGE). Three bands were separated in the region of 200 kD, corresponding (in order of migration from the fastest to the slowest) to MHC-1, MHC-2A and MHC-2X. **Results** Data collected before the training shown that only six subject (35,3%) presented a correlation between the number of repetition and the MHC isoform and only four subjects (31,3%) presented the same correlation after 8-week of RT. There wasn't any significant correlation between fiber type composition and number of repetitions performed at 85% 1 RM. **Discussion** Our data refute the method suggested by Poliquin to estimate muscle fiber type. Moreover we hypothesize that the limit of 5 repetitions suggested to identify fast twitch fibers is too restrictive. More data are needed to identify a correlation between muscle fiber composition and a submaximal test. **References** Schiaffino S, Reggiani C. (2011). *Physiol Rev*, 91(4), 1447-531. ### **HEAT DISSIPATION EVALUATION IN EXERCISE BY INFRARED THERMOGRAPHY**

Ludwig, N., Formenti, D., Gondola, M., Gargano, M., Alberti, G.  
*state university of milan*

**INTRODUCTION** Heat dissipation during sport exercise is very important to improve athlete performance. An help to physiological mechanism of generation and transport of heat in the muscle under stress and in surrounding districts, is given by IR thermography to evaluate the surface heat dissipation locally. Thermography is useful because of its high sensitivity (0.05°C) and global representation of thermal process. Its use is recommended for the athletic evaluation because it is a non-invasive technique that doesn't need any contact with the skin, avoiding physic and psychologic conditioning (Merla et al., 2010). **METHODS** We tested two groups of female subjects: 9 athletes and 9 sedentaries (mean age 19.39±3.26 y, weight 53.82±5.36 kg, height 1.64±0.06 m). They performed an exercise (standing calf raise with both feet) that limits the work to one group of muscle (gastrocnemius and soleus) and allows a perfect visibility for a correct thermographic shoot. It consists to raise and lower heels (rate 1 s) without over load (N.S.C.A., 2010). Thermal images was recorded (1 Hz frame-rate) during 14 minutes (2 min. of pre-exercise to determinate basal temperature, 2 min. of exercise, 10 min. of recover). Two Regions of Interest (ROI) were selected following anatomical and functional correspondence with the muscles involved in exercise, one on each calf (Zaidi et al., 2007). The data were analyzed with a dedicated software for thermal images. The considered parameter was the mean temperature over an area of 2 mmq of the hottest spot in the calf. **RESULTS** Both groups show a minimum in temperature after few seconds of the exercise. The calves temperatures increase with linear trend during the whole exercise and in the first minutes of recover, but with a different slope. Temperature variation in 2 min. recovery-time of the athletes is 1.07°C, while for the group of sedentaries is 0.76°C. **DISCUSSION** From these preliminary results is clear that IR thermography is a valid diagnostic method in evaluation of heat dissipation during and after physical exercise. The different slopes of the temperature trends during exercise and the two minutes post exercise indicate that calves of athletes dissipate more heat than calves of sedentaries. It can be explained with a better muscular efficiency in trained subjects, used to do exercise, and probably due to a less fat mass in the calves of athletes than in calves of sedentaries (Merla et al., 2010). **REFERENCES** Merla, A., Mattei Peter A., Di Donato L., Romani G. ### **INFLUENCE OF EMG SIGNAL DETERMINATION ON THE RELIABILITY OF SOME EMG PARAMETERS OFTEN USED FOR THE EVALUATION OF EXPLOSIVE FORCE PRODUCTION**

Trost Bobic, T., Sarabon, N., Markovic, G.  
*School of Kinesiology*

**INFLUENCE OF EMG SIGNAL DETERMINATION ON THE RELIABILITY OF SOME EMG PARAMETERS OFTEN USED FOR THE EVALUATION OF EXPLOSIVE FORCE PRODUCTION** Trošt Bobić, T.1, Šarabon, N.2, Marković, G.1 1: School of Kinesiology, University of Zagreb, Croatia, 2: Science and Research Centre, University of Primorska, Koper, Slovenia **Introduction** The aim of this study was to asses if the method used for EMG signal onset determination would affect inter- and intra-session reliability of multiple electromyographic (EMG) indexes often used to asses explosive force production of m. soleus (EFPs). **Methods** Thirty-seven physical education students (22.5±1.3 years) where included in the intra-session, while ten (22.7±0.9 years) where included in the inter-session reliability study. Sitting on a custom made dynamometer, participants were asked to perform three unilateral maximal voluntary isometric plantar flexions (MVIC) of the right foot stressing explosive force production. EMG signals of m. soleus where recorded by means of surface bipolar electrodes. In order to test if the method used for EMG signal onset determination would affect inter- and intra-session reliability of EFPs indexes, firstly, the Hodges and Bui method for EMG signal onset determination was used, and inter- and intra-session reliability was calculated for 27 EFPs indexes. The same

procedure was repeated with the four most reliable indexes, setting onset of EMG signal: 1) at 3% MVIC, 2) at 3% MVC - 5ms, and 3) at 3% MVIC - 70 ms (Aagaard et al., 2002). Three components of reliability were calculated: systematic bias, within-individual variation, and retest correlation (Hopkins, 2000). Results Intra-session reliability - The within-individual variation (expressed as CV), did not differ dramatically between different onset methods for MVIC normalized root mean square (R), average EMG value (A) and time integral (I) calculated in the time interval of 200ms. The within-individual variation of the rate of EMG rise (RER), calculated in the time interval of 75ms resulted significantly lower when the onset was set on 3%MVC - 70ms (27.59 %, CI: 23.45 - 33.54 %), than when it was set on 3% MVC (117.33 %, 99.70 - 142.59 %). ICC values followed the same trend. Inter-session reliability - Again, only the within-individual variation of the RER0-75 index resulted significantly lower when the onset was set on 3%MVC - 70ms (39.71 %, CI: 28.47 - 65.55 %), than when it was set on 3% MVC (151.38 %, 108.55 - 249.89 %), indicating greater inter-session reliability when the first method is used. Discussion Contrary to previous findings (Hodges & Bui, 1996), the method of EMG onset determination did not influenced the reliability of all the indexes tested. On the other hand, it influenced noticeably the reliability of the RER0-75 index. References Aagaard, P. et al., (2002). *J Appl Physiol*, 93(4):1318-26. Hopkins WG (2000). *Sports Med*, 30(1):1-15. ## EFFECT OF TRAINING CESSATION ON MUSCULAR PERFORMANCE: A META-ANALYSIS

Bosquet, L., Berryman, N., Dupuy, O., Mekary, S., Arvisais, D., Mujika, I.

*Université de Poitiers*

Laurent BOSQUET 1,2, Nicolas BERRYMAN 1,2, Olivier DUPUY 1,2, Said MEKARY 2, Denis ARVISAIS 2, Inigo MUJIKKA 3 1. Laboratoire MOVE (EA 3813) – Université de Poitiers – France 2. Département de kinésiologie – Université de Montréal – Canada 3. USP Araba Sport Clinic – Vitoria – Spain Purpose: to perform a meta-analysis of the effect of training cessation on maximal force, maximal power and muscular endurance. Methods: Studies were eligible for inclusion if: 1) they implemented a training intervention followed by a training cessation period and give relevant details about the procedures, 2) the outcome included valid tests and measures of the upper or lower limb muscular performance in healthy humans, and 3) the paper included the number of participants and all necessary data to calculate effect sizes. One hundred and five of 265 studies were included in the analysis. Standardized mean difference in muscular performance was calculated and weighted by the inverse of variance to calculate an overall effect and its 95% confidence interval. Subgroup analyses of moderators variables including population and training cessation characteristics was performed in the presence of statistical heterogeneity (as measured by the I<sup>2</sup>). Results: The overall standardized mean difference indicated a detrimental effect of training cessation on all components of muscular performance, since we found a moderate decrease in muscular endurance (SMD [95% CI] = -0.64 [-0.82 to -0.45], p<0.01, I<sup>2</sup>=13.0%) and a small decrease in maximal force (SMD [95% CI] = -0.42 [-0.46 to -0.38], p<0.01, I<sup>2</sup>=78.8%) and maximal power (SMD [95% CI] = -0.23 [-0.32 to -0.14], p<0.01, I<sup>2</sup>=67.8%). The effect of training cessation was found to be larger in older people (≥ 65 years old) for maximal force and muscular endurance, but not for maximal power. The effect of training cessation was also larger in inactive people for maximal force when compared with recreational or competitive athletes, but not for maximal power or muscular endurance. We did not found any difference between males and females, whatever the type of muscular performance. We performed a metaregression analysis that did not revealed any relationship between the exact duration of training and the magnitude of the effect of training cessation on muscular performance, since the slope was not different from 0. In contrast, the slope of the relationship between the magnitude of the effect of training cessation and the exact duration of training cessation was significantly different from 0, whatever the type of muscular performance, thus suggesting a close association between both variables. Conclusion: training cessation decreases maximal force, maximal power and muscular endurance. Subgroup analysis of moderator variables suggest an effect of age, training status and duration of training cessation. This meta-analysis provides a framework that can be useful for athletes and coaches to optimize the planification of training load as well as the choice of appropriate training contents during the taper period.

### PP-PM45 Health & Fitness: Physical Activity 1

#### FITOC : COMPARISON OF DAILY PHYSICAL ACTIVITY IN NORMAL AND OVERWEIGHT CHILDREN

Kreuser, F., Roettger, K., Gollhofer, A., Korsten-Reck, U.

*Institute of Sport and Sport Science*

Introduction: The Freiburg Intervention Trial for Obese Children (FITOC) is an interdisciplinary program for obese children (age: 8-11 years). The program includes 3 sports lessons a week nutrition and behaviour training. One of the main problems of overweight children compared to normal weight children is the absence of regular daily physical activity and the increase of screen time hours in combination with sedentary behavior (Metcalfe et al., 2010). To investigate if the intervention program enhances regular physical activity we compared FITOC participants to normal weight children. Methods: Daily physical activity of overweight (n=25) and normal weight children (n=21) was measured by direct accelerometry during three weekdays and two weekend days. Data was divided into "active" and "passive" time and 8 different activity levels. Anthropometrical data (weight, height, BMI, BMI-SDS) and leisure time/screen time entertainment questionnaire were obtained. Results: Median daily activity of weekdays shows no differences between normal and FITOC children (p=0.81). For passive times no significant differences were found (p=0.33). For weekend accelerometry revealed a tendency of more activity in normal-weight versus overweight children (p=0.07). Overweight children spend significant more time per day in screen time entertainment (PC and video games) than normal weight children (p=0.003) on weekdays and weekend. Conclusion: Results do not show differences in regular daily physical activity time between normal weight and overweight children who participate in FITOC. Only during the weekend normal weight children spend more time active than FITOC children. Regarding the sedentary behavior, overweight is related to higher screen time hours (Peart et al., 2011). Due to an intervention including 3 sports lessons a week obese children enhances their daily physical activity and can approximate to the daily activity of normal weight children on weekdays. To establish "healthier" leisure time habits (more PA, less screen-time) special strategies for obese children are required. References: 1. ### CHANGES IN HEART RATE, RATE OF PERCEIVED EXERTION, NUMBER OF STEPS AND WALK DISTANCE DURING WALKING WITH/WITHOUT A DOG IN JAPANESE ADULTS

FURUMOTO, K.1,3, HAYASHI, S.1, TAKAGI, Y.1, SAITO, T.1, SAITO, K.1, ONODERA, S.2

*1 Graduate School, Kawasaki University of Medical Welfare, 2 Kawasaki University of Medical Welfare, 3 Kurashiki University of Science and The Arts*

Introduction Dog owner has health benefits as a result of increased physical activity through dog walking (Thorpe RJ et al., 2006; Hayley C. et al., 2008; Oka et al., 2009). Dog is the most popular pet also in Japan. Few studies have examined the association between the amount of physical activity and dog walking in Japan. The objective of this study was to investigate changes in heart rate, rate of perceived exertion, number of steps and walk distance during walking with/without a dog in Japanese adults. Methods Japanese healthy adult and their dogs volunteered to participate in this study. After resting on sitting down for 5 minutes (R1), the subjects walked with/without their dogs for 20 minutes (WK). After walking, they rested on sitting down for 10 minutes (R2). R-R interval was measured between R1 and R2 using the sport heart rate monitor (Polar). Heart rate (HR) was calculated using the HR variability real-time analyzing system MemCalc/Tarawa (Suwa Trust Co.) Rate of perceived exertion (RPE) was asked at the end of WK and R2 using the Borg scale. Number of steps and walk distance were recorded with the small triaxial activity-meter (Kenz) during WK. Results In both condition (walking with/without dog), no significant differences were found in the amount of change of HR between R1 and R2, RPE at WK and R2, number of steps and walk distance during WK. Discussion Only 30% of Japanese adults participate in the recommended level of physical activity. Various variety interventions need for increasing the physical activity level of population. The walking speed with a dog was controlled by a dog owner. Because, pulling power of a small or medium dog during dog walking didn't influence the walking speed of dog owner. And some dogs were trained in the loose leash walking. This study indicates that a dog walks according to their owner's walking speed. And the approach for physical activity promotion with dog would be useful for increasing the owner's physical activity level. ### PHYSICAL ACTIVITY FOR HYPERTENSIVE PERSONS

Oviedo, G.R., Bellomío, C., Guerra Balic, M.E.

*Universitat Ramon Llull*

PHYSICAL ACTIVITY FOR HYPERTENSIVE PERSONS Oviedo, G. R.1; Bellomío, C.2; Guerra Balic, M. E.1 1: FPCEE Blanquerna. URL (Barcelona, Spain), 2: FM. UNT (Tucumán, Argentina) Introduction Arterial Hypertension (AH), one of the most prevalent diseases, is increasingly associated with all-cause of cardiovascular mortality. Aerobic exercise programs prevent the development of hypertension and decrease blood pressure (BP) in adults with normal BP and those with hypertension (Pascatello et al., 2004). Studies have shown that BP, regardless of their values, was reduced in those who participated in regular physical activity (PA) programs, with mean decreases equal to 7.4/5.8 mm Hg in hypertensive and 2.6/1.8 mm Hg in normotensive. (Kelley, Kelley & Tran, 2001) Methods The objective was to study the effectiveness of a PA program on the BP and fitness levels changes on pre and hypertensive adults. Participants were 16 (9 men, 7 women) 52.8±9.7 years old with pre-HT and HT patients following the JNC 7 Report classifications. The PA program was realized during 16 weeks, 1 hour 3 times a week, consisting of aerobic activities complemented by strength training. The evaluation was made before and after PA activity program. We calculated descriptives of each variable and a test-retest using SPSS v.19. In each case, a confidence interval of 95% was used. Results Basal systolic blood pressure (SBP) was reduced 13,43±6.76 mm Hg (p=0,0001); SBPpeak increased 1,56±7,46 mm Hg (p=0,415); basal diastolic blood pressure (DBP) was reduced 10,31±7,40 mm Hg (p=0,00005); DBPpeak increased 5,56±11,03 mm Hg (p=0,062); basal heart rate (HR) was reduced 12,18±6,93 bpm (p=0,000004); HRmax increased 7,18±8,03bpm (p=0,00275); VO2peak increased 9,06±4,91 ml/Kg/min. (p=0,00055); fat reduction was 2,79±0,72 % (p=0,000000001); BMI decreased 2,43±0,88 points (p=0,000000145); triglycerides were reduced 17,23±17,86 mg/dL (p=0,00456); cholesterol was reduced 15,69±13,45 mg/dL (p=0,00122); HDL-c increased 8,83±6,09 mg/dL (p=0,00021); LDL-c decreased 11,84±12,60 mg/dL (p=0,00539); weight decreased 6,94±2,86 Kg (p=0,00000007). Discussion The impact of physical activity was positive, reducing arterial BP values, increasing the fitness level values and diminishing risk factors of cardiovascular diseases. It will be necessary to control diet, hydration and lifestyle, increase the number of participants and increase PA monitoring among general population and among health professionals. ### EFFECTS OF A COMBINED PHYSICAL ACTIVITY- AND BEHAVIOR INTERVENTION ON OVERWEIGHT CHILDREN

Wagner, P., Müller, K., Grützmacher, N., Wulff, H.

*University of Leipzig*

Introduction Against the background of the global problem obesity and regarding the fact that, in Germany, 15 % of the children suffer from overweight and 6% are obese (Kurth & Schaffrath Rosario, 2007), effective interventions preventing overweight are necessary. In this context, physical activity has to be considered as a resource enhancing health and wellbeing. However, there is a lack of studies concerning effects of long-term interventions on physical and psychosocial aspects of overweight children (Summerbell et al., 2005). Therefore, the purpose of the present study was to examine effects of a combined physical activity- and behavior intervention in the setting of a sports club on overweight children and their level of physical activity, level of quality of life, physical and psychosocial resources as well as the reduction of risk factors (Wagner, 2010). Methods At the beginning, in the middle, and at the end of the structured 30-week intervention, including a weekly physical activity class of 90 minutes and 3 parents workshops, data giving evidence about anthropometric (BMI-SDS), physical aspects (KATS-K), psychosocial aspects (self-concept, FSK1), and quality of life (KINDL) as well as data concerning the level of physical activity and inactivity (HBSC-index) of the 8 to 12 years old children (IG: n= 17; CG: n= 20) have been collected. Results The results indicate significant main effects on physical (increased values of speed and strength) as well as the behavior aspects (HBSC-index), psychosocial aspects and quality of life (increased values of health related quality of life; self-concept and self-efficiency) as well as on several risk factors of overweight (reduction of BMI-SDS). Discussion With the help of the program, participants realized that there was a

need to change their way of life and that they were able to put these changes into practice. The positive effects on the children's quality of life and their level of physical activity serve as a good basis for continuous changes in their behavior. Additionally, the setting of a sports club simplifies the process of continuing different types of physical activity. References Kurth, B.-M. & Schaffrath Rosario, A. (2007). ### COMPARISON OF OBJECTIVELY MEASURED PHYSICAL ACTIVITY LEVELS OF YOUTH SOCCER PLAYERS BETWEEN FRANCE, ENGLAND & GREECE

Krommidas, C.1, Van Hoye, A.2, Fenton, S.A.M.3, Galanis, E.1, Bosselut, G.2, Duda, J.L.3, Keramidis, P.1, Nicaise, V.2, Barrett, T.G.3, Zourbanos, N.1, Heuze, J.P.2, Papaioannou, A.1

1: University of Thessaly, (Trikala, Greece), 2: Université Joseph Fourier (Grenoble, France), 3: University of Birmingham (Birmingham, UK)

Introduction Soccer is one of the most popular sports across the world with approximately 265 million players. Soccer plays a significant role in the prevention of cardiovascular diseases and different causes of mortality (e.g., Krstrup, Aagaard, Nybo, Petersen, Mohr, & Bangsbo, 2010). Therefore, the purpose of this study was to examine possible differences in objectively measured physical activity (PA) levels, BMI and aerobic capacity between French, Greek and English youth soccer players and to examine whether participants meet the recommended guidelines of 60 minutes of moderate to vigorous PA (MVPA) per day needed to accrue health benefits. Methods 356 players (M age: 11.51 ± 1.45 y. old) from Greece (N=133), France (N= 98), and England (N=125) wore the GT3X accelerometer for 7 days. A 15 second epoch, Freedson equation and a minimum of three valid days (8 hours of wear) were chosen to accurately catch PA intensities. Body weight and height were objectively measured. The 20m multistage shuttle run test was used to measure aerobic capacity (Leger & Lambert, 1982). Results The mean of MVPA per day in the whole sample was 123.29 minutes (SD=46.31). One-way ANOVA revealed no significant differences among the three countries in minutes per day spent engaged in sedentary behaviour (<1.5 METs), moderate PA (3 to 4 METs), moderate PA (4 to 6 METs), MVPA (>3 METs), BMI index and 20m shuttle run fitness test (ps>.05). However, there were significant differences (p<.05) found for light (1.5-3 METs) and vigorous PA (>6 METs). Specifically, UK players displayed lower scores in light PA than in the other two countries, while Greek players had significantly higher vigorous PA than French. Discussion Results indicated that there were no significant differences in sedentary behavior and MVPA levels of youth soccer players among the three countries. There were however, differences between countries with respect to PA intensities. In addition, players across the 3 countries met the guidelines of "60 minutes of MVPA per day" and have normal BMI for their age. This underlines the potential role organised sport (particularly soccer) could play in increasing PA practice and ensuring children meet the recommended PA guidelines. ### "THE EFFECT OF STAIR DESCENDING VERSUS STAIR ASCENDING EXERCISE ON HUMAN HEALTH: THE SMARTESCALATOR PROJECT"

Panayiotou, G.1, Theodorou, A.A.1, Paschalis, V.3, Nikolaidis, M.G.2, Giakas, G.3, Koutedakis, Y.3

1: European University Cyprus (Nicosia, Cyprus), 2: Center For Research And Technology, Thessaly (Volos, Greece), 3: University of Thessaly (Volos, Greece).

Introduction Several studies provide evidence that eccentric exercise, except for its muscle-damaging nature, can induce health-promoting effects that may improve quality of life (Theodorou et al. 2011; Paschalis et al. 2011; Nikolaidis et al. 2008). Based on the evidence derived from these studies, participation in activities including eccentric muscle work such as stair descending may be able to confer multiple beneficial effects on human health and it seems to be a promising life style factor for the elderly and people with chronic diseases like heart failures. Methods 20 males were allocated randomly into two equal-sized groups, the stairs descending group and the stairs ascending group. Volunteers performed two exercise bouts (descending and ascending stair) on an automatic escalator that has been designed and developed from our group. Exercise bouts were separated by 6 weeks. In each of the two sessions, volunteers had to accomplish 5 sets of 5 min of stair descending or ascending exercise. Speed was set at 60 stairs/min for both groups (total 1500 steps). Muscle performance indices (isometric torque, range of motion, delayed onset muscle soreness and creatine kinase) and blood lipid profile (plasma triacylglycerols, total cholesterol, high-density lipoprotein cholesterol and low-density lipoprotein cholesterol) were assessed before, immediately after and at 2 and 4 d post exercise after both exercise sessions. Results All muscle indices used in the present study were elevated at day 2 only after the first exercise session in the descending stairs group indicating severe muscle damage. No indices of muscle damage appeared after the second bout of exercise. After the first exercise session, triacylglycerols decreased only in the descending stairs group at day 2. For the rest blood lipid profile indices, there was a trend for favourable changes only after the first exercise session for the stair descending group. Discussion The present results revealed that stairs descending training compared to stairs ascending exercise induced greater muscle damage. The repeated bout of stair descending training induced significantly less changes in indices of muscle damage than the first bout. Except triacylglycerols in stair descending group, no significant changes have been observed in lipid profile after both protocols. This fact might implies that a more prolonged exercise protocol is needed before favorable changes in blood profile appear as reported after intense eccentric exercise (Paschalis et al. 2011). ### TEST-RETEST RELIABILITY STUDY OF A SELF-ADMINISTERED QUESTIONNAIRE ABOUT PHYSICAL ACTIVITY PATTERNS OF PORTUGUESE ADOLESCENTS

Botelho, G., Ferrao, A., Aguiar, M.

Coimbra College of Agriculture, Polytechnic Institute of Coimbra

TEST-RETEST RELIABILITY STUDY OF A SELF-ADMINISTERED QUESTIONNAIRE ABOUT PHYSICAL ACTIVITY PATTERNS OF PORTUGUESE ADOLESCENTS Goretii Botelho<sup>1,2</sup>, António Ferrão<sup>3</sup> and Marco Aguiar<sup>3</sup> 1: Department of Food Science and Technology, Coimbra College of Agriculture, Polytechnic Institute of Coimbra, (Coimbra, Portugal), 2: CERNAS Research Unit, Coimbra College of Agriculture, (Coimbra, Portu-

gal, 3: University of Trás-os-Montes and Alto Douro (Vila Real, Portugal). Introduction Questionnaires are tools to obtain reliable and useful information in nutritional and physical activity (PA) studies of adolescents around the world. The Quantification de l'Activité Physique en Altitude Chez le Enfants (QAPACE) developed by Barbosa et al. (2007) and the HBSC – Health Behavior in School-Aged Children survey (2001-02) are valid tools to assess PA in population studies. This study aimed to determine the test-retest reliability of a new questionnaire entitled "Questionnaire to Assess Physical Activity and Sedentarism, QAPAS" modified and improved from the QAPACE and the HBSC to evaluate PA patterns of Portuguese adolescents. Methods The developed questionnaire comprised 20 questions and was self-administered. Reliability was assessed by test-retesting 22 males and 19 females, randomly selected (11.10±0.70 years), after an eight-day interval. These 41 adolescents represent 2.9% of the population (1403 students from 7 public schools) under study. Pearson correlation and Cohen's kappa test were performed using SPSS software v. 20.0. Results Pearson's correlation between answers of the two periods were statistically significant for all the 58 items and the r-values were above 0.600 ( $p < 0.01$  and  $p < 0.001$ ). A great fraction of these correlations ranged from 0.900 to 1.000, thus showing that questions were appropriate. Moreover, Cohen's kappa test also demonstrated an high concordance level between the answers of the adolescents, with 51 items (from 58 items) above 0.600. Discussion The questionnaire developed in the study complies with the requirements of reproducibility. In fact, the internal consistency of answers evaluated during the test-retest study proved to be good. Moreover, inter-answer reliability determined through Cohen's kappa test was above 0.700 in 65.5% of questionnaire items. Thus, QAPAS can be applied to the whole adolescents' population. ### MATCH RUNNING PERFORMANCE IN JAPANESE OLDER SOCCER PLAYER

Ishizaki, S.I, Yasumatsu, M.2

*Shibaura Institute of Technology*

Introduction Time-motion analysis of soccer games, many researchers have been analyzing quantity of the distance covered in soccer players (Bangsbo et al. 1991). However, the previous data used for their analysis were collected only from players in top-level soccer club or national teams. Actually, there was no studies used the data from older soccer players. Therefore, the purpose of this study was to examine running performance in Japanese older soccer players. Methods This study was carried out with eight games for Over-70 years old soccer league. Twenty-one amateur Japanese soccer players (age: 71.9±/-1.5 years, height: 166.7±/-4.1 cm, body mass: 64.9±/-7.5 kg, BMI: 23.3±/-2.5) participated in this study, including defenders (n=7), midfielders (n=7), and forwards (n=7). All players were filmed during the entire match (40 min.). The digital video cameras (HDR-XR550V, Sony, Japan) were positioned at the side of the pitch, at the level of midfield line, at a height of about 30m and at a distance of about 30m from a touchline. The digital movies were later replayed on a monitor. Then, total distance and running speed were analyzed using Track Performance software (Sports Code, Australia). This software system was applied most effectively with the use of a drawing tablet (PTK-1240, Wacom, Japan) connected to laptop computer. The locomotion categories were used for standing (0~2km/h), walking (2~7km/h), jogging (7~9km/h), low-speed (LS) running (9~13km/h), moderate-speed (MS) running (13~16km/h), high-speed (HS) running (16~22km/h), sprinting (>22km/h). These locomotion categories were chosen in accordance with Randers et al. (2010). Results & Discussion The mean total distance covered in 40 min. was 3502.5 ±/504 m and ranged from 2468m to 4566m. The average distance covered (absolute & relative data) consisted of standing (118.0m, 18.0%), walking (1653.0m, 57.3%), jogging (537.0m, 10.1%), LS running (729.5m, 10.0%), MS running (332.0m, 3.5%), HS running (127.5m, 1.1%), and sprinting (0m, 0%). There was significant difference between the first (1848.1 ±/276.0 m) and the second (1654.3 ±/240.5 m) half of the total distance covered (absolute data) ( $P < 0.05$ ). In addition, relative data in the second half regarding standing was significantly increased compared to the first half ( $P < 0.05$ ). On the other hand, jogging, LS running, MS running were significantly decreased compared to the first half ( $P < 0.05$ ). Therefore, in Japanese older soccer players, it was suggested that fatigue accumulated during the games affected faster running speed especially in the second half. References 1. ### A "START TO SWIM" PROGRAM FOR HEALTH-ENHANCEMENT PURPOSE: A DELPHI STUDY

Mouton, A., Warnotte, J., Cloes, M.

*Ulg (Liège, Belgium)*

Introduction Popularity of "start to run" or "start to cycle" programs increases with the evidence that regular physical activity contributes to the prevention and management of a wide range of chronic diseases (Rippe and Angelopoulos, 2010). Nevertheless, start to swim programs could lead to even more health-enhancing outcomes (Chase et al., 2008). The aim of this study was to obtain a "start to swim" model program by means of a two-round Delphi study. Methods In the first round, 10 key-experts in sport physiology (n=4) or in swimming coaching (n=6) outlined possible relevant components of the "start to swim" program in a semi-structured interview. Initial exclusion criterion, program set-up, program key principles, program progression and final goals were interrogated. Then, a facilitator provided an anonymous summary of the experts' suggestions from the previous round as well as the arguments they provided for their choice. In the second round, experts were asked to comment on this summary before providing a final form to this program. Results After two rounds, the experts agreed on a collective and coached intervention with 2 sessions per week and a progressive replacing of the coach by a group leader during a 4 months program. People without medical contraindication and able to swim 25 meters could take part to this program. The final goal-setting is personal and based on each individual progression and motivation. Sessions are endurance-oriented and divided between traditional swimming sessions and diversified aquatic activities. In order to support this active lifestyle in a long-term basis, referring to swimming clubs or other aquatic activities associations are performed by the coach at the end of the program. Discussion The start to swim program take into consideration behavioural and social aspects necessary for a successful adoption and maintenance of physical activity (Khan et al., 2002). Consistent with previous findings, a group-based program (Cox et al., 2008) with individually adapted-goals (Marcus and Forsyth, 2003) could lead to a long-term adherence to exercise. Future studies should include systematic evaluation of the "start to swim" program before translation into the community. References Chase NL, Xuemei S., Blair SN (2008). ### PP-PM46 Health & Fitness: Exercise

#### A TRAINING PROTOCOL INTEGRATED OF PILATES- AND YOGA-BASED EXERCISES FOR WOMEN WITH BACK PAIN

Bellafiore, M., Battaglia, G., Caramazza, G., Fantauzzo, V., Bianco, A., Palma, A.

*University of Palermo*

A TRAINING PROTOCOL INTEGRATED OF PILATES- AND YOGA-BASED EXERCISES FOR WOMEN WITH BACK PAIN Bellafiore, M.1,3, Battaglia, G.1,3, Caramazza, G.2,3, Fantauzzo, V.1, Bianco, A.1,3, Palma, A.1, 3. 1: DISMOT (Palermo, Italy), 2: PhD in "Human Diet and Nutrition" (Palermo, Italy), 3: Regional Sport School of Sicily CONI (Olympic National Italian Committee, Italy). Introduction Pilates and Yoga are body-mind activities recently become very popular in Italian fitness gyms. Their outcomes have been studied separately and it has been reported that both reduce low back pain affecting either the physiological and mental aspects (Posadzki et al., 2011; Tilbrook et al., 2011). However, few evidences are present in the scientific literature. The aims of our study were to test the influence of a training protocol including exercises of Pilates Matwork and Yoga Poses on several fitness parameters as muscle strength and spine flexibility in women with back pain; and whether improvements in these factors were associated with a decrease in symptom frequency. Methods Twenty one women (age:  $37.8 \pm 8.2$  years; weight:  $60.1 \pm 7.4$  kg; height:  $163 \pm 6$  cm; BMI:  $22.4 \pm 3.2$ ) were recruited to participate in a 8-month training protocol for 1 hour 3 times per week under the guide of the same instructor for all length of training period. This protocol consisted of an initial step of 10 min aimed at activating the muscles involved in the central step of training (35 min), which included Pilates mat exercises (Marmaid, Hundred, Swimming, Spine twist, ecc.), followed by a final step of 15 min of Yoga Poses. The exercise difficulty, the number of sets and repetitions gradually increased during the training period. Before, during (4 months) and after 8 months of exercise training, fitness tests were performed (sit and reach test, trunk lift, sit up, push up, squat). We used the visual rating scale (VRS) to select participants with a frequency of low back pain ranging from 'occasionally' to 'always'. One-way ANOVA test with Bonferroni's correction and Chi-squared test were used to analyze significant differences ( $p < 0.05$ ). Results After 4 and 8 months of the training period, we found a significant improvement in the low back and hamstring flexibility; abdomen, upper- and lower-body strength ( $p < 0.001$ ). These changes were associated with a bigger number of participants who showed a significant reduction of low back pain frequency ( $p < 0.05$ ). Discussion The training protocol integrated of Pilates- and Yoga-based exercises appears to be practicable, safe and repeatable for long time by women with back pain. Muscle isometric contractions and stretching induced by Pilates and Yoga methods can reduce the onset of low back pain in women. References Posadzki P, Lizis P, Hagner-Derengowska M. (2011). #### CARDIORESPIRATORY RESPONSE TO ZUMBA DANCING

Mamen, A.1,2, Sødem, A.3, Sødem, P.3

*1 University College of Health Sciences Campus Kristiania, Oslo, 2 Sogn og Fjordane University College, Faculty of teacher education and sport, Sogndal, 3 Nesbru trim & helse, Nesbru, Norway*

Introduction Zumba(R) dancing has become a popular form of fitness training worldwide. The music is inspired by Latin rhythms and incorporates a wide variety of musical genres, old and new. The activity differs from traditional Aerobics exercise in more use of core muscles and a more advanced choreography. It has been argued that the higher level of difficulty may compromise training efficiency, at least for beginners. The aim of this presentation is to describe the cardiorespiratory response to Zumba(R) dancing by Zumba(R) instructors and ordinary participants with different levels of experience with Zumba(R) dancing. Methods Two instructors (one male and one female) and two participants (females), one well used to Zumba(R) dancing, performed the same session taking 60 min to complete. During their work out they wore a MetaMax II metabolic analyser (Cortex Biophysik, Leipzig, Germany) on their back for recording cardiorespiratory variables. Results are presented as mean values unless otherwise noted. Results The oxygen uptake rose to a peak value of  $39.7$  ml/kg/min, whereas the mean uptake was  $27.1$  ml/kg/min. The highest values were found among those most experienced with the activity. Breathing frequency levelled off after about 15 min of exercise at  $\sim 40$  breaths/min. Respiratory Exchange Ratio likewise showed a similar pattern with a relatively stable value of  $\sim 0.95$  the last 30 min of the session. Breathing efficiency, expressed as  $E_{QO_2}$ , showed individual differences, the most experienced subject showed lower values, and better breathing economy, than the inexperienced participant. By and large, the instructors showed higher exertion than the participants, and the experienced participant again more than the less experienced. The energy expenditure was calculated to be  $\sim 400$  kcal. Discussion The peak  $VO_2$  was 80% of maximal capacity, the mean value 60% of max. In group exercises like Aerobics and Spinning(R), peak values of  $>90\%$  of max and average values of 70% have been found (Mamen, 2001). Also the breathing frequency and  $E_{QO_2}$  indicate that exertion was substantial. Zumba(R) dancing should therefore be suitable for cardiorespiratory fitness training. The difference seen between the experienced and not so experienced subjects indicates that beginners may need some time to practice before the full potential of the exercise is reached. The particular movement pattern in Zumba(R) may make it especially suitable for people who enjoy dancing and who are not afraid of moving in new and unfamiliar ways. References Mamen, A. (2001). Energy expenditure in Spinning(R) training. 34. Int. Congress of Physiological Sciences; Christchurch, New Zealand, 2001-08-26 - 2001-08-31.

#### BIOPHYSICAL CHANGES IN AQUA-SKY EXERCISE WITH DIFFERENT MUSICAL CADENCES: INSTRUCTORS EVALUATION

Morouco, P., Neves, L., Tavares, J., Amaro, N.

*POLYTECHNIC INSTITUTE OF LEIRIA*

Introduction The Aquatic Exercise Association (AEA, 2011) recommends music with a rhythm of 125-150 beats per minute (b.min-1), for water aerobic classes. Other authors suggest that for healthy and physically active subjects, the instructors should opt for rhythmic cadences between 136 and 158 b.min-1 (Barbosa et al., 2010). Several studies aimed to assess the physiological responses during the execution of basic water aerobics exercises. However few are those that focused an instructor's perspective. Therefore, the aim of the

present study was to assess biophysical changes in Aqua-Sky at two different cadences. Methods Six aquatic fitness male instructors (29.3±2.7years-of-age; bmi 25.0±2.5kg.m<sup>-2</sup>; more than 3 years of experience) took part in the study. Tests were performed on land, where the practical sessions of water aerobics take place. Each subject after a warm-up, completed two trials (30min rest) of Aqua-Ski with different rhythmic cadencies (130b.min<sup>-1</sup>,140b.min<sup>-1</sup>). Each trial had 6min duration, permitting the stabilization of the physiological parameters studied. It was asked to the subjects to perform the exercise as in real class situation, according to the pattern recommended by the technical literature (AEA, 2011), and also mentioned in scientific work (Barbosa et al., 2010). Heart rate was measured every 5-s (Polar). Blood lactate concentrations from the lobule of the left ear were measured with a portable device (Lactate-Pro) at two different moments: pre-test and post-test. For the kinematical analysis a digital camera (Casio Exilim F1, 60fps) was placed on a sagittal plane 3 meters from the area of execution. Calibration volume (3m<sup>3</sup>) was used to allow Utilius Easy Inspect (CCCsoftware) analysis. The distance between foot-supports was estimated using the digitalization of the anatomic reference point of the right medial malleolus when the foot was completely in contact with the floor for two moments (i) most posterior and (ii) most anterior. Results No significant differences in maximum and medial HR were obtained between repetitions (p>0.05). The [La<sup>-</sup>] showed a small increase with the rhythmic cadence of 140b.min<sup>-1</sup>. Subjects maintained the amplitude of support, and consequently an increase in segmental velocity. Discussion Similar results were verified in the analysis of other exercises (e.g. jumping-jacks and side-kicks). The increase in rhythmic cadence from 130b.min<sup>-1</sup> to 140b.min<sup>-1</sup> does not cause an acute physiological response in water aerobics instructors when practiced in the location where they administer their sessions. Additionally, increase in movement rate keeping the same displacement, is the common procedure to higher cadences. References Aquatic Exercise Association (2011). Global Resource in Aquatic Fitness, Florida. Barbosa et al. (2010). J Strength Cond Res, 24(1), 244-250.

### EFFECTS OF CIRCUIT RESISTANCE TRAINING ON HEART MORPHOLOGY AND FUNCTION, CARDIOVASCULAR RISK FACTORS AND SERUM INFLAMMATORY CYTOKINES LEVELS IN SEDENTARY WOMEN.

Ferreira, F.C., Nunes, J.E.D., Verzola, R.M.M., Baldissera, V., Perez, S.E.A.

*Federal University of São Carlos*

**Introduction** The risk factors for cardiovascular disease often cluster together, most notably increase in body fat mass (overweight/obesity) mainly in central adiposity, dyslipidemia, hypertension, and insulin resistance, showing increase of circulating cytokines and low degree of inflammation. Exercise can elicit cardiac benefits and benefits or damage on the immunologic system. This study aimed to analyze the effects of circuit resistance training (CRT) on body mass (BM), lean mass (LM), fat mass (FM), trunk fat mass (TFM), percentage of FM (%FM) and TFM (%TFM), left ventricular mass (VM), relationships VM/body surface (BS), VM/BM, VM/LM, final diastolic volume (FDV), final systolic volume (FSV), and systolic volume (SV) in rest, relationship double product [heart rate (HR).systolic blood pressure (BP)]/load of cycle-ergometer at the anaerobic threshold (DP/L), fasting glucose (FG), lipid profile and serum cytokine levels in sedentary women, 39.71 ± 3.8 years old (n=14). **Methods** The women played 3 sessions/wk, 2 rounds in 9 stations, one set of 8-12RM for 10 wks. In pre and post CRT, were analyzed the body composition by DXA, heart parameters by EchocardiDoppler; BP by sphygmomanometer, HR by frequency counter, FG and lipid profile by enzymatic colorimetric methods, serum cytokines levels by flow cytometry (IL-1β; IL-6; IL-8; IL-10, IL-12p70 and TNF, in 96h rest, and 5 min, 24h and 48h post 2nd and last session of training) and the nutritional standard by 24-h dietary recall in period. Used Friedman's with Tukey post hoc tests for cytokines and nutritional standard, and Student's t test or Wilcoxon's test for others variables (α=0.05). **Results** Values: mean±SD. The %FM reduced markedly (37.1±10.8-31.2±6.1) with 1.5Kg only in TFM (8.86±2.9-7.33±1.9). There were increases in the LM (35.94±4.9-39.13±4.9), LVM (139,57±11,9-145,9±17,6g), LVM/BS and LVM/BM, maintenance of LVM/FF, reducing DP/L (218.98±85.7-155.96±45.2) and tendency to increase of VSF, SV and FSV. Reduction in FG (92.0±8.5-74.0±3.5mg/dl), CT (193.4± 33.6-183.2±29.4) and HDL (54.71±10.3-47.79±8.8), without changes in others variables. **Discussion** The proposed CRT improved cardiovascular health of women, improving glucose uptake, reducing the CT, the total body fat and central (trunk) which is more linked with cardiovascular disease and low-grade inflammation with increased levels of circulating cytokines (Ren and Kelley, 2009), which was not observed in present work. Cardiac hypertrophy coupled with the upward trend of the VSF and VS, probably helped in better cardiovascular performance during the anaerobic threshold in ergometer, with a smaller increase in DP/L for the same load. **References** Ren J, Kelley RO (2009). Obesity, 17, 1114-1123.

### DIFFERENCES IN BONE STRENGTH IN THE RADIUS AND TIBIA IN ADOLESCENT CYCLISTS.

Gómez-Bruton, A., González-Agüero, A., Gómez-Cabello, A., Matute-Llorente, A., Morales, S., Guillén-Ballester, A., Olmedillas, H., Casajús, J.A., Vicente-Rodríguez, G.

*GENUD research group, Universidad de Zaragoza, Spain.*

**INTRODUCTION:** Many studies have been performed with dual energy X-ray absorptiometry (DXA) techniques demonstrating that cycling training is associated with decreased bone mineral density (BMD) and lower bone mass acquisition during growth periods (1). However, bone strength indexes and therefore, fracture risk have a high relationship with structural aspects of the bone such as cortical thickness and bone cross-sectional area, among others, which cannot be calculated with DXA parameters. Therefore the aim of this study was to evaluate bone strength at the radius and tibia, in adolescent cyclists compared with controls. **MATERIALS AND METHODS:** Peripheral quantitative computed tomography (pQCT) measurements were taken at the tibia and radius of 20 male adolescent cyclists and 17 sex and age-matched active peers. Stress strain index (SSI) and resistance to fracture load (FRC\_LD) were calculated in X and Y axis. Bone strength index (BSI) (2) and polar strength strain index (SSIPol), which is an estimate of bone strength to bending and torsion were also calculated. Student's t-tests were applied to evaluate differences between cyclists and control groups. **RESULTS:** Cyclist group showed lower BSI at radius (76±17 vs. 89±21 mg2/mm4) and tibia (309±44 vs. 377±74 mg2/mm4) than the control group. Also lower FRC\_LD (3467±560 vs. 4091±1056 N) and SSI (963±155 vs. 1136±293 N) at the tibia Y axis were found in the cyclist group compared with the control group (all p<0.05). **DISCUSSION:** Cyclists showed lower bone strength indexes than their active peers, mainly at the tibia. Therefore the relative risk of suffering osteoporotic fractures of this group of adolescents may be augmented later in life. In addition, we should not forget the increased risk of fall during cycling practice, which could increase the risk of bone fracture in these athletes also due to weaker bones. Future interventions are needed in order to increase the bone strength of this population and hence eliminate the negative effects that this sport may have on bone development. **REFERENCES** 1. ## EFFECTS OF RESISTANCE TRAINING ON BASAL METABOLIC RATE, BODY COMPOSITION, AND SLEEP PARAMETERS IN HEALTHY ELDERLY

Boscolo, R.A., Santana, M.G., Viana, V.A.R., Grassmann, V., Tufik, S., De Mello, M.T.

*Universidade Federal de São Paulo*

**Introduction** During the process of aging, neurochemical, morphological and functional changes occur such as the decline of some characteristics of sleep, of fat-free mass and of basal metabolic rate (BMR). These factors may possibly be related because the decrease in basal metabolic rate is due to the decrease in fat-free mass. Physical training can minimize such effects and/or bring positive results to sleep pattern, body composition and metabolism. The aim of this study was to evaluate the effects of resistance training on BMR, body composition and sleep parameters, and to verify their possible relationship in elderly men. **Methods** The sample consisted of 37 elderly men (65-75 years old) randomly assigned into two groups: control (CG) and resisted (RG). The protocol included 72 sessions of progressive resistance training (three times weekly), and evaluation of basal metabolism, body composition, sleep and food consumption. **Results** Muscle strength increased in all muscle groups in the RG. In the morphological variables, CG increased fat mass and decreased fat-free mass in the final evaluation, however RG remained with the same variables of body composition. The BMR and daily energy consumption remained unchanged in both groups during the evaluations. Sleep variables are statically altered, CG increased total sleep time, arousals, and score of Pittsburgh index, while stage 1 of NREM sleep was significantly reduced. There was association of causality between fat-free mass, stage 1, and BMR with the final model of regression ( $BMR = 539.81 + 21.99 \text{ fat-free mass, kg} - 26.01 \text{ stage 1, \%}$ ), explaining 34% change in BMR. **Discussion** Although not altering the relationships between BMR, sleep parameters and body composition, the results suggest that resistance training was effective, increased muscle strength, maintained fat-free mass and BMR and improved the quality of sleep in healthy elderly, reflecting a quality of life more active for a healthy longevity. Some studies suggest that the prevalence of sleep problems and daytime sleepiness is less in physically active individuals (Sherril et al., 1998) and resistance training also found, in addition to increased neural activity and muscle, improvement in other aspects such as the quality of sleep (Ferris et al., 2005), enabling the elderly and greater autonomy in their daily provision (Perrig -Chiello et al., 1998). **References** Ferris LT, Williams JS, Shen C, O'Keefe KA, Hale KB (2005). *Sports Sci Med* 4: 354-60. ## COMPARABLE EFFECTS OF SLOW RESISTANCE TRAINING AND BRISK WALKING ON BODY COMPOSITION AND BONE STATUS IN SEDENTARY YOUNG WOMEN

KIMURA, Y., OHKI, K., NAKAGAWA, N., YAMAZAKI, S., SATO, T.

*Reseach Center for Fitness and Health Sciences*

**Introduction** Regardless of age or gender, children and adults who maintain an active lifestyle have significantly greater body composition and bone mass than sedentary counterparts. The aim of the present study is to evaluate the effects of resistance training (RT) and walking exercise (WK) on body composition, bone and mental health status in sedentary young women. **Methods** Thirty-five subjects (Mean age 20.8 yrs.) were divided into RT group (n=12), WK group (n=13) and control group (CN; n=10). RT group trained four exercises (squat, bent-leg sit-ups, push-up, back extension) using body weight as a load, with slow maneuver four times per week. WK group instructed to wear a pedometer, and walked briskly, more than 10,000 steps a day four times per week. We evaluated body composition, bone status (ultrasound parameters of the calcaneus and urinary deoxypyridinoline (DPD) levels), and mental health, at baseline and after 12 weeks of training session. **Results and Discussion** RT showed significant changes in fat mass (-5.9%), waist (-4.3%), hip (-2.6%), thigh (-2.8%) and upper arm (-2.5%) circumferences, and triceps (-2.9%), abdominal (-10.2%) and thigh (-9.5%) thickness. WK showed significant changes only in thigh (-2.3%) circumference, and abdominal (-5.7%) and thigh (-7.6%) subcutaneous fat thickness. RT showed significant changes in ultrasound parameters, such as speed of sound (+0.4%) and stiffness (+1.1%). WK showed small changes in these three items, but the changes were not significant. There was a significant decrease in DPD (-1.2%) only in RT. A significant improvement in RT was seen in regard to subjective health (+9.7%), everyday feelings (+12.2%), human relations (+10.8%) and subjective happiness (+8.9%). The subjective health (+9.2%) and subjective happiness (+8.0%) increased significantly in WK. CN shows no significant changes in any measurements. **In conclusion**, 12 weeks of RT (squat, bent-leg sit-ups, push-up, back extension, using body weight as a load) or WK (walked briskly, more than 10,000 steps/day) in sedentary young women has affected body composition, bone status and mental health. RT was more effective in increasing body composition variables and bone status markers, in addition to improving mental health profile. These findings suggest that RT can promote better adaptations than WK isolated during intervention period.

## EFFECT OF TWO DIFFERENT ABDOMINAL EXERCISES ON RESPIRATORY MUSCLES

Cavaggoni, L., Parisi, Y., Ongaro, L., Alberti, G.

*Università degli Studi di Milano, Italy*

**BACKGROUND AND PURPOSE** The abdominal muscles have an important role in control and movement of the lumbar spine and pelvis. The contraction of the lumbo-pelvic muscles is dependent on the type of movement of the trunk and arms [1,2]. Its stability is important to transfer force and to return to balance after destabilization. Only a few studies have investigated the effects on respiratory parameters and respiratory muscle fatigue during abdominal exercises [3]. The aim of this study was to analyse the effects of two types of abdominal exercises on abdominal muscle force, and on the main respiratory parameters. **METHODS** 16 male subjects were randomly divided into two treatment groups for 5 weeks: the Training Group (TG) performed 4 static abdominal exercises in an extended position of the trunk. Arms and legs were extended, with emphasis on a vocal sound emission with the muscular chains stretched. The Control Group (CG) performed traditional exercises like sit-up, crunch with trunk rotation and flexion, and lateral bridge. We measured the respiratory parameters like FVC, FEV1 and PEF with the spirometer Pony Fx (Cosmed, Roma, Italy), and the dynamic abdominal endurance with ACSM Curl-up (Cadence) test. **RESULTS** Compared to the CG group, the TG group performed much better in all parameters. In the Curl-up test with the TG group, we found significant differences ( $p < 0.05$ ) with an improvement of 34% from pre and post conditions. FVC, FEV1 and PEF also showed a significant difference ( $p < 0.05$ ) with a mean average increase of 10%. With the CG group, we found a minor improvement in the Curl-up test with statistical differences ( $p < 0.05$ ) but much less than the TG group. With regards to respiratory parameters, we found no statistical improvements with the CG group ( $p > 0.05$ ). **DISCUSSION** The abdominal exercises performed in an extended position with the muscular chain stretched induce many more improvements than traditional exercises. The use of the voice to produce a sound conducts a contraction of the transversus along with an active recruitment of the respiratory muscles. The role of the diaphragm produced a high transdiaphragmatic pressure which increased the function of the abdominal muscles. We suggest to athletes and common

people to practice this type of exercise, combined with traditional ones, because they lead to an increase of core stabilization, pulmonary function and a correct spinal posture. ### DIFFERENCES IN CALCANEAL ULTRASOUND PARAMETERS IN ADOLESCENT CYCLISTS VS. CONTROLS.

Gómez-Bruton, A., González-Agüero, A., Gómez-Cabello, A., Matute-Llorente, A., Morales, S., Guillén-Ballester, A., Olmedillas, H., Casajús, J.A., Vicente-Rodríguez, G.

*GENUD, Research Group, Universidad de Zaragoza*

Differences in calcaneal ultrasound parameters in adolescent cyclists vs. controls. Gómez-Bruton A1, González-Agüero A1, Gómez-Cabello A1; Matute-Llorente A1, Morales S1, Guillén-Ballester A 1, Olmedillas H 1, Casajús JA1, Vicente-Rodríguez G 1 1GENUD research group, University of Zaragoza, Spain. INTRODUCTION: Studies performed with dual energy X-ray absorptiometry techniques demonstrated that cycling training is associated with decreased bone mass acquisition during growth periods(1) which could lead to osteoporosis later in life. Other cheaper and innocuous techniques such as quantitative ultrasound (QUS) have not yet been used to evaluate bone parameters in a cyclist population. Therefore, the aim of this study was to evaluate bone parameters measured with QUS in a population of adolescent cyclists and to compare them with a control group (CG). MATERIAL AND METHODS: 19 male adolescent cyclists and 17 male age-matched controls participated in the study. QUS values (speed of sound [SOS] and broadband ultrasound attenuation [BUA]) of both heels were measured at the calcaneus with an Aquiles equipment (Lunar Achilles InSight). Stiffness Index (SI) was also calculated from a combination of SOS and BUA. Student's t-tests were applied to evaluate differences between cyclists and CG. RESULTS: Compared with the CG, cyclist group showed lower values of SOS (1589±35 vs. 1612±35 m/s), BUA (110 vs. 122 dB/MHz) and SI (98±18 vs. 113±15) for the right foot; and also lower SOS (1587±33 vs. 1624±36 m/s), BUA (107±12 vs. 122±12 dB/MHz) and SI (95±15 vs. 116±16) for the left foot (all p≤0.05). ANCOVA results adjusting for age, height and weight did not modify the results. DISCUSSION: Cyclists group showed lower QUS parameters for bilateral calcanei than the CG even after adjusted for age, weight and height. Therefore, properties such as composition and geometry of the bone might be affected by cycling training. Hence the relative risk of suffering osteoporotic fractures in this determined population may be augmented later in life. Moreover, the increased risk of fall during cycling practice could increase the risk of bone fracture in these athletes due to weaker bones. Future studies using QUS in a larger sample are needed in order to confirm these results. 1. Nicholson PF. Ultrasound and the biomechanical competence of bone. #### DIFFERENT ADAPTATIONS OF ACTN3 & ACTN2 GENE EXPRESSION TO 8 WEEKS PROGRESSIVE RESISTANCE TRAINING IN SPRAGUE-DAWLEY RATS

Khaledi, N., Gaeini, A.A., Fayazmilani, R.

*University of Kharazmi -Shahid beheshti University*

Introduction Alpha (α)-actinins are located in the skeletal muscle Z-line and form actin-actin cross-links(Frank et al 2006). The human ACTN3 gene encodes the protein α -actinin-3, a component of the contractile apparatus in fast skeletal muscle fibers. Kathryn et al (1999) identified a common polymorphism in ACTN3 (R577X) that results in absence of α -actinin-3 in more than one billion people worldwide, despite the ACTN3 gene being highly conserved during human evolution. They demonstrated that ACTN3 genotype influences elite athletic performance (North et al 2008). However, the response of α-actinin to exercise training is little understood. Methods Forty female Sprague-Dawley rats were assigned randomly to a control (C; n = 18) or exercise training (T; n = 22) group. This study examined the effects of 8 weeks progressive resistance training on α-actinin-2 and α -actinin-3 expression levels, in the flexor hallucis longus muscle (FHL) . In addition, changes in the myosin heavy chain (MyHC) composition were assessed. Real-time PCR & Immunohistochemistry techniques were used to measure gene expression levels & MyHC composition, respectively. Results Results showed that α -actinin-3 gene expression levels increased in T animal's muscle. (P < 0.05).However, no significant difference was found in α -actinin-2 expression levels between C and T animals. Subsequent MyHC analyses of all muscle showed a MyHC shift with direction from IIb to IIx. Discussion The results of this study demonstrate that progressive resistance training alters the expression of α-actinin3 at the cellular levels in skeletal muscle (P < 0.05).Ogura et al (2008) demonstrated that α-actinin- 3 levels adapt to changes in skeletal muscle characteristics along with hind limb unloading and transformation of muscle fiber type. These results are in line with our finding. This study demonstrate probably α -actinin-3 has an important function to produce and progress of force in sarcomere in response to resistance training. #### ACE AND ACTN3 GENOYPTE IN KOREAN POWER PERFORMANCE

Kim, C.1, Kwon, I.S.2, Kim, H.J.3, Cho, J.Y.2

*1 Korea National Sport University, 2 Korea National Sport University, 3 Korea National University of Education*

INTRODUCTION: There has been intensive research on the ACE ID or ACTN3 R577X polymorphism in the athletic trait of power performance due to the phenotypic influence of their genotypes on skeletal muscle power or muscle fiber structure(Hagberg et al. 2011). How-

ever, there is in need to identify the impact of combined association of ACE and ACTN3 on human performance because power performance is genetically determined by polygenic profiles (Rodríguez-Romo et al., 2010; Santiago et al., 2010). This study aimed to examine whether the combination of ACE and ACTN3 is associated with power performance in Korea. **METHODS:** For this study, 106 top-class power athletes (top-class group), 158 elite power athletes (elite-class group) and 676 healthy adults (control) aged 18-39 yrs were recruited and their genotypes were analyzed. **RESULTS:** The top-class group showed higher frequencies of II genotype and I allele in ACE and also higher frequencies of RR genotype and R allele in ACTN3 (Top-Class vs. Control: 41.4% vs. 32.1% for II genotype, 67.1% vs. 57.7% I allele,  $p < 0.05$ ; 42.3% vs. 29.0% for RR genotype, 65.3% vs. 54.8% for I allele,  $p < 0.05$ ). In polygenic profile, the top-class group had significantly higher frequencies of combined-II/ID+RR/RX genotype than control (Top-Class vs. Control: 82.9% vs. 66.7% for II/ID+RR/RX,  $p < 0.05$ ). The combined-II/ID+RR/RX genotype showed the possibility of success in the top-class muscle power performance with odds ratio of 2.3 times (CI:1.4-4.1,  $p < 0.05$ ). **DISCUSSION:** These results suggested that ACE and ACTN3 should be in interaction with each other to affect muscle-power performance in an additive form. Also, multigenic profile of ACE and ACTN3 can predict muscle performance with homogeneous dominant combined genotype (II/ID+RR/RX) having high success. **References** C Santiago, JR Ruiz, CA Muniesa, M Gonzalez-Freire, F Gomez-Gallego. *A Lucia*. 2010. *Scand J Med Sci Sports*. 20, e188-94. **Introduction** In recent years, the use of cold water immersion (CWI) following heavy training sessions has become common among athletes aiming to reduce soreness, although there isn't any strong scientific rationale behind this method. HSP25 as one of the stress proteins that have been shown to play an important role after damage and following remodeling process in skeletal muscle (Koh, 2002) have been discussed in this study. The purpose of this study was to investigate the expression of Hspb1 after damaging exercise followed by CWI in different recovery time courses. **Methods** Male Wistar rats ( $n=168$ ;  $W=300 \pm 10$ gr) were divided into two groups of exercise (Ex) and exercise followed by cold water immersion (Ex+CWI). Each group divided to seven subgroups for seven time-courses (0, 0.5, 3, 24, 48, 72, and 168 hours after exercise). Eccentric exercise consist of 45min downhill running on treadmill (20 m/min,  $-17^\circ$ ) and CWI consist of 10min immersion in  $-10^\circ\text{C}$  water. Hspb1mRNA level was measured in Soleus muscle using Real-Time PCR and the protein level of HSP25 using WB and ELISA methods. **Results** We observed that the level of HSP25 in exercised muscles was increased significantly in all time courses except 168 h ( $p < 0.05$ ). The increment pattern was the same in both groups. Although, in Ex group, HSP25 level reach to its peak level 48 h post exercise, while the peak time course for Ex+CWI group was 72 h post exercise. Gene expression of Hspb1 increased 3 h post-exercise in both groups, although Hspb1mRNA level in Ex+CWI, 48h hr post-exercise was significantly less than Ex. **Discussion** Delay in recovery late phase increase of HSP25, which may overlap with secondary damage time course, suggests that CWI may postpone this phase. Also, the level of expression after CWI was higher that could be occurred due to more myofibrillar damage (Koh, 2002). Besides, decrease in Hspb1 gene expression 48 h following CWI may suggest suppression of cellular mechanisms in this regard (Peiffer et al., 2009; Paulsen et al., 2007). Furthermore, the level of HSP25 one week after exercise in Ex+CWI group, equal to control level indicate that CWI may suppress the acute adaptation of Hspb1 in skeletal muscle which exists in Ex group (Yamane et al., 2006). **References** Koh TJ. ## EFFECTS OF RESISTANCE EXERCISE INTENSITIES AND BLOOD FLOW SUPPLY ON REGULATORS OF MYOGENESIS IN HUMAN SKELETAL MUSCLE

Popov, D.1, Furalyov, V.2, Kravchenko, I.2, Miller, T.1, Bachinin, A.1, Kurochkina, N.3, Moroz, A.3, Vinogradova, O.1

1: SSC RF Institute for Biomedical Problems RAS (Moscow, Russia), 2: A. N. Bach Institute of Biochemistry RAS (Moscow, Russia), 3: Lomonosov Moscow State University (Moscow, Russia)

**Introduction** Choosing an optimal contractile activity protocol associated with resistance exercise for improving an increase in muscle mass is an important task for a rehabilitation medicine and a sporting activities. The aims of the present study were to compare an expression of myogenesis regulators in human skeletal muscle 1) after moderate-intensity resistance exercise with (MI) and without (with blood flow restriction) relaxation (MIWR) and 2) after high-intensity (HI) and MI resistance exercise. **Methods** Seven men adapted to strength training performed three resistance exercise sessions three times on separate days in a randomized order: 1) MIWR (8 x 12 knee extensions without relaxation, 50% 1RM, 7 min recovery), 2) MI (8 x 12 knee extensions, 50% 1RM, 7 min recovery), 3) HI (8 x 12 knee extensions, 75% 1RM, 7 min recovery). The duration of muscle activity during exercise in different sessions was equalized. The venous blood samples were taken before, during and 15 min after exercise sessions for determination of lactate, glucose, cortisol (C), testosterone (T), growth hormone (GH), insulin (I) and insulin-like growth factor 1 (IGF-1) concentrations. The vastus lateralis muscle biopsies were collected before, 40 min, 5 and 22 h after the exercise session and analyzed by qPCR for mRNA expression of IGF-1EA, IGF-1EC (MGF), Myostatin, MyoD, p21 and MyHC-2x. **Results** The lactate concentration after MIWR was 7.9(6.6-8.7) mM that was significantly higher ( $p < 0.05$ ) than after both HI: 5.8(5.0-7.3) mM and MI: 2.6(2.5-4.3) mM sessions. The concentrations of glucose, I, IGF-1 after exercise did not change and did not differ between sessions. The concentrations of C after HI and after MIWR were higher ( $p < 0.05$ ) than after MI. The decrease ( $p < 0.05$ ) of T concentration was found after MIWR only. MIWR led to a decrease ( $p < 0.05$ ) of Myostatin mRNA abundance at 40 min and 22 h of recovery: 0.35(0.23-0.78)- and 0.2(0.01-0.5)-fold relative to initial level, respectively. Myostatin mRNA abundance decreased ( $p < 0.05$ ) 22 h after HI: 0.1 (0.08-0.23)-fold relative to initial level, and did not change during recovery after MI session. Difference ( $p=0.06$ ) of myostatin mRNA abundance was found between HI and MI at 5 h of recovery: 0.6(0.16-1.27)- and 1.3(0.28-6.6)-fold relative to initial level, respectively. MyHC-2x mRNA abundance increased at 5 h of recovery after MIWR: 2.75(0.88-16.7)-fold relative to initial level, and did not change during recovery after HI and MIWR. The expression of IGF-1EA, IGF-1EC (MGF), MyoD and p21 mRNA did not change during recovery and did not differ between exercise sessions as well. **Discussion** The current study demonstrated that in skeletal muscle of men adapted to strength training 1) the decrease of myostatin mRNA abundance after MIWR was comparable with the decrease of myostatin mRNA abundance after HI. 2) Myostatin mRNA expression during recovery was associated with intensity of resistance exercise, if it was performed without blood flow restriction. The work is supported by RFBR grant # 12-04-01668-a.

## PROTEOMIC COMPARISON OF HIGH AND LOW RESPONDERS TO ECCENTRIC EXERCISE

Hody, S.1, Croisier, J.L.2, Leprince, P.1, Wang, F.3, Rogister, B.1

*University of Liège*

Introduction Intense and unaccustomed eccentric exercise can produce muscle damage associated with elevation of muscle protein levels in the blood and development of muscle soreness and stiffness (Howell et al. 1993). It is well documented that the blood level of creatine kinase (CK) after eccentric exercise shows a marked interindividual variability (Clarkson and Ebbeling, 1988). Nevertheless, the reasons for this wide susceptibility are still unknown. The present study compared the muscle proteome of healthy human subjects characterized either by high or low elevation of plasma CK activity after an eccentric protocol. Methods Six untrained men ( $23 \pm 0.9$  y) performed 3 sets of 30 maximal eccentric contractions of the knee extensor muscles of the right leg (on a Cybex Norm dynamometer) at the angular velocity of  $60^\circ \cdot s^{-1}$  and throughout constant motion amplitude of  $100^\circ$ . The plasma CK activity was determined spectrophotometrically before and 24 hours after exercise. Needle biopsies of the rectus femoris muscle were obtained from the volunteers four weeks before (control) and 24 hours after the injuring unilateral protocol. The muscles samples were subjected to a proteomic 2D-DIGE analysis coupled with mass spectrometry protein identification. Results Subjects were classified into HR and LR groups by using the median of the plasma CK activity measured one day post-exercise (5199 IU/l). Mean values of the post-test plasma CK level were significantly different between HR ( $15106 \pm 6359$  IU/l,  $n=3$ ) and LR ( $1203 \pm 1230$  IU/l,  $n=3$ ) groups ( $p < 0.05$ ), with no significant difference in basal values (respectively,  $102 \pm 11$  IU/l and  $129 \pm 22$  IU/l). The proteomic comparison of both groups under control condition revealed that glycolytic enzymes and fast isoforms of contractile or structural proteins were more abundant in HR muscles than those of LR. One day after the eccentric protocol, the HR group showed a differential expression of only four proteins while the LR group presented a modulation of seventeen proteins compared to control condition. Discussion This study suggests that the higher susceptibility of HR muscles to eccentric exercise could be explained, at least in part, by a predominant fast glycolytic phenotype. In addition, the greater number of proteomic modifications observed for the LR subjects could reflect a better ability to adapt in response to lengthening protocol. ## ACE I/D AND ACTN3 R577X POLYMORPHISMS, BODY COMPOSITION AND SOMATOTYPE IN TOP-LEVEL ITALIAN GYMNASTS.

MASSIDDA, M.1, TOSELLI, S.2, BRASILI, P.2, CALO, C.M.1

*1: University of Cagliari (Italy), 2: University of Bologna (Italy)*

Introduction ACE I/D and ACTN3 R577X polymorphisms have been associated with elite athletic status, and recently with differences in muscle strength and power, body fat and bone mineral density in human (Puthuchery et al. 2011; Yang et al. 2011). Purpose The purpose of this study was to analyze the influence of ACE I/D and ACTN3 R577X polymorphisms on body composition and somatotype of elite Italian gymnasts. Methods Nineteen athletes of the Artistic Gymnastic Italian National Team ( $n=10$  males,  $n=9$  females) who were competitive at Olympic levels were genotyped for ACE I/D and ACTN3 R577X. The athletes had been gymnasts for an average of 14.3 years, and they trained for  $31.2 \pm 2.5$  h/week. The analysis was computed for each gender separately. Correlations were computed by mean of Pearson's  $r$  test. Differences between genotypes and phenotypes were determined using one-way analysis of variance (ANOVA). Results None of the tested athletes was deficient for the  $\alpha$ -actinin-3 protein (XX genotype). In females, we found a significant negative correlation between ACTN-3 and triceps skinfold ( $r = -.92$ ), and endomorphy ( $r = -.83$ ). Gymnasts carrying RR genotype showed higher values of body fat parameters than those with RX genotype ( $P = 0.41$ ). ACE polymorphism was significantly correlated with thigh ( $r = .91$ ) and triceps ( $r = .84$ ) skinfolds. Athletes carrying DD genotype showed higher values of skinfolds thickness than those with ID and II genotypes ( $P = 0.17$ ). In males, only the R577X polymorphism displayed a significant correlation with arm ( $r = .74$ ) and thigh ( $r = .80$ ) muscle area (TMA and AMA, respectively), mesomorphy ( $r = .83$ ) and femur diameter ( $r = .81$ ). Particularly, gymnasts with RR genotype showed significant higher values of AMA ( $RR = 85.7 \pm 8.7$  vs  $RX = 72.6 \pm 9.1$  cm<sup>2</sup>;  $P = 0.04$ ) and TMA ( $RR = 200.2 \pm 8.7$  vs  $RX = 178.4 \pm 10.8$  cm<sup>2</sup>;  $P = 0.008$ ), mesomorphy ( $RR = 7.0 \pm 0.5$  vs  $RX = 5.6 \pm 0.5$ ;  $P = 0.002$ ) and femur diameter ( $RR = 9.5 \pm 0.2$  vs  $RX = 8.9$  mm;  $P = 0.02$ ) with respect to those with RX genotype. Discussion Our results suggested a possible effect of ACTN3 on muscle mass in males, while in female gymnasts both genes seem to have a small influence on body fat. In line with other previous researches (Massidda et al. 2009), it can be confirmed that the presence of a functional ACTN3 in fast-twitch muscle fibers might improve the potential to achieve better performance level in male and possibly female gymnasts, while ACE does not seem beneficial for gymnastic performance in both sex. ## MECHANICAL STRETCHING OF ARTIFICIALLY AGED MYOBLASTS IN PHYSIOLOGICALLY RELEVANT 3-DIMENSIONAL BIOENGINEERED CONSTRUCTS

Sharples, A.P., Player, D.J., Martin, N.R.W., Stewart, C.E., Lewis, M.P.

*Muscle Cellular and Molecular Physiology Research Group (MCMPRG), Institute for Sport and Physical Activity Research (ISPAR Bedford), University of Bedfordshire, Bedford, UK.*

Degeneration of skeletal muscle (SkM) with age (sarcopenia) is a major contributor to functional decline, morbidity and mortality. However, it is often difficult to embark on exercise interventions in already frail and diseased elderly individuals. Creating an in-vitro model of in-vivo muscular ageing using three dimensional (3D) bioengineered structures that incorporate a representative extracellular matrix, are under tension and display morphological, histological and transcript expression of mature SkM (Smith et al. 2011) would: 1) More accurately represent a more physiological tissue and; 2) provide greater experimental manipulation to mechanically stretch, perform gene knockdown, chemically inhibit, transfect and introduce pharmacological interventions. Overall, with the aim to elucidate cellular and molecular underpinnings for the deterioration of muscle mass with age and provide future targets for therapy. The present study implemented an already published cellular model that uses 'artificially aged' myoblasts, where multiple population doubled (MPD) murine myoblasts are compared with low population doubled cells (CON) originally used to derive the MPD cells (Sharples et al. 2011). MPD cells have been previously shown to display reduced regeneration in monolayer cultures vs. CON (Sharples et al. 2011) with similar morphology, transcript and signalling processes observed in cells isolated from elderly human muscle (Bigot et al. 2008; Beccafico et al. 2010) and measured in biopsies (Cuthbertson et al. 2005; Leger et al. 2008). Both MPD and CON cells were seeded into 3D type I collagen matrices under uniaxial tension and allowed to attach and differentiate over 14 days. These constructs were then tethered to a custom built ten-

sioning culture force monitor for intermittent mechanical stretching (10% resting length) for 10 reps followed by a 90 secs rest (1 set). 3 sets were completed in total, followed by 3 min rest with the whole cycle repeated 4 times. CON bioengineered constructs, immediately post intermittent loading, had significantly increased transcript expression of IGF-I, IGF-IEa, MGF, myogenin and decreased IGFBP5 vs. MPD constructs ( $P \leq 0.05$ ) that had no change in these transcripts, with the exception of MGF (yet a smaller magnitude increase vs. CON constructs). Interestingly, mechanical stretch in MPD constructs significantly reduced myostatin and TNF- $\alpha$  mRNA expression vs. no-stretch controls ( $P \leq 0.05$ ). In conclusion, CON bioengineered constructs responded positively to the intermittent mechanical stretch with the up-regulation of hypertrophic genes whereas artificially aged constructs had an impaired response. Mechanical stretch also down-regulated genes associated with atrophy in artificially aged constructs. The present study suggests that artificially aged myoblasts in physiologically relevant 3D bioengineered constructs can be used to study exercise induced phenotypes associated with ageing muscle.

##### EFFECTS OF LOAD ON MUSCLE ACTIVATION AND OXYGENATION DURING REPEATED ELBOW FLEXIONS

Sarrazin, S., Baudry, S., Duchateau, J.

*Université Libre de Bruxelles*

Effects of load on muscle activation and oxygenation during repeated elbow flexions Sarrazin, S., Baudry S., Duchateau J. Laboratory of Applied Biology, Université Libre de Bruxelles (Belgium). Introduction The maximal number of repetitions that an individual can perform decreased with the intensity of the load along a non linear function that suggests differences in mechanisms contributing to limit the duration of the effort (Shimano et al. 2006). A possible limiting factor with the increase in load magnitude is the impairment of muscle oxygenation resulting from a progressive reduction in muscle perfusion caused by the increase in intramuscular pressure in response to greater motor unit recruitment (Felici et al. 2009). The present study investigated the contribution of neural adjustments and muscle oxygenation in the maximal number of dynamic contractions performed depending on load magnitude. Methods The task required lifting and lowering a load of 20, 40, 60 or 80% of one repetition maximum (1RM) until failure with the elbow flexor muscles, over a range of motion of 40 degrees. The surface electromyograms (EMG) of biceps brachii, brachioradialis and triceps brachii were recorded. Muscle oxygenation (TOI) and haemoglobin concentration (nTHI) of biceps and triceps brachii were assessed by near-infrared spectroscopy. Results The number of repetitions was greater for the 20% load ( $154 \pm 82$ ,  $P < 0.001$ ) compared with 40% ( $36 \pm 9$ ), 60% ( $20 \pm 6$ ) and 80% ( $8 \pm 3$ ) loads. The EMG of elbow flexor muscles increased during tasks performed with loads up to 60% of 1RM but decreased for the 80% load. The TOI in biceps brachii decreased to a greater extent ( $P < 0.001$ ) for the 80% load (-49.1%) compared with 20% load (-19.9%). Step-wise multiple-regression analyses revealed that factors related to muscle activation limited the number of repetitions for loads up to 60% of 1RM whereas factors involving both muscle activation and oxygenation predicted the maximal number of repetition for the 80% load. Discussion The maximal number of repetitions during repeated contractions against the different loads is mainly limited by neural factors (muscle activation). For load of 80% of 1RM, however, oxygenation appears to contribute also to this limitation. The reduced oxygenation observed at such load may be caused by an increased intramuscular pressure that was high enough to impair muscle perfusion during the lengthening phase of the movement compared with lower loads. In conclusion, these results allow a better understanding of the limiting factors of the number of repetitions during different loadings used in strength training. ##### EFFECT OF FATIGUE OF THE ANKLE DORSIFLEXOR MUSCLES ON BALANCE CONTROL

Booghs, C., Baudry, S., Duchateau, J.

*Université Libre de Bruxelles*

Effect of fatigue of the ankle dorsiflexor muscles on balance control Booghs, C., Baudry, S., Duchateau, J. Laboratory of Applied Biology, Université Libre de Bruxelles (Belgium). Introduction Upright standing involves the integration of afferent information from vestibular, visual, and proprioceptive systems that are modulated depending on the context (Peterka, 2002). For example, a decrease in balance stability is accompanied by a decrease in the amplitude of the Hoffmann (H) reflex indicating a decrease in muscle spindle afferents input at the spinal level (Earles et al. 2000). Moreover, upright stance depends on ankle stiffness generated partly by plantar and dorsiflexor muscles activation. Therefore, changes in the force capacity of the main ankle dorsiflexor muscles could alter balance. The present study investigated the effect of fatigue of the ankle dorsiflexor muscles on balance stability and soleus H-reflex modulation. Methods Eight adults performed 5 sets (1 min apart) of lifting and lowering a load of 30% of their maximum until failure with the ankle dorsiflexor muscles, over a range of motion of 30 degrees. Before and immediately after the fatiguing task, subjects were asked to stand on one leg on a force platform for 90s during which H reflexes and Mmax (maximal M wave) in the soleus were elicited by electrical stimulation of the tibial nerve. Surface electromyogram (EMG) of the soleus, medial and lateral gastrocnemii, and tibialis anterior were recorded during balance and fatigue tasks. Results The fatiguing task reduced the maximal isometric voluntary force of the ankle dorsiflexor muscles (-43%,  $p < 0.001$ ) but did not influence significantly the excursion of the centre of pressure ( $p > 0.05$ ). Immediately after the fatiguing task, the average EMG (aEMG) of the calf muscles was increased (+15%,  $p < 0.05$ ) during the balance task whereas the aEMG for the tibialis anterior did not change. As a consequence, the cocontraction ratio (tibialis anterior/calf muscles) tended to decrease ( $p = 0.08$ ). The soleus H reflex (normalized to the Mmax that did vary after the fatiguing task) was significantly increased immediately after the fatigue task (+23%,  $p < 0.001$ ), as well as the H reflex/Soleus aEMG ratio (+11%,  $p < 0.05$ ). Discussion Even though fatiguing the ankle dorsiflexor muscles did not alter unipodal stability, the results show that stronger calf muscle contractions are required to control balance after fatigue. Moreover, the increased H-reflex/soleus aEMG ratio, while the cocontraction ratio was slightly decreased, might be due to a reduction in reciprocal inhibition from tibialis anterior to soleus immediately after the fatigue task. This study indicates that balance control when the ankle

dorsiflexor muscles are fatigued requires neural adjustments in calf muscle activation to maintain stability. References Earles DR, Koceja DM, Shively CW. (2000). *Int J Neurosci*; 105:1-13. Peterka RJ (2002). *J Neurophysiol*; 88:1097-118.

### **MOTOR UNITS DISCHARGE RATE AND TORQUE VARIABILITY DURING STEADY ISOMETRIC CONTRACTIONS PERFORMED WITH THE DORSIFLEXOR MUSCLES**

Klass, M.1, Jesunathadas, M.2, Enoka, R.M.2, Duchateau, J.1

*Université Libre de Bruxelles; University of Colorado*

Motor units discharge rate and torque variability during steady isometric contractions performed with the dorsiflexor muscles Klass M<sup>1</sup>, Jesunathadas M<sup>2</sup>, Enoka RM<sup>2</sup>, and Duchateau J<sup>1</sup> <sup>1</sup> Laboratory of Applied Biology, Université Libre de Bruxelles, Belgium <sup>2</sup> Department of Integrative Physiology, University of Colorado, USA Introduction The purpose of this study was to record the discharge characteristics of tibialis anterior motor units and torque variability over a range of target torques, (1) to compare them with data obtained in first dorsal interosseus muscle and (2) to improve the ability of a motor unit model to predict experimentally measured torque variability across a wide range of torques. Methods The discharge characteristics of tibialis anterior motor units were measured in one session and the variability in the torque exerted by the foot during steady isometric contractions performed with the dorsiflexor muscles at several target torques was recorded during a second session to avoid fatigue. The discharge times of 44 motor units were recorded from 10 individuals (32.9 ± 6.75 yrs; 9 men) and the variability of ankle dorsiflexion torque was measured from 11 volunteers (30.0 ± 4.71 yrs; 9 men). Results and discussion The coefficient of variation for dorsiflexion torque was significantly less than that for the force exerted by the index finger abduction at targets of 2, 50, 70, and 85% of MVC torque ( $P \leq 0.001$ ). The relative discharge variability of most (55%) motor units of the tibialis anterior decreased exponentially as torque increased above recruitment threshold torque. The mean coefficient of variation for interspike interval for all motor units was  $15.9 \pm 9.61\%$  at recruitment and  $12.2 \pm 4.55\%$  at the greatest torque at which motor units could be identified. The relative discharge variability at recruitment was positively related to the recruitment threshold torque. Although these associations were somewhat similar to those reported for first dorsal interosseus, the discharge rate variability of tibialis anterior motor units was not the main factor contributing to a close approximation between the simulated and experimental coefficients of variation for dorsiflexion torque. The ability of the model to approximate the experimentally observed torque variability over the operating range of the dorsiflexors was achieved only when the relation between motor unit twitch torques and contraction times was changed from a power function to a weak linear relation. These results indicate that the discharge variability of tibialis anterior motor units is of lesser significance in influencing torque variability of the dorsiflexors. ### **PRESERVED DORSAL-FLEXION TORQUE AND FATIGABILITY AFTER CYCLING TO EXHAUSTION IN VARIOUS ENVIRONMENTAL CONDITIONS**

Girard, O., Racinais, S.

*ASPETAR - Qatar Orthopaedic and Sports Medicine Hospital*

Background: Previous studies have demonstrated that plantar flexors are subjected to fatigue after cycling to exhaustion. Although it's possible that fatigue in ankle dorsal flexor also exists, literature is scarce. A question that remains unresolved is also to determine whether the degree of end-exercise fatigue is conditioned by the nature of the environmental challenge. Purpose: To investigate the effect of cycling to exhaustion in conditions of various environmental temperature [neutral (22°C/30%rH) versus warm (35°C/40%rH)] and altitude [sea level (FIO<sub>2</sub> 0.21) versus reduced oxygen content (FIO<sub>2</sub> 0.15)] stress on dorsal-flexion torque and fatigability. Methods: Eleven physically active males cycled to exhaustion at constant workload (66% of their maximal aerobic power) in four different environmental conditions [Neutral/Sea level (Control), Warm/Sea level (Hot), Neutral/Reduced O<sub>2</sub> content (Hypoxia) and Warm/Reduced O<sub>2</sub> content (Hot+Hypoxia)]. Dorsal-flexion torque was measured from brief (5 s) and sustained (2 min) maximal voluntary isometric contractions (MVC) before and 5 min after exercise. Results: Compared to Control (average performance: 66 min and 17 s), time to exhaustion was reduced ( $P < 0.05$ ) in Hot (-35%) and Hypoxia (-36%), while Hot+Hypoxia (-51%) further decreased performance. During brief MVC, there was no significant ( $P > 0.05$ ) main effect of exercise on force production capacity (29.4±1.4, 31.3±2.1, 29.9±1.8 and 27.6±2.0 Nm versus 29.5±1.3, 28.8±1.7, 30.9±2.0 and 29.2±2.5 Nm in control, hot, hypoxia and hot+hypoxia before versus after exercise, respectively), nor any significant effect of temperature or altitude. During the 2 min sustained MVC, torque loss as measured from the onset to the endpoint of the contraction ( $P < 0.001$ ) was similar between all trials (-57%; -59%; -59% and -61% versus -60%; -59%; -52% and -62% in control, hot, hypoxia and hot+hypoxic before versus after exercise, respectively), independently of the environmental temperature or altitude. Conclusion: Combining environmental temperature and altitude challenges alleviate cycling, time to exhaustion performance. However, dorsal-flexion torque and fatigability were affected neither by exercise nor by environmental stress level.

### **ACUTE EFFECTS OF TWO STANDARDIZED WHOLE BODY VIBRATION SESSIONS ON H-REFLEX AND MUSCLE ACTIVATION**

Colson, S.S., Pensini, M.

*University of Nice-Sophia Antipolis*

Introduction A whole-body vibration (WBV) session is characterized by the interaction between the vibration frequency and the peak-to-peak displacement of the platform that determines the WBV acceleration and the load imposed on the neuromuscular system. Although WBV affects neuromuscular performance, it remains unclear whether the effects are due to a modification of spinal reflex excitability because of the discrepant results of the H-reflex reported in the literature (Armstrong et al. 2008; McBride et al. 2010; Ritzmann et al. 2011). Therefore, the aim of this study was to examine the effects of two standardized WBV sessions yielding a similar acceleration on the neuromuscular adaptations of the plantar flexor muscles. Methods 10 active students participated in two randomized interventions. The participants completed a series of 5 bouts (60s of exercise followed by 60s of rest) of unloaded static squatting positions on a vertical vibrating platform. Depending on the intervention, the WBV frequency and peak-to-peak displacement were respectively set at 50 Hz/2mm and 40Hz/4mm. Measurements were performed before and immediately post-intervention. They included maximal voluntary isometric contraction (MVC) of the plantar flexor muscles and electrical stimulation of the tibial nerve for the assessment of maximal voluntary activation, H-reflex, M-wave responses and mechanical twitch. Surface electromyography (EMG) activity was collected from the triceps surae muscle complex. Results No significant difference was observed between the two interventions. MVC, voluntary activation of

the plantar flexor muscles as well as EMG/M-wave values of the triceps surae muscle complex were significantly reduced after the interventions. In addition, doublet peak twitches (at rest and potentiated) were also depressed after the interventions. However, no significant modification of the H-reflex/M-wave ratios was found. Discussion Our data revealed that two WBV sessions with an equivalent maximal acceleration combining a different frequency and peak-to-peak displacement led to identical neuromuscular adaptations of the plantar flexor muscles. Our results also showed that WBV exercise has a depressive impact on MVC and triceps surae muscle's activation. In opposition with previous studies, spinal reflex excitability remained unchanged after our WBV protocols. Within the limits of our experiment, the findings of this study suggest that: 1) the maximal acceleration can be used as an index to quantify the load of a WBV session, and 2) the decrease of MVC observed after WBV exercise is partly ascribable to central activation failure. ### ACTIVATION PATTERNS IN DRAWING ARM MUSCLES AND EFFECTS ON PERFORMANCE IN RECURVE ARCHERS

Eroglu Kolayis, I., Ertan, H., Knicker, A., Soylyu, A.R.

*Sakarya University*

Skill in archery is defined as the ability to shoot an arrow to a given target in a certain time span with accuracy. The discipline is described as a six phase movement in terms of shooting technique by Nishuzono et. al. (1987); Bow Hold, Drawing, Full Draw, Aiming, Release and Follow Through. These phases have details. For example, for collecting good points in the competition; use time effectively, releasing should be stable and same each shooting and strong posture is important. It is investigated to contraction strategies after and before falling of clicker on forearm muscle of archers who have different performance level (Ertan et.al, 2003). The purpose of the study was investigated to activation of drawing arm muscles before and after falling of clicker and the effects on the performance. Methods 4 Female (Age: 28,75+10,5; Training age: 7,75+4,5) and 6 male (Age: 27,6+16,04; Training age: 5+4,24) subject were involved in the study. Each subject participated in one test session and each archer shot 12 arrows and drawing arm Deltoid Posterior, Triceps Brachii, Biceps Brachii, Forearm extensors and flexors EMG activities have been measured in the test. EMG recordings 1 s prior and after the fall of the clicker have been rectified, integrated and normalized. Target scores have been divided in to three section. 10 and 9 as yellow, 8 and 7 as red, below 6 point as blue. iEMG differences among target scores were analysed in one-way ANOVA test. Results According to the results of the study, there were significant differences in Deltoid posterior and Biceps brachii muscle ( $p < 0,05$ ) on the basis of comparisons of the mean values before and after clicker fall. Deltoid Posterior muscle has differences between yellow and blue target scores and red and blue target scores both before and after clicker fall. In biceps Brachii muscle there were statistical differences between red and blue target scores only in before clicker fall. Discussion As a result, differences have been observed in Deltoid posterior muscle in the drawing arm. Deltoid Posterior muscle has an importance for transferring the drawing weight of the bow to the back. In high scores, activity of Deltoid posterior muscle has been increased before clicker fall. But the activity of the Deltoid Posterior after clicker has been increased in low scores. It means that Deltoid posterior activity is important before clicker fall to show good performance and should decrease after clicker. Significant differences in Biceps brachii muscle has been observed between red and blue target scores before clicker fall. It shows that if drawing weight of the bow carried by biceps muscle in drawing arm target points show decrease. References 1. Nishuzono, H. Shibamaya, H. Izuta, T. Saito (1987) "Analysis of Archery shooting Techniques by means of Electromyography. 2. Ertan, H., Kentel, B., Tumer S.T. ### LACK OF ASSOCIATION BETWEEN CHANGES IN MAXIMAL ISOMETRIC JOINT TORQUE AND CHANGES IN MUSCLE SIZE AND ACTIVATION FOLLOWING 10 WEEKS HEAVY STRENGTH TRAINING IN PREVIOUSLY UNTRAINED MEN

Treize, J., Blazeovich, A.J.

*Edith Cowan University*

Introduction Maximising muscle force is pivotal to the success of both sports performances and activities of daily living. Therefore, identifying the mechanisms that drive changes in muscle force is important. Traditionally, increases in muscle size (particularly CSA) and muscle activation have been thought to promote changes in strength. In this case, there should be a clear association between changes in muscle size and activation and changes in strength (i.e. significant  $R^2$  values). Despite a substantial number of studies examining the effects of strength training on changes in muscle strength, these associations are rarely examined. The purpose of the present study, therefore, was to assess the relationship between peak muscle torque, muscle size, and EMG amplitude in previously untrained men. Methods Fifteen untrained men ( $29.5 \pm 5.3$  y) participated in a lower limb heavy resistance training protocol for 10 weeks (total of 20 sessions). The regime included 3 sets of 6 repetitions of leg press, leg extension and hamstring curl exercises. Before and 3-5 days after the training, muscle CSA, unilateral knee torque, peak muscle activity and peak twitch torque were assessed. Torque variables included the maximal voluntary peak torque (PTMVC) and peak potentiated twitch torque (PTTW) as indicators of contractile capacity, torque per cross sectional area (T/CSA) as an indicator of specific torque, and the ratio of the potentiated and unpotentiated twitch torques (TRATIO) to identify possible changes in phosphorylation efficiency of the muscle fibres. Muscle activity was defined by the average quadriceps EMG amplitude (EMGQUAD), antagonist EMG amplitude (EMGGBF) and the vastus lateralis EMG-to-Mwave ratio (EMG/MVL) ratio. Muscle cross sectional area was assessed at 30%, 40% and 50% of the thigh (CSA30, CSA40 and CSA50) using extended field of view ultrasonography. Changes in these variables over time were compared by three separate one-way ANOVAs with repeated measures, and coefficients of determination (linear model) were used to examine associations between the variables. Results Peak torque and muscle size (CSA30, CSA40 and CSA50) increased following training ( $P < 0,05$ ), whilst changes in other measures were not statistically significant but showed substantial inter-individual variability. Changes in muscle size (CSA40 and CSA50) and activation (EMGQUAD) were moderately associated ( $0.27 < r^2 < 0.5$ ).

### COMPARISON OF BILATERAL SYMMETRY IN RECTUS FEMORIS CONTRACTION PROPERTIES BETWEEN ELDERLY AND YOUNG SUBJECTS

Harley, S.

*University of Primorska*

Background: Numerous studies have described the important role of the rectus femoris (RF) in gait and posture. Studies in sarcopenia report that particularly the quadriceps, seems to be affected by age-related loss of muscle mass and a decline in maximum strength. Aim: This study aimed to compare bilateral symmetry of muscle contraction properties of the RF between elderly and younger subjects in

order to better understand the effects of aging on RF function and associated effects on gait and posture. Materials and methods: Thirty nine healthy elderly subjects (mean age  $77 \pm 10$ , BMI  $28 \pm 7$ ) and 50 healthy young subjects (mean age  $29 \pm 5$ , BMI  $24 \pm 4$ ) were randomly selected to participate in the study. Tensiomyography (TMG) was used to measure muscle contraction time (Tc), reaction time (Td), relaxation time (Tr), maximum radial displacement (Dm) and contraction sustain time (Ts). Lateral symmetry was determined as the absolute difference between TMG parameters of the left and right RF. An unpaired t-test was used to determine statistical significance between results obtained from both groups. Results: Significant differences were found for Dm ( $\Delta Dm=5.19$  mm,  $p<0.0001$ ), Td ( $\Delta Td=2.58$  ms,  $p=0.001$ ), Tc ( $\Delta Tc=3.26$  ms,  $p=0.018$ ) and Ts ( $\Delta Ts=34.31$  ms,  $p=0.026$ ) between elderly and young subjects. For lateral symmetry, only Td was found to be significantly different ( $\Delta$  lat Td=1.95 ms,  $p=0.014$ ). Discussion: Previous studies have correlated Dm with muscle strength. The significantly lower Dm scores in the elderly study group indicate a significant loss in muscle strength. The significantly longer Td in elderly subjects may be due to lower potentiation levels and reduction of type II fibres in the RF. The significantly larger lateral differences in Td, found in elderly subjects, may suggest that the left and right RF reach their proper activation level at different times during the stance-to-swing transition and posture responses. Type II fiber atrophy could be associated with the longer Tc in elderly subjects. The significantly longer Ts in the elderly group may be indicative of a shift in muscle fibre composition to a higher type I/type II ratio. Conclusion: Using TMG, significant differences in RF contraction properties between elderly and young subjects were found. These findings are consistent with documented age-related change in muscle function and fibre ratios, attributed to the process of sarcopenia. Although it is not possible to make statements connecting RF muscle function with age-related gait and posture response changes, based on TMG measurements alone, it could be an effective modality in assisting the assessment of the effects of sarcopenia on superficial skeletal muscles and associated changes in posture and gait.

### NEUROMUSCULAR FATIGUE MEASURES AFTER PROLONGED CONCENTRIC - ECCENTRIC ISOKINETIC QUADRICEPS ACTIVITY

Knicker, A.J., Schmieder, Ph., Fricke, H., Edeler, Ch., Rojas, S., Strüder, H.K.

*German Sport University Cologne*

Introduction In experimental protocols fatigue has been studied during isometric contractions or in pre/post fatigue conditions. (Cairns et al. 2005; Knicker et al. 2011). Our study wanted to reveal central and peripheral fatigue during long lasting maximum concentric eccentric contraction conditions for quadriceps muscles in isokinetic mode. Methods 37 healthy male subjects took part in the study. Isometric (ICC) torque, muscle activation, resting twitch responses were measured with the subjects sitting upright on a dynamometer in three different knee angle positions both before and after 50 fatiguing isokinetic (40 deg./s), knee flexions (eccentric) (ECC), knee extensions (concentric) (CCC) at submaximal (75%) effort over a knee angle ROM of 80deg. Bipolar Surface EMG readings were obtained from selected quadriceps femoris muscles during all contraction conditions. Results During ICC the fatigue protocol caused a shift of voluntary and stimulated torque-angle relations towards lower knee angles. Level of activation decreased by app. 36% in the pre / post fatigue comparison with biggest deviations in the most extended knee position. During ECC and CCC a steady decline of mean and maximum torque values could be identified in the course of contractions until a stable level of generated torque was achieved after 20 to 30 repetitions for CCC and 15 to 25 repetitions for ECC. Post fatigue values ranged from 32,4% to 63,6% compared to pretest. Decreased EMG median frequencies for all muscles were identified in the pre – post comparison of ICC in all knee angles and during ECC and CCC in phase to the time course of decline of torque values. Central fatigue was estimated via twitch interpolation under ICC, ranged from 13,7% to 31,3% and was evident in the most extended knee position. Discussion Peripheral and central fatigue effects could be identified as a consequence of the underlying contraction protocol. The exercise protocol caused severe declines of force output which can be attributed to inhibition of MUAPs as the force decrease was accompanied by a pronounced downshift of the EMG median frequency due to a) deteriorated excitation-contraction coupling at cellular level, b) actin-myosin interactions. As the target force output was 75% of maximum effort the muscles compensated the loss of contraction force by recruitment of additional MUs. Central fatigue can develop in all structures above the neuromuscular interface and can also involve motivational aspects. References Cairns, S. et al. (2005). Evaluation of models used to study neuromuscular fatigue. *Exerc SportSciRev*. Knicker, A. et al. (2011). ### EFFECT OF SHORT-TERM CONCURRENT TRAINING ON INTRAMUSCULAR FAT

Ugrinowitsch, C., de Souza, E.O., Roschel, H., Laurentino, G.C., Brum, P.C., Bacurau, A., Tricoli, V.

*School of Physical Education and Sport, University of Sao Paulo*

Introduction Some endurance training methods seem to affect intramuscular fat content. However, less attention has been devoted to unravel the changes in intramuscular fat content when endurance training (i.e. interval training) is combined to strength training (i.e. concurrent training). Thus, the purpose of this study was to test the effects of short-term concurrent training on intramuscular fat stores. Methods Twenty eight participants were divided into a control group (CG – 24.1 $\pm$ 7.1 yrs, 66.5 $\pm$ 5.1 kg, 172.7 $\pm$ 7.1 cm), strength training group (STG – 26.7 $\pm$ 7.1 yrs, 74.5 $\pm$ 21.4 kg, 170.4 $\pm$ 4.9 cm), endurance training group (ETG – 24.1 $\pm$ 7.1 yrs, 66.6 $\pm$ 5.7 kg, 172.7 $\pm$ 7.1 cm), and concurrent training group (CTG – 22.9 $\pm$ 3.6 yrs, 75.7 $\pm$ 10.2 kg, 176.9 $\pm$ 9.5 cm). Intervention groups trained for eight weeks. Quadriceps cross-sectional magnetic resonance imaging, leg press 1RM and VO<sub>2</sub>max were performed pre- and post-training. Intramuscular muscular fat was assessed through spectral analysis of the magnetic resonance image of the vastus-lateralis cross-sectional area. Results STG and CTG increased strength significantly after training compared to the GC and ETG ( $p<0.001$ ). VO<sub>2</sub>max enhanced only in the ETG group after training ( $p<0.05$ ). The cross-sectional area presented a main time effect increasing from the pre- to the post-training assessment ( $p=0.05$ ). There were no significant changes in intramuscular fat content as assessed through spectral analysis of the vastus lateralis muscle cross sectional area from pre- to post-training (CG: 253.2 $\pm$ 12.9 – 264.8 $\pm$ 17.8; STG: 246.4 $\pm$ 16.5 – 258.3 $\pm$ 9.6; ETG – 218.4 $\pm$ 96.3 – 219.4 $\pm$ 112.4; and CTG 260.8 $\pm$ 13.4 – 246.4 $\pm$ 16.5). Discussion The endurance training protocol (i.e. interval training) employed in the present study did not change intramuscular fat stores both in the endurance training and concurrent training groups. Maybe a longer duration and lower intensity endurance exercise program is more effective to change intramuscular fat stores than high intensity interval training. ### MUSCLE MORPHOLOGY AND PERFORMANCE IN SPRINTING, JUMPING AND THROWING

Methenitis, S.1, Zaras, N.1, Stasinaki, A.1, Spengos, K.1, Papadopoulos, C.1, Karampatsos, G.1, Krekoulia, M.1, Krase, A.1, Kavouras, S.2, Georgiadis, G.1, Manta, P.1, Terzis, G.1

1: University of Athens, 2: Harokopio University of Athens

Introduction Sprinting, throwing and jumping are three commonly used human explosive activities (Newton & Kraemer 1994). Performance in such activities relies upon a wide range of muscles' morphological factors (Cormie et al. 2011). Indeed, significant correlations exist between muscle morphology and performance in these activities. However, the impact of each one of these parameters on sprinting, throwing and jumping is not clear. The purpose of the present study was to identify the impact of selected muscle morphological parameters on sprinting, throwing and jumping performance in novice participants. Methods Sixty eight novice males performed in random series the following tests: 60m sprint, countermovement and squat jumps, squat underhand and one-arm standing throws. Body composition was evaluated via dual x-ray absorptiometry. Vastus lateralis (VL) thickness (VLT), pennation angles (VLPA) and fascicle lengths (VLFL) were determined with ultrasonography. Thigh muscles cross sectional area (TMCSA) was estimated with skinfold thickness. VL's fiber type composition was histochemically determined in muscle samples (n=37). Results Pearson's r coefficients revealed low to moderate correlations between performance and morphological factors ( $r$ : 0.246 - 0.783,  $p < 0.05$ ). Canonical correlation analysis revealed higher correlations between the combination of selected morphological factors and sprinting ( $r_c = 0.650$ ,  $p = 0.03$ ), throwing ( $r_c = 0.782$ ,  $p = 0.006$ ) and jumping performance ( $r_c < 0.856$ ,  $p = 0.000$ ). Cross loadings revealed that the order of significance for the muscle morphological factors in sprinting was: lower body lean mass (LLBM; 0.499), VLPA (0.476), TMCSA (0.406), VLT and VLFL (0.386 and -0.387) and % CSA of Type IIX fibers (-0.354), for throwing: LLBM (0.750), body mass index (BMI; 0.721), TMCSA (0.670), VLT (0.511), type IIA % CSA (0.459) and VLFL (0.384), and for jumping: LLBM (0.800), TMCSA (0.534), BMI (0.512), type IIA % CSA (0.439), VLT (0.401) and VLFL (0.392). Discussion It appears that performance in sprinting, throwing and jumping depends primarily on lower body lean mass and secondary to VL's architecture characteristics and fiber type composition. ### NEUROMUSCULAR AND PERCEPTUAL FATIGUE IN ENGLISH MALE HANDBALL PLAYERS DURING INTERNATIONAL COMPETITION

Moss, S.1,2, McWhannell, N.1, Twist, C.1

1: University of Chester; 2: England Handball Association

Introduction Elite handball tournaments require players to compete on successive days with limited recovery time between matches. This scheduling can result in player fatigue, which may have potential consequences on match performance. Therefore, the purpose of this study was to investigate the demands imposed on England squad players competing in the U19 European Open Championships, and the subsequent impact of competition on neuromuscular and perceptual fatigue. Methods Fourteen handball players (age  $17.1 \pm 0.73$  years) competing for England agreed to participate. The tournament consisted of eight matches played over five days, with players competing in two matches on days one, three, and four, and one match on days two and five. Player loading was quantified through measurement of heart rate (HR) during matches and session rating of perceived exertion (sRPE), taken 30 minutes after each match. Neuromuscular function was measured using a maximal 10 m sprint performed after matches one, five, and eight and flight time during a counter-movement jump (CMJ), performed immediately before and after each match. Subjective measures of fatigue, sleep quality, general muscle soreness, stress and mood were monitored daily using a 1 (negative) to 5 (positive) likert scale. Individual component scores were also totalled to give an overall rating of player well-being. Results Average playing time, sRPE and HR during matches was  $20:20 \pm 4:19$  min,  $148.3 \pm 41.6$  AU and  $86 \pm 3\%$  of maximal HR, respectively. Sprint time over 10 m increased during the tournament ( $P < 0.001$ ), with values of  $1.84 \pm 0.7$  s,  $1.89 \pm 0.6$  s, and  $1.98 \pm 0.12$  s, on day one, five and eight, respectively. Similarly, there was a trend for a decrease in CMJ flight time during the tournament ( $P = 0.06$ ). Overall well-being decreased during the tournament ( $P = 0.008$ ), with values of  $20.08 \pm 1.98$ ,  $18.17 \pm 1.53$ ,  $18.17 \pm 1.03$ ,  $17.83 \pm 1.7$  at baseline, day two, four and five, respectively. Analysis of individual components revealed increased fatigue on day four compared to baseline ( $P = 0.04$ ), and increased muscle soreness, which was different to baseline on days two, three, four and five ( $P = 0.001$ ), as well as between day three and day five ( $P = 0.03$ ). Discussion The physiological loading and limited recovery time between matches during an international tournament caused progressive decrements in neuromuscular performance and well-being in English handball players. This information should be used to identify how players fatigue during competition, as well as providing important information for coaches on effective interchange strategies to optimize individual and team performance.

### THE INFLUENCE OF TRAINING AND DETRAINING PERIODS ON FREE HORMONES, BODY DIMENSIONS AND EXPLOSIVE POWER IN YOUNG SOCCER PLAYERS

Moreira, A., Mortatti, A., Arruda, A.F.S., Freitas, C.G., Aoki, M.S., Crewther, B.T.

University of São Paulo, Swansea University, Ceará Federal University.

THE INFLUENCE OF TRAINING AND DETRAINING PERIODS ON FREE HORMONES, BODY DIMENSIONS AND EXPLOSIVE POWER IN YOUNG SOCCER PLAYERS Moreira, A.1, Mortatti, A.5, Arruda, A.F.S.1, Freitas, C.G.1, Aoki, M.S.2, Crewther, B.T. 3, 4. 1: School of Physical Education and Sport, USP (São Paulo, Brazil), 2: School of Arts, Sciences and Humanities, USP (São Paulo, Brazil), 3: Hamlyn Centre, Imperial College (London, UK), 4: Health and Sport Portfolio, College of Engineering, Swansea University (Swansea, UK), 5: Physical Education and Sports Institute, Ceará Federal University (Fortaleza, Brazil). Introduction Some authors have proposed that testosterone (T) helps to signal acute and chronic changes in neuromuscular capacity for explosive performance (Crewther et al. 2011). During puberty, T increases markedly in

boys such that both physical development and performance could be associated with changes in endocrine status (Naughton et al., 2000). However, training factors add to the complexity of understanding the development of young male athletes. Therefore, the study aim was to assess the effect of training and detraining on free hormones, body dimensions and explosive power in elite young soccer players. Methods 26 elite young ( $12.7 \pm 0.2$  yr) soccer players were monitored across a 12-week preparatory training phase, a 7-week competitive and a 2-week detraining phase. Salivary free T and cortisol (C) concentrations, body dimensions and countermovement jump height (CMJ) were assessed before (T1) and after (T2) the pre-season phase, and after the competitive (T3) and detraining phases (T4). As a marker of maturity status, years from peak height velocity (YPHV) was verified. None of the players reached PHV during the study period. Results Salivary T was higher at T4 compared with T2 and T3 ( $p < 0.05$ ), but no significant changes in salivary C were noted. Increments in height and body mass were verified throughout the investigation. We also verified significant increments in CMJ height from T2 to T3, but performance declined after the detraining period (to T1 values). Estimated YPHV changes (nearer from estimated PHV) revealed expected maturational development. Discussion Increases in free T concentrations mirrored expected age-related changes in physical development. The increases in CMJ height and change in years from PHV also coincided with body mass alterations. The detraining phase did not affect morphological and hormonal development, but did influence CMJ performance. Thus, age-related changes in endocrine function and training factors need to be considered in tandem when monitoring youth athletes. References Crewther et al. (2011). *Sports Med*, (41), 103-123. ## HEART RATE AND LACTATE FORMATION DURING FLOOR EXERCISE ROUTINE IN COMPETITIVE YOUNG FEMALE GYMNASTS.

Mattei, C.1, Matta, D.1, Cugusi, L.1,2, Massidda, M.1,3

*University of Cagliari*

**Introduction** The studies of the physiological demands during actual artistic gymnastic (AG) performance are few due to its peculiarities in duration and in nature of activities (Goswami and Gupta, 1998). In fact, the movements performed by females on the four apparatus are characterized by quick postural change causing profound effect on bodily responses (Le Marr, 1983). The aim of this study was to analyze the effects of competitive floor exercise routine on heart rate (HR) and blood lactate (BL) formation in young competitive female gymnasts. **Methods** Ten young gymnasts (mean age  $9.1 \pm 1.4$  yrs) practicing AG at Italian Club were examined. The athletes had been gymnasts for an average of 3.2 yrs, they trained for  $16.2 \pm 1.5$  h/week and they were competitive at National level. The HR (bpm/min) was recorded continuously during a simulation of competition on floor using a telemetric system (Polar Team Pro). All gymnasts performed three floor routine separated each other by four minutes of passive recovery. Three finger prick samples ( $25 \mu\text{L}$ ) for each floor routine were collected and analyzed for BL ( $\text{mmol}\cdot\text{L}^{-1}$ ) before, immediately after, and at 2 minutes (min) of rest period following exercise using a portable lactate analyzers (Arkray Lactate Pro). For the data analysis we have considered the mean parameters' values of the three routine. Results The duration of floor exercise was  $1.26 \pm 2.1$  min. The mean HR during the entire routine was  $176.5 \pm 16.0$  bpm, with mean HR peak of  $191 \pm 18.1$  bpm. For the 42% of the total time of exercise, athletes maintained a very high HR (90-100% of HR max). During the remain time of the floor routine, the HR was comprised between the 80-90% and the 70-80% of the HR max. Gymnasts have produced a low-moderate BL values following each exercise ( $3.2$  to  $5.6 \text{ mmol}\cdot\text{L}^{-1}$ ), that were reverted back to basal values at 2 min rest. **Discussion** Our results showed that cardiovascular load required to young gymnasts during a competitive floor exercise routine is very heavy and it is dominated by anaerobic metabolism. The data suggest the need to develop a training protocol aimed to improve the lactate tolerance of young gymnasts. It would be useful highlight the importance of improve the lactate tolerance specifically if we consider that fatigue in gymnasts is more than a simply metabolic problem, due to its correlation with a higher risk of injuries (Jemni et al., 2003), particularly on floor exercises. **References** Goswami A, Gupta S. ## THE EFFECTS OF POWER BAND PERFORMANCE TECHNOLOGY ON MOTORICAL ABILITIES OF YOUNG SOCCER PLAYERS

Puzovic, V.1, Djordjevic, D.1, Djurovic, M.2, Jakovljevic, V.1

*1 Medical Faculty University of Kragujevac, 2 Football club Red Star (Belgrade, Serbia)*

**Introduction** Athletes are constantly looking for the aids that would help them improve their performance. One of the most popular ergogenic aids is Power Band bracelet. Power Band contains thin polyester hologram, which is broadcasting the natural frequencies associated with the energy field of the human body. According to manufacturer's assertion, it improves balance and muscle strength and flexibility of up to 30%. However, no scientific study confirms this claim. Thus the aim of our study was to investigate the influence of Powerband hologram on balance, flexibility, explosive strength and acceleration of young football players. **Methods** Forty nine football players (age:  $17.4 \pm 1.1$ ) were subjected to: 1) one leg standing balance test, 2) sit and reach test, 3) squat and countermovement jump test and 4) sprint 10, 20 and 30m. Each subject performed each test 3 times: 1) without any bracelet, 2) with placebo bracelet and 3) with Powerband bracelet. Subjects were divided into 2 groups that differed in the order in which they placed bracelets (group A: 1) without bracelet, 2) with placebo bracelet, 3) with Power Band bracelet; group B: 1) without bracelet, 2) with Power Band bracelet, 3) with placebo bracelet) in order to test if warm up and habituation to the task affected results achieved with bracelets. **Results** When wearing both placebo and Power Band bracelet athletes performed better than when not wearing a bracelet in two tests: balance (no bracelet:  $49.60 \pm 5.79$  sec, with placebo bracelet:  $60.04 \pm 6.37$  sec, with Power Band bracelet:  $66.60 \pm 5.99$  sec) and flexibility (no bracelet:  $9.95 \pm 1.12$  cm, with placebo bracelet:  $10.42 \pm 1.11$  cm, with Powerband bracelet:  $10.71 \pm 1.13$  cm). Two way ANOVA repeated measures showed that wearing a bracelet was a factor that influenced results (Power Band vs no bracelet:  $P=0.002$  and  $0.021$  for balance and flexibility retrospectively) and that observed differences in tests results were not dependent on the order in which athletes placed bracelets during performance of tests. **Discussion** Contrary to the results of previously published studies (1-3), our study found that athletes performed significantly better in tests of balance and flexibility when wearing a bracelet. Those effects may be in part based on placebo effect, but the results of Two way ANOVA repeated measures suggests that there may also be the real effect of hologram on athletes energy field. **References** Brice SR, Jarosz BS, Ames RA, Da Costa C. ## ANALYSIS OF LINEARS SPRINTS PERFORMED WITH A DIFFERENT ARRIVAL TASK IN YOUNG SOCCER PLAYERS

Tessitore, A.

*University of Rome*

Analysis of linear sprints performed with a different arrival task in young soccer players Tessitore A., Capranica L., Messina R., Di Giuseppe F., Lupo C., Condello G. Department of Human Movement and Sport Sciences, University of Rome "Foro Italico", Italy. Introduction In soccer, the attainment of maximal speed in an action could be unnecessary due to the tactical demands of the game (Carling, et al., 2008). Instead, more decisive could be the player's ability to perform short accelerations, as well as decelerations with a quick stop (Tessitore et al., 2008). Thus, the purpose of this study was to evaluate the linear sprinting ability of young players on sprints performed with different arrival tasks: flying and quick stop. Methods Following parental consent, 39 Italian U.12 soccer players (born in 2001 and 2002) four straight sprint tests were administered on a 4th generation artificial grass field, with players wearing soccer shoes. Performance was assessed in a single session with the following order: a flying 15-m sprint with timing gates positioned at 5m, 10m and 15m, and 3 sprints at corresponding distances with a quick stop (QS) arrival (5mQS, 10mQS and 15mQS). Players performed two trials of each test, with at least 2min and 5min rest between trials and tests, respectively. Sprint time was recorded to the nearest 0.01s using a telemetric photocells system (Microgate, Bolzano, Italy). The best score was used for statistical analysis. A 2 (condition: flying and quick stop) x 3 (distance: 5m, 10m, and 15m) ANOVA for repeated measures ( $p < 0.05$ ) was applied. A correlation matrix was calculated between tests. Results As expected, main effects ( $p < 0.0001$ ) emerged for condition and distance with faster flying performances (5m=1.31±0.06s, 10m=2.23±0.10s, 15m=3.09±0.16s), with respect to the quick stop ones (5mQS=1.53±0.12s, 10mQS=2.61±0.18s, 15mQS=3.54±0.23s). Differences between conditions were 0.22±0.08s, 0.39±0.11s and 0.44±0.10s for 5m, 10m, and 15m, respectively. High correlations emerged between the three distances in the two conditions (flying:  $r = 0.88-0.98$ ; quick stop:  $r = 0.79-0.81$ ). Between conditions, correlations tended to increase with increasing sprint distance (5m:  $r = 0.72$ , 10m:  $r = 0.80$ , 15m:  $r = 0.90$ ). Discussion In critical match activities such as being first on the ball, moving into space before an opponent, increasing the ability to perform short decelerations with a quick stop can be very helpful for players. The findings of this study demonstrated as the ability showed in a flying sprint tasks is not as closely related with a sprint with a quick stop task, especially on a short distance (5 m). This aspect opens a question about the necessity to train this ability in a specific manner and to assess it. References Carling C, et al. (2008). Sports Med, 38(10): 839-62. Tessitore A, et al. ## ANALYSIS OF COMPETITION IN YOUNG SOCCER PLAYERS BETWEEN 16 AND 18 YEARS OLD

Torres-Luque, G., Cachón-Zagalaz, J., Zagalaz-Sánchez, M.L., Calahorro, F.

*University of Jaén*

Introduction There have been many studies evaluating soccer competition in adults, however, these investigations are limited during formative stages, which usually have a control of heart rate (Stoyer et al., 2004). The aim of the study is to assess physiological and physical demands during a soccer competition between players from 16 to 18 years old, intending to provide a better understanding of competition at these ages. Methods Competition assessment consisted of playing a soccer match among 22 players, assessing temporary structure of the game (TS), heart rate (HR), blood lactate concentration ([BL]) and rate of perceived exertion (RPE). The TS was analyzed with a digital camera after establishing Total Time of the Game (TT), Real Time of play (RT) and Non play Time (NT). Control of HR was measured using a Polar Team 2, identifying minimum HR (HRMin), Mean HR (FCMed), Maximum HR (HRMax) and the percentage of maximal HR (%HRMax). To determine [BL] was carried out lactate analyzer LactatePro, completing 5 tests throughout during the game. Finally, every 10 min of the game there was registered RPE using the Borg scale. Results Results were presented for each period. The TT was 45min 15s, RT was 32min 38s and NT was 12min 53s during First Half. During the second, the TT was 45min 18s, RT 31min 29s, NT 13min 47s. The competition involves an average HR Min of 127,25±18,37 lat/min, HRMed 163,07±7,07 lat/min, HRMax 191,50±7,68 lat/min, %HRMax 80,34 ±3,85. The [BL] and RPE during first half were 4,42±1,63 mmol/l and 14,54±1,57 respectively; and 3,44±1,06 mmol/l and 15,07±1,84 during second half respectively. Discussion It shows an average and maximum intensity similar to Stroyer et al. (2004) and lower % of MaxHR in Castagna et al. (2009). [BL] and RPE data do not appear to players at formative stages. [BL] results are lower compared with adults (Schulpis et al., 2009), however RPE are similar (Clarke et al., 2008). In addition, there is a tendency to increase RPE the second half on the first. It is observed that there is a great utility in using tools, subjective (RPE) and objective (HR and [BL]) to assess requirements for these ages during a soccer competition. ## LONG-TERM PERFORMANCE DEVELOPMENT IN NATIONAL TEAM WOMEN SOCCER PLAYERS DURING THE AGES OF 16 – 21

Sonderegger, K., Tschopp, M.

*Swiss Federal Institute of Sports*

Introduction A certain level of athletic performance is required to become an elite player in women's soccer (1). Some studies with men soccer players show significant development in performance from adolescence to adulthood (2, 3). But no such studies have been conducted for female players. The aim of this longitudinal study was to detect possible changes in anthropometric and physical parameters of elite national team women soccer players from youth to adulthood. Methods Twenty-three members of a Swiss national women's soccer team were tested three times over four years, starting at the age of 16. (U17: age 16.6±0.3, U19: 18.4±0.4, A-Team: 20.7±1.2y). Besides body weight and body height (no body fat measurement), the battery consisted of four physical tests. Speed was assessed with a 40m all-out sprint (t40m) with time measurement intervals of 10m (t0-10m, t30-40m); explosive strength with countermovement jump (CMJ); endurance with the Yo-Yo intermittent recovery test level 1 (YoYo IR1) and trunk muscle strength with a standardised protocol (4). Longitudinal data were analysed with a one-way repeated measures ANOVA (\* $p < 0.05$ ). Results Linear sprinting performance did not significantly improve with increasing age (t40m: U17: 5.99±0.21, U19: 5.97±0.21, A-Team: 5.95±0.24sec). Both time for acceleration (t0-10m) and maximum speed (t30-40m) did not change between the age groups. No significant development was observed in CMJ (U17: 47.3±5.4, U19: 49.1±7.4, A-Team: 49.3±5.3W/kg body weight). YoYo IR1 (U17: 1262±328, U19: 1369±302, A-Team: 1397±346m) as well as trunk muscle strength did not differ among the three measurement points. In contrast, there were significant changes in body weight

(+3.8% from U17 to A-Team), height (+0.5%) and body mass index (+2.6%). Discussion While there were small but significant changes in anthropometric parameters, no significant developments in the measured performance parameters were observed. This contrasts with results in talented men soccer players aged 14 – 18y (2) and aged 12 – 19y (3), which show an improvement in the intermittent endurance capacity and the shuttle sprint performance. Differences in body composition development (increase in fat mass) between men and women in these age groups or differences in training content could explain this. In order to stay in a women's elite national team with a Fifa World Ranking of around 25, maintaining the level of athletic performance one has between 16 and 21 years seems sufficient. ### MAXIMUM AND DYNAMIC STRENGTH DOES NOT DETERMINE SPRINT PERFORMANCE AND VERTICAL JUMP HEIGHT IN YOUNG ELITE FOOTBALL PLAYERS

Li, F.X.1, Bowen, L.1, Taberner, M.2, Ross, F.2, Needham, O.2, Wilson, C.2

1- University of Birmingham / 2- Aston Villa Football Club Academy

**Introduction** Football is often considered an endurance sport; however, strength and power have equal importance in top level performance, as high forces must be generated repeatedly. Power is largely reliant on maximal strength; for example, Wisløff et al. (2004) found that maximum strength half squats determine sprint speed and jump height in elite football players. To date, this relationship has not been tested for in young elite footballers and therefore cannot be generalised to all age groups, as previous data suggests that biological maturity can influence the functional capacity of adolescent football players (Malina et al., 2004). **Aims** The present study aims to examine the relationship of maximal and dynamic strength with sprint speed and jump height in young elite footballers. **Method** Ten young male elite footballers were tested (mean age  $17.2 \pm 0.6$  years, height  $178.0 \pm 6.9$  cm and weight  $71.5 \pm 9.5$  kg). They performed one and three repetition maximum (1RM and 3RM respectively) strength in hexagonal barbell dead lifts, two 10 m and 10 m shuttle run sprints and three vertical jumps. **Results** Regression analyses revealed that 1RM accurately predicts 3RM ( $R^2 = .83$ ,  $p < 0.05$ ). Sprints are also moderate predictors of shuttles ( $R^2 = .54$ ,  $p < 0.05$ ). However, there was no significant relationship between maximal strength or dynamic strength with the sprint and jump variables, or jumps and sprints or shuttles (1RM  $123.0 \pm 20.0$  kg,  $7.1 \pm 1.0$  kg/(kg body weight) $^{0.67}$ ; 3RM  $111.0 \pm 16.8$  kg,  $6.4 \pm 1.0$  kg/(kg body weight) $^{0.67}$ ; vertical jump  $52.3 \pm 7.8$  cm; 10 m sprint  $1.821 \pm 0.1$  s; 10 m shuttle run  $4.229 \pm 0.2$  s). **Discussion** This is the first study to demonstrate that, in top level footballers, the strong correlation of strength with sprint performance and jump height in adults (Wisløff et al., 2004), cannot be replicated in young players. The findings of Malina et al. (2004) suggest that this may be due to the different maturation levels of the players in this study. However further research is needed to establish the precise mechanisms preventing generalisation. Although 1RM and 3RM are strongly related, the explosive power activities are not. This suggests that in young elite footballers, maximal and dynamic strength deadlifts are inappropriate to ascertain sprint, shuttle and jump ability; therefore, an accurate predictor is yet to be established. **References** Malina, R. M., Eisenmann, J. C., Cumming S. P., Ribeiro, B., & Aroso, J. (2004). *Eur J App Physiol*, 91, 555-562. Wisløff, U., Castagna, J., Helgerud, J., Jones, R., & Hoff, J. ### EVALUATION OF PHYSICAL FITNESS IN JUNIOR SOCCER PLAYERS

Torres-Luque, G., Calahorra, F., Cachón-Zagalaz, J., Lara-Sánchez, A.J.

University of Jaén

**Introduction** Monitoring and assessment of physical fitness is currently employed to determine the physical state of soccer players at certain times during the season and it provides control and possible adaptation's of planning and training according to the capabilities of players. The footballer, to yield a competitive level requires a combination of qualities. These physical and functional parameters are essential for performance in competition, requiring adequate levels of endurance, strength, flexibility and speed, along with proper coordination, balance, agility and cognitive ability for taking the right decisions during the game (Reilly et al., 2000). In addition, they argue that it would be interesting to control and monitor these variables during the player's development, as they can determine the future athletic performance at this age of formation. **Methods** 29 players were selected to determine their body composition (Inbody 720), maximum strength in bench press, hamstring flexibility (Sit and Reach test), countermovement jump and Abalakov jump (Platform Muscledab 4000), and maximal oxygen consumption (Course Navette test) during 3 days. For statistical analysis SPSS v.15 for Windows was used. **Results** The following results were found. The body fat percentage and body muscle percentage were  $10.94 \pm 3.09\%$  and  $31.52 \pm 1.55\%$  respectively. There was a maximum volume of oxygen consumption of  $61.60 \pm 2.51$  ml·kg $^{-1}$ ·min $^{-1}$ , a maximal aerobic speed of  $14.48 \pm 0.41$  km/h, a maximum strength bench press of  $66.44 \pm 9.82$  kg, a countermovement jump of  $38.08 \pm 3.70$  cm, an Abalakov jump of  $46.22 \pm 5.00$  cm and a hamstring flexibility of  $24.96 \pm 7.26$  cm. **Discussion** The average values of results indicate similar values or slightly lower values compared to elite for body mass index, body fat percentage, maximum volume of oxygen consumption, Abalakov jump and hamstring flexibility. Results are similar in maximal aerobic speed to amateurs and much higher values for maximum strength bench press in amateurs and lower in countermovement jump and body fat percentage (Stroyer et al., 2004; Le Gall et al., 2008). The results show that group values are similar to those found in the literature for junior and young soccer players. **References** Le Gall, F., Carling, C., Williams, M., Reilly, T. (2008). ### CHANGES IN FIELD TEST RESULTS DURING COMPETITIVE SEASON OF YOUNG SOCCER PLAYERS

Vucetic, V., Sukreski, M.

Faculty of Kinesiology

**Introduction:** Because of the game duration and intensities, soccer is mainly dependent upon aerobic metabolism. The studies have shown that football players at a lower level of aerobic capacity ( $VO_{2max}$ ) have much lower average distance, with a more walking and jogging, while players on the higher level of  $VO_{2max}$  cover more distance by running and sprinting (Verheijen, 1997). In most cases, laboratory tests for assess  $VO_{2max}$  are not available in practice, so we're forced to evaluate aerobic capacity with field tests. Two very common field tests in football are multistage fitness test (MST) and Hoff test (HOFF). Correct training program can improve  $VO_{2max}$ , and guided with this thought, we have asked ourselves if there are any changes in the  $VO_{2max}$  at young football players in competitive season. **Methods:** Twenty young football players (Age= $13.0 \pm 0.2$  yrs; H= $156.3 \pm 1.9$  cm; W= $47.7 \pm 2.3$  kg) were taken from the football school

in Croatia. All subjects performed MST and HOFF, as specific football. Tests are conducted approximately every 3 months, at the beginning and end of the spring and autumn season. Based on the results of the tests we estimate VO<sub>2</sub>max for each player. The ANOVA and the Bonferroni test were used to determine differences in observed variables between the four time points. Results: By analyzing the data we obtained statistically significant differences in VO<sub>2</sub>max in both tests. The result (in finish level) of MST in four time points was (9.0±0.2 at 1st; 9.7±0.2 at 2nd; 9.9±0.9 at 3th and 10.8±0.2 at 4th) and estimate VO<sub>2</sub>max (43.2±0.9 at 1st; 45.9±0.7 at 2nd; 46.9±0.8 at 3th and 49.6±0.7 mlO<sub>2</sub>/kg/min at 4th). The result of HOFF (in m) was (1458.1±24.1 at 1st, 1569.9±26.6 at 2nd, 1524.5±26.0 at 3th and 1576.5±24.4 at 4th) and estimate VO<sub>2</sub>max (ml/kg/min) was (55.8±1.2 at 1st; 61.2±1.2 at 2nd; 59.7±1.1 at 3th and 61.7±1.2 at 4th). The trend of body height and weight was regular for all 4 measurements (H1=156.3cm; H2=160.8cm; H3=162.8cm; H4= 167.5cm; W1=47.8kg; W2=18.7kg; W3=162.8kg; W4=167.5kg). Conclusion: Based on the test results we can conclude that change in VO<sub>2</sub>max in young footballers is statistically significant. Although we can see the difference in VO<sub>2</sub>max between MST and HOFF, which is probably a consequence of specific movement structures of HOFF, we can see a trend of growth in one and another for approximately 10.5%. In this study raises the question how great the impact of the growth and development on VO<sub>2</sub>max is and how great is the impact of training on VO<sub>2</sub>max. ### STEP FREQUENCY AND RUNNING SPEED IN YOUNG FOOTBALL PLAYERS

Bonfanti, L., Di Palo, G., Arcelli, E., Alberti, G.

*Università degli Studi di Milano*

Introduction Speed is a necessary skill in different sports: its different use is established by technical and physiological model of specific sports. Speed can be considered as a quality influenced by three expressive attitudes that determine the performance: muscular strength, technique and rhythm (1). Literature showed that highest speeds are the best compromise between steps frequency and length (2). The purpose of this study is to check, in young amateur soccer players, whether steps frequency improvements, after a specific workout protocol, could increase the speed in short sprint ability. Methods 29 male young amateur football players (12.43 ± 1.7 years) have been evaluated, splitted into three groups by age: 2000 (G00), 1999 (G99), 1998 (G98). Running speeds (RS), tested by Polifemo photocells and Racetime (Microgate, Bolzano, Italy), and step frequency (SF), evaluated with video analysis by camera at 50 Hz, were assessed. Three tests were performed on 30m distance, with 3 minutes of recovery, in two non-consecutive days, before and after a specific training protocol to improve step frequency. All data were analyzed with Student's t-test for paired data on SPSS v.15 software, and P<0.05 was chosen as the significant rate. Results Maximum values of SF significantly increased of 5% (p<0.01), in particular in G98 (8% and p<0.001). Also the average values of SF significantly increased of 3% (p<0.05), and G98 of 8% (p<0.001). Finally, RS significantly raised of 1% (p<0.05), G98 in particular improved the speed performance of 3% (p<0.001). Discussion Like other studies that have analyzed greater distances (2), this study indicates that a specific training can improve step frequency and speed in short sprint ability. Therefore, to improve short sprint ability, it would recommended to include training of the step frequency in workout plans for young football players. ### EFFECT OF MATCH PLAY ON GROIN INJURY RISK FACTORS IN YOUNG SOCCER PLAYERS

Paul, D.1, Whiteley, R.2, Marques, J.1, Nassis, G.P.1

*ASPETAR-Qatar Orthopaedic and Sports Medicine Hospital*

Introduction The propensity of groin injuries (1.0-1.1 per 1000 playing hours, accounting for 11 to 16% of all soccer injuries) among soccer players has stimulated much interest in the research and applied domain. Risk factors include age, high level of play, previous injury, amongst others (Engebretsen et al., 2010). However, there is limited data pertaining to the effects of match load on groin injury risk factors such as strength and flexibility. Therefore, the aim of present study was to 1) determine the reliability of hip flexibility and strength measures, and 2) identify the effects match play load has on these measures. Method Sixteen elite national level youth team soccer players (15-17 years old) performed strength (adduction and abduction) and flexibility (bent knee fall out test) measures on 2 separate occasions 24hr apart. Reliability was evaluated with the Intraclass Correlation Coefficient (ICC). The same players repeated these tests ~9hrs before and 14hrs after an international friendly match. Minutes played x rate of perceived exertion was used to quantify match play load (Foster et al., 1996). Statistical analysis was performed with paired T-test. Results A moderate ICC was reported for right (0.610) and left leg (0.551) flexibility measures. A low ICC was found for adductor and abductor strength for both legs. Left leg flexibility deteriorated significantly from before to after the match (pre: 16.8±5.3, post: 19.8±5.1cm, mean±SD, p=0.01). A similar trend was shown for the right leg (pre: 17.3±5.1, post: 18.4±5.7cm, p=0.09). An exponential relationship was found between match load and changes in flexibility for the left leg (R<sup>2</sup>=0.26). Discussion The main findings of this study were 1) reliability was moderate for flexibility and low for strength, and 2) a decrease in flexibility was found as a result of match play. With regards to the first finding, it seems greater familiarisation is needed to improve strength test reliability. Despite no evidence of a linear correlation between match load and flexibility measures, it seems that there might be a match load threshold after which flexibility is negatively affected. However, this warrants further investigation using direct recording of match activity (e.g., distance) or physiological load (e.g., time x heart rate). In conclusion, given the time constraints and logistical issues surrounding strength testing, groin flexibility might be a sensitive and reliable measure to detect changes as a result of fatigue. **THE RELIABILITY OF MUSCLE OXYGEN SATURATION AND BLOOD VOLUME CHANGES DURING CONTINUOUS AND INTERMITTENT RUNNING EXERCISE**

Ihsan, M., Watson, G., Lipski, M., Abbiss, C.R.

*Edith Cowan University*

THE RELIABILITY OF MUSCLE OXYGEN SATURATION AND BLOOD VOLUME CHANGES DURING CONTINUOUS AND INTERMITTENT RUNNING EXERCISE Ihsan, M.1, Watson, G.1,3, Lipski, M.2, Abbiss, C.R.1: 1: ECU (Joondalup, Australia), 2: GSU (Cologne, Germany), 3: UTAS (Tasmania, Australia) Introduction Near infrared spectroscopy (NIRS) is often used to determine muscle oxygen saturation and blood volume changes during continuous exercise. We are unaware of any study that has established the reliability of NIRS in vastus lateralis (VL) during continuous (CR) and intermittent (INT) exercise. The purpose of this study was to determine the test-retest reliability of muscle oxygen saturation and blood volume responses during CR and INT running. Methods On two occasions, ten subjects performed 30 min of CR at 70% of maximal aerobic speed (MAS), followed by 10 bouts of INT at 100% of MAS. Oxygenation (TOI) and blood volume (tHb) changes in VL were monitored using NIRS. Mean TOI (TOI-Av) and the difference in TOI amplitude change (TOI-Diff) during CR were determined. Muscle de-oxygenation and re-oxygenation rates during INT were determined with (Deoxy-TD, Reoxy-TD) and without (Deoxy, Reoxy) time delay in de-oxygenation (TD-WI) and re-oxygenation (TD-RI). tHb decline (tHb-DR) and recovery rate (tHb-RR) during INT were also determined. The intraclass correlation coefficient with 90% confidence intervals (ICC, 90% CI) and coefficient of variation (CV, %) were determined. Results The reliability of TOI-AV (ICC; 0.90 (0.71-0.97), CV; 3±2%) during CR was better than TOI-Diff (ICC; 0.75 (0.38-0.91), CV; 23±17%). The reliability of Deoxy and Deoxy-TD were similar (Deoxy; ICC; 0.88 (0.67-0.96), CV; 9±7% vs Deoxy-TD; ICC; 0.86 (0.61-0.95), CV; 9±7%). However re-oxygenation rates were more reliable when TD was accounted for (Reoxy-TD; ICC; 0.94 (0.80-0.98), CV; 12±7% vs Reoxy; ICC 0.68 (0.19-0.88), CV; 16±14%). Mean TD-WI (ICC; 0.89 (0.68-0.96), CV; 8±6%) and TD-RI (ICC; 0.85 (0.60-0.95), CV; 6±6%) were moderately reliable during INT. The tHb response during CR (tHb; ICC; 0.96 (0.88-0.99), CV; 7±4%) and INT (tHb-DR; ICC; 0.98 (0.93-0.99), CV; 6±6%, tHb-RR; ICC; 0.97 (0.90-0.99), CV; 7±6%) showed moderate reliability. Discussion Results of this study indicate that TOI and  $\Delta$ tHb during CR are moderately reliable (CV= 3-23%; ICC=0.75-0.90). These results are similar to that reported in the gastrocnemius during running at lactate threshold (R=0.87) and at VO<sub>2</sub>max (R=0.88) (Austin et al., 2005) but considerably lower than in bicep brachii during arm cranking exercise (CV=22-36%) (Muthalib et al., 2010). The reliability of  $\Delta$ tHb and the TD of de-oxygenation and re-oxygenation during INT, which have not previously been investigated, were also moderate (CV= 6-15%). **THE RELATIONSHIP BETWEEN PEAK MUSCLE OXYGEN CONSUMPTION AND MUSCLE OXYGENATION RECOVERY TIME AFTER SUBMAXIMAL EXERCISE**

Ichimura, S., Moriguchi, T.

*Tokyo University of Science*

Purpose We investigated the relationship between pulmonary and muscle oxygen consumption (mVO<sub>2</sub>) and the muscle oxygenation recovery time after exercise to establish a convenient method with less onerous for subjects during estimating the muscle oxygen capacity. Methods Subjects were seven healthy male volunteers (age 26±6yrs; height 169.4±6.7cm; weight 66.0±9.3kg) performed the dynamic knee extension and cycling exercise with stepwise incremental load method. The exercise load during dynamic knee extension exercise was started at 24watts and increased by 12watts every 6 minutes including 3 minutes recovery time (3min Ex + 3min Rec). That during cycling exercise was started at 60watts and increased by 30watts every 6 minutes within 3 minutes recovery time. The each exercise was performed until the subjects reached exhaustion and was performed the twice to evaluate the mVO<sub>2</sub> and muscle oxygenation recovery time, respectively. Pulmonary O<sub>2</sub> uptake and CO<sub>2</sub> output (AE-280, Minato) and muscle oxygenation at the vastus lateralis using near-infrared spectroscopy (HEO-200, Omron) were measured. We performed arterial occlusion on upper thigh proximal to the measurement sites before the start of the exercise for 3 minutes and repeated arterial occlusion immediately after each exercise load for 1 minute to evaluate the mVO<sub>2</sub> at rest and during each exercise load during estimating the mVO<sub>2</sub> (Hamaoka et al. 1996 JAP). The muscle oxygenation recovery time was evaluated the using the half recovery time of muscle oxygenation (T<sub>1/2</sub>reoxy) (Ichimura et al. 2006). Results Pulmonary O<sub>2</sub> uptake, CO<sub>2</sub> output and mVO<sub>2</sub> were increased with the increased load during dynamic knee extension exercise and cycling exercise. In dynamic knee extension exercise, the value of CO<sub>2</sub> output was significantly higher than that of O<sub>2</sub> uptake during 63% of peak workload. In cycling exercise, the value of CO<sub>2</sub> output was significantly higher than that of O<sub>2</sub> uptake during 73.7% of peak workload. T<sub>1/2</sub>reoxy in dynamic knee extension exercise and cycling exercise were not significant increased since 63% and 73.7% of workloads, respectively although the increase of the T<sub>1/2</sub>reoxy observed with increased load. In dynamic knee extension exercise, there was an inverse correlation between the peak mVO<sub>2</sub> and the T<sub>1/2</sub>reoxy after peak workload exercise (r=-0.849, p<0.05). It was observed the tendency of an inverse correlation between the peak mVO<sub>2</sub> and the T<sub>1/2</sub>reoxy during 63% of peak workload (r=-0.726, p=0.06). In cycling exercise, the inverse correlation between the peak mVO<sub>2</sub> and the T<sub>1/2</sub>reoxy after peak workload exercise (r=-0.881, p<0.05) and 73% of peak workload exercise (r=-0.823, p<0.05) were observed. The value of peak oxygen uptake also inverse correlated with T<sub>1/2</sub>reoxy after peak workload exercise (r=-0.941, p<0.01) and 73% of peak workload exercise (r=-0.930, p<0.01). Conclusion We found that the T<sub>1/2</sub>reoxy after maximal exercise relate to the peak mVO<sub>2</sub>, as well as that after submaximal exercise intensities corresponding to the ventilator threshold.

### COMPARISON OF POST-EXERCISE CHANGES IN OXIDATIVE STATUS IN UNTRAINED MEN IN RELATIONSHIP TO FAT CONTENT IN THEIR BODIES

Szygula, Z., Wiecek, M., Maciejczyk, M., Szymura, J., Wiecha, S.

*University School of Physical Education, Krakow*

**Introduction** The elevation of metabolism during exercise leads to enhanced production of free radicals resulting in oxidative stress and damage of cellular constituents. **Aim** The aim of the study was to compare post-exercise changes in oxidative status of plasma in untrained men in relation to the fat content in their bodies. **Methods** Participants: Fourteen untrained non-smoking, healthy men (18-25 yrs old) participated in this study. Body composition and percentage of body fat (PBF) were assessed by the means of bioimpedance device (Jawon Medical Body Composition Analyzer Model ioi 353, Korea) as well as by skinfolds measurements. According to PBF participants were divided into two groups with different body composition: HF – high fat (n=5): PBF = 22.9±2.28%; LBM = 81.66±2.85; VO<sub>2</sub>max = 51.77±5.49 ml/kg/min and NF – normal fat (n=8): PBF 16.04±2.17%; LBM = 60.79±1.2; VO<sub>2</sub>max = 55.44±6.77 ml/kg/min. **Exercise test:** Each participant performed an incremental exercise test on the mechanical treadmill (model) till exhaustion. They started with initial speed of 7 km/h and every 2nd min speed increased by 1.2 km/h. Ventilatory variables such as VE, VT, fR, VO<sub>2</sub>, RQ, and HR were monitored using ergospirometer Medikro-919 (Medikro Oy, Finland). **Blood analysis:** Venous blood samples were collected before and 3 min after exercise. The total oxidative status (TOS), the total antioxidative status (TAS), and lactates concentration were measured in blood plasma using commercially available kits. **Statistical analysis:** Data were expressed as the mean ± SD. Statistical analysis was performed using nonparametric U Mann-Whitney and Wilcoxon tests. The relationship between measurements were tested using the Spearman rank test. Significance was defined as P<0.05. **Results** Statistically significant increase in TOS was observed in both groups after exercise – by 34.2% in group HF and by 29.2% in group NF, whereas an increase in TAS was only minor, by 3.5% and 2.1% in both groups HF and NF respectively. Post exercise values of TAS were statistically greater in group HF comparing to NF. A negative correlation was observed between VO<sub>2</sub>max and post exercise values of TAS (r=-0.57) and positive correlation between PBF and TAS before (r=0.59) and after physical effort (r=0.85). There were no correlations between changes (deltas) of TAS, TAS and PBF. **Conclusions** Physical effort caused significant increase of total oxidative status in both groups, however, the increase was more pronounced in group of people with greater amount of fat in their organisms. The study was financed by NCN; project No N N404 071240

### THE EFFECTS OF CHEST WALL RESTRICTION ON CARDIO-RESPIRATORY RESPONSES, MUSCLE DEOXYGENATION AND PERFORMANCE DURING MAXIMAL EXERCISE

Ishida, K., Katayama, K., Iwamoto, E., Sugiura, H., Hotta, N.

*Nagoya University*

**The Effects of Chest Wall Restriction on Cardio-respiratory Responses, Muscle Deoxygenation and Performance during Maximal Exercise** Ishida, K. 1, Katayama, K. 1, Iwamoto, E. 1, Sugiura, H. 2, Hotta, N. 3 1: Nagoya University (Nagoya, Japan), 2: Nagoya Isen (Nagoya, Japan), 3: Chubu University (Nagoya, Japan) **Introduction** Sometimes while playing sports people have to wear tight fitting equipment or clothing around their chest (e.g. scuba diving, fencing, and kendo). Additionally, patients with restrictive ventilatory impairment and athletes suffering from chest and back pain, who wear corsets, also do exercise. In all of these cases, the movements of the chest wall are restricted to the point that respiration and circulation should be affected during exercise. Only a few investigators (O'Connor et al. 2000, Coast et al. 2002) observed the effects of chest wall restriction on maximal exercise, and they could not reveal the physiological background. The purpose of the present study was, therefore, to elucidate the effects of chest wall restriction on endurance performance, and cardio-respiratory responses and deoxygenation during incremental exercise to exhaustion. **Methods** Nine male subjects performed maximal exercise to exhaustion (MAX) under chest wall restriction (CR) and non restriction control (NR) conditions. CR was achieved by tightening 3 non-stretch fiber belts (5 cm wide) with the traction of 5 kg around the subjects' chest. We confirmed that this restriction caused more than a 30% decrease in the vital capacity of the subjects. In both the CR and NR conditions, the subjects performed cycling exercise tests with an incremental load until exhaustion (start: 20W, 20 W/2 min increase). During exercise we measured oxygen uptake (VO<sub>2</sub>), minute ventilation (VE), tidal volume (TV), respiratory frequency (fr), heart rate (HR), tissue oxygen saturation (SpO<sub>2</sub>), blood lactate concentration (La), and muscular deoxygenation levels by near-infrared spectroscopy. **Results and Discussion** We found that under CR conditions, as compared with NR, 1) peak VO<sub>2</sub> and endurance time were less by about 9%, indicating decrease in maximal performance, 2) VE was greater at the sub-maximal exercise, but the maximal value was lower, 3) TV was less while fr was higher throughout the experiment, 4) SpO<sub>2</sub> became less at a higher exercise intensity during MAX, 5) HR was higher at exhaustion, 6) the muscle deoxygenation rate estimated by near-infrared spectroscopy only tended to decrease more, 7) La was less at the maximal value in MAX, but showed no difference during sub-maximal exercise. These last two data may suggest little involvement of peripheral functions. **Conclusion** These results indicate that endurance performance should be decreased by CR, and this would be attributed directly to impaired respiration due to CR, not to peripheral factors. **References** O'Connor S, McLoughlin P. et al. ### RAPID CARDIOVASCULAR RESPONSES TO BREATH-HOLDING DURING EXERCISE

Perini, R., Capogrosso, M., Donati, S., Sivieri, A., Ferretti, G.

*University of Brescia*

**Introduction** Breath-holding induces a rapid cardiovascular adjustment, eliciting a decrease in heart rate (HR) and a slight but significant increase in blood pressure (BP) within the initial 30 s of both dry and immersed apnea. These responses have been ascribed to augmented vagal and sympathetic activity, respectively. The level of activity of the autonomic nervous system prior to apnea may nevertheless affect the initial cardiovascular responses to breath-holding. Thus, since vagal and sympathetic activities are modified during muscular work compared to rest, we tested the above hypothesis by investigating the HR and BP time courses of short apneas during exercise. **Methods** 8 divers (age 36±7 yrs) performed two apneas, each lasting 30 s: A) sitting at rest; B) pedaling at 30 W on a cycle-ergometer. BP profile was continuously recorded (photo-plethysmography, Portapres) and beat to beat values of systolic and diastolic pressures (Ps and Pd) and HR were obtained. Metabolic rate was measured before and after apnea by a metabolic cart. **Results** A) HR progressively decreased from 98±11 b/min, i.e. about 20 b/min above control value (ctrl), to 83±13 b/min. Both Ps and Pd dropped after 5±1 s, respectively, by 52±14 mmHg and 18±4 mmHg, returning in the following 7-8 s to ctrl (Ps: 140±11 mmHg; Pd: 70±8 mmHg). Then, Ps did not change further, while Pd increased by 14± 6 mmHg (p<0.05). B) metabolic rate was twice as at rest and HR was 18±13 b/min above ctrl. HR did not change throughout the initial 21±5 s of apnea, remaining stable at 113±9.5 b/min (i.e. 15 b/min above exercise steady state

values). Then, HR slightly decreased by 10-12 b/min. Ps and Pd decreased by  $71 \pm 13$  mmHg and  $22 \pm 8$  mmHg, respectively, after  $3 \pm 1$  s, recovering initial values at about 10 s. Then, while Ps remained stable, Pd progressively increased by  $16 \pm 8$  mmHg ( $p < 0.05$ ). Discussion Chronotropic cardiac response to breath-holding was significantly delayed in exercise apnea, possibly due to the reduced vagal tone prior to breath-holding. On the other hand the increase in BP was not different in the two conditions, suggesting similar circulatory responses. These findings are consistent with the hypothesis of separate cardiac and vascular control at the beginning of apnea. The very rapid drop in BP systematically found in the first seconds of apnea is probably expression of the reduction in venous return due to breath-holding.

### **INFLUENCES OF DIAPHRAGM FATIGUE ON MUSCLE SYMPATHETIC NERVE ACTIVITY AND BLOOD PRESSURE DURING SUBMAXIMAL EXERCISE**

Katayama, K., Iwamoto, E., Ishida, K., Koike, T., Saito, M.

*Nagoya University*

**Introduction** It has been reported that high intensity whole body exercise elicits diaphragm fatigue (Romer et al., 2008). The fatiguing diaphragm affects cardiovascular regulation and blood flow distribution during heavy exercise (Dempsey et al., 2008). However, it is still unclear whether diaphragm fatigue leads to alterations in sympathetic nerve activity and blood pressure (BP) during submaximal exercise. The aim of this study was to elucidate the influences of inspiratory muscle fatigue on sympathetic vasoconstrictor outflow and blood pressure during dynamic leg exercise. **Methods** Seven males participated in this study. On day 1, to estimate peak oxygen uptake ( $VO_{2peak}$ ), a maximal exercise test was performed using a cycle ergometer in a semi-recumbent position. On day 2, the subjects performed two 10 min exercises at 40% $VO_{2peak}$  (spontaneous breathing for 5 min and with or without inspiratory resistive breathing for 5 min). Before and immediately after exercise, maximal inspiratory pressure (P<sub>I</sub>max) as an index of inspiratory muscle strength was estimated. On day 3, the subjects performed two 15 min exercises at 40% $VO_{2peak}$  (spontaneous breathing for 5 min, with or without inspiratory resistive breathing for 5 min, and spontaneous breathing for 5 min). During exercise, muscle sympathetic nerve activity (MSNA) and BP were measured. MSNA was recorded via microneurography of the right median nerve at the elbow. Results P<sub>I</sub>max decreased significantly following exercise with resistive breathing, but not without resistance. A progressive increase in MSNA occurred during exercise with inspiratory resistance, accompanied by an augmentation of BP. Discussion A decrease in P<sub>I</sub>max occurred after exercise with inspiratory resistance. The decreased inspiratory muscle strength would be the principle cause of diaphragm fatigue. The diaphragm has an abundance of type IV metaboreceptors, and fatiguing the diaphragm via phrenic nerve stimulation caused an increase in type IV afferent discharge. Furthermore, when metaboreceptors in the diaphragm were stimulated electrically, pharmacologically, or with local lactic acid infusions, efferent sympathetic nerve activity increased and vascular conductance decreased in selected vascular beds. In the present study, the time-dependent increase in MSNA and BP appeared during exercise with resistive breathing. Consequently, these results suggest that the fatiguing diaphragm, and thereby the metaboreflex, has a powerful influence on sympathetic vasoconstrictor outflow during exercise. **References** Dempsey JA, Amann M, Romer LM, Miller JD. ### **PHYSIOLOGICAL BREATH-HOLD BREAKING POINT DURING REPEATED APNEAS IN YOUNG ANEMIC WOMEN**

Triantafyllou, D.

*National & Kapodistrian University of Athens*

**Introduction** Breath-hold time (BHT) consists of an "easy going" and a "struggle" phase separated by a physiological breaking point (PBP) denoting the onset of involuntary ventilatory activity (IVA) (Dejours 1965). Repeated apneic attempts with short intervals improve BHT due to prolongation of both phases (Schagatay et al. 2000). Apnea elicits cardiovascular changes [bradycardia, rise in mean arterial pressure (MAP) and total peripheral resistance (TPR)], known as "diving reflex" (Schagatay et al. 1998). We studied the effect of repeated apneas on BHT, PBP and cardiovascular response during apnea in young women with normal (C) and low (An) hemoglobin concentration ([Hb]). **Methods** Two groups of young ( $20.6 \pm 2.6$  yrs) physically active women, 8 with normal [Hb] ( $12.9 \pm 0.2$  gr/dl), Fe and ferritin levels and 8 with mild iron-deficiency anemia ([Hb]:  $11.3 \pm 0.1$  gr/dl) with no previous diving experience were studied at early follicular phase. Subjects performed 5 apneas with face immersion in cold water ( $12^\circ\text{C}$ ) separated by 2-min rest. BHT, breathing movements via respiratory muscle EMG (BIOPAC) and cardiovascular parameters (Finometer) were recorded during the experimental protocol. Results BHT was similar in the 1st (A1) as well as in the 5th (A5) apnea in An and C, and it was improved by repeated apneas similarly in the two groups (by 23 sec in average from A1 to A5;  $p < 0.01$ ). The PBP, expressed as a percentage of total BHT, was not different in C at A1 (68.4%) and A5 (72.1%), whereas in An it occurred earlier at A5 (56.5%) compared to A1 (74.6%). Despite that An had lower arterial oxygen content (CaO<sub>2</sub>) than C (An:  $14.8 \pm 0.3$  gr/100ml, C:  $17.2 \pm 0.3$  gr/100ml) the two groups did not differ at heart rate, MAP and TPR during the course of 5 apneas. **Discussion** Both control and mildly anemic subjects improved BHT during repeated apneas, but this was achieved differently by the two groups; An exhibited the PBP earlier during the 5th apnea but they could tolerate the struggle phase for longer, thus managing during that last apnea to achieve BHT similar to that of C, who did not change their PBP during the series of the 5 apneas. Moreover, although it has been suggested that anemia modifies cardiovascular regulation especially under stressful conditions (Calbet et al. 2006), the mild level of anemia used in the present study did not affect the magnitude of diving reflex during apnea. **References** Dejours P. ### **DIFFERENCES IN LOCAL AND TOTAL OXYGEN CONSUMPTION DURING INCREMENTAL CYCLING EXERCISE**

Skovereng, K., Ettema, G., van Beekvelt, M.

*Norwegian University of Science and Technology*

**Introduction** The human body depends heavily on oxidative metabolism, which makes the study of oxygen consumption ( $VO_2$ ) an important and interesting field of research. Measurement of whole body  $VO_2$  has been done extensively, but does not necessarily reflect the energy expenditure within the active muscle(s). Measuring local  $VO_2$  is more complicated and has been studied to a far less extent, but several previous studies have reported differences between  $VO_2$  in the local muscles and the whole body during exercise (1, 2). The purpose of this study was to investigate changes in total and local  $VO_2$ , measured simultaneously with pulmonary gas exchange and near-infrared spectroscopy (NIRS) during cycling exercise at various constant-load work rates. **Methods** 18 trained male subjects

(VO<sub>2</sub>peak 55.9 ± 4.5 ml/kg/min) performed an incremental exercise protocol on a cycle ergometer with 5-6 workloads of 5 minutes, until exhaustion. NIRS was used to measure changes in oxyhemoglobin and deoxyhemoglobin in the right vastus medialis and vastus lateralis muscles during cycling and was used in combination with a short-duration vascular occlusion in order to calculate local muscle VO<sub>2</sub>. In order to compare local and whole body VO<sub>2</sub>, values were normalized to percentage of peak values. Results While whole body VO<sub>2</sub> increased linearly with increasing work rate, local VO<sub>2</sub> in both muscles showed a different time response. A significantly faster initial increase in local VO<sub>2</sub> was seen at lower work rates (from 100 W to 150 W) when compared to the increase in whole body VO<sub>2</sub> ( $p < 0.001$ ), while at higher work rates (200-300 W), the increase in local VO<sub>2</sub> leveled off and was significantly lower than that of whole body VO<sub>2</sub> (200-250W:  $p < 0.01$ , 250-300W:  $p < 0.001$ ). Discussion/Conclusion The main finding of the present study was a significantly different effect of work rate on local VO<sub>2</sub> as compared to that of whole body VO<sub>2</sub>. The steep initial increase in local VO<sub>2</sub> of both vastus medialis and vastus lateralis muscles indicate that they are probably two of the primary contributors to the total work rate at low intensity. During the increase to high intensity, no additional increase in local VO<sub>2</sub> is seen, which might indicate that although the vastii are remaining active, they probably reached their maximum VO<sub>2</sub> and the increased work rate may have been met by increased contribution from other muscles (e.g. hamstrings and gluteals) and anaerobic metabolism. However, measurements of additional muscles are necessary for a more definitive conclusion. The results of the present study indicate that caution should be taken when interpreting whole body VO<sub>2</sub> as an indication of what happens in the local muscles. ### THE INFLUENCE OF ROWING-RELATED POSTURES UPON RESPIRATORY MUSCLE PRESSURE AND FLOW GENERATING CAPACITY

Griffiths, L., McConnell, A.

*University of Worcester*

THE INFLUENCE OF ROWING-RELATED POSTURES UPON RESPIRATORY MUSCLE PRESSURE AND FLOW GENERATING CAPACITY Griffiths, L.I., McConnell, A.2. 1: UW (Worcester, UK), 2: BU (Uxbridge, UK) Introduction During the rowing stroke, the respiratory muscles are responsible for postural control, trunk stabilisation, generation/transmission of propulsive forces and ventilation (Biersteker et al., 1986; Mahler et al., 1991). The challenge of these potentially competing requirements is exacerbated in certain parts of the rowing stroke due to flexed (stroke 'catch') and extended postures (stroke 'finish'). The purpose of this study was to assess the influence of the postural role of the trunk muscles upon pressure and flow generating capacity, by measuring maximal respiratory pressures, flows, and volumes in various seated postures relevant to rowing. Methods Eleven male and five female participants took part in the study. Participants performed two separate testing sessions using two different testing protocols. Participants performed either maximal inspiratory or expiratory mouth pressure manoeuvres (Protocol 1), or maximal flow volume loops (MFVLs) (Protocol 2), whilst maintaining a variety of specified supported or unsupported static rowing-related postures. Starting lung volume was controlled by initiating the test breath in the upright position. Results Respiratory mouth pressures tended to be lower with unsupported recumbency with a significant decrease in expiratory mouth pressures in all unsupported postures (3-9% compared to upright seated;  $p < 0.05$ ) There was a significant decrease in function during dynamic manoeuvres, including PIF (5-9%), FVC (4-7%) and FEV1 (4-6%), in unsupported recumbent postures ( $p < 0.0125$ ). Discussion Thus, respiratory pressure and flow generating capacity tended to decrease with recumbency; since lung volumes were standardised these differences are attributed to the influence of postural co-contraction of the trunk muscles. The findings demonstrate a potential decrease in respiratory function when rowing in extreme layback positions (>110°) thus supporting the use of a more upright finish position. ### THE EFFECTS OF ENDURANCE TRAINING ON LOCOMOTOR AND RESPIRATORY MUSCLE CHARACTERISTICS IN RATS

Vinogradova, O., Borzykh, A., Boleeva, G., Kuzmin, I., Tarasova, O.

*Institute for Biomedical Problems*

Introduction Respiratory muscles are rhythmically active during whole life of the organism and differ from locomotory muscles by their structure and metabolic characteristics. Therefore, mechanisms of adaptation to exercise training may be also different in these functionally different skeletal muscles. The aim of the present study was to compare the effects of endurance training on myosin composition, fiber cross-section area (CSA) and citrate synthase activity in medial head of gastrocnemius muscle (GM) and costal part of diaphragm (DIA). Methods Male Wistar rats were treadmill trained for 8 wks (6 days per week). The load was gradually increased; so that from the 5th week the rats were running 85.5 minutes per day at a speed 18.8 m/min and 5-degree incline of the belt. During the running sessions lactate concentration was measured electrochemically in blood microsamples taken from the tail tip. Expression of MHC isoforms and CSA were studied in individual muscle fibers by immunohistochemistry. Citrate synthase activity was measured in whole muscle homogenates spectrophotometrically. Results During the training sessions blood lactate did not exceed 4 mmol/L confirming mainly aerobic energy supply of working muscles. 8-week training resulted in a prominent rightward shift of the running speed – lactate concentration relationship, evidencing effectiveness of the employed training protocol. In sedentary rats citrate synthase activity in DIA was 1.8 times higher compared to GM; CSA of both fast and slow fibers in DIA was less than in GM. After training citrate synthase activity increased by 28% in GM but was not changed in DIA. The training had no effect on either myosin composition or fiber CSA in GM. However, in DIA of trained rats, the fractions of slow and hybrid fibers were increased by 14% and 92% respectively. Along with that cross-sectional areas of slow and fast muscle fibers were reduced by 16% and 18%. Discussion The strategy of adaptation to endurance training in DIA is different from GM. Chronically loaded DIA does not change its oxidative potential but demonstrates fast-to-slow shift of fiber composition and smaller fiber sizes. On the functional level these changes must reduce DIA fatigability and facilitate oxygen delivery because of shorter diffusion distance. Supported by the RFBR (grant 09-04-01701-a).

### THE IMPACT OF POSTURE DIFFERENCE ON OXYGEN UPTAKE IN HEALTHY SUBJECTS

Nogami, Y., Seo, Y., Ishizu, T., Yamamoto, M., Kawamura, R., Sakamaki, F., Yanaka, S., Nakajima, H., Iida, N., Aonuma, K.

*University of Tsukuba*

Introduction Exercise capacity reduces with aging. This age-related decreased exercise capacity is associated with reduced stroke volume (SV) during exercise. The previous study was reported that SV was greater in supine position than upright position (James et al.,

2007). Therefore, the purpose of this study was to evaluate whether exercise capacity was affected by difference posture or not. Methods Twenty-one healthy subjects (58±13 years; male/female n=7/14) underwent a symptom-limited incremental exercise on a cycle ergometer using a ramp protocol with continuous breath-by-breath analysis of respiratory gas exchange. All subjects underwent two trials, one was using with supine ergometer and the other was using with sitting ergometer. The index of exercise capacity was assessed by peak oxygen uptake (peakVO<sub>2</sub>) and VO<sub>2</sub> at anaerobic threshold (AT). Blood pressure (BP) and heart rate (HR) were measured every one minutes. Results PeakVO<sub>2</sub> with supine ergometer was significantly lower compared with sitting ergometer (25.7±4.4 vs. 26.6±4.7 ml/kg/min, P<0.05). However, O<sub>2</sub> pulse at peak exercise with supine ergometer was significantly higher than sitting ergometer (9.8±2.4 vs. 9.6±2.3, P<0.05). There was no difference between supine and sitting ergometer at peak work load (120±27 vs. 120±27 watt). On the other hand, VO<sub>2</sub>AT and AT work load with supine ergometer were higher than sitting ergometer (AT, 17.6±2.7 vs. 15.7±2.7ml/kg/min, P<0.01; work load, 74±17 vs. 62±15watt, P<0.01). Increased HR from rest to peak, systolic and diastolic BP at peak exercise were not significantly difference between supine and sitting ergometer. Discussion Parasympathetic nervous system is predominant in supine posture compared to sitting posture. In this study, using with supine ergometer, VO<sub>2</sub>AT and O<sub>2</sub> pulse were higher than using with sitting ergometer. Normally, AT level exercise is recommended for elderly and patients with exercise therapy. The present study was suggested that using with supine ergometer was more efficient than sitting ergometer in suitable exercise for therapy. Methods: A total of 26 obese adolescents were enrolled in the program. They aged 15-19 y, with BMI ≥ P95 and were submitted to 1 year of interdisciplinary intervention (clinical support, nutrition, psychology and physical exercise), randomized in two groups, aerobic training (AT) (n=13) and aerobic plus resistance training (AT+RT) (n=13). The Patients of AT group were matched according to gender and body mass. Blood samples were collected to analyze AGRP (ng/ml), NPY (ng/ml), MCH (ng/ml) and alfa-MSH (ng/ml). Results: No differences were found between groups in the baseline condition for body mass (kg), height (cm), BMI (kg/m<sup>2</sup>), body fat mass (kg and %) and body lean mass (kg and %). AGRP (ng/ml), which is an orexigenic factor, increased only in AT+RT group after 6 months of interdisciplinary intervention (0.25 + 0.08; 0.25 + 0.08; 0.28 + 0.05 and 0.74 + 0.34; 1.09 + 0.67; 0.80 + 0.28 in baseline condition, 6 months and 1 year of intervention for AT and AT+RT groups, respectively). For the other hand, alfa-MSH (ng/ml), which is an anorexigenic factor, increased only in AT group after 1 year of interdisciplinary intervention (4.05 + 2.51; 4.90 + 2.46; 8.56 + 2.61 and 1.28 + 0.32; 1.18 + 0.43; 1.62 + 1.08 in baseline condition, 6 months and 1 year of intervention for AT and AT+RT groups, respectively) Conclusion: Aerobic Training (AT) as part of an interdisciplinary therapy is more effective than Aerobic plus Resistance Training (AT+RT) in improving energy balance in obese adolescents after an interdisciplinary intervention. #### **RELATIONSHIP BETWEEN FOOT GRIP STRENGTH AND JUMP PERFORMANCE**

Yamauchi, J.

*1: Tokyo Metropolitan University, 2: Future Institute for Sport Sciences*

[Introduction] Muscular power capability in lower limb is associated with muscle functions of dynamic movement. It has been demonstrated that the muscle function of lower limb multi-joint movement measured with the servo-controlled dynamometer (Yamauchi et al. 2007) is profoundly correlated with the vertical jump performance (Yamauchi & Ishii 2007). Many physical activities are performed with a standing position on the foot and foot bears body weight as it carry the body through daily or sports activities. There are numerous studies on muscle functions of lower limbs in dynamic movements; however, only few studies have demonstrated foot muscle functions underling the dynamic characteristics of lower limb multi-joint movement such as vertical jump performance. Therefore, the present study was to investigate how isometric foot grip force generation influenced the vertical jump performance. [Methods] Thirty-nine healthy young individuals were measured their foot length, foot width, foot arch height and calf circumference. Foot arch height was measured the distance between tuberosity of scaphoid and floor, and it relative to foot length stated to the relative foot arch height. For MVC measurement of foot grip force, subjects exerted maximum force for ~3 seconds on a foot grip dynamometer with either sitting or standing position. Subjects also performed two different types of vertical jump: i) a countermovement jump without arm swing (CMJ) and ii) a squat jump without arm swing starting from a semi-squatting position (SJ). Measurements were repeated three times with at least one-minute rest period between bouts, and the highest value among the measurements was used. [Results and Discussion] During standing as compared with sitting position, foot arch height was lower while foot length and width was increased by body weight so that foot configuration changed. Foot grip forces at the sitting and standing position were positively correlated with SJ ( $r=0.34$ ,  $p<0.05$ ;  $r=0.5$ ,  $p<0.01$ , respectively). Also, foot grip force at the standing position was positively correlated with CMJ ( $r=0.49$ ,  $p<0.01$ ); however, foot grip force at the sitting position was not correlated with CMJ ( $r=0.27$ ,  $p>0.05$ ). The present results indicate that the ability to generate higher foot grip force is an important factor for the jump performance. Practically, foot grip force at standing position is more useful for evaluating the

performance of vertical jump performance. [References] Yamauchi J & Ishii N. J Strength Cond Res. 21: 703-709, 2007. Yamauchi J et al. J Biomech. 40: 1433-1442, 2007.

### EFFECT OF CREATINE SUPPLEMENTATION ON SERUM MDA OF STRENGTH TRAINED MEN

Uba ChupeL, M., Letieri, R.V., Borba-Pinheiro, C.J.

*Faculty of Sports Science - University of Coimbra*

EFFECT OF CREATINE SUPPLEMENTATION ON SERUM MDA OF STRENGTH TRAINED MEN UBA CHUPEL, M.1, LETIERI, R.V.1, BORBA-PINHEIRO, C.J.2 1:FCDEF-UC (Coimbra-Portugal) 2:UNIRIO (Rio de Janeiro-Brazil) Introduction It is well established that endurance athletes produce large quantities of reactive oxygen species, which leads to oxidative stress. This oxidation of biomolecules is directly related with several diseases, including cardiovascular disease, cancer and neurodegenerative diseases. Some studies show that this type of training has increased plasma MDA levels (Souza Jr. et al, 2005). Thus, the main objective of this study was to examine the effect of resistance training and supplementation with Creatine (Cr) on serum MDA of trained men. Methods Our study was consisted of 36 trained men separated by two groups that trained at 75% 1RM of resistance training. Group 1 (n = 18) with Cr supplementation of 3g.kg.day during 7 days, and 0,05g.kg.day in the three weeks remaining (Saremi et al, 2010). Group 2 (n = 18) used placebo. After 4 weeks, blood sample was collected before and after a training session for analysis of plasma MDA. Results The results show that after training there was a statistically significant difference (p <0.05) between groups. The Group 1 exhibited increase of % = 0,873% and Group 2 increase of % = 1,057%. Discussion The resistance training promoted the increase of serum MDA in both groups. In our study, the level of MDA in subjects who had not supplemented was significantly higher than the group supplemented with Cr. This is probably because the Cr intake with strength training keeps longer the ATP values without encouraging greater activation on intramuscular cycle degradation of purines, main catabolic process independent of O2 responsible for intramuscular ROS production (Casey & Greenhaff, 2000). It's established that there is decrease in both ammonia and in hypoxanthine during intense exercise preceded the consumption of Cr (Bellinger et al. 2000). Thus, it's speculate that the lower production of hypoxanthine resulting from this procedure can reduce its catabolism to xanthine and urate lowering the production of hydrogen peroxide, superoxide and hidroxil. ### ANALYSIS OF CHANGE OF 1RM ACCORDING TO INTENSITY OF EXERCISE IN 12-WEEKS MUSCULAR RESISTANCE TRAINING PROGRAM FOR ELDERLY WOMEN WITH OBESITY

Kyung Ryul, C.1, Sa Yup, K.1, Seong bin, P.1, Gi Duck, P.2

*1:Korea Institut of industrial Technology, 2:Namseoul University*

Introduction The purpose of this research was to provide important basic information for muscular resistance training program by investigating effect of 12-weeks muscular resistance training program for elderly women with obesity on 1RM which is recognized as a standard of measuring muscular strength. In this research, an analysis was made on change of 1RM according to intensity of exercise in 12-weeks muscular resistance training program for elderly women with obesity. Methode For that purpose, 39 elderly women with obesity were put into 3 groups for 3 different types of muscular resistance training high(60-70%/max), middle(40-50%/max), low(20-30%/max) strength and 1RM were checked after 6 weeks and 12 weeks respectively. 1RM test were leg extension, leg curl, hip abduction, leg press, arm curl, shoulder press, chest press, lat pull down, abdominal machine, total 9 factor measured. Result The was as follows. As for change of 1RM, there was meaningful difference between groups according to period of exercise, and especially in 12th week, higher increase of 1RM occurred in the high strength and middle strength groups than in the low strength group. Introduction: Antioxidants, such as vitamin C and E, are popular nutritional supplementations and are used by both the general population and athletes. Antioxidants protect against oxidative cell damage; however, oxidative stress seems important for stimulating some of the cellular pathways that drive the adaptations to training. Thus, high doses of antioxidants may inhibit the effects of exercise due to diminution of the normal exercise-induced oxidative stress. Therefore, the aim of the study was to investigate whether intake of high doses of vitamin C and E could hamper some of the physiological adaptations to strength training. Methods: Twenty-nine recreational strength trained subjects (10 females and 19 males; 25±5 years) were randomised to supplementation of either 1000 mg vitamin C and 235 mg vitamin E per day (n=16) or placebo pills (n=13) (double-blinded design). The subjects exercised 4 times per week for 10 weeks. All major muscle groups were exercised twice a week; 2-3 x 7-10RM. Changes in muscle mass were evaluated by Dual-emission X-ray absorptiometry (DXA) and 1RM tests were used to assess changes in muscle strength. Biopsies were collected before and after the training period, and the samples are currently being analysed for myofibre cross-sectional area, fibre type distribution and satellite cells. Results: Both groups increased knee-extension 1RM (C+E-vitamin: 12±7 % and placebo: 13±8 %, both p < 0.01) and biceps curl 1RM (C+E-vitamin: 8±5 % and placebo: 17±17 %, both p < 0.01). The increase in biceps curl 1RM was larger in the placebo group than in the C+E-vitamin group (p < 0.01). Fat free mass (DXA) increased by 1.1±1.1 and 1.1±1.1 kg in the C+E-vitamin and placebo group, respectively (both p < 0.05). Discussion: High dosage C and E vitamin supplementation did not affect whole body muscle growth during 10 weeks of strength training. Although both groups increased muscle strength, the placebo group demonstrated a larger increase in elbow flexor strength. Therefore, it appears that high dosages of antioxidants may inhibit some of the adaptations to strength training.

## BLOOD LACTATE CONCENTRATION AS A POTENTIAL MEDIATOR OF RATINGS OF PERCEIVED EXERTIONS DURING RESISTANCE EXERCISE

Sousa, N.1,2, Silva Junior, A.3, Bertucci, D.3, Souza, M.4, Ferraresi, C.4, Rodrigues, M.4, Arakelian, V.1, Togashi, G.1, Martins, R.5, Baldissera, V.1

1:EEESC/FMRP/IQSC, USP (São Carlos, Brazil), 2:FCT (Portugal), 3:UNESP (Rio Claro, Brazil) 4:UFSCar (São Carlos, Brazil), 5:FCDEF (Coimbra, Portugal)

Introduction Interest in using ratings of perceived exertion (RPE) to regulate the intensity of resistance exercise has increased in recent years. Blood lactate concentration (BLC) is also investigated as a possible physiological mechanism that may mediate the intensity of resistance exercise. The aim was to determine whether BLC is a potential mediator of RPEs during four consecutive sets of bench press (BP) exercise. Methods Ten healthy men ( $20.3 \pm 4.2$  yr; IMC  $23.6 \pm 2.9$  kg/m<sup>2</sup>) performed four sets of ten repetitions in BP exercise at 70% of their 1RM. Participants rested three minutes between sets. Two separated RPEs were estimated immediately after the last repetition at each set of exercise using the Borg (6-20) Perceived Exertion Scale and the OMNI Resistance Exercise Scale. During the interval between stages, 25  $\mu$ l of capillary blood were collected for blood lactate analysis (YSI 1500S). BLC and RPEs were evaluated using repeated measures ANOVA and Pearson correlations. The alpha level was  $p < 0.05$ . Results The means ( $\pm$  SD) of RPEs were  $9.7 \pm 2.3$  in set 1 (S1),  $12.3 \pm 1.6$  in S2,  $13.8 \pm 1.0$  in S3 and  $15.1 \pm 1.9$  in S4 for Borg scale and  $3.0 \pm 1.4$  in S1,  $4.6 \pm 1.3$  in S2,  $6.4 \pm 1.2$  in S3 and  $7.5 \pm 1.5$  in S4 for OMNI scale. The BLC was  $2.43 \pm 0.90$  mmol/L in S1,  $4.20 \pm 1.10$  mmol/L in S2,  $5.27 \pm 1.31$  mmol/L in S3 and  $6.20 \pm 1.38$  mmol/L. The ANOVA results indicate a significant increase over the sets for both RPEs scales and BLC. There is high and significant correlation between Borg and OMNI scales ( $r = 0.78$ ,  $p < 0.05$ ), high and significant correlation between OMNI scale and BLC ( $r = 0.73$ ,  $p < 0.05$ ) and moderate and significant correlation between Borg and BLC. Discussion There were corresponding increases in both RPEs and BLC as sets of resistance exercise increased, even working with the same intensity of exercise. There is a positive relation between BLC and RPEs, especially between the OMNI scale. Previous studies have demonstrated similar associations (Suminski et al. 1997; Lagally et al. 2002). However, previous investigations have also demonstrated strong relationships between RPEs and resistance exercise intensity (Lagally and Robertson 2006). In this study, the RPEs increase during four sets of exercise at the same intensity. It is possible that parallel increases in both RPEs and BLC are really a covariate of the greater muscle activity even during the same exercise intensity. Meanwhile, this study suggests that BLC is a better mediator of the intensity on OMNI scale than on Borg scale during four consecutive sets of BP exercise. References Lagally, K. M. and R. J. ## POSTEXERCISE HYPOTENSION IN STRENGTH-TRAINED ATHLETES

Saito, Y., Nakamura, M., Eguchi, K., Arai, K., Takemata, T., Otsuki, T., Ajsaka, R., Takahashi, H.

*Japan Institute of Sports Sciences*

【Background】 Postexercise hypotension (PEH), considered as an explanation to antihypertensive nonpharmacological effect of exercise, occurs in young, middle-aged and older men and women (1). It can be seen in trained subjects, especially endurance-trained athletes, after long submaximal (2) or short maximal exercise (3). In such population the occurrence of PEH is reported to be more frequent in trained subjects with lower cardiopulmonary fitness level or higher resting blood pressure (BP) (3). Whereas, PEH response in strength-trained subjects, who have increased arterial stiffness (4), was unclear. The purpose of this study was to investigate the occurrence and mechanisms of PEH in strength-trained subjects after short maximal exercise. 【Method】 Nine male weight lifters ( $19.2 \pm 0.2$  years) and eight sedentary controls ( $19.6 \pm 0.4$  years) were studied. BP, cardiac output (CO), and total peripheral resistance (TPR) were determined before and after 30, 60, and 90 minutes after a graded cycling to exhaustion. 【Result】 Strength-trained men demonstrated higher baseline BP than the controls ( $p < 0.05$ ). BP was reduced after exercise from baseline ( $p < 0.05$ ), although the degree of change was not different between the groups. There were no group differences in TPR reduction with slight CO increase after exercise. Moreover, no correlation was found between the decrease in BP and baseline BP or maximal oxygen uptake. 【Conclusion】 We conclude the magnitude of PEH is similar in the strength-trained and sedentary men. The occurrence of hypotension did not seem to depend on cardiopulmonary fitness level or resting BP in the present subjects. 【Reference】 1)Pescatello LS, Franklin BA, Fagard R, Farquhar WB, Kelley GA, Ray CA. ## ACUTE RESISTANCE EXERCISE AND CYTOKINES LEVELS IN METABOLIC SYNDROME

PEREZ, S.1, TIBANA, R.2, NAVALTA, J.3, SOUZA, N.1, CÔRDOVA, C.2, SOUZA, V.4, NÔBREGA, O.4,5, PRESTES, J.2, PEREIRA, G.1

1-Physiological Sciences Department, Federal University of Sao Carlos, Brazil. 2-Graduate Program in Physical Education and Health Catholic University of Brasília, Brazil. 3-Western Kentucky University

Introduction Chronic inflammation has been identified as an important component of the metabolic syndrome (MetS). The inhibition of the inflammatory mediator signals is a promising strategy against insulin resistance, atherosclerosis, and other problems associated with MetS. Regular exercise decreases the risk factor of MetS, including some inflammatory cytokines. However, the relationship between an acute resistance training (RT) session, cytokine levels, and MetS is unclear. Therefore the aim of the present study was to evaluate the effects of a single bout of acute RT on tumor necrosis factor (TNF- $\alpha$ ), interleukins (IL) IL-1 $\alpha$ , IL-1 $\beta$ , IL-12, IL-6, IL-10 and osteoprotegerin (OPG) in women with MetS. Methods Twenty-four women were divided into 2 groups: metabolic syndrome (MetS) and non-metabolic syndrome (Non-MetS). After the familiarization and testing for 1 repetition maximum (1RM), participants completed 3 sets of 10 repetitions in the following exercises: machine leg press, leg extension, leg curl, chest press, lat front pull-down and machine shoulder press with 60% of 1RM followed by 15 repetitions of abdominal crunches. A rest interval of one minute was allowed between sets and exercises. Plasma TNF- $\alpha$ , IL-1 $\alpha$ , IL-1 $\beta$ , IL-12, IL-6, IL-10 and OPG were measured before, immediately and 60 minutes after the RT. Results and Discussion

MetS group showed significant higher concentrations of IL-1 $\beta$  (P=0.024), IL-6 (P=0.049) and a trend for higher TNF- $\alpha$  values (P=0.092) compared with Non-MetS. There was no group x time interactions after the RT session on the measured cytokines and osteoprotegerin. Conclusion These data indicate that an acute RT session induced no additional increase of pro- nor a decrease of anti-inflammatory cytokines in women with MetS.

### EFFECTS OF MENSTRUAL CYCLE PHASE-BASED STRENGTH TRAINING IN FEMALES WITHOUT VERSUS WITH ORAL CONTRACEPTION

Sung, E., Han, A., Hinrichs, T., Vorgerd, M., Platen, P.

*Ruhr-University Bochum*

Purpose: The follicular (FP) and the luteal phase (LP) of the menstrual cycle are characterized by a certain profile of different hormones, including variations in anabolic and catabolic hormones. Oral contraception (OC) alters the profile of these hormones. We could recently demonstrate that adaptation to strength training is significantly higher in females who mainly conduct their training in FP compared to LP. This study compares the effects of menstrual cycle-based strength training in OC-users with the effects in non-OC users. Methods: 37 healthy females (n=20 non-OC users (25.9 $\pm$ 4.5 yrs, 164.2 $\pm$ 5.5 cm, 60.6 $\pm$ 7.8 kg) and 17 OC users (22.5 $\pm$ 2.4 yrs, 167.1 $\pm$ 6.6 cm, 62.9 $\pm$ 9.4 kg) completed a one-leg strength training on a leg press machine for each leg for 3 months. Both groups trained one leg mainly in the 1st half of the menstrual cycle (follicular and quasi-follicular phase-based training (FT and qFT) and the other leg mainly in the 2nd half of the cycle (luteal and quasi-luteal phase-based training (LT and qLT). Concentrations of estradiol (E2), progesterone (P4), total testosterone (T) and free testosterone (free T) were analyzed in FP and LP. Maximum isometric force (Fmax), muscle diameter (Mdm), muscle fiber diameter (Fdm) and cell nuclei to fiber ratio (N/F, biopsies of m. vastus lateralis, n=15) were analyzed prior to and after training. Results: Concentrations of E2, T and free T were significantly higher in non-OC users compared to OC users, while P4 was highest in LP compared to all other phases. Absolute increase of Fmax did not differ between FT and qFT but was lower (p<0.05) in LT compared to qLT (FT: +269 $\pm$ 101, qFT: +266 $\pm$ 115, LT: +188 $\pm$ 98, qLT: +282 $\pm$ 114 (values in N)). Increase in Mdm was not different between groups. Fdm increased after FT (+6.7 $\pm$ 7.1 $\mu$ m, p<0.05), but did not change after the other interventions (LT: +5.1 $\pm$ 8.1, qFT: +1.8 $\pm$ 11.4, qLT: +6.4 $\pm$ 7.0, values in  $\mu$ m, p>0.05). N/F increased after FT (+0.9 $\pm$ 1.0, p<0.05) and remained unchanged after the other interventions (LT: +0.0 $\pm$ 0.7, qFT: +0.5 $\pm$ 0.6, qLT: -0.2 $\pm$ 1.2, p>0.05). Conclusions: Although non-OC users had higher anabolic hormone concentrations compared to OC users, increase in Fmax was higher after qLT compared to LT. Alterations in muscle cell parameters, however, were only observed after FT under the predominant influence of anabolic hormones. Effects of anabolic and catabolic hormones might be different concerning training-induced changes in muscle strength and muscle cell parameters.

### EFFECT OF STRENGTH TRAINING PROGRAM ON SHOULDER ROTATOR MUSCLES IMBALANCE.

Mascarin, N.

*Universidade Federal de São Paulo*

Mascarin, N.C., Silva A.C., Andrade, M. Department of Physiology – UNIFESP (São Paulo, Brazil) Introduction Shoulder rotator muscles imbalance has been found to increase athletes risk for shoulder injuries, then preventive strength training programs (STP) aiming the reduction of this imbalance are warranted. Previous studies were not conclusive concerning efficient preventive strength training programs. Therefore, the aim of this study was to verify the effectiveness of a strength training program to improve shoulder muscular balance. Methods Twenty-eight female handball players were assigned to either experimental group [EG, (n=16)] or control group [CG, (n=12)]. EG athletes included in their usual training schedule 6 wk of individual progressive elastic resistance STP, 3 times a wk. CG athletes performed only the usual training sessions. All athletes performed concentric and eccentric strength tests of both dominant and non-dominant upper limbs on an isokinetic dynamometer. Internal (IR) and external rotator (ER) muscles peak torque (PT) was evaluated at angular velocities of 60 $^{\circ}$ /s and 240 $^{\circ}$ /s in the concentric (conc) mode and at 240 $^{\circ}$ /s in eccentric (ecc) mode. Based on ERcon/IRcon and ERexc /IRcon peak torque ratios a preventive STP was developed. Isokinetic strength tests were performed by all athletes before and after the intervention. Results STP improved IR PT values for dominant and non-dominant limbs (60 $^{\circ}$ /s) in EG (p=0.026 and p= 0.003, respectively), but not in CG. Significant differences were also found for dominant ER PT values pre X pos STP in EG (p= 0.021). Neither PT values assessed at 240 $^{\circ}$ /s nor PT strength ratios for both groups were significantly different before and after STP. Discussion Results showed that individual progressive elastic resistance STP effectively improves PT values for shoulder rotator muscles. In the same way, Niederbracht et al (2008) also found positive strength gain in rotator shoulder muscles following strength training program with dumbbells. Although PT improvement observed in our study was not enough to change muscular imbalance ratio, as it also has been demonstrated by Niederbracht et al (2008), a longer or more intense STP potentially decreases shoulder rotator muscle imbalance and the risk of shoulder injuries in overhead activity athletes. ### COMPARISON BETWEEN ELBOW FLEXORS AND KNEE EXTENSORS FOR CHANGES IN MUSCLE STRENGTH FOLLOWING MAXIMAL ECCENTRIC CONTRACTIONS IN OLD SUBJECTS

Nogueira, F.1, Libardi, C.1,2, Nosaka, K.3, Vechin, F.1,2, Berton, R.1, Souza, T.1, Lixandrao, M.1, Cavaglieri, C.1, Chacon-Mikahil, M.P.1

1: UNICAMP (Brazil), 2: USP (Brazil), 3: ECU (Australia)

Introduction Unaccustomed eccentric exercise (ECC) results in prolonged decreases in muscle strength. The magnitude of decrease in muscle strength following ECC is smaller for knee extensors (KE) than elbow flexors (EF) in young individuals, probably due to a protective effect in the lower limb muscles conferred by submaximal ECC performed in daily activities (1,2). However, it is not known whether this is also the case for old individuals. It is possible that the difference between KE and EF is small for old individuals, because of less eccentric contractions of lower limb muscles performed in daily activities. This study compared changes in muscle strength following maximal ECC between KE and EF in the elderly. Methods Healthy old men (n=5) and women (n=3) with low daily activity level (61.6  $\pm$  1.8 y, 75.6  $\pm$  3.5 kg, 1.66  $\pm$  0.04 m) volunteered for the study. They performed 5 sets of 6 maximal isokinetic (90 $^{\circ}$ /s) eccentric contractions of the EF (range of motion: 80-20 $^{\circ}$ ) and KE (30-90 $^{\circ}$ ) of the non-dominant limb in a randomized, counterbalanced order with 2 weeks between bouts. Maximal voluntary contraction isometric (MVC-ISO) and concentric strength (MVC-CON) were measured before, immediately after, and 24, 48, 72 and 96 h following ECC, and changes over time were compared between KE and EF by a two-way repeated measures ANOVA. Results Following ECC, KE and EF showed significant (P<0.001) decreases in MVC-ISO and MVC-CON, but returned to the baseline by 96h

post-exercise. The magnitude of decrease in MVC from baseline was similar between KE (e.g. MVC-CON at 24h:  $15.1 \pm 4.4\%$ , 48h:  $9.8 \pm 5.3\%$ ) and EF ( $17.7 \pm 3.0\%$ ,  $10.0 \pm 4.0\%$ ). Discussion No significant difference was found between KE and EF for muscle strength changes following ECC. This is in contrast to young individuals showing greater strength loss for EF than KE (1,2). It appears that the decreases on muscle strength following EF were smaller in the present study compared with the previous studies (1,2). This seems to be a reason why no significant difference between KE and EF was found. We also compared KE and EF for young subjects in the same way as that of the present study, and found that the decreases in MVC-ISO and MVC-CON following EF were greater ( $P < 0.01$ ) compared with KE. Thus, it seems that the difference in muscle damage between KE and EF is smaller for old than young individuals. It is concluded that the susceptibility to ECC induced muscle damage is similar between KE and EF for healthy but sedentary old individuals. References 1) Jamurtas et al. ### EFFECTS OF A SHOULDER INJURY PREVENTION STRENGTH TRAINING PROGRAM ON THROWING EFFECTIVENESS

Andrade, M.S., Mascarin, N.C., Silva, A.C.

*Federal University of Sao Paulo*

**Introduction** As a result of repetitive throwing motion, the concentrically activated internal rotator (IR) muscles significantly increase in strength, which may not be accompanied by a proportionally increase in external rotator (ER) muscles strength. These disproportional strength gains cause shoulder rotator muscles imbalance, which has been found to be a primary risk factor for glenohumeral joint injuries (Forthomme et al 2005). This adaptive imbalance may be beneficial for throwing performance. Therefore, the aim of this study was to verify if a strengthening program directed to correct adaptive strength imbalance may influence throwing effectiveness. **Methods** Twenty-eight female handball players were assigned to either an experimental group [EG, (n=16)] or a control group [CG, (n=12)]. EG athletes included in their usual training schedule 6 wk of individual progressive strength training program (STP), 3 times a wk. CG athletes performed only the usual training sessions. Athletes performed strength tests on an isokinetic dynamometer. IR and ER muscles peak torque (PT) values were evaluated at angular velocities of  $60^\circ/\text{s}$  and  $240^\circ/\text{s}$  in the concentric (con) mode and at  $240^\circ/\text{s}$  in eccentric (ecc) mode. Based on ERcon/IRcon and ERecc /IRcon peak torque ratios a preventive STP was developed. Athletes performed 2 tests to assess ball velocity and accuracy throwing. Tests consisted of 5 jumping or 5 standing shots on the spot towards a target from 7 m distance. The mean of 5 throws was calculated. Both tests were performed before and after the intervention. Results STP improved ER and IR PT ( $60^\circ/\text{s}$ ) values in EG ( $p < 0.05$ ) but not in CG. There were no significant differences for shoulder rotator muscle imbalance before and after STP for both groups, even though mean values for muscular imbalance were closer to those values suggested by previous studies. After STP throwing ball velocity was significantly higher in EG than in CG ( $p = 0.006$ ). There were no significant changes on aiming accuracy. **Discussion** Although Zapartidis et al (2007) have demonstrated that ER and IR PT values were not related to ball velocity the present study showed significantly higher ball velocities after STP in EG. Therefore, data suggest that STP is effective to increase muscular rotator strength, to correct shoulder muscle imbalance and to increase throwing ball velocity, without producing harmful effects on aiming accuracy. ### THE INFLUENCE OF SPRINTING SPEED TEST AND KINEMATIC PARAMETERS TEST ON RESULTS OF 100M DASH RACE PARTICULAR SEGMENTS SPRINTING

Babic, V., Blazevic, I.

*University of Zagreb; University of Pula*

**Introduction** Sprinting speed has certain dynamics which is constantly changing throughout the sprint race phases, whereas the sprint time is the consequence of the optimal coherence of all of these phases. Different qualities attribute differently to sprint race result; reaction time with 1%, the speed of start blocks push-off with 5%, start acceleration with 64%, maximal speed maintainance with 18%, and the ability to resist speed decline in deceleration phase with 12%. The aim of the present research was to investigate the relations of two variables of specific motor tests and eight variables of kinematic parameters with four variables of sprinting dynamics in 100m sprint race. **Methods** Participants in this study were 133 male students (aged  $21.7 \pm 1.08$ ; BH  $180.8 \pm 6.98$  cm; BW  $76.6 \pm 7.62$  kg). For all variables the basic descriptive parameters were computed. Relations of variable 20m sprinting from crouch start (sprinting speed in acceleration phase) and variable 20m sprinting from flying start (sprinting speed in maximum speed phase), as well as their kinematic parameters: average stride frequency, average stride length, foot-ground contact average duration, flight average duration in different phases of 100m sprint (0-30m; 30-60m; 60-80m; 80-100m) were determined using regression analysis. **Results & Discussion** Tests of specific motor abilities and kinematic parameters at different segments of 100 race explained 50%–63% of overall 100m sprint results. The multiple correlation coefficients were from 0,71 to 0,79 with p value of 0,01. The results showed the dominance of maximal sprinting speed influence in all 100m sprint race segments. 20m sprint from flying start is an indicator of quality and efficiency of sprinting motorics. 20m sprint from crouch start, the test used to assess quality of start acceleration, showed to be statistically significant only in start acceleration segment of a race. Sprinting technique kinematic parameters were statistically significant for prediction of all criterion variables of different segments of sprint race (0-30, 30-60, 60-80, 80-100m). In start acceleration segment (0-30m), statistically significant values were obtained for: stride length (for both 20m sprinting tests), whereas in all other sprint race segments (30-60m, 60-80m, 80-100m), statistically significant values were obtained for stride length and stride frequency from 20m sprint flying start test. No other variables showed to be statistically significant although it was expected that foot-ground contact average duration, as an integral indicator of maximal sprinting speed, would have better predictive values. However, this variable was not statistically significant for this population sample. References Babić, V., Harasin, D., Dizdar, D. (2007). *Kinesiology*, 39 (1), 28-39. Delalija, A., Babić, V. ## BIOMECHANICAL VARIABLES AND RUNNING ECONOMY DURING AN INCREMENTAL RUNNING TEST IN ELITE AND WELL-TRAINED RUNNERS

Tam, N., Santos-Concejero, J.

*University of Cape Town and University of the Basque Country*

**Introduction** The importance of running economy (RE) as a marker for running performance has been noted since the 1970s. However, our understanding of RE is relatively low compared to other markers of running performance. Contact time (CT) has been found to be a predictor of greater RE. Our aim of this study was to characterize changes in various biomechanical variables between well-trained and elite long distance runners at different running speeds and their influence on RE. **Methods** Twelve recreational and 14 elite Caucasian long distance runners participated in this study. Recreational inclusion criteria were 10km race time between 35-45 minutes. Inclusion criteria in the elite group included current participation in competitions and a 10km race time < 33.5 minutes. All subjects completed an incremental running test at 1% slope on a treadmill starting at 9 km/h. Speed increased by 1.5 km/h every 4 minutes until exhaustion, with 1 minute recovery between stages. Oxygen uptake (VO<sub>2</sub>) was continuously measured, with this data the last 30 seconds of each workload was considered steady state. Respiratory exchange ratio (RER) was determined and RE was calculated as steady-state VO<sub>2</sub> (ml/kg/km). Stride and step length, stride angle (SA), stride frequency (SF), CT, flight time (FT) and three sub-phases of CT (contact, foot-flat and propulsion) were measured during the test using the Optojump-next system (Bolzano, Italy). **Results** Differences were found in SA, SF, RER, RE, CT, FT, stride and step length as speed increased. Group differences were found in RER, RE, SF, SA and CT sub-phases (foot flat and propulsion phase). A greater RE was correlated with increased SA, SF, step and stride length and in the elite group a decreased CT but no relation with RER. **Discussion** To perform at increased running speeds, runners are required to increase SA, FT, SF, step and stride length, with a decrease in CT. These results are similar (except FT) to data previously reported elsewhere which clearly depict the adaptations needed to perform. Notably, RE decreased as the speed increased which shows an increased reliance on the anaerobic metabolism (increased RER) and changes in gait essential to generate the required effort to perform at high speeds. Greater SA (indicating a fore/midfoot striking pattern), FT and stride and decreased SF in the elite group may explain why there was only a significant correlation between a better RE and lower CT. It appears the elite athletes are able to best manipulate their gait to improve force output efficiently. This is further emphasized with the increased propulsive phase and decreased foot flat sub-phase of CT when compared to the recreational group. These data support the hypothesis that differences in RE between these two groups may be due to differences in CT (including sub-phases), other biomechanical variables.

## DIFFERENCES BETWEEN OCCASIONAL AND REGULAR TENNIS PLAYERS SHOES DIMENSIONS PREFERENCES

Herbaut, A., Guéguen, N., Foissac, M.

*Oxylane*

**Introduction** Fit is a major factor in footwear purchasing act and is necessary to practice sports safely. However, its measure is uneasy because it relies on subjective feeling. Thus, comparison of last and foot dimensions combined with questionnaire have been used to assess fit quality in both dress (Witana et al., 2004) and running shoes (Cheng & Hong, 2010). Nonetheless, level of expectation of fit and comfort are different among shoe type (Nacher et al., 2005) and feeling of tennis players has never been investigated. Therefore, the aim of this study was to determine the effect of foot dimensions and level of expertise on shoe dimensions preferences in tennis players. **Methods** Thirty-five tennis players (Eur 43) were divided in 2 groups of expertise (OP: Occasional Players / RP: Regular Players) and 2 groups of forefoot width (TF: Thin Feet [94; 101 mm] / WF: Wide Feet [103; 109 mm]). Subject's feet were measured with a tape. Four different pairs of tennis shoes with a shoe-hide were evaluated randomly. A 17 items questionnaire with 7-point Likert scales was filled for each shoe. It contained 2 types of questions of perception on each area: fit and comfort. A two-way repeated measures ANOVA was applied ( $P < 0.05$ ). **Results** RP felt a better overall comfort of shoes than OP ( $F(1, 33) = 6.72$ ;  $P < 0.05$ ). RP with WF felt a worse comfort of shoes at the forepart width than those with TF ( $P < 0.05$ ). RP WF judged them in average too tight while RP TF judged them rather suitable. No significant difference of perceived comfort and fit were found between TF and WF in OP ( $P > 0.05$ ). TF and WF OP judged the shoes in average too narrow. Similar results were found for waist girth. No significant difference between OP and RP was found for length, seat width and long heel girth shoes preference. However, players with a foot length of [260; 268 mm] felt the shoes length more suitable and comfortable than those with foot length of [269; 276 mm]. **Discussion** The comfort perceived of shoes by RP compared to OP could be due to their habit to wear tennis shoes and thus to appreciate the fit for this shoe type (Kouchi et al., 2005). Comfort of forefoot width was low for both TF and WF in OP. Either OP prefer wider shoes or they have a less accurate feeling and a lower understanding of their expectations than RP. These findings imply that the shoes should be different in width among player's expertise. Offer two shoe widths to RP should satisfy TF and WF while one shoe width should be sufficient to satisfy all OP. **References** Cheng YL & Hong Y (2010). *Footwear Science*, 2, 149-158. ## THE INFLUENCE OF THE DIRECTION OF THE DRAG-FLICK ON THE PLAYERS' PERFORMANCE

Gomez, M., Lopez de Subijana, C., Antonio, R.

*Sport Science Faculty - Technical University of Madrid - Spain*

**Introduction** The penalty corner is one of the most important scoring plays in field hockey (Laird & Sutherland, 2003). Previous researches have studied the biomechanical pattern of drag-flick, trying to find the cues for an optimal performance (López de Subijana, Juárez, Mallo & Navarro, 2010; McLaughlin, 1997; Yusoff et al., 2008). To date, none of them have analysed the different drag-flick patterns depending on the direction of the shot. The aim of this study was to analyse the individual differences in the drag-flick pattern between right and left shots. **Methods** One female skilled drag-flicker participated in the study. A VICON optoelectronic system was used to capture the drag-flicks with six cameras, sampling at 250 Hertz. A total of 50 retro-reflective markers were attached to anatomical landmarks. Fifteen trials from each side were randomly captured from the subject. **Results** The results showed significant differences between right and left shots ( $p < 0.05$ ) in the stick angles, stick minimum angular velocity and front foot-ball distance before the dragging action. During the front heel contact with the floor, the stick position of the right drag-flicks ( $-90.62 \pm 22.96^\circ$ ) was significantly behind the stick position of the left ones ( $-77.28 \pm 31.80^\circ$ ). At the same time, the distance between the front foot and the ball was significantly longer in the right hand side ( $-1.58 \pm 0.05$ m) than in the left drag-flicks ( $-1.51 \pm 0.07$ m). The minimum angular velocity of the stick before the release of the ball was significantly higher in the right drag-flicks ( $-185.04 \pm 31.06^\circ/s$ ) than in the left ones ( $-114.75 \pm 69.52^\circ/s$ ). **Discussion** The findings of this study showed that the main differences between right and left drag-flicks are the position of the stick and the ball when the front foot heel

contacts the floor and at the minimum velocity of the stick, before the dragging action. It is remarkable that both side shots are equally efficient because there were found no differences in ball velocities neither at the kinematic sequences of both goal areas. #### **DETERMINING THE CUSHIONING PROPERTIES OF ATHLETIC SOCKS USING AN IMPACT TESTING METHOD.**

Blackmore, T., Scurr, J., Jessop, D., Bruce-Low, S.

*Southampton Solent University*

**Introduction** Socks may have the potential for injury protection through the absorption and redistribution of impact forces (Howarth and Rome, 1996). Previous research has been participant-based which may increase variability whereas an impact testing methodology would reduce this variability and be more representative of the cushioning properties of the socks alone. This study used an impact testing method and aimed to determine the effect of athletic socks on peak impact force, time to peak impact force and loading rate. **Methods** The impact testing system utilised a vertical impact striker (8.5 kg) released from 0.05 m to impact the specimen on the vertical axis (impact velocity = 1.02 m/s). A Kistler load cell (5000 Hz) was integrated into the system. Five samples of 13 sock conditions, a no sock and shoe only control condition were used. Each specimen was subjected to 25 pre-impacts as part of a conditioning process followed by 10 recorded impacts. Results Repeated measures ANOVA and Friedman tests revealed significant differences between sock and sock/shoe conditions for peak impact force time to peak impact force and loading rate respectively. Contrast analysis and Wilcoxon Signed Ranks Test revealed that when compared to a control condition, athletic socks significantly reduced peak impact force by up to 20%, loading rate by up to 47%, whilst significantly increasing the time to peak impact force by up to 33%. When tested in conjunction with a shoe sole, the athletic socks significantly reduced peak impact force by up to 6%, loading rate by up to 9% whilst significantly increasing the time to peak impact force by up to 15%. Significantly strong correlations were observed between thickness and the three dependant variables in the sock only condition. **Discussion** Whilst all socks demonstrated an ability to attenuate impact force, superior cushioning properties were observed in socks composed predominantly of wool which is one of the most resilient natural fibres (Howarth and Rome, 1996) and may provide resilience to compression forces (Blackmore et al., 2011). However, these effects were diminished when tested in conjunction with a shoe sole, suggesting that the superior cushioning properties of the shoe may mask the cushioning properties of the socks. Correlation coefficients revealed that there was a significantly strong linear relationship between thickness and the three dependant variables in the sock only condition suggesting that attenuation of impact force is a function of sock thickness. #### **THE USE OF A MINIMAL MARKER SET FOR PELVIC MOTION ANALYSIS DURING RUNNING**

Hébert-Losier, K.1, Almstrom, P.2, Holmberg, H.C.1

*Mid Sweden University*

**Background** A decade ago, the use of a 3D motion capture system to analyze running technique was reserved to professional runners, Olympic-medal contenders, or researchers. Nowadays, numerous clinical and training based facilities access these technologies and provide biomechanical analysis services to runners of all skill level. In these circumstances, it is important for testing protocols to be user-friendly; and for results to be relevant to individuals and clinicians. Considering the apparent role of core stability in injury prevention and sports performance, and gender differences in running, the aim of this study was to use a minimal marker set in a clinical-base setting to analyze pelvic motion in male and female recreational runners. **Methods** Twenty-eight recreational runners (18M: 10F, age 28±8yrs) ran on a treadmill at incremental velocities of 10, 12, 14, 16, and 18km•h<sup>-1</sup>. Whole-body kinematics were recorded using an 8 infrared cameras 3D motion analysis system (Qualisys AB, Gothenburg, Sweden) capturing at 200Hz. Markers for capturing and reconstructing pelvis motion were positioned on the right and left anterior superior iliac spines, and on the sacrum between the two posterior iliac spines. Pelvis vertical displacement (cm), and pelvis obliquity and tilt at foot strike were computed. Measures were fitted into a generalized estimation equation to provide estimates on kinematic parameters of pelvis motion at various speeds during running and between genders. **Results** The vertical displacement of the pelvis during running was on average 8.2±1.8cm. The vertical motion decreased as velocity increased (P<0.001), with no influence from gender (P=0.102). On the contrary, gender had a significant effect on the obliquity of the pelvis at foot strike (P=0.047), with no influence from velocity (P=0.693). The amount of side bending was 1.1° (%CI: 0.02-2.2°) greater in males than females. The anterior-posterior tilt at foot strike was not influenced by running velocity (P=0.072) or gender (P=0.120). On average, it was 14.6±7.4°. **Discussion** This study applied a simple set of movement markers to describe pelvic motion in a group of recreational runners. The range of vertical pelvic motion decreased as running velocity increased, consistent with biomechanical efficiency of running. The results suggest that there are biomechanical differences between male and female runners in pelvic motion, particularly in the frontal plane. This user-friendly clinical approach to 3D motion capture has the potential to develop into a usual screening tool, particularly if a good database is available for use as normative comparative values.

#### **EFFECT OF ANKLE BRACING ON ANKLE STABILIZER MUSCLES STRENGTH AFTER EXERCISE AT THE INTENSITY OF BASKETBALL MATCH-PLAY**

Gonçalves, M., Castro, A., Spinoso, D.H., Almeida Neto, A.F., Milanezi, F.C., Cardozo, A.C.

*São Paulo State University*

**EFFECT OF ANKLE BRACING ON ANKLE STABILIZER MUSCLES STRENGTH AFTER EXERCISE AT THE INTENSITY OF BASKETBALL MATCH-PLAY** Gonçalves M1, Castro A1, Spinoso DH1, Almeida Neto AF1, Milanezi FC1, Cardozo AC1. 1: UNESP (Rio Claro, Brazil) **Introduction** The lateral ankle sprain is the most common injury in basketball. The use of braces and the identification of strength deficits of the ankle muscles are suggested to minimize the gravity and the occurrence of the injuries. Due to the high complexity in analyzing the muscular demands in the actual match situation this study aimed to analyze the effect of the use of ankle bracing on isokinetic peak of torque (PT) and functional ratio of the ankle stabilizer muscles after an exercise at the intensity of a basketball match-play. **Methods** Ten health college basketball players performed an exercise at the intensity of basketball match-play under two conditions: with and without ankle bracing. The test

was composed of a succession of intermittent physical effort equally distributed in four periods of 10 min each, considering the mechanical and physiological demands of a basketball match-play. Prior to the start of the trial (Evaluation 1) and after 2° (Evaluation 2) and 4° (Evaluation 3) period, the subjects performed five maximal isokinetic concentric and eccentric contractions of ankle invertors and evertors muscles, separated by two minutes rest, at 60°/s and 120°/s. The functional ratio were determined by eccentric eversion PT divided inversion concentric PT for the ankle inversion movement. Repeated Measures two factors was used for comparison of variables between the assessments and conditions ( $p < 0.05$ ). Results There were no differences for the PT and functional ratio between the assessments and conditions at 60°/s and 120°/s ( $p > 0.05$ ). It was observed the decreasing of EVEEXC and EVECON PT, when was compared the Evaluation 1 with the 2 and 3 in both conditions and velocities tested ( $p < 0.01$ ). The INVEXC and INVCON PT values decreased only between the Evaluation 1 and 3, in both conditions and velocities ( $p < 0.01$ ). The INVEXC PT at 120°/s also decreased from the Evaluation 2 to 3 ( $p < 0.05$ ). Discussion The decline of the ankle stabilizer muscles strength, in fatigue situations, may harm the joint position sense. Thus, the mechanisms of evertor muscles activation, which have shown higher strength deficits than the invertor muscles during the proposed protocol, particularly the peroneal muscles that act eccentrically during inversion, could not respond fast enough and predispose the individual to an ankle sprain during the basketball match. Conclusion The use of ankle braces does not influence the torque production and the functional ratio of the ankle stabilizer muscles during simulation basketball match intensity. However, the strength of the ankle stabilizer muscles, predominantly, in high isokinetic velocities and the evertor muscles was harmed, which suggests the increasing of ankle injury risk in this activity.

### **EFFECT OF ACCOMMODATIVE CUSHION FOOT ORTHOSES IN PLANTAR PRESSURES ON PROFESSIONAL CYCLISTS: PRELIMINARY STUDY. ANOTHER RELEVANT PARAMENTRES.**

Navarro, D.

*Catholic University of Valencia*

EFFECT OF ACCOMMODATIVE CUSHION FOOT ORTHOSES IN PLANTAR PRESSURES ON PROFESSIONAL CYCLISTS: PRELIMINARY STUDY. ANOTHER RELEVANT PARAMENTRES. Navarro, D.1, Huertas, F.1, Vera, P.2, Zahonero, J.1, Barrios, C.2 1: Sports Sciences and Physical Activity Department, Catholic University of Valencia, 2: Collaborator of Sports Sciences and Physical Activity Department, Catholic University of Valencia. Introduction. The purpose of this preliminary study is to obtain previous information on the differences in plantar pressures when cyclists use accommodative cushion foot orthoses and the effects of position and different power on plantar pressures. Previous studies (Hennig, Sanderson, 1995; Sanderson, Henning & Black, 2000), claim that there is a pattern of pressure on the insoles for cyclists, where most pressure is exerted on the first metatarsian and hallux (first finger). Methods. 4 cyclists with mean age of 25 years ( $\pm 2$  years) belonging to UCI professional teams, have been made accommodative cushion foot orthoses. Recordings were made with the Biofoot/IBV, grouping the 64 sensors in 9 zones, recording 6 seconds of constant and stable pedaling at 250 Hz. Cyclists ride on a hill between 6 and 8% slope in sitting position, standing on the pedals, two different powers (2W/kg and 4w/kg), with placebo and study insoles. The power has been controlled by commercial validated powermeter. The statistical treatment used was a repeated measures ANOVA on the values of average and maximum pressure. Results. Significant differences were found in plantar pressure in different positions of sitting and standing ( $p = 0,04$ ) and different powers depending on the area ( $p = 0,00$ ). We also found specific differences ( $p = 0,5$ ) in the distribution of pressure between the study and placebo insoles. Discussion. The effect of position is justified by the distribution of support points, there are 3 points when the subject is seated and 2 when is in standing position, so the weight of the subject that supports the seat rests on the pedals. Results supports Hennig and Sanderson (1995) conclusions, increase of power involve plantar pressures increase. Differences between cushion foot orthoses and placebo insoles, could be that ones are standard manufactured insoles and the others are custom. References. Hennig, E. M., & Sanderson, D. J. (1995). #### **CONTROL OF SHOULDER EXTERNAL ROTATION WITH A LONG SLEEVE COMPRESSION GARMENT DURING ISOTONIC CONTRACTIONS**

Tsuruike, M.1, Ellenbecker, T.S.2

1: *Osaka University of Health and Sport Sciences, Osaka, JAPAN*, 2: *Physiotherapy Associates Scottsdale Sports Clinic, Scottsdale, Arizona USA*

Introduction The shoulder external rotation (ER) has been considered an important role in the follow-through phase for overhead athletes. One reason for this is that a decrease in strength of ER can be associated with the overuse injury. Consequently, the athletes may seek performance enhancing aid in their overhead skill training, such as a compression garment (CG). The purpose of this study was therefore to determine the effect of both CG and ongoing visual feedback information (OVFI) on muscular performance during the isotonic contraction. Methods Twelve male college tennis players and 12 male college soccer players were tested in this study. The subjects stood upright, and performed 5 consecutive repetitions of both concentric and eccentric ER of the shoulder joint at 20 to 30% and 40 to 50% of MVIC. Conversely, the lever arm was not moved below or above the limited range of loads set for each performance. Each subject was also asked to wear a long sleeve compression garment (YONEX Inc. Tokyo Japan, Muscle Power STB). Additionally, each subject was given ongoing visual feedback information (OVFI) of the torque generated on the monitor of the personal computer in front of the subject during the performance of the isotonic contractions. The orders of CG-wearing and the presence of OVFI were both randomly assigned across the subjects for both 20-30% of MVIC and 40-50. A mixed ANOVA design was used to examine differences for each dependent variable of 5 consecutive repetitions. Results The analysis of the results indicated a significant three-way interaction between CG-wearing and OVFI across loads ( $p < 0.05$ ). Specifically, the mean value of the completion times with OVFI was significantly faster than without OVFI

when the subjects performed without CG-wearing at 40-50% of MVIC, (33.4 and 28.6 sec respectively), whereas no difference was identified with and without OVFI when the subjects wore the CG, (25.5 and 26.8 sec respectively). Discussion An increase in maximal rotator cuff activation occurred when the scapula was stabilized (Kibler et al, 2006). CG-wearing exhibited an increase in the postural balance mediated by the complicated motor task during the standing position. This study focused the complicated task on ER of the shoulder which was of importance to overhead athletes. Taken together, a long sleeve upper CG may help the rotator cuff and scapular muscles adequately work together during complicatedly demanded tasks without visuomotor control imposed on force outputs as compared without CG wearing References Kibler, WB, Press, J, Sciascia, A. (2006) The role of core stability in athletic function. Sports Medicine 36, 189-198.

### FATIGUE INDUCED IN LEG MUSCLES BY CYCLING INFLUENCES THE EXCITABILITY OF CONNECTIONS BETWEEN DORSAL PREMOTOR AND THE HAND AREA OF PRIMARY MOTOR CORTEX

Maruyama, A.1,2, Yoshida, T.1,2, Kojima, S.1, Yamashiro, K.1,2, Sato, D.1,2, Onishi, H.1, Rothwell, J.C.3

1,2: NUHW (Niigata, Japan), 3:UCL (London, UK)

**Introduction** We have previously reported that fatigue of leg muscles reduces intracortical inhibition in non-exercised hand and arm muscles during recovery period despite the fact that there is no overlap or known anatomical connection within primary motor cortex (M1) that might link activity in the leg with that of the arm. However, there are shared connections between dorsal premotor cortex (PMd) and arm and leg areas of M1 which are thought to be involved in facilitating isodirectional movements of hand and foot (Byblow et al. 2007). We therefore tested in the present experiments if exhaustive exercise of leg muscles changed the excitability of connections between PMd and M1 projections to non-exercised hand muscles. **Method** Seven (five male and two female) active subjects (age: 21-24yrs) participated this experiment. Maximal work rate (WRmax) was previously determined using a progressive incremental load method to exhaustion. All subjects exercised on the cycle ergometer at 100% of WRmax for 7 min or until exhaustion. PMd-M1 connectivity was tested with a paired pulse TMS design before, immediately after exercise and then 5, 10, 15, 20 and 30 min later. MEPs recorded in the left (non-exercised) relaxed FDI muscle were evoked by a TMS stimulus over right M1 hand area. Intensity was adjusted to produce an MEP of 1.2mV peak to peak amplitude. These were conditioned in random trials by a TMS pulse given 8ms earlier over left PMd at an intensity of 90% resting motor threshold (PMd-M18ms) (Mochizuki et al. (2004)). Results As reported previously MEPs evoked by the M1 stimulus alone were facilitated immediately after exhaustive leg exercise compared to baseline values. They were slightly suppressed at 5min, and then increased at 10 and 15min until returning to baseline levels after 30 min. At baseline, stimulation of PMd suppressed the MEP to 78% of its control value. This effect was abolished immediately after exercise, and at 5min, stimulation of PMd facilitated the MEP rather than suppressing it; inhibition returned gradually and was at baseline levels by 30min after exercise. **Discussion** Cycling fatigue of leg muscles increased the excitability of M1 projections to a non-exercised left hand muscle. Connections from PMd-M1 also changed after exercise from inhibition at baseline to frank facilitation 5min after exercise before slowly returning back to normal. It is possible that the effect of leg muscle fatigue on M1 excitability is mediated in part by an indirect effect on connectivity from PMd-M1. References Byblow et al. ### WHAT PRODUCES THE CONSTRAINT IN TWO-LIMB COORDINATED MOVEMENT IN THE SAGITTAL PLANE?

Kento, N., Muraoka, T., Kanosue, K.

Waseda University

What produces the constraint in two-limb coordinated movement in the sagittal plane? Nakagawa K.1,2, Muraoka T.3, Kanosue K.4 1Graduate School of Sport Sciences, Waseda University (Saitama, Japan) 2Research Fellow of the Japan Society for the Promotion of Science 3College of Economics, Nihon University (Tokyo, Japan) 4Faculty of Sport Sciences, Waseda University (Saitama, Japan) **Introduction** In various situations in daily life as well as in sports, humans perform complex actions that require the coordination of multi-limbs. Previous studies have shown that difficulty appears when two limbs are moved simultaneously in the opposite direction in the sagittal plane, whereas the difficulty almost never appears when movements are in the same direction (Swinnen, 2002). Additionally, the difficulty depends on the combination of two limbs (Kelso & Jeka, 1992). To investigate the factors involved in the constraint that simultaneous movements in the opposite directions are difficult, we examined the effects of 1) the number of motor commands sent from the brain, 2) interference of the kinesthetic afferent signals, 3) necessity of monitoring feedback information, and 4) combination of two limbs. **Methods** In the first experiment, we compared movement behaviors of ipsilateral hand and foot in two conditions. First, both limbs were actively moved by the subject. Second, one limb was actively moved by the subject, while another limb was passively moved by an experimenter. In both conditions, movements in the same and opposite directions were executed. The subjects performed with their eyes closed. The movement frequency was set at 2.5 Hz. We evaluated the performance by calculating the relative phase between movements of two limbs. The second experiment was done using both hands with the similar protocol. **Results & Discussion** Regardless of whether one limb was moved actively or passively, the opposite directional movements were difficult than the same directional movements. However, when ignoring the movement of the passively-moved foot, even moving hand in the opposite direction could be easily performed. These results suggest that monitoring the feedback information from moving two limbs rather than number of motor commands or interference of afferent signals would be the critical factor for the constraint. Additionally, while difficulty of two-limb movements in the opposite direction changed depending on the combination of limbs when they were performed actively, the movements became equally difficult in any combination of two limbs, either ipsilateral hand and foot or bilateral hands when one limb was moved passively. This suggests that the motor control algorithms of voluntary coordinated movement differ substantially depending on the combination of two limbs. Reference Swinnen SP. (2002). ### THE RELATIONSHIP BETWEEN EYE DOMINANCE AND DYNAMIC PROPERTIES OF BINOCULAR EYE MOVEMENTS IN COLLEGE BASKETBALL PLAYERS

Kokubu, M.1,2, Higashi, A.1, Araki, M.1

1: Osaka University of Health and Sport Sciences, 2: Japan Society for the Promotion of Science

**Introduction** In ball sports which require the athletes to execute target-aiming movements, it is important to make use of eye movements and visual information. For instance, expert basketball players have a longer fixation on the target before taking the actual shot (e.g., Vickers, 1996). However, earlier studies regarding ball game players have taken only one eye movement into account. Thus it is still unclear whether there are differences in their dynamic response properties between two eyes, which might be concerned with eye

dominance. The purpose of the present study was to investigate whether ocular dominance is related to the characteristics of binocular eye movements in basketball players. Methods Eye dominance and binocular eye movements (saccade and vergence) were examined for 86 participants in college basketball teams. The two standard tests (i.e., Miles and Porta tests) were used for the determination of their eye dominance. In the binocular eye movement tasks, they were seated with their head position stabilized by a head rest. For saccade, visual stimuli were presented 20 deg. to the left and right from the central one. For vergence, they were located 20 and 150 cm from the center of the two eyes in the mid-sagittal plane. The participants were asked to make eye movements to the appearance of the visual stimulus as quickly as possible. Horizontal movements of the left and right eyes were recorded respectively with the electrooculogram. Results On the basis of the eye dominance test, 63 participants were right eye dominance, 19 were left eye dominance, and 4 did not show clear dominance. For vergence, latency of the left eye was significantly longer than that of the right eye in the right eye dominant group ( $p < .01$ ), but there was no statistical difference between the two eyes in the left eye dominant group. Divergence showed less symmetrical movements for the two eyes than convergence and contained versional components (i.e., both eyes moved in the same direction) in the early response phase. For saccade, there were no significant differences in the response property between the eyes for both eye dominant groups. Discussion The present study revealed that the response of the non-dominant eye was slower than that of dominant eye in the right eye dominant players when shifting binocular fixation in the depth direction, possibly reflecting differences in sensorimotor processing between the two eyes. These findings suggest that eye dominance becomes an important factor when quickly aiming at a farther target. References Vickers, JN. (1996) *J Exp Psychol Hum Percept Perform*, 22, 342-354.

### EFFECT OF DIRECTION AND CONSISTENCY OF HANDEDNESS ON MANUAL PROFICIENCY OF CHILDREN WITH AND WITHOUT DOWN SYNDROME

Reyes, A.C.1, Corredeira, R.2, Rodrigues, P.3, Vasconcelos, O.1

1:Motor Control and Learning Laboratory, CI/F2D, Faculty of Sports, University of Porto, Portugal; 2:Adapted Physical Activity Department, CIAFEL, Faculty of Sports, University of Porto, Portugal; 3:Inst. Piaget

Introduction: It has been proposed that left-handedness is linked to pathology. However, recent studies on developmental disorders tend to show that lack of asymmetry, rather than left-handedness, is associated with pathology (Carlier et al., 2011). Hand preference (HP) and its relation with manual proficiency were studied in Down Syndrome (DS) and typically developing (TD) children. Methods: The participants were pre-schoolers (age range: 3-5 years) divided in groups according to the HP direction (DS: 16 right-handers and 8 left-handers; TD: 32 right-handers and 4 left-handers) and consistency (DS: 13 consistent and 11 inconsistent; TD: 29 consistent and 7 inconsistent). Laterality was assessed using a preference test (Gabbard & Rabb, 2000; Harris & Carlson, 1993) and a manual dexterity test adapted to children. Results: Although the two groups did not differ for the frequency of left-handers ( $\chi^2(1) = 1.333$ ,  $p = 0.248$ ), the occurrence of left-handedness was higher in children with DS ( $n=8$ ) than in TD ( $n=4$ ) children. Moreover, inconsistent left-handers were higher in the group of DS ( $n=7$ ) compared to TD ( $n=2$ ), although differences did not reach statistical significance ( $\chi^2(1) = 1.000$ ,  $p = 0.317$ ). Concerning performance, the interaction between group and consistency ( $F(1,56) = 5.632$ ;  $p = 0.021$ ) revealed that in the TD group the more strongly consistent lateralized individuals exhibited better performance while the opposite was found for the DS children. Discussion: These results somewhat support other studies indicating that less rightward asymmetry and inconsistency are associated with intellectual deficiency in children and hence with atypical patterns of lateralization. ### MUSCLE RELAXATION OF THE FOOT REDUCES THE CORTICOSPINAL EXCITABILITY OF THE HAND MUSCLES

Kato, K., Mizuguchi, N., Nakata, H., Muraoka, T., Kanosue, K.

Waseda University

Muscle relaxation of the foot reduces the corticospinal excitability of the hand muscles Kato, K.1, Mizuguchi, N.1, Nakata, H.2, Muraoka, T.3, Kanosue, K.2, 1: Graduate school of Sport Sciences, Waseda University (Saitama, Japan) 2: Faculty of Sport Sciences, Waseda University (Saitama, Japan) 3: College of Economics, Nihon University (Tokyo, Japan) Introduction Muscle relaxation is an important factor to make good performances in sports, but the mechanism has not been well understood. It has been suggested that muscle relaxation is accomplished by an active process in the brain, and not the mere end of contraction. Transcranial magnetic stimulation (TMS) study suggested that corticospinal excitability was reduced just prior to the voluntary muscle relaxation (Begum et al., 2005). On the other hand, previous studies that focus on motor control of multi limb movements have shown that simple contraction induces increase of corticospinal excitability in other ipsilateral muscles (Baldissera et al., 2002). Moreover, we have observed that EMG level of contraction in one hand decreased during the relaxation of the ipsilateral foot. The purpose of the present study was to clarify the effects of relaxation of foot muscles on the corticospinal excitability of hand. Methods Nine subjects performed relaxation of the right foot dorsiflexor immediately in response to an audio cue. The completion of relaxation (offset-time) was defined by the offset of the EMG. TMS stimulation was delivered to the hand area of the left motor cortex at -100, -50, 0, 50, and 100 ms (TMS stimuli-time) from the offset-time predetermined from 10 pre-trials without stimulation. Motor evoked potentials (MEPs) were recorded from the wrist extensor (ECR) and flexor muscles (FCR). Actual TMS timing was determined from the period between the offset-time of each trial to TMS stimuli-time. Corticospinal excitability was assessed by peak-to-peak amplitude of MEPs. Results The MEP amplitudes of ECR and FCR were higher in the periods of “~ -101 ms” than that in the resting condition. The MEP amplitude of ECR was smaller in the period of “100 ms~” than that in the resting condition. The MEP amplitude of FCR was smaller in the periods of “50~99 ms” and “100 ms~” than that in the resting condition. Discussion Corticospinal excitabilities of both ECR and FCR increased before ankle relaxation compared to resting condition. After ankle relaxation, on the other hand, corticospinal excitability decreased compared to resting condition. It is suggested that inhibitory commands were conveyed not only to the relaxing muscle (TA) but also to other resting muscles (ECR and FCR) during muscle relaxation. In conclusion, relaxation of foot dorsiflexor decreased in the excitabilities of hand muscle, both flexor and extensor. ## THE EVALUATION OF JOINT POSITION SENSE IN FOLK DANCERS

Akdogan, E.I, Ertan, H.I

*Anadolu University*

**Introduction** Proprioception has been defined as an awareness of joint position in space as sensed by the central nervous system. In this study it is aimed that in the positions of weight bearing (WB), partial weight bearing (PWB) and non weight bearing (NWB) proprioception is examined among the participants of the study -the regular folk dancers and sedantaries. **Methods** Totaly 30 men - 15 folk dancers ( Average age: 21.33 ± 0.89, Average exercise age: 3 ± 0.76 year)-and 15 sedantaries ( Average age: 21. 2 ± 0.75) have participated in this study as volunteers. The subjects did not report any knee, hip and ankle injuries. For the propriceptive measurements, 15°, 30°, 45° and 60° has been chosen. The subjects has been asked first to bring their joints to given angles by open eyes using three passive repetitions, than after to find the correct angle eyes-closed with three active repetitions in of weight bearing (WB), partial weight bearing (PWB) and non weight bearing (NWB) positions. **Results** According to the results, when the proprioception was examined on dominant leg in three different measurement positions, with 15°,30°,45° and 60° degrees, meaningful differences were identified in favour of folk dancers in the position of lie back down non weight bearing (NWB) 45° and 60° degrees ( $p \leq 0,05$ ) . However, no meaningful diffrences were found in the position of non weight bearing (NWB) lie back and face down 15° and 30° degrees , partial weight bearing (PWB) and in the position of weight bearing (WB), 15°, 30°, 45° and 60° degrees. **Discussion** Folk dancers perform repetitive movements by carrying the whole body weight. However, The sedanter group has been composed of the subjects not participating regular physical activity except for their daily routines. So, the type of physical activity being heavy or medium weight-bearing exercise may have an effect on the proprioceptive sense on the knee joint. **References** Barrack R.L., Skinner H.B., Buckley S.L., Proprioception in the Anterior Cruciate Deficient Knee, *Am J Sports Med*, 17(1): 1-6 (1989) Bellew JW, Fenter PC, Chelette B, Moore R, Loreno D., Effects of a Short-Term Dynamic Balance Training Program in Healthy Older Women, *J Geriatr Phys Ther*; 4-8, 27 (2005) Beynnon BD (Eds), Validation of Techniques to Measure Knee Proprioception, In: Lephart SM, Fu FH, Proprioception and Neuromuscular Control in Joint Stability, Human Kinetics USA, 127-138 (2000) Biedert R.M., Contribution of the Three Levels of Nervous System Motor Control: Spinal Cord, Lower Brain, Cerebral Cortex Proprioception and Neuromuscular Control in Joint Stability, *Human Kinetics USA*, 23 (2000)

## EFFECTIVES OF DIFFERENT VERBAL FEEDBACK DURING LEARNING COMPLEX MOTOR TASK

Niznikowski, T., Sadowski, J., Mastalerz, A.

*University of Physical Education in Warsaw*

**Introduction** From theoretical and applied perspective, one of the major issues of interest in motor skill acquisition is how information feedback influences learning. Many researchers (Salmoni, Schmidt, Walter, 1984, Wulf & Shea, 2004, Sadowski et. al., 2011) attempted to find the most appropriate methods of providing information through feedback to refine and develop motor skills. However, less is know about of effectiveness of verbal feedback in the learning motor complex task. Therefore, the aim of this study was to investigate how different types of corrective verbal feedback improve learning one double leg tuck jump with the knees bringing up to chest and hands grip on shin in the flight phase and then squat landing with the arms straight on the side. **Methods** Nineteen students were randomly divided into three experimental groups. The first group (P) received verbal feedback on the correctness in the task performance (mean stature 177 cm ± 5.0 cm, body mass 81.2 kg ± 3.8 kg, age 20.3 ± 1.3 yrs). The second group (E) received verbal feedback about errors in the task performance (mean stature 178 cm ± 4.0 cm, body mass 79.4 kg ± 3.6 kg, 20.4 ± 1.2 yrs). The third group (E&P) received verbal feedback about errors and correctness in the task performance (mean stature 181 cm ± 3.9 cm, body mass 83.4 kg ± 3.8 kg, age 20.2 ± 1.1 yrs). The progressive-part method was employed in this study. Each component and the whole task were learned separately. All participants completed three practice sessions per sixteen weeks. Prior to practicing, all of the participants received a demonstration of the task along with verbal guidance. Three qualified judges viewed each trial and provided a performance score. Results It was established the increase of judge assessments for all groups. The ANOVA with repeated measures analysis revealed a significant effect of test time ( $F(2,32) = 8.30$ ;  $p < .001$ ). Post hoc comparison indicated that significant improvement of performance was observed only in group P (4.4 %,  $p < .007$ ) and E (14.5%,  $p < .001$ ). All judges ratings in the group E&P improved insignificantly. **Discussion** It was shown that the amount of verbal information is not cornerstone for learning complex motor task whit many degree of freedom. The group E outperformed groups P and E&P. Probably the amount and precision of Knowledge Performers are often too overwhelming, which exceeds the ability to correct the response. **References** Salmoni AW, Schmidt RA, Walter CB. ## THE ABILITY OF MAINTENANCE OF STATIC AND DYNAMIC BALANCE IN RHYTHMIC GYMNASTICS. COMPARISON OF FORMER ELITE GYMNASTS AND NO GYMNASTS

Skoura, D.I, Tsopani, D.I, Papouliakos, S.2, Korres, S.2

*National and Kapodistrian University*

**Introduction** Balance is vital to many aspects of our daily lives and in rhythmic gymnastics the ability to maintain a stable position is indispensable for the implementation of every element of the sport ( Karpenko, 2003). The purpose of this research is to study the degree of balance capacity among former athletes skilled Rhythmic Gymnastics and non-athletes to determine whether and to what extent the special training in rhythmic gymnastics at high level develops the ability to balance. **Methods** Participants were 35 female volunteers aged 19 to 25 years, divided into two groups. Experimental group: 15 were former elite gymnasts of rhythmic gymnastics and the control group: consisted of 20 participants who have not worked systematically in a sport. The measurements were made at an otolaryngology workshop of Medical School in Athens using a platform of computerised posturography for assessing the ability to balance (NeuroCom). A key test, Sensory Organization Test, reflects the overall coordination of the visual, somatosensory and vestibular systems that contribute to postural control ( Hans Chaundry, 2004). Other tests evaluated: motor adaptation to different vibrations of the platform, reaction time, movement velocity, directional control, on-axis velocity. **Results** According to statistical data analysis it is shown that elite athlets excel in reaction time after auditory stimulus ( 0,5/1,1 sec), in movement velocity ( 2,4/6,8 deg/ sec) and in balance with swaying the environment and the surface ( 58,3%/51%) **Discussion** The statistical results confirmed the initial hypothesis that elite athletes have better ability of balance probably due to the content of training in rhythmic gymnasts that includes quick reflexes and abilities to keep the balance under adverse conditions. **References** Hans Chaundry, Thomas Findley, and al, Measures of postural stability, *Journal of Rehabilitation Re-*

### EFFECT OF DEGREE OF HANDEDNESS ON INTERMANUAL TRANSFER OF LEARNING

Batista, S.I, Freitas, C.I, Botelho, M.I, Rodrigues, P.2, Vasconcelos, O.I

1: *Motor Control and Learning Laboratory, CIFI2D, Faculty of Sports, University of Porto, Portugal*; 2: *Instituto Piaget, CIIERT/Edutec, Portugal*

**Introduction** The majority of studies of intermanual transfer use right-handers as participants. To our knowledge, only a few studies took into account direction (Kumar & Mandal, 2005; van Mier & Petersen, 2006) and degree of handedness (Chase & Seidler, 2008). The aim of this study was to evaluate whether the magnitude of learning and intermanual transfer were influenced by either direction and/or degree of handedness. **Methods** Forty nine male and female children from 6 to 10 years of age were analysed performing the Purdue Pegboard task. Following learning with either the dominant or non-dominant hand, 32 right-handers (17 consistent and 15 non-consistent) and 17 left-handers (5 consistent and 12 non-consistent) transferred to task performance with the other hand. Transfer direction was tested from the dominant to non-dominant hand and vice versa. **Results** No significant differences were found between right- and left-handed participants, males and females, and transfer directions. **Discussion** Like other previous studies, our results seem to indicate that in some tasks motor control takes place at a higher level independent of the effector system. **References** Chase, C., & Seidler, R. (2008). Degree of handedness affects intermanual transfer of skill learning. *Experimental brain research*, 190(3), 317-328. Kumar, S., & Mandal, M. K. (2005). ### EFFECT OF SUPRAPOSTURAL TASKS ON POSTURAL PERFORMANCE: A META-ANALYSIS

Bund, A., Lippens, V.

*University of Oldenburg*

**Introduction** In opposite to the classical "quite stance"-paradigm of research on postural control, it is sup-posed from an ecological point of view that postural control is functionally integrated into a specific context, which is determined by superordinate tasks or goals ("suprapostural tasks", e.g., Stoffregen et al., 2007). Thus, postural performance should be superior if a suprapostural task is given compared to a non-suprapostural task setting. The purpose of this meta-analysis was to examine the effect of suprapostural tasks on postural performance and the impact of relevant moderator variables (e.g., age of subjects, visual condition). **Methods** A total of 47 studies with N = 917 participants fulfilled the following criteria: (a) measure of postural sway with and without suprapostural task in a crossover design, and (b) published in english or german language after 1990. The studies were coded independently by two raters with Cohen's Kappa ranging from 0.80 to 1.00. Mean effect sizes (Hedges' g) were computed using the random effect model and analyzed in terms of significance (Z), heterogeneity (Q), and publication bias (Funnel plot, Orwin's fail-safe N). As effects of crossover studies are commonly overestimated, the calculation of effect sizes was performed conservatively. **Results** In fact, suprapostural tasks significantly reduce postural sway both in anterior-posterior ( $g = 0.49$ ,  $p < .001$ ) and medio-lateral direction ( $g = 0.46$ ,  $p < .001$ ), that is, suprapostural tasks generally improve postural performance. However, the study effect sizes are not homogeneous ( $Q = 139.39$ ,  $p < .001$ , and  $Q = 149.83$ ,  $p < .001$ ). The suprapostural task effect is significantly greater for perceptual tasks ( $g = 0.84$ ) than for motor tasks ( $g = 0.31$ ); cognitive tasks have no sway-reducing effect ( $g = 0.01$ ). Furthermore, the mean effect size for young adults ( $g = 0.43$ ) is significantly greater than the mean effect size for old adults ( $g = -0.08$ ) and the mean effect size for eyes closed condition ( $g = 0.49$ ) is insignificantly greater than that for eyes open condition ( $g = 0.34$ ). **Discussion** Results of the meta-analysis clearly support the ecological approach to human postural control. According to this approach, postural control can be understood as an adaptable set of well learned strategies, which is an inherent part of the broader action-perception system to facilitate the execution of suprapostural tasks (Stoffregen et al., 2007; van Emmering & van Wegen, 2002). However, the effect of suprapostural tasks is not homogenous but depends from personal and contextual variables (i.e., age, physical health, visual condition, relationship between postural and suprapostural task). Further research on this variables is needed to clarify the functioning of postural control and to develop effective postural trainings. **References** Stoffregen, T.A., Hove, P., Bardy, B.G., Riley, M., Bonnet, C.T. (2007). *J Mot Behav*, 39, 126-138. Van Emmerink, R.E.A., van Wegen, E.E.H. (2002). *Exerc Sport Sc Rev*, 30, 177-184.

### A COMPARISON OF RUNNING GAIT IN CHILDREN WITH AND WITHOUT DEVELOPMENTAL COORDINATION DISORDER

Chia, E., Licari, M.K., Guelfi, K.J., Reid, S.

*The University of Western Australia*

**Introduction** Children with developmental coordination disorder (DCD) demonstrate low levels of motor proficiency which affects their ability to perform many activities, including running. Running is an important fundamental movement skill, as it is the most basic skill to participate in a variety of common sports. Given the qualitative nature of previous research investigating running proficiency in this population, further research is needed to quantify potential differences to clearly understand the movement constraints within this population. Therefore, the aim of this study was to quantify running gait patterns of children with DCD to identify differences in technique. **Methods** Twenty seven boys participated in this study, 13 with DCD (9y 3mo, SD 1y) and 14 typically developing controls (9y 6mo, SD 1y 1mo). Motor proficiency was assessed by the Movement Assessment Battery for Children-2, with all children in the DCD group falling below the 15th percentile (3.5, SD 3.01), while the typically developing group scored above the 25th percentile (71.43, SD 16.9). Kinematic and kinetic data was obtained using a 12-camera Vicon MX system and AMTI force plate. The children ran at a velocity of  $2.44 \pm 0.25$  m/s across a 15 m track, with data for 3 cycles of each limb collected. Three-dimensional kinematics and kinetics of the trunk and lower limbs were produced. **Results** Spatio-temporal analysis of running gait showed a trend for children with DCD to have a longer stance period than their typically developing peers ( $p = 0.061$ ). The features of the kinematic and kinetic trajectories were similar between both groups. However, the DCD group displayed increased variability in the sagittal plane kinematics of the hip and ankle during toe off as compared to their typically developing peers. Kinetic analysis revealed that typically developing children had significantly greater knee extensor moment ( $p=0.001$ ) and ankle plantarflexor moment ( $p=0.03$ ) during the stance phase of the running cycle. Consequently, peak knee power absorption and peak ankle power generation was significantly greater in the typically developing children ( $p=0.014$ ;  $p=0.018$ ). **Discussion** The reduced power absorption at the knee and power generation at the ankle in children with DCD suggests that they are less efficient in producing power and transferring energy in the stance phase of the running gait cycle. These power production inefficiencies may have

implications for the energy cost of running in children with DCD. In addition, the greater variation in the running kinematics of children with DCD may reflect the need for individualised training to improve running gait technique.

#### PATIENTS WITH SCHIZOPHRENIA SUBMITTED TO 20 WKS OF RESISTANCE EXERCISE: A BLIND STUDY

Cassilhas, R.C., Andrade, B., Attux, C., Gadelha, A.L., Telles, B.A.S., Bressan, R.A., Tufik, S., de Mello, M.T.

*Federal University of Sao Paulo*

**Introduction** Schizophrenia is a serious mental disease characterized by a combination of positive and negative symptoms. Recently, it has been hypothesized that alterations in neuroplasticity and IGF-1 may be an important factor for the development of schizophrenia. In addition to antipsychotic medications, resistance exercise not only may be another way to increase IGF-1, but also decrease disease symptoms and improve quality of life. Therefore, the aim of this study was to evaluate the effects of 20 weeks of resistance training on psychotic and depressive symptoms, quality of life and serum IGF-1 concentration. **Methods** Nine paranoid schizophrenic patients participated in a blind, randomized clinical trial for 20 weeks. The patients were divided into two groups: CTRL (n=5) and RESEX (n=4). The exercise program consisted of resistance exercise with increasing intensity (40 – 85% of 1RM, 2 – 3 sets of 6 – 15 repetitions) twice per week. The blindly evaluation (scales for psychotic symptoms, depression and quality of life, serum IGF-1) were conducted at three time points (beginning, 10 weeks and 20 weeks). **Results** After intervention, the RESEX group had a decrease in psychotic and depressive symptoms and an improved quality of life. Serum IGF-1 levels were higher in the RESEX group at the end of treatment. **Discussion** These findings corroborate previous studies used aerobic (Pajonk et al., 2010) and concurrent training in this population (Marzolini et al., 2009) which improvements in mental health were observed after the exercise. Moreover, the patients who trained increased serum IGF-1 levels. We suggest that resistance exercise could improve the symptoms of schizophrenia/ depression by stimulating the IGF-1 pathway in the brain. Therefore, we propose that resistance training be incorporated as a non-medicinal treatment for the management of schizophrenia to support antipsychotic drug treatment and psychotherapy; to possibly increase IGF-1 in the body; to improve disease symptoms and quality of life; and to alleviate potential motor, cognitive and metabolic side-effects. **In summary**, 20 weeks of progressive resistance training improved the quality of life and symptoms of schizophrenia and depression and decrease both negative and positive symptoms, while also increasing serum IGF-1 levels. These findings support the existence of a neurobiological mechanism for exercise. **References** Marzolini, S., Jensen, B. & Melville, P. #### THE EFFECT OF SYNCHRONOUS MUSIC ON MOOD AND CYCLING ECONOMY DURING AEROBIC EXERCISE.

Kiyota, N.1, Morita, Y.2,3, Uchida, S.4,5

*1)School of Sport Sciences, Waseda University, 2)Graduate school of Sport Sciences, 3)Research Fellow of Japan Society for the Promotion of Science, 4)Faculty of Sport Sciences, Waseda University,*

**The effect of synchronous music on mood and cycling economy during aerobic exercise.** Natsuki Kiyota<sup>1)</sup>, Yuko Morita<sup>2)3)</sup>, Sunao Uchida<sup>4)5)</sup> *1)School of Sport Sciences, Waseda University, 2)Graduate school of Sport Sciences, Waseda University, 3)Research Fellow of Japan Society for the Promotion of Science, 4)Faculty of Sport Sciences, Waseda University, 5) Institute for Sport Sciences* **Introduction** Previous studies indicated listening to music during aerobic exercise reduced rates of perceived exertion (RPE). However, most past studies studied the effect on psychological parameters during exercise. There have been only few studies that evaluated the effect of music during on physiological parameters during exercise. Further question is that the exercise performance itself is influenced by listening to music. The purpose of this study was to investigate the effect of listening to music during aerobic exercise on physiological and psychological parameters, and exercise performance. **Method** Subjects were 9 healthy female (age: 21.9±0.9, height: 160.7±4.4cm, weight: 51.7±5.8kg). All of them did not have a menstrual irregularity and did not exercise more than three times a week. They took cycling exercise with music at 60%VO<sub>2</sub>max and 65rpm for 30 minutes (music condition), and they also did the same exercise with the metronome (control). These two conditions were separated by three days. Both conditions were measured in low temperature phase of menstrual cycle. In both conditions, RPE, pedaling rhythm and VO<sub>2</sub>/min were measured during exercise. Pedaling rhythm measured by electromyography (EMG) at vastus medialis muscle at three sections (0-5min, 10-15min, 25-30min). RPE was measured by Borg scale at every five minutes. Two-way ANOVA (time × condition) was used to analyze. **Result** Data from RPE, there were significant main effects of time and condition (for each p < 0.05), although time × condition interaction did not reach significant difference. RPE score in music condition showed significantly low compared to the control (p < 0.05), although time × condition interaction did not reach significant difference. Pedaling rhythms had a significant main effect of time (p < 0.05) and interaction trend between time and conditions (p = 0.065). There was no significant difference time × condition interaction in VO<sub>2</sub>/min. VO<sub>2</sub>/min showed a significant main effect of time (p < 0.05). In both conditions, VO<sub>2</sub>/min increased with time. **Discussion** These results indicated listening to music reduced subjective fatigue during exercise. Further, it suggested listening to music during exercise could improve cycling economy.

#### RELATIONSHIP BETWEEN HEART RATE VARIABILITY AND COGNITIVE FUNCTION. INFLUENCE OF PHYSICAL FITNESS.

Luque, A., Sanabria, D., Morales, E., Mateo-March, M., Zabala, M.

*University of Granada and University Miguel Hernandez of Elche, Alicante*

**Introduction** The quotation of our ancestors “mens sana in corpora sano” is supported by recent studies suggesting that physical activity has an important role as a protective factor at the physical and mental health (Albinet, Boucard, Bouquet, & Audiffren, 2010). The aim of

the present study was to investigate the relationship between exercise, heart rate variability (HRV) and cognitive performance. Methods Two groups of participants (athletes and sedentary) participated in this study. Both groups completed three cognitive tasks at rest: Psychomotor Vigilance Task (PVT), temporal orienting (TO) and time perception (TP). To record the HRV we used a FirstBeat Bodyguard (Firstbeat Technologies Oy-Jyväskylä) and obtained time-domain indicators (mean R-R, SDNN and rMSSD), frequency domain indicators (HF and LF bands) and non linear results (SD1 and DFA-1). Results The results showed a clear main effect of cognitive task in all measured indicators of HRV that did not interact with the variable Group. The PVT was associated with greater involvement of the parasympathetic (mean R-R, SDNN, rMSSD, SD1 and DFA-1). TO and TP tasks showed the least variability, respectively. There were apparently contradictory results with the frequency indicators that showed less vagal involvement in the PVT. We also found a group effect in time domain indicators and SD1. A significant benefit in the PVT's reaction times was found in the group of athletes compared to sedentary. Discussion In the present study we showed that the benefits of training on cognitive performance are produced selectively (Thayer, Hansen, Saus-Rose, & Johnsen, 2009). Crucially, the type of task and cognitive load also influence directly and differentially the HRV. There were some contradictory results in the frequency domain indicators. Additionally, our results provide information also from non-linear indicators that support those obtained in time domain and give the possibility of new interpretations in the disagreement present in the literature. ## EFFECTS OF CAFFEINE INTAKE ON TEMPORAL ESTIMATION AT REST VS. DURING A MODERATE AEROBIC EXERCISE

Blasco, E., Monleón, C., Llorens, F., Moratal, C., Correa, A., Huertas, F.

*Universidad Católica de Valencia San Vicente Mártir*

INTRODUCTION The effect of caffeine intake on physical and cognitive performance are well documented. This fact together with its removal from the list of prohibited substances by World Anti-Doping Agency, have raised the prevalence of caffeine use by the athletes of different sports disciplines. There are many studies about the effects of caffeine on physical performance, looking for increased energy, improved efficiency, and reduced fatigue (Ganio et al., 2009) and also interested in the effects on cognitive performance (Brunyé et al., 2010). However, there are a few references related to the study of the interaction between caffeine and temporal attention (Gruber & Block, 2005). Aim of this work was to determine whether caffeine intake (4 mg / kg) modulates the temporal estimation of activity in different conditions (rest vs. effort). METHODS Sixteen subjects participated in four experimental counterbalanced conditions (exercise/caffeine, exercise/placebo, rest/caffeine, rest/placebo). Previously, participants performed an incremental cycle ergometer test to determine the intensities of effort would develop attentional task in the exercise condition. Repeated measures ANOVAs were used to estimate the main effects and interactions of different variables. RESULTS Our results show that only the variable activity modulated the temporal estimation. Higher temporal underestimation were observed in the effort condition compared to the rest condition. The caffeine does not appear to influence temporal estimation. DISCUSSION According to the findings from Botella et al. (2001) this result could be related to the increased level of Arousal induced by the effort, which will accelerate the operation of our 'cognitive clock' due to increased secretion of dopamine. Moreover, under 'dual-task' contexts, in which it develops our exercise condition, the available cognitive resources are directed towards the realization of the cognitive task and less to the temporal estimation of it. ## THE ANALYSIS OF MOOD STATE AND INSOMNIA SEVERITY DURING SIX MONTHS OF WTK EXERCISE

Cheng, C.M.1, Chao, K.L.2, TING, W.C.3, CHANG, K.M.4

1 : KUAS (KAOHSIUNG, TAIWAN), 2 : YITC(PINGTUNG, TAIWAN), 3 : CSU (KAOHSIUNG, TAIWAN), 4 : TJUI(PINGTUNG, TAIWAN)

Introduction:Regimen exercise is traditionally viewed as a health care exercise used to improve health and to expand of life. The uniqueness of the traditional Taiwanese body-mind Wai Tan Kung (WTK) exercise is due to its usage of whole-body trembling and coordinated movements. It combines Han Calisthenics 9 forms, and consists of a sequence of 12 postures that are smooth, harmonic, and relaxing. During WTK exercise, the body is constantly trembling from feet to fingers and head, while deep and slow breathing and mental concentration are required to achieve harmony between the body and the mind (Chang CT, 1986).Therefore, practicing WTK might improve variety of health benefits in human being. Methods:Participants and study design. Both WTK practitioners (N=49, M=25, F=24) were recruited from a WTK association in Taiwan, and the control group's participants (N=51, M=51, F=50) without WTK experience were recruited from the communities. All subjects had normal lifestyles and were capable of daily activities without limitations. The Institute Review Board of Kaohsiung Medical University Chung-Ho Memorial Hospital had approved this study (KMUH-IRB-980568). The procedure was fully explained to the subjects, and obtained written consent from them before study. After baseline recording, the WTK practitioners had practiced WTK calisthenics at least 1 hour each time, 3 times per week and the normal controls did not treat. All the participants had filled in survey per 3-month and lasted for half a year.Data analysis. The test-retest was executed to compare the baseline characteristics and the SHPS, ISI, POMS and PANAS survey measures between WTK practitioners and normal controls. A P< 0.05 was considered statistically significant. All data are presented as mean ± SD. Results: There were no significant differences in the age, gender, body weight, body height and body mass index. There were no significant differences between WTK and controls with SHPS and PANAS survey, but with practice-time differences, there were significant differences in the SHPS domains scores of ARB, SST, EDB and SE. The other dimensions showed significant difference in confusion, vitality, fatigue, and Self-respect of POMS. There were significant differences in ISI, except the baseline score.Discussion:The basic principle of WTK exercise is performed in sequence with varying degrees of trembling and relaxation of various groups of muscles and it can get rid of distracting ideas and allow one's inner energy to rise up automatically from inside and make the whole body tremble by itself.Owing to the WTK regular practice, the domains scores decreasing in SHPS and ISI, and reducing score of fatigue, nervousness, confusion, anger and depression in POMS. The conclusions of this study are that WTK can decrease insomnia severity, confusion, fatigue, and increase vitality, self-respect and ultimately enable one to become healthy and happy as showed above. ## A STUDY OF THE DEPRESSIVE TENDENCY FOR JAPANESE COLLEGE ATHLETES: INFLUENCES OF SOC AND NEUROTICISM

Kase, T., Endo, S., Yano, M., Oishi, K.

*Rikkyo University*

**Introduction** Recently, maladjusted youths who possess depressive tendencies have been increased in Japan, and then the importance of prevention and improvement of the depressive tendency have been paid attention. It is known that the depressive tendency relates various factors individually, such as personality traits (especially, neuroticism), life orientation (e.g., Sense of Coherence; SOC), and sports activities, etc. However, the relationships among these factors were not fully known. Therefore, investigating the relationships among these factors, it is expected to find the effective interventions which prevent and/or reduce the depressive tendency. This study investigated the differences of the relationships between athlete and the other groups, to clarify the effects of sporting activities on those relationships. **Methods** Subjects were 249 college students (137 males, 112 females, mean age: 20.0±1.0 years). The depressive tendency and SOC were measured by using Self-rating Depression Scale (SDS), and Japanese version of SOC-29 individually. Neuroticism, one of the Big Five personality factors, was measured by using the Big Five Scales (Wada, 1996). Additionally, sports activities were surveyed in terms of the purpose in their activities and frequencies, etc. Based on these sports activity data, subjects were categorized into three groups, i.e., athlete, hobby, and non-exercise groups. **Results** For SOC scores, one-way analysis of variance revealed the significant differences in three groups  $F(2, 246) = 3.73, p < .05$ , and multiple comparisons showed significant differences between athlete and hobby groups ( $p < .05$ ). A multiple regression analysis showed that neuroticism was not associated with SDS, and SOC was negatively associated with SDS ( $\beta = -.687, p < .01$ ) in athlete group ( $R^2 = .472, p < .001$ ). On the other hand, neuroticism was positively associated with SDS ( $\beta = .224, .370, p > .05$  or  $.01$ ), and SOC was negatively associated with SDS ( $\beta = -.563, -.528, \text{both } p < .01$ ) in hobby and non-exercise groups respectively ( $R^2 = .511, .472, \text{both } p < .001$ ). **Discussion** These results showed that neuroticism was more effective on the depressive tendency in hobby and non-exercise groups. In contrast, SOC was the most effective factor to improve the depressive tendency in athlete group. It was suggested that competitive sports strengthened SOC, and then SOC reduced the expression of neuroticism and enabled us to cope with the depressive tendency more appropriately. **References** Wada S. (1996). Construction of the Big Five Scales of personality trait terms and concurrent validity with NPI. *Japanese Journal of Psychology*, Vol.67(1): 61-67.

## ATHLETE BURNOUT: RELATIONSHIPS BETWEEN BEHAVIORAL REGULATION, PERFECTIONISM AND SATISFACTION AND THWARTING OF PSYCHOLOGICAL NEEDS

Guillet-Descas, E., Moiret, S., Isoard-Gauthier, S.

*Université Claude Bernard Lyon 1*

**ATHLETE BURNOUT: RELATIONSHIPS BETWEEN BEHAVIORAL REGULATION, PERFECTIONISM AND SATISFACTION AND THWARTING OF PSYCHOLOGICAL NEEDS** Guillet-Descas, E.1, Moiret, S.1, & Isoard-Gauthier, S.1 1: CRIS (Lyon, France) **Introduction** Athlete burnout is defined as a syndrome with three dimensions: reduced sense of accomplishment, sport devaluation, and emotional and physical exhaustion (Raedeke & Smith, 2009). Gustafsson, et al. (2011) proposed an integrated model of athlete burnout (IMAB). This model include major antecedents, early signs, entrapment, vulnerability factors, and maladaptive consequences. The present study focused on the relationships between two early signs: motivation and psychological needs; and one vulnerability factor: perfectionism. The frustration over lack of accomplishment and perceived competence is one of the first signs of burnout. Research guided by basic psychological need theory has established that negative outcomes are hypothesised to occur when individuals perceive their psychological needs to be actively undermined (i.e., thwarted) in their immediate social environment. We examined the satisfaction and thwarting of psychological need simultaneously (Bartholomew, et al. 2011). The extent to which these needs are satisfied or thwarted determines the degree to which an athlete's behaviour is regulated by self-determined motivation. Research suggest that individuals whose needs are frustrated show greater amotivation and controlled motivation, and these have been associated with maladaptive outcomes. The alternative measure of self-determined motivation, by Lonsdale, et al. (2008) was used. The IMAB postulated that several personality factors appear to increase burnout risk. One personality characteristic that has been found is perfectionism. Hewitt & Flett (1991) identified three distinct forms of perfectionism: self-oriented, other oriented, and socially prescribed perfectionisms. The purpose was to examine whether perfectionism forms would moderate any association between satisfaction or thwarting of psychological needs with self-determined motivation and dimensions athlete burnout. **Method** Adolescents involved in elite sport have participated. Regression analyses will be used to examine the multivariate association between athletes' perfectionism scores, psychological needs, behavioural regulations and burnout. **Expected Results** We expect that the thwarting of psychological needs would be positively associated with less self-determined motives, would show positive associations with burnout. This interaction would be moderate by some perfectionism forms, such as other oriented or socially prescribed. **References** Bartholomew K, Ntoumanis N, Ryan R, Thøgersen-Ntoumani C. ## NEW DIRECTIONS IN THE CONCEPTUALISATION OF ATHLETE BURNOUT

Isoard-Gauthier, S., Guillet-Descas, E.

*Université Claude Bernard Lyon 1*

**Introduction** Athlete burnout (AB) has been a growing subject of interest during the past decade. Raedeke and Smith (2009) developed a multidimensional definition based on the workplace definition, and characterized AB as a syndrome with three key dimensions: (a) reduced sense of accomplishment, which correspond to a sense of ineffectiveness and a tendency of an individual to evaluate himself negatively in terms of performance and athletic achievements, (b) sport devaluation, which corresponds to a negative and detached attitude towards sport, resulting in a lack of interest about sport and performance, and (c) emotional and physical exhaustion, which refers to a feeling of emotional and physical fatigue stemming from the high demands associated with trainings and competitions. AB is considered as a syndrome with three dimensions that means that in order to consider that an athlete is burned out, he might report moderate to high scores on all the three dimensions (Eklund & Cresswell, 2007). Recent qualitative studies using retrospective interviews have proposed that the three dimensions of AB develop among time and that sport devaluation might be the last step of a sequence involving emotional/physical exhaustion and reduced sense of accomplishment (Cresswell & Eklund, 2007; Gustafsson, Hassmén, Kenttä & Johansson, 2008). Otherwise, Lonsdale, Hodge and Jackson (2007) have suggested to reconsider the emotional and physical exhaust-

tion dimension of AB. In line with the items in the Athlete Burnout Questionnaire (ABQ; Raedeke & Smith, 2009) it can be supposed that the two aspects of exhaustion can be two separate dimensions of AB. The first aim of the present study was to examine the prevalence of AB and its developmental sequence. The second aim was to develop a revised version of the ABQ (ABQ-R) by splitting exhaustion in two dimensions. Methods Adolescents involved in elite training centres have participated in two studies aimed to test the hypothesis. Growth curve and cluster analyses were used to examine the prevalence and the developmental sequence of AB. Expected Results and Discussion A developmental sequence involving the three dimensions of AB should be found. Specifically, we assume that sport devaluation should be the last step of the developmental sequence. Moreover, we expect that the ABQ-R offer good properties and could be used to reveal different profiles of AB among adolescents in elite training centres. References Cresswell S, Eklund R. ## DOES PERSONALITY AFFECT NEUROFEEDBACK PERFORMANCE? AN EXPLORATORY STUDY WITH ELITE YOUTH ATHLETES

Rowley, C., Earle, K.

*University of Hull*

**Introduction** The current study aims to expand upon the limited amount of research utilising neurofeedback devices within the sporting domain. A number of researchers have recently made calls for personality to be considered as a potential mediating factor in regulating the efficacy of psychological interventions (Hardy et al., 2010, Woodman et al., 2010). On this justification, the present study aims to analyse the potential moderating effect that personality traits have on a neurofeedback performance task. Method 31 male academy level rugby league players completed the 16PF-5 personality measure (Cattell et al., 1995) as well as completing a one-off neurofeedback task using the Mindball Trainer® device. The task involved participants optimising their levels of relaxation and focus in order to move a ball from one end of the device's scale to the other. The electrode headband which they wore during the completion of the task measured their corresponding brain activity which in turn produced forwards or backwards movements in the ball. Their overall aim was to complete the first level of the training program within the allotted time period of 2 minutes. A scoring scale of 1-10 was employed in which 1 represented the lowest score possible, and 10 represented the highest. A 1 was awarded if a participant failed to reach any of the 4 quadrants on the scale in the allotted time, whereas a 10 was awarded for full completion of the task within 0-24 seconds. Results Regression analyses revealed Rule Consciousness as being the only significant personality trait in terms of predicting actual neurofeedback performance ( $r = 0.41$ ,  $p < .05$ ). Discussion The relationship between personality and performance has been well established (e.g. Fisher et al. 1977). However, in this study the only aspect of personality that related to performance was rule-consciousness. An explanation for this finding may be that this trait has particular relevance when performing a novel or 'unusual' task. It would appear that the more dutiful and conforming individuals are able to produce higher levels of performance on the neurofeedback task, indicating a greater ability to focus and concentrate when faced with such tasks. This provides further support for a recent paper by Cupples and O'Connor (2011) who found that personality (encompassing coachability) was one of the top five performance indicators required to reach the elite level in rugby league. ## EFFECT OF A 5' BOUT OF ANAEROBIC EXERCISE ON COGNITION

Llorens, F.1,2, Huertas, F.1, Sanabria, D.2

*Universidad Católica de Valencia*

Llorens, F.1,2, Sanabria, D.2, & Huertas, F.1. Departamento de Gestión y Ciencias Aplicadas a la Actividad Física, Universidad Católica de Valencia, Spain. 2. Departamento de Psicología Experimental, Universidad de Granada, Spain **Introduction** There is growing evidence regarding the effect of acute bouts of aerobic exercise in the functioning of attention (McMorris, Tomporowski & Audiffren, 2009). Executive control is responsible for selecting the correct response and the inhibition of automatic unwanted responses (Posner & Digirolamo, 1998) (e.g., basketball players have to decide within a few seconds whether to shoot, bounce or to dribble). Spatial visual attention select potential relevant stimuli in the visual field, enhancing its processing while ignoring stimuli that are irrelevant for the task at hand (Reynolds & Chelazzi, 2004) (e.g., the movement of a member of the audience can capture the attention of a basketball player throwing a free shot). In the present study, we measured the deployment of the exogenous spatial attention and executive control in three different conditions. **Methods** We used a Cardgirus Medical Pro cycle ergometer, RS800CX Polar monitor to record the heart rate (HR) and a Lactate Pro lactate test meter and Lactate Pro strips to determinate the anaerobic threshold and for experimental conditions. Participants performed a spatial attention task at rest, immediately after an acute bout of anaerobic exercise, and after recovering the basal HR following an acute bout of anaerobic exercise. **Results** The results showed that the magnitude of the Stimulus-response compatibility was larger in the Post-effort session than in R and Pe+r session. In contrast, we did not observed any modulation of exogenous spatial attention by the 5' bout of anaerobic exercise. **Discussion** Regarding executive control, the current findings replicate other studies (e.g., Del Giorgio et al., 2010), which observed a worse functioning of executive control while performing an acute bout of anaerobic exercise. Our results lend support to the Transient Hypofrontality Theory. References Del Giorgio, J. M., Hall, E. E., O'Leary, K. C., Bixby, W. R., & Miller, P. C. (2010). ## MEASURING ATTENTION AFTER AN ACUTE BOUT OF AEROBIC AND ANEROBIC EXERCISE

Llorens, F.1,2, Huertas, F.1, Sanabria, D.2

*Universidad Católica de Valencia*

Llorens, F.1,2; Huertas, F.1; Sanabria, D.2. 1. Departamento de Gestión y Ciencias Aplicadas a la Actividad Física, Universidad Católica de Valencia, Spain. 2. Departamento de Psicología Experimental, Universidad de Granada, Spain **Introduction** There is growing evidence regarding the effect of acute bouts of aerobic exercise in the functioning of attention (Tomporowski, 2003). This study explored the effects

of aerobic and anaerobic bouts of physical activity on the deployment of exogenous spatial attention and stimulus-response conflict. Executive control and spatial orienting processes play an important role in sport competition. Methods We used a VIA sprint 150 P cycle ergometer, RS800CX Polar monitor to record the heart rate (HR) and analysis of expired gases occurred using the MasterScreen CPX Metabolic Cart to obtain anaerobic threshold. Participants performed a spatial attention task at rest, during an acute bout of 100% anaerobic threshold, 80% of anaerobic threshold and after recovering the basal heart rate (HR) following an acute bout of anaerobic and aerobic exercise. These sessions were counterbalanced across participants. Results Anaerobic exercise induced an increase in the stimulus-response compatibility effect magnitude (i.e., RT incompatibles – RT compatibles) compared to a situation in which the cognitive task was performed at rest. This effect disappeared when participants recovered their basal HR. Exogenous attention was not modulated by anaerobic exercise. On the contrary aerobic exercise modulated exogenous spatial attention but did not affect executive control. Discussion Regarding executive control, the current findings replicate other studies (e.g., Del Giorno et al., 2010), which observed a worse functioning of the executive control network while performing anaerobic exercise. This effect disappeared after recovering the basal HR. This result lends support to the Transient Hypofrontality Theory. On the contrary, aerobic exercise only modulated the deployment of exogenous spatial attention. We argue that aerobic exercise enhanced participants' attentional reactivity to peripheral stimuli, replicating Sanabria et al.'s (2011) study. References Del Giorno, J. M., Hall, E. E., O'Leary, K. ## GROUP AND INDIVIDUAL DIFFERENCES DURING THE STUDY OF PERCEPTUAL CUES FOR TENNIS SERVES

Zawadzki, P., Roca, J.

*Barcelona University*

Introduction During a tennis match, the ability to anticipate an opponent stroke is composed in part from what one can perceive from his technique. Over matches players normally formulate knowledge based on a group or a single player. With the aim of explore this argument an analysis over a study of perceptual cues of tennis serves were made. Methods Kinematics analysis was used to describe 19 professional tennis players during competition through four groups of perceptual cues: position of serve (pos), ball toss (bal), knee bend (kne) and racket arm location at appearance to returner (rac). Canonical Correlation Analyses were performed between groups on all professionals, and on three participants random assigned. Results Canonical correlation coefficient (Rc) showed for the group value of 0.2402 ( $p=0.01$ ), with canonical variates of pos=0.0031, bal=0.299, kne=0.0746, and rac=-0.1598. Player 1 showed results Rc=0.8909 ( $p=0.05$ ) for the first coefficient, with canonical variates of pos=0.0517, bal=-0.0969, kne=0.0909, and rac=0.0019. Player 2 showed Rc=0.9109 ( $p=0.004$ ), with canonical variates values of pos=0.493, bal=-0.0261, kne=0.1363, and rac=0.0122. Player 3 showed Rc=0.8805 ( $p=0.0013$ ), with canonical variates values of - pos=0.199, bal=0.0499, kne=0.0007, and rac=-0.047. The greater canonical weight on the result group was ball speed for all results. Discussion Despite all correlations resulted significant ( $p<0.05$ ), power of correlations comes from 0.2 on the group to 0.9 on one player. Canonical variates also are different for each case. This evidence suggests that knowledge should be elaborated starting on the single player to be more efficient. Baker, Farrow, Elliott, and Anderson (2009) and Farrow, Abernethy, and Jackson (2005) showed evidences that support the kinematic content of a server as responsible for the anticipatory skill of their participants, justifying the need of a perceptual cue description at individual level. Zawadzki and Roca (2010) relates the Opponent Technique Study as a field plenty of opportunities to help players to fit their responses faster and more accurate. #### ALL FOR ONE AND ONE FOR ALL! DISPARITY BETWEEN OVERALL CREW AND INDIVIDUAL ROWERS PACING STRATEGIES DURING ROWING

Renfree, A., Martin, L., St Clair Gibson, A.

*University of Worcester*

ALL FOR ONE AND ONE FOR ALL! DISPARITY BETWEEN OVERALL CREW AND INDIVIDUAL ROWERS PACING STRATEGIES DURING ROWING Renfree, A.1, Martin, L.1, St Clair Gibson A.2 1: University of Worcester UK, 2: Northumbria University UK Introduction During on-water 2000m rowing a common parabolic race profile has been reported (Muehlbauer et al 2011). Previous studies have reported total boat speed when analysing pacing strategies during rowing, and no published study has reported individual rower or overall boat power profiles. The aim of this case study was therefore to describe overall and individual rower power profiles of a coxless four boat during 2 km and 5 km trials. Methods A crew of four male rowers with at least three years competitive experience at varsity level participated in this study. Following familiarisation trials, the crew performed maximal trials over 2 km and 5 km in a Janousek 4- boat (Janousek Racing, Surrey, UK). The oarlocks were replaced with power-line gates (Peach Power-Line systems, Peach Innovations Ltd. Cambridge UK). The Power-line system was interfaced to a PC equipped with Power-Line V3-3 software which calculated power output (Watts) generated during each stroke. For both trials, mean overall boat and individual rower stroke power was calculated for each 25% epoch (25% of total strokes taken), and power for each individual epoch was calculated as a percentage of mean power maintained over the entire distance. The coefficient of variation was used to determine stroke to stroke and epoch to epoch variability for individual rowers and the overall boat. Results Power profiles indicate that in both trials the overall pacing strategy consisted of a high power output in the initial 25% that decreased in the middle 50% and increased again in the final 25%. Individual rower data indicates that each has a different power profile, and not all mimic the overall boat profile. In both trials, the stroke and bow seats produced their highest power during the final

epoch whereas rowers in the middle positions produced their highest power outputs in the opening epoch. Additionally, each individual also demonstrated a high degree of oscillation in stroke-to-stroke power output throughout the trials. Discussion This study demonstrates that overall boat power profiles during 2 km and 5 km rowing trials are similar to velocity profiles previously reported for individual ergometry and on-water racing events. However, this overall profile is achieved despite considerable variation within individual rower profiles. Further research is warranted in order to determine the mechanisms through which individual contributions to overall pacing strategy are regulated, and the effectiveness or otherwise of seemingly disparate individual strategies on overall performance. ### CHARACTERISTICS OF MATCH ACTIVITY IN JAPANESE SOCCER REFEREES.

Ishihara, Y., Naito, H., Katamoto, S.

*Juntendo university*

INTRODUCTION: Previous studies demonstrated that the match intensities of referees in premier league were positively correlated with the levels of competition (Weston et al. 2006). However, the effect of competition standard on match activities of referees in highschool and university football matches has yet to be thoroughly examined. Therefore, this study aimed to quantify the characteristics of the match activity with respect to referee's running distance and speed, and heart rate during Japanese amateur U-18 and U-22 football matches, and to investigate the influence of match technical-tactical data of field players on these measures. METHODS: Twenty male football referees (25 ± 3 year-old) holding a 1st or 2nd class licence accredited by Japan Football Association participated in this study. Match activity data were collected using a GPS (15 Hz, Gpsports, Australia) from 20 referees: 10 refereed for Takamado trophy U-18 football league (U-18), and the rest for the Kanto university league (U-22) during the 2011 season. The recorded movement speeds of the referees were classified into the following categories (1) Walking: ≤ 6 km/h, (2) Jogging: 6-8 km/h, (3) Low speed: 8-12 km/h, (4) Moderate speed: 12-15 km/h, (5) High speed: 15-18 km/h, and (6) Sprinting: ≥ 18 km/h. The high-intensity running (HIR) was defined as the speed greater than 15 km/h. Heart rate (HR) was recorded using short-range radio telemetry. All matches were video filmed to record the distance of the referees from infringements, and players' match technical-tactical data using a broad video camera. Technical-tactical data were the numbers of (1) passes, (2) shots, (3) infringements, (4) penetrations into attacking zone, and (5) offence-defence turnovers. RESULTS: Of all the matches observed, the mean total distance covered by the referees was 11209 ± 665 m. 17 % of that (1872 ± 472 m) was covered by HIR. Mean running speed and HR were 7.1 ± 0.4 km/h and 167 ± 8 beats/min (86 ± 4 %HRmax), respectively. A significant negative correlation was observed between the total distance covered and the mean distance from infringements ( $r = -0.56$ ,  $p < 0.05$ ). These measured variables did not significantly differ between U-18 and U-22 matches, nor were they affected by the players' technical-tactical behaviors and appeared to be similar to previously reported values of FIFA referees. DISCUSSION: The age-related competition level and players' technical-tactical data had no effect on the referees' match activities. moreover, the match activity level observed in this study resembled that of FIFA top level referees. These results could suggest that the referees moved independently of players' moves or skills but predicted the flow of events with a broad view in cooperation with the assistant referees. ### 100 M BACKSTROKE TIME ESTIMATION FROM AGE: A MODEL BASED ON REGRESSION ANALYSIS

MORALES, E., Dominguez-Castells, R., Femia, P., Arellano, R.

*Faculty of Sport Sciences*

Introduction The dynamic process of training needs as much information as possible from performance and training testing, which will help the coach monitor the training program. It must be designed according to swimming time and age. Performance in 100 m backstroke (B) improves with age during the growing period. Race components change with gradual development of many physical fitness factors. Regression equations were obtained through the race components analysis in different competitions (Absaliamov and Timakovoy, 1990; Arellano et al., 1996; Nomura, 2006). This investigation aimed to estimate the event times (ET) in 100m backstroke from age. Methods Data from different competitions (Age group Andalusia Championship 2004, European Youth Olympics 2001, Junior European Championship 2000 to 2004, and Senior European Championship 2000 to 2005) were used to develop the regression analysis. These times were published in a web: <http://www.swim.ee//competition>. 100 m backstroke semifinalists and finalists were analyzed. The Kolmogorov-Smirnov test, which confirmed the normal distribution, was used. Regression analysis was used to determine the tendency and model of the event time. Inverse function approximation of the event time by age (AGE) and gender (GEN) was carried out. The generic equation obtained was:  $ET = a + a' * GEN + b/AGE (1 - b' * GEN)$  The time estimation formula from age according to gender was as follows: ET men =  $a_1 + b_1/AGE$ ; ET woman =  $a_2 + b_2/AGE$  Furthermore, regression analysis and inverse function for the event time were calculated. Results The type of equations obtained for event time according to gender were inverse functions: ET men =  $26.752 + 556.094 * AGE^{-1}$  ( $R^2 = 0.646$ ); ET woman =  $35.852 + 458.654 * AGE^{-1}$  ( $R^2 = 0.593$ ) Discussion 200m freestyle times for young swimmers during growth were estimated through regression analysis (Nomura, 2006). The model proposed for backstroke enhances this estimation, allowing to determine swimming times according to age and gender. Peak performance times were estimated until 35 years old (maximum swimmers' age found in these competitions). A progressive time increase until 70 years old was obtained in the analysis of different competitions in the US Masters Swimming, which was characterized by a steep quadratic term (Donato et al., 2003). In conclusion, bearing long-term planning in mind, with internal and external development factors, this regression model can be used as a reference guide for a correct swimmer development. ### VO2MAX ESTIMATION USING SUB-MAXIMAL METABOLIC RESPONSES IN MIDDLE-AGED WOMEN, AGES 40~60 YEARS

Jeon, Y.J.1, Yoon, J.H.2, Lee, B.K.3, Kim, C.H.4, Kim, B.W.5, Im, J.H.6

1,2,6 : KAIST(Daejeon, S.Korea), 3 : SangMyung U.(Seoul, S.Korea), 4,5 : Daejeon U.(Daejeon, S.korea)

Introduction The purpose of this study is to make regression equation which estimates maximal oxygen uptake of middle-aged women. Maximal oxygen uptake is known as a standard of person's cardio-respiratory capacity. Methods 153 women subjects, ages 40~60

years ( $48.6 \pm 5.5$  years old in average) were participated in this study. Maximal exercise test was carried out on a treadmill followed by Bruce protocol, and data of metabolic responses were recorded when test time was 3 and 6 minutes especially. We used these sub-maximal metabolic responses and physical property variables and made 2 models by applying multiple regression analysis with step-wise method. Results The equation of 3 minutes model is  $VO_{2max}(ml/kg/min) = 61.363 - 0.155Age - 0.414Weight - 0.128HR(3) + 0.028VO_2(3) - 0.015VCO_2(3)$  made by age, weight, HR at 3 minutes (HR(3)),  $VO_2$  at 3 minutes ( $VO_2(3)$ ) and  $VCO_2$  at 3 minutes ( $VCO_2(3)$ ). R (multiple correlation) of this model was 0.728, SEE was 2.72 ml/kg/min and CV was 9.16% ( $p < 0.05$ ). And the equation of 6 minutes model is  $VO_{2max}(ml/kg/min) = 33.705 - 0.433Weight + 0.026VO_2(6) - 0.011VCO_2(6)$  made by age,  $VO_2$  at 6 minutes ( $VO_2(6)$ ) and  $VCO_2$  at 6 minutes ( $VCO_2(6)$ ). R of this model was 0.823, SEE was 2.24ml/kg/min and CV was 7.50% ( $p < 0.05$ ). Discussion The result of cross-validation of these models with rest 45 subjects showed very little errors. And compared with other studies, statistical data between models were similar. Therefore both models are suitable for predicting maximal oxygen uptake. But maximal oxygen uptake of subjects who had good cardio-respiratory capacity was underestimated little.

### FREE KICKS IN FOOTBALL: COORDINATING TO SUCCESS

Vicente, A., Lopes, H., Fernando, C.

*University of Beira Interior, University of Madeira, CIDESD*

Introduction In the FIFA World Cup 2010 there was 2011 fouls on the 64 matches (an average of 31.42 fouls per game). From these fouls resulted a huge percentage of direct or indirect free kicks. However, from the 1018 total shots in the FIFA World Cup 2010 only 159 were free kick shoots, and even a lower percentage resulted in goal. The free kick is a very important opportunity to score. However, studies on this situation are essentially empirical and there is not enough knowledge to understand this situation functionally and by this how it can be improved so that its success can increase. The aim of this study was to analyse a set of free kicks from a major football competition in order to understand this situation functionally in the continuation of previous studies (e.g. Vicente et al., 2011). Methods Using a model of team sports (Almada et al., 2008) we've defined limits for  $t$  (being  $t$  - the time the ball takes to reach the goal area) and the intermediate times in that we can decompose this  $t$  and what actions can be made in those times by the attacking team. We compared all these times with the times that concomitantly were used by the defending team ( $t'$ ), and the parcel times that compose this  $t'$ . We've compared the reached conclusions with what we have analyzed in 10 free kicks from the FIFA World Cup 2010 Final (Netherlands vs. Spain), trying to understand if our definitions were coherent. We've calculated the time the ball took to reach the goal area using the ballistic trajectory formula and defined the different conditions that were possible in acceptable limits. We've measured the time the ball took until being touched by any player or enter the goal. Results The ball took a minimum of 320 up to a maximum of 3420 milliseconds to reach the goal or being touched/shot by a player. The attacking players mostly started their movement before the defending players and, in average, 240ms before the ball being kicked. No goal was scored from this situation in this match. Discussion The definition of possible strategies in a free kick situation for the attacking team with the knowledge of the variables limits is possible and can improve the performance of football teams if the right strategy is prepared. Ecological studies that we are still carrying out tend to corroborate that there are limits that can be reached and are useful, but depending on the objectives aimed there are others that are neither reachable nor useful. Their definitions are useful to orientate practice and improve player's and team's performances in these situations. References Almada F., Fernando C., Lopes H., Vicente A., Vitoria M. (2008). ### EXECUTION TIME OF MAWASHI-GUERI IN KARATE COMPETITION AND TRAINING SITUATIONS

Fernando, C., Vicente, A., Lopes, H.

*University of Madeira, University of Beira Interior, CIDESD*

Introduction Training is a preparation for the competition; however, in order to actually accomplish this aim efficiently it is necessary that the conditions under which it is made suit the training goals (Almada et al., 2008). Understanding the inherent variables in the ecological situation of a mawashi-gueri is essential to build coherent training models but it is also important to test whether the starting conjectures are consistent with the data obtained. Methods In a sample of 5 senior level male individuals with experience in karate (karateka) we recorded and measure the execution time of mawashi-gueri in three different situations: 1) In a combat situation in competition; 2) In a training situation where from the usual displacement movement in combat the karateka performed the mawashi-gueri for a pre-defined area; 3) In a training situation starting from a static position the karateka performed the mawashi-gueri. The films from each situation were edited with Adobe Premiere Pro C4, with a breakdown of 25 frames/minute and quantified the time of 7 mawashi-gueri for every situation and every karateka. Results The average time for the execution of mawashi-gueri in situation 1) was 377ms, in situation 2) 398ms and in situation 3) 598ms. The standard deviation was respectively 0.45ms, 0.27ms and 0.44ms. In all the situations the values range was 400ms, being the maximum value of 680ms and the minimum of 280ms. Discussion The obtained data from the ecological situation of combat (228-248ms) are far below those known for the execution time of the mawashi-gueri, including the data presented by Villani et al. (2009) where the times were reported between 610-640ms. Also Mori et al. (2002) in punching and kicking techniques indicate values between 430-660ms. This difference is easily explained by the fact that the values presented by these studies were collected in laboratorial situations where the karateka starts moving from a static position. However, through the experimental situations made, we have verified that even in an isolated situation of mawashi-gueri training it is possible that the karatekas present time values closest to the ecological situation if the exercise is designed with this concern. Moreover, we believe that the difference in the execution times of mawashi-gueri in a static situation (situation 3) found when compared to data from other studies may have been caused by the fact that karatekas were influenced by the other held situation (situation 2) or even by their competition experiences. ### UNDERSTANDING THE CORNER KICK IN FOOTBALL – QUANTIFYING FOR TRAINING

Lopes, H., Fernando, C., Vicente, A.

*University of Madeira, University of Beira Interior, CIDESD*

Introduction The corner kick is an important opportunity to score in football. However although, on average, 10 corners occur per game the ones that achieve goal are very low. Knowing that the ball takes on average between 1500ms and 3000ms to reach the front of the goal (Vicente et al. 2011) and that even 21 players can be involved in this situation it is important to quantify some of the execution times involved so that training should decrease it's empirical dominance. Methods Using the model for functional analysis of the corner kicks in

football developed by Almada et al. (2010) a laboratorial situation was created where a forward had a defender on its back and tried to pass over him in the shortest possible time, placing himself ahead of the opponent (the defender). The defender could move in an area of 1.2meters by 0.6 meters and the forward moved from an area of 0.6m by 0.6m placed behind the defender zone (with three positions: in the middle, the entire left and all the right) and had to reach an identical area placed in front of the defender zone. The sample consisted of 20 football players who assumed the forward and defender functions. Each forward repeated the situation 30 times (10 starting from the center, 10 starting at left and 10 at right). Results The obtained times varied in a ranged between 690ms and 2420ms with an average of 1380ms (SD+400ms). There were no significant differences between the times from the three forward starting positions (center, left and right). Discussion Considering that in the corner kick in football the ball takes in average between 1500ms and 3000ms to reach the front of the goal, and the forward that seeks to gain advantage over the defender in order to be in a better position to be able to intercept the ball route and try to score takes between 690ms and 2420ms to do it, this may mean that the forward has enough time to gain position over the defender by choosing the best moment to do so even after the ball starts. But we must not forget that the forward can know in advance the ball route and the area where it begins to be possible to act over it, so that it is possible an articulation between the different forwards so that their movements can not only give the wrong information to the defenders about what will happen, but also blocking the defenders, preventing them, including the goalkeeper from intercepting the ball. ### **INFLUENCE OF CODE OF POINTS IN BRAZILIAN MEN'S GYMNASTICS TRAINING**

Carrara, P.1, Mochizuki, L.1, Araujo, C.2, Botelho, M.2

1: USP (São Paulo, Brasil), 2: FADEUP (Porto, Portugal)

Introduction: The Gymnastics' Code of Points (CP) had great changes after 2006. With a new dimension for competitions evaluation criteria, the traditional ten point score was substituted by the top ten elements of difficulty and maximum ten points of presentation in an exercise (Carrara and Mochizuki, 2011). The aim of this study is to verify the influence of the CP new rules on the systematization of high level men's gymnastics training. Methods: To understand these alterations, fifteen senior coaches of Brazil, including those working with national team, were questioned about the changes in the CP rules and their respective influence on training. For the interviews, a comparative analysis between the rules of the 2001 and 2006 CP was performed, whose results were used to construct and validate the questionnaire. A questionnaire of 12 items were answered and commented upon. Content analysis was used for evaluation of the comments (Bardin, 2004), where the emerging themes were the training components. Results: The coaches expressed some tendencies toward training changes. In this respect, an increase in training volume to develop elements of higher difficulty in different groups; and intensity increase to execute routines with more elements of higher difficulty, including the dismount was introduced into Physical Preparation. In Technical Preparation a wider element variety and element difficulty of the different groups were necessary. In Tactical Preparation routines involving a larger number of more difficult elements, including dismount, were observed. Discussion: The coaches mentioned that the new rules imply changes in routines composition and noticed new tendencies in training systematization. The main results permit to conclude that the 2006 CP led to changes in routine composition, with the use of a more varied number of elements on the apparatuses. Specifically, floor exercise is the only with maximum presentation time, what requires greater number of elements and acrobatic sequences to earn bonus score. Rings routines require changes in strength training, to develop new elements and connections in static elements. Rings also need a wide range of group elements, and were considered the most complex apparatus to dismount at the routine's end. Comparing coaches' interviews with international results, Brazil's team improved from one gymnast classified to 2008 Olympic Games (OG) to three gymnasts in 2012 OG. In world championships hold two medals, 2007 and 2011, on floor exercises and reached on rings its first medal in 2011. It is important to consider that gymnast performances on the different apparatuses are not only conditioned by training characteristics, but also by the gymnast's individual potential (Arkaev, 2004). ### **CRITICAL ACCELERATION-DECELERATION ALLOWS ESTIMATES REAL METABOLIC DEMAND DURING A SOCCER GAME.**

Argemi, R., Ortega, G.P.

*Club Boca Juniors*

Since 1950 many different efforts have been made to estimate the metabolic demands of a soccer game, despite the different tools the only published information is about distance and speed during the game. We hypothesize that this approach underestimates the real metabolic demand of a soccer game compared to accelerations and decelerations measure. PURPOSE: To determine the physical demand of a soccer game comparing, running speed vs. acceleration-deceleration. METHODS: We evaluate 10 field players of the professional team of Boca Juniors, Argentina. First, they done endurance intermittent level 2 Yo-Yo Test, with GPS (gpsport®, Australian). We establish the critical velocity (CV) (average velocity of the last step) and critical acceleration-deceleration (CAD). ( acceleration and desacceleration of the last step in 0,5 1, 2 and 3 seconds) Using a commercially available semi-automatic video analysis system we compare the distance covered at different speeds and at different intensities of acceleration-deceleration during an official Argentine first division soccer game. RESULTS: the results for the distance covered in meters; the percentage of the total distance covered; the average distance covered; and the number of efforts are shown for >80%, >100% or >200% of critical velocity (CV) and critical acceleration desacceleration (CAD) Distance in meters (CV: 2271, 1279 and 0) (CAD: 3881\*, 2323\* and 534\*). % total Distance (CV: 22,52, 1274 and 0) (CAD: 38,44\*, 23,02\* and 5,3\*)Average distance per entry (CV: 5.24, 6.49 and 0) (CAD: 2.60\*, 3.12\*, and 5.3\*). \* p: < 0,05 . CONCLUSION: Running speed underestimates the real metabolic demands of a soccer game. The average distances of each effort are very short to develop high velocities, even when the players are accelerating at their maximal or near maximal capacity. Considering acceleration and deceleration, the efforts double the values of intense exercise from the traditional methodology which measure only velocity.

### **PLOTTING PAIRED DATA SAMPLED FROM DIFFERENT GROUPS USING THE DISTRIBUTION-FREE R PACKAGE 'PAIREDATA'**

Champely, S., Verdot, C., Monteil, K.M.

*University Lyon 1*

Introduction "The most common design in sports and exercise science involves one between-subject factor at two levels and one within-subject factor also at two levels" (Newell et al., 2010). Before analysing such data (by gain score analysis, repeated measures ANOVA or

ANCOVA), a data visualisation is important in order to detect the existence of outliers, clusters, heteroscedasticity, granularity, or still departures from normality. Such a visualisation stage could also suggest some data cleaning, a convenient data transformation or simply a more suitable data description. Several specific plots exist for the genuine paired data situation: the correlation plot, the Bland-Altman plot, the profile plot and the paired dotplot. Nevertheless, all these graphic methods are rarely available in usual statistical software and not often described in statistics handbooks. Furthermore, to differentiate paired data sampled from different groups, it is essential to use more complex visual strategies such as faceting (small multiples of the simple plot) or grouping ones (overlapping plots). Methods The layered grammar of graphics (Wickam, 2011) considers a statistical graphics as a mapping from data to aesthetic attributes (colour, shape...) of geometric objects (points, lines...) drawn on a given coordinate system, with faceting implemented in this framework. We indeed propose in the distribution-free R package 'PairedData' some innovative plotting tools based on this powerful grammar. Results The interest of these tools will be shown on two datasets: firstly through a comparison of the flexibility of left and right shoulders between swimmers and sedentary people; and secondly through an analysis of the evolution of prisoners' stress between a group physically trained during a five month period and a control group (comparison of stress rates at the beginning and at the end of the five month period). Discussion The display devices proposed in the 'PairedData' package can also be used with a between-subject factor at multiple levels or even with a combination of two between-subject factors. In addition, this package implements some statistical tools for studying the simple paired two-sample design. A robust location test, two robust scale tests and one robust procedure for computing an effect size, were especially written for paired data. A graphical user interface is currently under construction to provide an easy-to-use environment to these new functionalities. References Newell J, Aitchinson T, Grant S (2010). ### TIME SPENT IN MODERATE INTENSE PHYSICAL ACTIVITIES VARIES DEPENDING ON TYPE OF ANALYSIS AND SELECTED METS CUT-OFFS.

Van Remoortel, H., Hornikx, M., Demeyer, H., Burtin, C., Langer, D., Janssens, W., Decramer, M., Gosselink, R., Troosters, T.  
*Katholieke Universiteit Leuven, Faculty of Kinesiology and Rehabilitation Sciences*

Time spent in moderate intense physical activity is a health-related outcome frequently used in clinical trials and physical activity guidelines. Different age-dependent cut-offs to define moderate intensity are existing. The aim of the present study is to investigate the adherence of an elderly population to different cut-offs of moderate intense physical activities. Hundred sixty-seven older adults (50 non-smokers, 63 (ex-)smokers and 54 mild COPD patients; age  $62 \pm 7$  y, 66% male and BMI  $26.4 \pm 4.0$ ) wore a multisensor activity monitor (SenseWear Pro Armband) for 7 consecutive days. Metabolic Equivalent of Tasks (METs) were recorded minute-by-minute during >22h wearing time on at least 3 days. Cut-offs to define moderate intense physical activities were based on 1) ACSM physical activity guidelines (ACSM:  $\leq 65$ y; 3 METs, >65y; individual METs level corresponding to 50% of VO<sub>2</sub> reserve), 2) Individual METs level (50% of VO<sub>2</sub> reserve) for each person (INDIVIDUAL) and 3) age-dependent cut-offs from Haskell and Pollock (HP: age  $\leq 65$ y; 4.5 METs, >65y; 3.6 METs). Time spent in at least moderate intense physical activities was analyzed with (BOUITS) and without (NO BOUITS) bouts of at least 10 minutes consecutive activity above the threshold. 'Physically active' was defined as  $\geq 30$  minutes (BOUITS) moderate intense physical activity per day. As expected, the median time spent in moderate intense physical activities was significantly less in BOUITS compared to NO BOUITS (38 [13 to 72] vs 106 [61 to 152] min/day with ACSM, 44 [15 to 79] vs 120 [68 to 173] min/day with INDIVIDUAL and 4 [0 to 18] vs 24 [9 to 60] min/day with HP, all  $p < 0.01$ ) and significantly lower values were observed for HP cut offs ( $p < 0.05$ ). Fifty-nine and 60% of the participants were classified as physically active corresponding to ACSM and INDIVIDUAL, respectively. HP cut-offs classified significantly less subjects (18%,  $n=31$ ) as physically active ( $p < 0.0001$ ). Underestimation of moderate intense physical activities with HP compared to ACSM was higher in adults of 60-65y (mean difference of  $-87 \pm 19\%$ ) compared to adults >65y (mean difference of  $-47 \pm 49\%$ ,  $p < 0.05$ ). The amount of moderate intense physical activity in bouts of at least 10 minutes is 2 to 3 fold lower compared to no bouts. Similar results in moderate intense physical activity are reported with individual cut-offs and ACSM whereas HP cut-offs are more stringent especially in older adults from 60 to 65 years. The present study showed that type of analysis and selected METs cut-off are important factors when using an activity monitor. Prospective validation of the cut offs related to adverse long term outcome seems needed.

#### SPATIAL AND TEMPORAL ANALYSIS EFFECTS OF HIGH FREQUENCY FOCUSED VIBRATION ON CERVICAL PAIN

Iodice, P., Bellomo, R.G., Di Pancrazio, L., Saggini, R.  
*University of Chieti*

Introduction. Several investigation have documented the ability of vibration to reduce or alleviate both experimental pain and pain of clinical origin. High frequency focused (120Hz) stimulus has been found to be more effective at activating the vibrotactile system and reducing musculoskeletal activity. Methods In the present study, we used rigorously controlled conditions to examine vibratory analgesia and muscle adaptation in participants (N = 15) with cervical pain. Results of 120 Hz vibration were compared with data from a no-vibration control condition. We measured its time course using continuous visual analog scale (VAS) recording, and its spatial aspects by asking subjects to indicate painful regions on standardized drawings. Moreover, before and after each treatment was carried out an electromyographic (EMG) investigation of trapezius muscle. Results VAS ratings and drawings both showed that pain is reduced by 120 Hz but not in control condition. EMGs results indicate that high frequency focused vibration treatment decrease trapezius muscle activity. Discussion Decrease of muscle activity and decrease of VAS were statistically correlated, suggesting that vibratory analgesia can be attributed to involving Pacinian corpuscles. Spatial analyses results suggest at least in part a involvement of central nervous system processes.

## EFFECTS OF BRIDGING EXERCISE METHODS ON THE MUSCULAR ACTIVITY OF THE NECK AND TRUNK

Dong-hyun, S., Gi Duck, P., Chul-ho, S., Han-Yong, L.

*Namseoul University*

**Introduction** Lumbar stabilization exercise trains patients to control force in unstable positions and consciously and unconsciously regulate motion so as to maintain the spinal neutral position in which the spine can be best adapted to external load. Recently, lumbar stabilization exercise has drawn attention as a therapeutic exercise as well as a method for preventive management. The purpose of this study was to investigate the effects of different bridging exercise methods varied by the position of the lower limbs on the muscular activity of the neck and trunk. **Methods** The subjects of this study were 14 males in their twenties. The muscular activity of the longissimus capitis and sternocleidomastoid in the neck, the erector spinae and rectus abdominis in the trunk was measured using a surface electromyography. **Results** The comparison of the muscular activity showed significant differences in the longissimus capitis, rectus abdominis, erector spinae muscle depending on bridging exercise method. **Conclusion** Using the theoretical mechanisms proposed in previous bridging exercise studies and the results in the study, it can be concluded that muscular activity can be changed by the variation of the position of the lower limbs when applying a bridging exercise. **Reference** Stevens, V. ## NEW PERSPECTIVES IN RECOVERY AND CORRECTING SPECIFIC SPINE DEFORMITIES FROM SCHEUERMANN'S DISEASE

Marinescu, Gh.1, Tataru, T.1, Ene, D.1, Cioroboiu, A.1, Dumangiu, M.1, Paunescu, C.2, Moscaliuc, C.3, Zamfir, V.1, Ticala, L.1, Prisacaru, R.1

*National University of Physical Education and Sport*

**NEW PERSPECTIVES IN RECOVERY AND CORRECTING SPECIFIC SPINE DEFORMITIES FROM SCHEUERMANN'S DISEASE** Marinescu, Gh.1, Tataru, T.1, Ene, D.1, Cioroboiu, A.1, Dumangiu, M. 1, Paunescu, C.2, Moscaliuc, C.3, Zamfir, V.1, Ticala, L.1, Prisacaru, R.1 1:NUFES (Bucharest, Romania), 2:UMFCD (Bucharest, Romania), 3:USM (Suceava, Romania), **Introduction** Scheuermann's Disease (juvenile kyphosis) is a disease affecting children and young people. Results in an deformity in the thoracic or thoracolumbar spine in children and adolescents, characterized by accentuated curvature at an angle over 45 degree (typical form), wedging vertebrae and the presence of Schmorl nodes - characteristic of the disease. The two forms of manifestation determine specific disorders of spine alignment. Therefore, we consider necessary therapeutic approach and recovery of disease by treating the differentiation of the two forms and enrichment by means of recovery, hydrokinotherapy (complex mean of recovery) and adapted programs for those forms. **Methods** The study was carried out by repeated evaluations in comparison, in the four groups: - group (I) with the typical form, which made physical therapy program; - group (II) with the typical form, which in addition to physical therapy made a program of hydrokinotherapy; - group (III) with atypical form, which performed the physical therapy program; - group (IV) with atypical form, which performed in addition to physiotherapy a program of hydrokinotherapy; **Results** Research was made longitudinal and transverse, using several methods and statistical-mathematical tests that contributed to the processing and interpretation of data obtained after assessments carried out before and after application of individualized physical therapy programs and hydrokinotherapy, designed for each form of manifestation of Scheuermann's disease. Where used: simple ANOVA test, dependent t test, Cohen index of size effect, etc. Final evaluations have revealed significant rises in all four groups that carried out physical therapy programs. Comparing the results between the groups which carried out the hydrokinotherapy and those who have not, data have shown rises for groups with both forms of programs. **Discussion** Programs of individualized exercises for every form of disease is prerequisite to the recovery of Scheuermann's Disease, clinical manifestations are quite different between the two forms. Hydrokinotherapy by new methods and techniques (i.e. the program in six stages) is updating and innovation required. **References** Koury, J., M. ## EFFECT OF AUGMENTED REALITY ON LOCAL DYNAMIC STABILITY OF PELVIS AND TRUNK MOVEMENTS IN HUMANS

Hamacher, D., Schega, L.

*Otto-von-Guericke-University Magdeburg*

**Effect of augmented reality on local dynamic stability of pelvis and trunk movements in humans** Hamacher, D.1, Schega, L.1 1: ISPW (Magdeburg, Germany) **Introduction** The application of Augmented Reality (AR) in gait retraining to improve trunk and pelvis movements in patients with total hip replacement (THR) has already been evaluated (Schega et al., 2011). However, the effect of AR-based gait training on the stability of pelvis and trunk trajectories remains unexplored. Hence, the purpose of the present study was to evaluate the effect of AR-based feedback 1) in healthy individuals and subjects with several gait disorders whilst using the AR-system and 2) in patients with THR in a retention test after having passed an AR-based training. **Methods** Kinematic parameters (MVN, Xsens) of 15 women without any motor and functional impairments (CG1, 65±4.2 years) and 11 women with several gait disorders (IG1, 65±5.5 years) have been captured in a clinical gait analysis (m1) and while using the AR-system (m2). Moreover a total of 21 patients (female, 58±4.3 years) with THR have been randomly assigned either to an intervention group (IG2, n = 11) or a control group (CG2, n = 10). Additional to the post-hospital curative treatment all patients passed a standardized gait training (3 weeks, 20 min/day). Corrections of gait patterns were given by either verbal therapeutic instructions (CG2) or with help of an AR-system (IG2). In order to identify differences between the intervention strategies, kinematic gait data was captured in a pre-test, a mid-test and post-test. The largest Lyapunov exponents of the 3 dimensional (3D) pelvis and trunk trajectories (3D angular velocity; 3D linear velocity) and for a detailed view in sagittal, transversal and frontal plane have been calculated. The Data have been tested for normal distribution (Kolmogorov-Smirnov test). Group differences were examined with t-test and ANOVA. **Results** The results show less stable pattern of the 3D pelvis movement in m2 vs. m1 for both, the IG1 (p=.011) and CG1 (p=.004). The interaction effect time times group (IG2 & CG2) indicated a significant different pattern of pelvis trajectories (angular velocity) in the frontal plane (F=4.577, p=.048). Furthermore the anterior-posterior movement of the trunk (linear velocity) is more stable in the IG2 vs. CG2 in post-test (p=.030). **Discussion** The AR-based intervention treatment causes a less stable movement of the pelvis whilst using the AR-system. Thus, there may be a larger risk of falling in healthy women. A more stable movement of trunk was observed in patients with THR after a period of training with AR-system compared to verbal information based intervention. Therefore, perturbations

occurring during walking to the trunk may be managed more appropriately after a training period with the AR-system. References Schega, L., Hamacher, D., Wagenaar, R. (2011). Archives of physical medicine and rehabilitation, 92 (10), 1734–1735.

### EFFECTS OF AN INDIVIDUALIZED REHABILITATION PROGRAM TO THE CROSSOVER POINT ON THE USE OF ENERGY SUBSTRATA AND PERCEIVED EXERTION IN WOMEN WITH METABOLIC SYNDROME

Garcin, M.

*University Lille Nord de France*

EFFECTS OF AN INDIVIDUALIZED REHABILITATION PROGRAM TO THE CROSSOVER POINT ON THE USE OF ENERGY SUBSTRATA AND PERCEIVED EXERTION IN WOMEN WITH METABOLIC SYNDROME Garcin, M.1 2, Borel, B.1 2, Coquart, J.3, Matran, R.1 4, Delsart, P.5, Mounier-Vehier, C.5 1: Univ Lille Nord de France (Lille, France), 2: UDSL, EA4488 (Ronchin, France), 3: Univ Rouen, EA 3832 (Rouen, France), 4: Service des Explorations Fonctionnelles et Respiratoires, Hôpital Calmette, CHRU Lille (France), 5: Service de Médecine Vasculaire et Hypertension Artérielle, CHRU Lille (France) Introduction The use of indirect calorimetry in effort is used in order to individualize the prescription of exercise intensity (Brun et al., 2007). Two exercise intensities may be used: one corresponding at most of oxidation of lipids (LIPOXmax) and another one corresponding to the crossover point of substrate utilization (COP) (Dumortier et al., 2003). The prescription of a rehabilitation program at this last intensity could be particularly relevant in patients with metabolic syndrome (MS). The study's aim was to show the effects of a rehabilitation program at an intensity related to the COP prescribed by means of the perceived exertion value associated to this point in women with MS on the use of energy substrata during exercise and perceived exertion. Methods Fifteen women with MS (age = 56.0 ± 8.2 yrs; mass = 87.7 ± 12.7 kg; height = 160 ± 6 cm) performed a test to exhaustion to measure the peak of oxygen uptake (VO2peak) and the power output peak (Ppeak), and a test of indirect calorimetry to determine COP and LIPOXmax. Then, these women followed a rehabilitation program (3 sessions of 45 min.wk-1 at the RPE related to their COP on cycle ergometer during 12 wks). After the rehabilitation program, the tests were performed again. Results VO2peak and Ppeak increased after the rehabilitation period (17.3 ± 3.9 vs 18.5 ± 4.3 ml.min-1.kg-1; 101 ± 25 vs 122 ± 29 W, respectively; p=0.01). RPE to COP and LIPOXmax (11.8 ± 3.0 vs 10.3 ± 3.2 and 12.1 ± 3.8 vs 10.2 ± 3.6, respectively), and the absolute power output values to COP (40 ± 18 vs 48 ± 16W) were significantly different after the rehabilitation program (p<0.05). However, no effect of the rehabilitation program on the relative power output values was noticed (p>0.05). Concerning RPE as well as the power outputs, both values related to COP were not significantly different from those to LIPOXmax (p>0.05). Discussion The prescription of an individualized rehabilitation program from the RPE related to COP allowed to improve the maximal work capacity and to decrease the RPE at COP and LIPOXmax in these women with MS, but the program did not seem to have any effect on the use of energy substrata during exercise. (2003) Diabetes Metab, 29, 509-518.

### THE ARCHITECTURAL AND MECHANICAL PROPERTIES OF PARALYZED TRICEPS SURAE MUSCLES IN PATIENTS WITH SPINAL CORD INJURY AND POST-STROKE.

Kato, E., Negishi, D., Niimi, M., Ogata, T., Kawashima, N.

*National Rehabilitation Center for Persons with Disabilities*

The architectural and mechanical properties of paralyzed triceps surae muscles in patients with spinal cord injury and post-stroke. Kato, E. 1, Negishi, D. 2, Niimi, M.3, Ogata, T. 1, Kawashima, N. 1 1: National Rehabilitation Center for Person with Disabilities (Saitama, Japan), 2: Shibaaura Institute of Technology (Saitama, Japan), 3: Ochanomizu University (Tokyo, Japan) Introduction It is well known that motor paralysis due to central nervous system disorder, i. e., spinal cord injury (SCI) and stroke, leads higher joint torque in response to passive joint motion. In order to establish an effective rehabilitation approach for the prevention of disuse syndrome, quantitative evaluation for the paralyzed muscle is quite important. The purpose of this study was to determine a better understanding with regard to muscle property due to motor paralysis. Methods Nine SCI, 13 stroke (paretic side or non-paretic side) and 13 neurologically normal subjects participated. We measured muscle thickness (MT) of the triceps surae muscles and stiffness of the gastrocnemius medialis (MG) as the architectural and the mechanical properties using ultrasound, respectively. The measurements of MG and gastrocnemius lateralis (LG) were taken at proximal level 30%, and the soleus muscle (SOL) was at 50% of the shank length from the popliteal crease to the lateral malleolus. To calculate stiffness, the ankle joint was passively dorsiflexed from 5 degrees of plantar flexion to 15 degrees of dorsiflexion (5deg/s) and passive torque was divided by the elongation of MG. In MT and stiffness, multi-group comparisons were performed by one-way analysis of variance followed by the Tukey-Kramer post-hoc test. Results In MT, there were statistically significant among four groups (F=13.3, 10.0 and 7.7 for MG, LG and SOL, respectively, p<0.001). Normal showed the highest value of all muscles and then non-paretic side and paretic side of stroke, and SCI showed the lowest. It showed significant interaction among four groups about stiffness (F=7.5, p<0.001). Paretic side of stroke showed the highest value in stiffness. SCI showed similar value as non-paretic side of stroke, and normal showed lowest. Discussion While muscle stiffness was not significantly different, the extent of the reduction of MT in SCI was greater than that in Normal and non-paretic side of stroke. Present result also indicated a larger inter-individual variability in SCI patient, suggesting that the inactivity-induced alteration of the paralyzed area largely affected by level of injury and extent of motor paralysis after SCI. The present result implies that the protocol of rehabilitation approach for reducing muscle stiffness should be carefully prescribed based on the characteristics of muscle property due to type of injury/disorder. ### EFFECTS OF FORTNIGHTLY AND WEEKLY THERAPEUTIC EXERCISE ON PHYSICAL FUNCTION AND HEALTH-RELATED QUALITY OF LIFE IN SUBJECTS WITH HIP OSTEOARTHRITIS

Jigami, H.1,2, Endo, N.2

*1:Tokyo University of Technology, 2:Niigata University Graduate School of Medical and Dental Sciences*

Background There are many studies of the effects of therapeutic exercise on the patients with osteoarthritis (OA) of the hip joint. However, in most of those studies, the subjects included are knee OA or postoperative patients. Moreover, therapeutic exercise on hip OA has been recommended in some systematic reviews, a consensus on the effective interventional frequency has not been reached. The purpose of this interventional prospective cohort study was to investigate the effects of therapeutic exercise performed at different interventional frequencies in subjects with hip OA. Methods The subjects who were diagnosed hip OA (36 women, aged 42–79 years; 19 in 2009 and 17 in 2010) were recruited from the cooperating medical institutions. The therapeutic exercise was implemented at two different interventional frequencies, according to which the subjects were divided: fortnightly in 2009 (fortnightly group) and once weekly in 2010

(weekly group). The subjects in the fortnightly and weekly groups performed the same therapeutic exercise program including land-based and aquatic exercises on the same day for a total of 10 sessions. Muscle strength of the lower extremity, timed "Up and Go" (TUG), time of one-leg standing with open eyes (TOLS), and health-related QOL by SF-36 were measured before and after the interventions. Results No significant differences were noted in physical functions and QOL between the fortnightly and weekly groups at before intervention. In lower muscle strength, the fortnightly group had no significant changes between before and after the intervention, but the strength of all the muscles in the weekly group improved significantly after the intervention ( $p < 0.05$ ). There were no significant differences in their SF-36 scores between before and after intervention in both two groups. TUG and the worse hip of TOLS showed significant improvement ( $p < 0.05$ ). Conclusions This result that once a week exercise at least effect to improve muscle strengthening is meaningful and may be useful for prescribing the effective frequency of therapeutic exercise for hip OA. In addition, the exercise program in this study consisted of both land- and water-based exercises which may markedly contribute to improved physical function regardless of the exercise frequency. ### DISSEMINATION OF A STANDARDIZED BACK SCHOOL: STRUCTURE AND NEEDS IN INPATIENT REHABILITATION FACILITIES PRIOR TO IMPLEMENTATION

Peters, S.

*University of Erlangen-Nuremberg*

Dissemination of a standardized back school: structure and needs in inpatient rehabilitation facilities prior to implementation Peters, S. (1), Pfeifer, K. (1), Schulze, A. (2), Faller, H. (2), Meng, K. (2) (1) Institute of Sport Science and Sport, University of Erlangen-Nuremberg (Germany), (2) Rehabilitation Sciences Unit, University of Würzburg (Germany) Introduction A back school is a mandatory part of the rehabilitation of chronic low back pain (clbp) in Germany. In recent years, the recommendations for the content of those programs have changed due to scientific evidence. Traditional back schools are often based on a biomedical approach and theory-based techniques to foster physical activity are rarely used. Currently, a biopsychosocial approach is recommended with the enhancement of physical activity as a major goal. Meeting those requirements, only one standardized and evaluated back school exists in Germany. The mere existence doesn't do the job of dissemination. Implementation of standardized programs into routine care in clinics is often performed incompletely. Evidence for the best strategy to implement a multidisciplinary rehabilitation program is lacking. In this study, two strategies (Train-the-Trainer seminar and written educational material) to implement the above-mentioned back school were developed and evaluated. Methods The purpose of this part of the study was to capture assets and barriers regarding the implementation of the standardized active back school and to detect the subjective need of the health professionals for advanced training. The sample consists of 10 rehabilitation facilities. Delivering the back school, 45 exercise therapists, 17 physicians, 13 psychologists and 2 persons from other professions were covered. A check-list was used to gather certain attributes of structure and processes. A questionnaire (110 items) was developed to survey other influencing factors based on 12 domains detected by Michie et al. (2009) (e.g. skills, motivation/goals) as well as the subjective need for advanced training. Results 90% of all health professionals favor the TTT over the written educational material. All in all, the interest on the seminar (max.=10) reaches a high level:  $M=8.3$  ( $SD=1.9$ ); Median=9. There is an ongoing evaluation of the rest of the data. So far, the descriptive analysis shows quite a variation in many factors between facilities and health professionals. Discussion Assets and barriers regarding an implementation of the above-mentioned standardized back school vary between rehabilitation facilities as well as between the health professionals. Regarding this implementation, exercise therapists, physicians and psychologists have different needs for advanced training. References Michie, S. et al. on behalf of the "Psychological Theory" Group (2005). Making psychological theory useful for implementing evidence based practice: a consensus approach. *Quality and Safety in Health Care*, 14, 26-33.

### WAVELET-BASED ENTROPY ANALYSIS OF ELECTROMIOGRAPHY DURING 100 JUMP

Daniuseviciute, L., Pukenas, K., Brazaitis, M., Skurvydas, A., Linonis, V.

*Lithuanian Academy of Physical Education, Kaunas University of Technology*

WAVELET-BASED ENTROPY ANALYSIS OF ELECTROMIOGRAPHY DURING 100 JUMP Daniuseviciute, L.1,2, Pukenas, K.1, Brazaitis, M.1, Skurvydas, A.1, Linonis, V.2. 1:Lithuanian Academy of Physical Education, 2:Kaunas University of Technology. Introduction For a measure of EMG system complexity that is applicable to noisy and short datasets, we chose Shannon entropy, where the complexity decreases in muscle fatigue condition. The nonlinear dynamic measure as Shannon wavelet entropy appears as a measure of the degree of order or disorder of the signal. Methods Healthy female ( $n=9$ ) have participated in the study. Bipolar Ag-AgCl surface electrodes were used for EMG recordings (silver bar electrodes, diameter 10 mm, centre-to-centre distance 20 mm) of the long head of the vastus lateralis and biceps femoris (DataLog type no. P3X8 USB, Biometrics Ltd, Gwent, UK). After 10 min of not-intensive warming-up 100 jumps on vertical jump force plate (New Test, Finland) from a 75 cm stage were made, when the participant got to amortization phase while the knee joints were flexed at 90°. EMG values were analysed by Shannon wavelet entropy and median frequency using software written in Matlab (The MathWorks, Natick, MA). The Symlet (sym5) wavelet was used for analysis and the decomposition of EMG was performed at 6 levels. Results There was reverse significant relationship between changes in jumping height and Shannon wavelet entropy of EMG vastus lateralis ( $r=-0.5$ ,  $P < 0.05$ ) and Shannon wavelet entropy of EMG biceps femoris ( $r=-0.7$ ,  $P < 0.05$ ). There was no significant relationship between changes in jumping height and median frequency of EMG vastus lateralis ( $r=-0.3$ ,  $P > 0.05$ ), but there was reverse significant relationship between changes in jumping height and median frequency of EMG biceps femoris ( $r=-0.7$ ,  $P < 0.05$ ). Discussion The findings of the present study indicate that during an eccentric exercise the complexity of EMG signals was higher using wavelet-based Shannon entropy than median frequency method. Pearson correlation coefficient was significantly stronger compare jumping height values with EMG Shannon wavelet entropy values. Muscles that contain a relatively greater proportion of type I fibers may not demonstrate increases in median frequency with greater forces, despite the additional recruitment of these fibers (Pincivero et al., 2001). Moreover, it has been suggested that increases in both synchronization and spike duration and slowing of conduction velocity would tend to increase the amplitude of the surface EMG (Hatzikotoulas et al., 2004). #### PULSE PRESSURE CENTILES FOR ITALIAN ATHLETES FROM 6 TO 80 YEARS OLD

Attisani, G., Castagna, A.

*Studio Medico Attisani*

**Objective:** Pulse pressure (the difference between systolic and diastolic blood pressures) is recognized as a leading predictor of cardiovascular disease. Independently of mean blood pressure, pulse pressure is a strong determinant of cardiovascular events, including coronary heart disease and stroke. The present study describes a representative cross section pulse pressure reference centiles for Italian athletes. **Design:** Analysis of blood pressure data from a people of athletes examined in a Sport Medicine Clinics from 2006 to 2010. Was excluded all athletes with cardiovascular disease. **Methods:** The blood pressure was always measured with the same protocol: athlete at rest and at the beginning of the medical examination. Pulse pressure (P systolic – P diastolic) was calculated. Data from 2000 male (aged 6-80 years) and 1000 female (aged 6-75 years) were included in the analysis, after excluding 0.3% missing or outlying data. Centiles were derived using the latent moderated structural (LMS) equations method of Cole. **Results:** We found that pulse pressure reaches a first peak at age 22 in males (Tab. 1) and at 18 age in females (Tab. 2) and a subsequent rise after 38.5 years old for males and after 35.5 years old in females. Knowledge of the variations from hormonal changes should help to explain these variations **Conclusion:** These centiles increase our knowledge of normal pulse pressure in athletes. The values between 5% and 95% centiles are probably representative of a reduced risk of cardiovascular disease. The pulse pressure may be a simple predictor of cardiovascular risk.

#### IS ADIPOSE TISSUE MICRO INFLAMMATION INFLUENCED BY 14 DAYS PROLONGED EXERCISE IN LEAN OLDER MEN?

Andersen, P.R., Christensen, K.K., Prats, C., Poulsen, S.S., Munch-Andersen, T., Morville, T., Mattson, N., Dela, F., Rasmussen, H., Helge, J.W.

*University of Copenhagen*

Is adipose tissue micro inflammation influenced by 14 days prolonged exercise in lean older men? Andersen PR1, Christensen KK1, Prats C1, Poulsen,SS1, Munch-Andersen T1, Morville T1, Mattson N2, Dela F1, Rasmussen, H, & Helge JW 1. 1Center of Healthy Aging, Department of Biomedical Sciences, University of Copenhagen. 2Department of Cardiology, H:S Bispebjerg Abstract. **Introduction.** Major changes have been observed in obese individuals as a response to lifestyle-interventions such as diet or exercise modifications. Among these changes is a shift in the inflammatory state of adipose tissue quantified by means of adipose tissue macrophage (ATM) count. However, the influence of regular exercise on micro inflammation in human subcutaneous adipose tissue is not well known. Therefore we investigated the effect of 14 days of very prolonged exercise on micro inflammation in adipose tissue in lean trained older individuals. **Methods.** Six lean (BMI;  $24 \pm 1$  kg/m<sup>2</sup>), moderately well trained (VO<sub>2</sub>max:  $48 \pm 2$  mlO<sub>2</sub>/kg/min) men (age  $61 \pm 4$  yrs) participated in the study. During 14 days the subjects cycled a total of 2770 km averaging a duration of  $580 \pm 30$  min cycling per day. Before and after the 14 days a basal blood sample and a biopsy from the abdominal subcutaneous fat depot were obtained. Adipose tissue macrophages (ATM) were immunohistochemically stained in cross sectional sections using a CD163 binding antibody. The ATM stain and adipocyte sizes were analysed blindly. **Results.** Subjects maintained their body weight across the 14 days ( $77 \pm 5$ ,  $78 \pm 5$  kg, pre and post). The plasma glucose ( $5.9 \pm 0.2$  mmol/l), C-reactive protein ( $0.19 \pm 0.08$  mg/dl), TNFalpha ( $0.19 \pm 0.08$  pg/ml) and IL-18 ( $310 \pm 44$  pg/ml) concentration at baseline were not changed after 14 days (data not shown). Plasma insulin ( $16 \pm 2$ ,  $33 \pm 2$  pmol/L), IL-6 ( $0.7 \pm 0.1$ ,  $1.1 \pm 0.1$  pg/ml), and insulin sensitivity (HOMA) ( $0.62 \pm 0.08$ ,  $1.3 \pm 0.1$  a.u.) all tended ( $P < 0.07$ ) to increase after 14 days; pre and post, respectively. The average CD-163 identified macrophage area ( $1251 \pm 693$ ,  $996 \pm 295$   $\mu$ m<sup>2</sup>) and the adipocyte average area ( $7609 \pm 640$ ,  $7489 \pm 493$   $\mu$ m<sup>2</sup>) were not significantly influenced after the 14 days. **Conclusion.** In the present study no effect of prolonged repeated exercise was detectable on adipose tissue macrophage content or adipocyte average size in abdominal adipose tissue. Prior studies in rodents have demonstrated decreased adipose tissue macrophage inflammation after longer exercise interventions. It is possible that the present exercise regimen is not of sufficient duration to induce a decreased macrophage inflammation, but probably more likely that the amount of exercise in this study was simply too high. The latter notion is supported by the trend towards an increased insulin resistance observed after the 14 days.

#### ANTHROPOMETRIC CHARACTERISTICS, BODY COMPOSITION AND SOMATOTYPE OF JUNIOR BADMINTON PLAYERS

Pugliese, L., Cirami, I., Salvati, A., Morino, F., La Torre, A., Faina, M., Gianfelici, A.

*Università degli Studi di Milano*

**Introduction.** Aims of this study were to describe the anthropometric characteristics, body composition and somatotype of male (M) and female (F) Italian junior badminton players and to determine differences between national team (NT) and regional level (RL). **Methods.** 154 (89M; 65F) athletes were divided into groups according to age (under 13-15 and under 17-19), gender and level. Height (H), body weight (BW), skinfolds, circumferences and diameters were recorded to determine body mass index (BMI), % fat mass (%FM) and somatotype. **Results.** In U13-15: anthropometric characteristics and body composition were not significantly different between M-NT and M-RL; F-NT had lower BMI ( $18.0 \pm 2.0$  vs  $20.1 \pm 2.5$  kg/m<sup>2</sup>;  $p = 0.047$ ) and %FM ( $14.3 \pm 6.5$  vs  $19.5 \pm 6.7$  %;  $p = 0.049$ ) compared to F-RL. In U17-19: H was significantly higher ( $181 \pm 3.2$  vs  $176 \pm 6.0$  cm;  $p = 0.048$ ) in M-NT, respect to M-RL and %FM was very low, but similar, in both group ( $6.6 \pm 1.5$  vs  $7.6 \pm 4.4$  %); BW was higher ( $66.1 \pm 10.3$  vs  $58.0 \pm 5.9$  kg;  $p = 0.025$ ) in F-NT than F-RL, without significant differences in %FM ( $21.3 \pm 9.3$  vs  $21.0 \pm 4.7$  %  $p = 0.89$ ). As for somatotype, there were no significant differences between NT and RL in both U13-15 and U17-19. The mean somatotype of M players could be defined as ectomesomorphic and the mean somatotype of F players could be defined as ectomorphic for U13-15 and endomorphic for U17-19. **Conclusions.** The data suggest that anthropometric and body composition parameters are not

able to discriminate Italian national and regional level male U13-15 badminton players. On the other hand, these parameters can be considered for selection of female U13-15, female U17-19 and male U17-19 in national team. Somatotype confirmed differences between M and F, but was not able to distinguish the national level. REFERENCES de Hoyo M, Sanudo B, Paris F. ### THE EFFECT OF 38°C WATER EXERCISE ON ARTERIAL STIFFNESS IN ELDERLY SUBJECTS

Nogami, J., Takehiro, N., Otsuki, T., Maeda, S., Ajisaka, R.

*University of Tsukuba., Teikyo Heisei University., Ryutsu Keizai University*

**Introduction** Age-associated change in the structure and function of arteries might induce increase the risk of cardiovascular disease. It has been reported that aerobic exercise decreased arterial stiffness in humans (Kingwell, et al., 1997, Naka et al., 2003, Hefferman et al., 2007). However, the effect of water exercise on arterial stiffness in humans is unknown. Therefore, the purpose of this study was to investigate the effect of 38°C water exercise on arterial stiffness in elderly subjects. **Method** Six healthy elderly subjects performed a 15min of cycling exercise in 38°C water with 50% peak VO<sub>2</sub>. Carotid-femoral PWV (aortic PWV) and femoral-ankle PWV (leg PWV), blood pressure, heart rate (HR), and rectal temperature (T<sub>rec</sub>) were measured at baseline, 30min, and 60min after the exercise. T<sub>rec</sub> were continuously measured from baseline to 60min after exercise. Resting control study was performed with sitting in air for 15min, measuring as the same method as 38°C water exercise. All measurements were performed in a quiet and air conditioned room at the same time of the day in the morning. Results T<sub>rec</sub> significantly maintain the elevation after the warm water exercise (P<0.0083). HR slightly but significantly increased at 30min after the exercise (P<0.0083). The aortic and leg PWV significantly decreased at 30min after the exercise and SBP also significantly decreased at 30min and 60min after the exercise (P<0.0083). There were no significant changes in the control study. **Conclusion** The effect of acute water exercise on arterial stiffness in elderly humans is unknown. The present study showed that aortic and leg pulse wave velocity decreased significantly after acute 38°C water exercise in the elderly subjects. Although the underlying mechanism is unknown, the results in the present study suggest that 38 °C water exercise may induce decrease of aortic stiffness in elderly subjects similarly to aerobic exercise on land. ### PREDICTIONS AND VALIDITY OF MAXIMAL AEROBIC POWER FOR SOUTH KOREAN MALE BY METABOLICAL RESPONSES IN SUBMAXIMAL EXERCISE AND DISTANCE RUNNING

Im, J.H.1, Jeon, Y.J.1, Chang, H.K.2, Kim, H.J.3, Kim, K.H.4, Lee, B.K.4

*1) KAIST(Daejeon, S Korea) 2) Seoul Women's University(Seoul, S Korea) 3) Chosun University(Gwangju, S Korea) 4) SangMyung University(Cheonan, S Korea)*

**Introduction** The purpose of this study was to develop the prediction model of maximal aerobic power or South Korean Male by submaximal metabolic responses from treadmill exercise(Bruce protocol) and general physical variables, and to compare and analyse the validity of these prediction models. The purpose of this study was to report the prediction equation of maximal aerobic power using metabolic responses in submaximal exercise from the Bruce protocol for S Korean adult male, and to validity of these prediction equation. **Methods** The subjects were consisted of 255 South Korean adult male. They were joined maximal treadmill exercise testing with Bruce protocol, and the metabolic responses were measured in the end of the first(3 minute) and second stage(6 minute). Measurement items were VO<sub>2</sub>, VCO<sub>2</sub>, VE, HR of 3 and 6 minute, time to HR 150bpm and HR 170bpm, HR difference between Bruce protocol 6 and 3 minute, 1,200m running record. To determine the predicted model of VO<sub>2</sub>max, multiple and simple regression analysis with stepwise methods and enter method were applied. **Results** Analyzing with all variables using enter method, the multiple R of total variable model was 0.64(p<.01), SEE was 4.4 ml/kg/min, CV was 10.8%. The multiple R of 3 minutes model was 0.46, SEE was 5.72ml/kg/min, CV was 14.1%. The multiple R of 6 minutes model was 0.46, SEE was 5.7ml/kg/min, CV was 14.2%. The R of 6-3 minutes HR difference model, HR 150, and HR 170 equation were 0.15, SEE were 6.4ml/kg/min, CV were 11.9%. The R of 1,200m running equation was 0.44, SEE was 4.8ml/kg/min, CV was 11.9%. **Discussion & Conclusion** Lee, et al.(2012) reported the prediction of maximal aerobic power with general variables and metabolic responses in submaximal exercise for South Korean adult female, and R of total model prediction and general variables model were 0.73 and 0.59(p<.001). In conclusion, the validity of estimation were appeared total, 6 minute, 3 minute, 1,200m running, and 3 HR equation by tunes. With considering usefulness and convenience through the validity of these prediction equations, the prediction equations of maximal aerobic power recommended total model, 6 minute, 3 minute, and 1,200m running. REFERENCES Bruce, R. A., Kusimi, F., & Hosmer, D. (1973). Maximal oxygen intake and nomographic assessment of functional aerobic impairment in cardiovascular disease. Predictions developments of maximal aerobic power by general variables and metabolic responses in submaximal exercise for south korean adult female. Unpublished Data.

### EVALUATION OF PERIPHERAL VASCULAR IMPAIRMENT IN THE FINGERS OF BASEBALL PLAYERS BY USING A LASER DOPPLER BLOOD PERFUSION IMAGER : A COMPARISON AMONG POSITIONS

Terada, K.1, Miyai, N.2, Nadamoto, M.1, Murakami, K.1, Nakatani, T.1, Maeda, S.3, Miyashita, K.2

*1: Tenri University (Nara, Japan), 2: Wakayama Medical University (Wakayama, Japan), 3: Kinki University (Osaka, Japan)*

**Introduction** Digital vessel trauma from repetitive impact on the fingers and hand is a concern in baseball players (Sugawara, 1986). Laser Doppler blood perfusion imaging (LDBPI) involves two-dimensional horizontal scanning of the blood flow in a specific tissue without the need for surface contact (Wårdell, 1993). The LDBPI method may facilitate detection of vasospastic abnormalities and occlusion of the digital artery, which are generally observed during an inhomogeneous reaction to cold (Miyai, 2005). Our previous study suggested that the LDBPI technique can be used to assess peripheral circulatory function in baseball players. This study used LDBPI to examine whether the changes in finger skin blood flow in response to a cold water immersion test depends on the position of baseball players. **Subjects and Methods** The study included 32 male university baseball players (age: 18–21 years) who play at 4 different positions (catcher [3 subjects], outfielder [9 subjects], infielder [12 subjects], and pitcher [8 subjects]). A cold provocation test was performed by immersing the subject's catching hand in 10°C water for 10 minutes. The blood flow in the skin of the palm was repeatedly scanned every 2 min before,

during, and after immersion by using a PIM-3 LDBPI (Perimed, Sweden). Mean blood perfusion values in the index finger were calculated for each color-coded image. Finger skin temperature was recorded using an electrode thermistor attached to the skin on the dorsal side of the index finger. Results Mean blood perfusion values of the infielders were significantly lower than those of the outfielders in the later phase of cold water immersion and early post-immersion. However, the finger skin temperature did not significantly differ among the different player positions at any measurement point. Discussion These findings suggest that the changes in finger skin blood flow in response to cold water immersion, as measured using LDBPI, are dependent on the position. Repetitive trauma caused by the impact of a baseball also leads to peripheral vascular impairment in the index finger of the gloved hand of infielders. References Sugawara M., et al (1986). ### SIMPLE ASSESSMENT OF PREDNISONE ADMINISTRATION IN ATHLETES

Collomp, K.1,2, Hevor, T.3, Cloix, J.F.3, Lasne, F.2

*Université Orléans*

**Introduction** The aim of this study was to assess prednisone intake and bioavailability using a simple method that takes advantage of (1) the structural similarity of prednisolone, the major prednisone metabolite, and cortisol ; (2) the suppressed adrenal function during glucocorticoid therapy. Given the high positive correlations between blood and saliva steroid hormone concentrations, saliva was taken for cortisol and dehydroepiandrosterone (DHEA) analysis, whether blood was taken for these parameters and adrenocorticotrophic hormone (ACTH) analysis. **Methods** According to a double-blind and randomized protocol, blood and saliva samples were taken from 8 healthy recreationally-trained females after placebo or prednisone (50 mg/day/7days) ingestion, at rest and during a 2-hour submaximal exercise starting 3 hours after the last intake. Prednisolone was estimated using an ELISA kit for cortisol (Maayan et al., 1988). ACTH and DHEA concentrations were measured in parallel by ELISA. **Results** After prednisone intake, "cortisol" concentrations reflected in fact prednisolone concentrations. The marked increase in these "cortisol" concentrations vs placebo (blood: x 3.9-5.7; saliva: x 12.5-20.9, P<0.001) was coupled with a significant decrease in both ACTH and DHEA (x 0.20-0.47, P<0.001). **Discussion** In agreement with the literature, a significant decrease in ACTH and DHEA basal values was observed in our subjects after 1 week of prednisone treatment, without any significant change from these basal concentrations during exercise. This inhibition in ACTH and DHEA lasts at least 24 hours, as shown previously after short-term glucocorticoid intake (Arlettaz et al., 2008; Jollin et al., 2010). This marked decrease in ACTH and DHEA concentrations after prednisone intake is combined with high prednisolone concentrations, resulting in a dramatically increase in the "cortisol"/DHEA ratio in both blood and saliva and in the "cortisol"/ACTH ratio in blood, versus placebo (P<0.001). The results thus suggest that blood ACTH, blood or saliva DHEA and cortisol measurement offer a practical approach for estimating indirectly prednisone, prednisolone or cortisol intake in athletes on a longitudinal basis. However, the practical constraints regarding the hormone circadian variation and the blood conservation for ACTH analysis need to be taken into account. **References** Arlettaz A, Collomp K, Portier H, Lecoq AM, Rieth N, Le Panse B, De Ceaurriz J (2008). *Br J Sports Med*, 42: 250-254. ### PP-PM54 Training & Testing 10

#### AGE-RELATED DIFFERENCES IN PEAK MATCH RUNNING SPEED IN HIGHLY-TRAINED YOUNG SOCCER PLAYERS

Al Haddad, H., Simpson, B.M., Buchheit, M., Mendez-Villanueva, A.

*Aspire Academy for Sports Excellence*

**Introduction** Sprint speed is believed to be a prerequisite to successful participation in soccer. However, it has been recently suggested that tactical constraints associated with soccer match-play may modulate the relationship between sprint speed (i.e., an intrinsic physical quality determined via a field test) and actual sprinting performance during the game (Mendez-Villanueva et al., 2011). While sprinting speed (as measured with field tests) increases with age and growth, the impact that age can have on peak match running speed is still unknown. Therefore, the aim of this study was to examine possible differences in maximal sprinting speed (MSS) and peak match running speed (PMRS) in highly-trained young soccer players (age groups U13 to U17). **Methods** Time-motion analysis of running activity was collected in 160 male youth soccer players (U13 = 30, U14 = 36, U15 = 40, U16 = 31 and U17 = 23) during 58 distinct friendly international level matches. A total of 253 player-files were analysed (U13 = 39, U14 = 62, U15 = 66, U16 = 49 and U17 = 35). MSS was determined as the fastest 10-m split time during a 40-m sprint performed on an indoor running track. PMRS was recorded using portable global positioning systems and was also expressed as a percentage of MSS (%PMRS). **Results** MSS ( $25.2 \pm 1.4$ ,  $27.6 \pm 1.9$ ,  $28.8 \pm 1.8$ ,  $29.7 \pm 1.7$  and  $30.7 \pm 1.2$  km.h<sup>-1</sup> for U13, U14, U15, U16 and U17, respectively) was greater in older players compared with younger players (U13 "almost certainly" U16, U17). **Discussion** The main findings of this study were that a) faster (and older) players reached higher absolute running speeds during games than their slower (and younger) counterparts, b) slower (and younger) players tended to use a greater percentage of MSS than their older (and faster) counterparts. Our results indicate that age and associated playing structure (e.g., tactical plays) has an important role in influencing the expression of MSS during soccer match play. **References** Mendez-Villanueva A, Buchheit M, Simpson B, Peltola E, Bourdon P (2011) *Journal of strength and conditioning research* 25:2634-2638.

## THE ACUTE AND CHRONIC EFFECTS OF SMALL-SIDED GAMES TRAINING ON SPECIFIC AEROBIC CONDITION OF YOUNG SOCCER PLAYERS.

Stanganelli, L.C.R., Pasquerelli, B.N., Rabelo, F.N., Matzenbacher, F.

*State University of Londrina*

**Introduction** The small-sided soccer games (SSG) have been indicated as an efficient method stimulate the aerobic energy system and its improvement has been reported to increase physical performance on match-play (Pasquarelli et al. 2010). The aim of the present study was to evaluate the acute and chronic effects of SSG training on aerobic conditioning of young soccer players. **Methods** Twenty soccer players from Londrina City – Brazil participated in the study during the regular season (age: 15.7 ± 0.5 years). Subjects were tested before and after the eight weeks of training for Running Economy (RE) in the laboratory and aerobic endurance in the field YoYo Intermittent Recovery Test Level 1 (YYIR1). According to the YYIR1 results, the players were divided into two groups: higher (HG) or lower (LG) than the median YYIR1 performance score. This division was used during 14 SSG training sessions (any format) when the LG always trained with numerical inferiority. **Results** At any format of SSG training, the average intensity was higher for the LG than for the HG (HRmax: 91.6-89.5%; HRreserve: 87.8-85.5%; RPE: 5.6-4.9) at P<0.5. After eight weeks of training the LG group had a larger increase (14.6%) than HG (4.6%) for YYIR1 maximal speed at P<0.01. The RE values decreased for 7 and 12 km/h but these adaptations were not statistically significant. The Hopkins' model was applied to estimate the practical inferences based on magnitudes. For the YYIR1 test, it was inferred that the LG had 70% chance of a positive improvement when compared to the HG; 27% chance of this improvement being irrelevant when compared to the same group and 3% chance of this type of training promotes a negative effect in the performance of this field test. In both groups there was an increase of the magnitude of changes for RE. The chances of the percent changes being positive, irrelevant and negative were 25/70/4 percent for RE at 7km/h and 20/79/1 percent for RE at 12 km/h. **Discussion** Based on these findings it could be inferred that training using the SSG is an efficient way of training young players. The summed effects of these loads significantly increased the specific aerobic conditioning of the subjects. Moreover, it was observed that LG, at first, may obtain magnitudes of change in aerobic conditioning more specifically, when including them in teams with numerical inferiority. Such changes were explained by higher intensities reached in the SSG (acute effects) and its subsequent effects summation (chronic adaptations). **References** Pasquarelli, B. N.; Souza, A.; Stanganelli, L. C. R. The small-sided games in soccer. *The Brazilian J of Soccer Sci* (2010), 3, 2-27.

## WHOLE BODY VIBRATION TRAINING – EFFECT ON JUMP HEIGHT, BALANCE CONTROL AND STRENGTH ENDURANCE

Ritzmann, R., Kramer, A., Gollhofer, A.

*Albert-Ludwigs-Universität Freiburg*

**Introduction:** Although exercise combined with WBV is becoming increasingly popular among trained adults, the additional effects of WBV on muscle fitness and performance is still controversially discussed in literature. One reason might be the diversity of WBV training settings. Therefore, this study aimed to (1) identify a favourable WBV training setting and to (2) validate this setting in a four-week intervention with respect to performance related parameters. **Methods** (1) In 18 subjects the electromyographic (EMG) activity of six leg muscles was recorded during WBV in order to identify those WBV training conditions that cause highest neuromuscular responses and therefore high activation intensities. The vibration parameters have been varied as follows: a) vibration type (rotational (RV) and vertical vibration (VV)), b) frequency (5-10-15-20-25-30Hz), c) amplitude (2 vs. 4mm) and d) stance condition (forefoot vs. normal stance). The statistical analysis consisted of an ANOVA. (2) In a repeated-measures matched-subject design, 38 participants were assigned in a WBV group (VIB) and training group (CON). Training duration, number of sets, rest periods and task-specific instructions were matched between the groups. The WBV training setting was based on the results of (1). The parameters balance control, jump height and strength endurance were assessed before and after the training period. The statistical analysis consisted of an ANOVA. **Results** (1) The combination of high vibration frequencies (30Hz, p<0.05), high amplitudes (4mm, p<0.05) and forefoot stance (p<0.05) on a RV platform (p<0.05) is associated with the highest EMG activity during WBV. (2) Significant interaction effect of group x time could be observed for balance and strength endurance. Hence, WBV causes an additional effect on balance control (CON +6%, p=0.33 and VIB +13%, p<0.05) and strength endurance (CON +11%, p=0.49 and VIB +36%, p<0.05). The effect on jump performance remained insignificant (CON ±0%, 0.25 and VIB +3%, p=0.82). **Discussion** There are two main outcomes: (1) an appropriate adjustment of specific WBV parameters provides high EMG activations in the selected muscles and therefore high activation intensities can be achieved. Thereby, a RV training setting in combination with high frequencies and amplitudes in the forefoot stance seems to be the most favourable parameter selection. (2) WBV training based on the above-mentioned recommendation causes an additional effect on balance control and strength endurance; however the jump performance remains unaffected. In conclusion this study provides evidence for an additional effect of WBV above conventional exercise alone.

## DOES MATURATION AFFECT THE RELIABILITY OF ANTHROPOMETRIC AND PHYSICAL FITNESS MEASURES?

Buchheit, M., Mendez-Villanueva, A.

*ASPIRE*

**Introduction** Monitoring changes in both anthropometry and physical fitness is important to optimize the training process, especially in young and developing athletes. In addition to accuracy, the reliability of any physiological measurement (i.e., degree of change in a particular measure when repeated on different occasions in similar conditions) is of great importance for practitioners and researchers to avoid biased interpretation when assessing changes in a marker (1). Biological maturity contributes to the inter-individual differences in both anthropometrical and physical fitness factors in young soccer players. Moreover, speed, endurance and power increase faster around the time of peak height velocity, which can increase the variability of these measures. To the best of our knowledge however, whether maturation affects the reliability of anthropometric and performance measures has not been addressed yet. **Methods** Data were collected in 80 highly-trained young soccer players (14.5 ± 1.5 yr) from an elite soccer academy. Anthropometric and performance tests were repeated twice within a month during the competitive season (during 'standardized' weeks), and included: standing height, body mass (BM), the sum of 7 skinfolds, counter movement jump (CMJ), acceleration (Acc, 10-m time), maximal sprinting speed (MSS, best 10-m split time over a 40-m sprint) and peak incremental test speed (used as an indirect measure of maximal aerobic speed, MAS). The reliability of each measure was assessed via the typical error of measurement, expressed as a coefficient of variation (CV) (1). Predicted age at peak height velocity (APVH) was used as an indirect indicator of biological maturation and was calculated from anthropometry during each testing session (2). Players were then allocated to either Pre- (<-1 yr from APVH, n = 14), Circum- (≥-1 yr from/to APVH ≤ 1, n = 32) or Post- (<-1 yr to APVH, n = 34) PHV groups, based on their estimated APVH obtained during the first testing session. **Results** For all players

pooled together, the CV was 0.4% (90% confidence limits [CL]: 0.3;0.5) for height, 1.4% (1.2;1.8) for BM, 4.9% (4.1;6.2) for the sum of 7 skin-folds, 0.6% (0.5;0.8) for APHV, 4.5% (3.9;5.3) for CMJ, 2.2% (1.9;2.5) for Acc, 1.4% (1.2;1.6) for MSS and 3.5% (3.0;4.1) for MAS. When comparing the different CVs obtained for each group, there was no clear difference in reliability: Post-PHV vs. Pre-PHV: effect size (ES) = -0.37 (-1.6;0.9), with chances of greater/similar/lower values of 20/20/60%, Post-PHV vs. Circum-PHV: ES = -0.01 (-0.9;0.8), 33/32/35% and Circum-PHV vs. Pre-PHV: ES = -0.27 (-1.5;1.0), 24/22/54%. Discussion In highly-trained developing soccer players, the reliability of anthropometry and performance measures is unlikely to be affected by biological maturation. Similar thresholds (i.e., 1/2 of the CV) can therefore be used to assess meaningful changes during the season in players differing in age/maturation status. References Hopkins WG. Sports Med. 2000;30(1):1-15. Mirwald RL et al. Med Sci Sports Exerc. 2002;34(4):689-69(2)

### TRAINING LOAD INSIGHTS INTO THE ELITE JUNIOR AUSTRALIAN FOOTBALLER USING GPS AND HR TECHNOLOGIES

Henderson, B.I, Cook, J.2, Kidgell, D.1, Gastin, P.1

1: C-ESS (Deakin University, Australia), 2: ACRISP (Monash University, Australia)

Introduction Physical activity information on the elite junior Australian football (EJAF) player is still under-explored, especially in the area of training load. With the aid of wearable athlete device technologies encompassing global positioning system (GPS) and heart rate (HR) sensors, accurate measures of training load can now be obtained. Methods This investigation examined the training loads within the elite junior AF player across the in season period. Objective measures of physical load were obtained via individual GPS time motion analysis and HR. A total of 187 training session files were collected from three clubs across 19 training sessions within the 2009 TAC Cup competition season. Descriptive analysis of the key summary variables was undertaken to ascertain an accurate account of training load. Results Summary GPS data revealed that the mean duration of training was 87 min. The mean distance covered by EJAF players was 6.0 km a training session. Further breakdown showed that low intensity activity (0-14.4 km/h) predominated with a mean distance of 4.5 km and high intensity running (above 14.4 km/h) contributed 1.5 km. A distance of 71.3 m/min was covered by players within a session. HR data revealed that players were exposed to an internal load relative to 70% of their predicted HRmax across the duration of training. Players spent on average, 21 minutes between 80-90% of their predicted HRmax. Session HRpeak of 190 bpm indicated that a player was exposed to a relative internal load between 90-95% of their predicted HRmax value at least once within a training session. Discussion As this is the first investigation to assess the typical physical training load exposure of the EJAF using GPS and HR technologies, there is limited data to compare the present results against. Further investigations using GPS and HR technology to serially monitor EJAF across the annual periodisation cycle will enable a better understanding of the current training practices and physical load exposure of this cohort. Furthermore, accurate monitoring of training loads has the potential to minimise the risk of injury, burnout and overtraining of elite junior athletes. This could possibly lead to improved performance and enhanced participation longevity across the career of an athlete (Hartwig, Naughton et al. 2009). References Hartwig, T. B., G. Naughton, et al. (2009). Journal of Sports Sciences 27(10): 1087-1094.

### DIFFERENCES IN MAXIMAL GRIP STRENGTH AND ISOMETRIC ENDURANCE BETWEEN ELITE AND NON-ELITE YOUNG JUDO ATHLETES

Ferliche, B., Almeida, F., Bonitch-Góngora, J., Bonitch-Domínguez, J., Padial, P.

FCAFD, University of Granada (Granada, Spain)

Introduction In judo, the grip strength is presented as one of the main determinants of success (Franchini et al., 2011). However, scientific literature has not related directly the role of maximal isometric strength (MIS) endurance with the result of the competition. The aim of this study is to compare the behavior of the MIS during an endurance test between elite and non-elite young judo athletes. Method 45 young judo athletes (U17) were assigned to two groups by their competitive results: medallists (Md) and non-medallists (NMd) in national championships. All participants performed a test to determine the MIS with the dominant hand. After that, subjects executed a MIS endurance test (e-MIS) by performing 8 maximal isometric contractions of 10 s with 10 s of passive rest between them. Results There were no differences in MIS between both groups (Md: 460.69 ± 92.34 N and NMd: 415.05 ± 70.93 N, p > 0.05). The e-MIS test revealed a significant loss of MIS during the first 3 repetitions in Md and during the first two in NMd (p < 0.001). Along of the 8 repetitions, Md group showed higher MIS values than NMd (p < 0.05). The difference between the 1st and the 8th repetition in the e-MIS test reached 24.47 ± 9.10% in the Md group and 18.81 ± 9.09% in the NMd one. Discussion The complexity of the technical and tactical actions of the judo combat makes difficult to establish a direct relationship between improved arm strength and success in the competition (Banobic, 2001). The differences observed between groups during the e-MIS test suggest that Md have better strategies to perform maximum levels of MIS in successive grips and/or better recover between them than NMd. Our findings are in agreement with other investigations (Garcia, 2004; Bonitch-Góngora et al., 2007; Franchini et al., 2011), which claim that endurance to the handgrip MIS appears to be the decisive factor to achieve success in judo above its own maximum value. ### PERCEPTION OF EFFORT UNDER FATIGUE AND CONTROL OF PACING IN YOUNG SWIMMERS

Scurati, R., Michielon, G., Longo, S., Invernizzi, P.L.

Faculty of Exercise Sciences - University of Milan

Introduction Pacing strategy is critical in middle- and long- distance performances to administer the power production related to the energy lost during the competition. In swimming, positive, negative, and even pacing approaches are then used. They suppose that the swimmer has an accurate and conscious perception of the effort (Borg, 1982), to properly manage his pace. The aim of this study was to observe how fatigue can alter the pacing in swimming, with relation to the perception of the effort. Methods Ten swimmers (12.2±0.5 years, 47.0±5.5 kg, 159±1.0 cm, 18.56±1.36 kg•m<sup>-2</sup>) volunteered to be included in the study. Pushing-off from the wall, the participants performed 50m front crawl at 100% of their maximum velocity and, after 2 minutes of recovery, a second 50m at 90% of their maximum velocity (step 1). Afterwards, once performing a fatiguing task (i.e. 2000m front crawl at the anaerobic threshold velocity), the swimmers repeated the 50m front crawl trials, as before (step 2). Perceived exertion, assessed through the CR10 scale before and after every 50m, as well as stroke length (SL), stroke rate (SR) and velocity (v), have been compared. Results At 100% of the maximum velocity, CR10 measured after the 50m trial was higher in step 2 than in step 1 (p<0.01; 5.1±1.3 vs. 7.3±0.7, AU). On the contrary, SR and v decreased after the fatiguing task (p<0.01, 0.97±0.06 vs. 0.91±0.05 cycles•s<sup>-1</sup> and p<0.001, 1.49±0.07 vs. 1.40±0.10 m•s<sup>-1</sup>, SR and v, respectively). SL did not change. At 90% of the maximum velocity, CR10 was higher in step 2 than in step 1 both before (p<0.01, 5.1±1.3 vs. 7.3±0.8, AU) and after

( $p < 0.05$ ,  $6.2 \pm 1.2$  vs.  $7.6 \pm 1.1$ , AU) the 50m trial. SR and  $v$  decreased ( $p < 0.05$ ,  $0.87 \pm 0.06$  vs.  $0.82 \pm 0.06$  cycles $\cdot$ s $^{-1}$  and  $p < 0.01$ ,  $1.42 \pm 0.10$  vs.  $1.33 \pm 0.09$  m $\cdot$ s $^{-1}$ , SR and  $v$ , respectively), whereas SL did not change. Discussion The drop of the velocity and the increase of the perceived exertion, measured every 500m during the long swimming effort, confirmed that fatigue raised (Knicker et al, 2011). As swimmers experienced after the fatiguing task an overall worsening of both the perceived exertion and the biomechanics parameters, it could be deduced that fatigue affected the 50m trials and, as a consequence, the ability to address to the pace. Therefore, the training of swimming pacing after fatiguing tasks might be recommended in order to practice the perception of proper pace and to manage it, even when fatigue raises and interferes on its administration. ### CARDIOVASCULAR STRAIN IMPOSED BY PHYSICAL EDUCATION CLASSES CONSIDERING CONTEXT VARIABLES

Póvoas, S.1,2, Martins, C.2, Silva, P.2, Soares, J.3, Teixeira, J.2

1: Research Center in Sports, Health Sciences and Human Development, 2: Maia Institute of Higher Education (Maia, Portugal), 3: Centre of Research, Education, Innovation and Intervention in Sport, Fac

CARDIOVASCULAR STRAIN IMPOSED BY PHYSICAL EDUCATION CLASSES CONSIDERING CONTEXT VARIABLES Póvoas, S.1,2, Martins, C.2, Silva, P.2, Soares, J.3, Teixeira, J.2. 1: Research Center in Sports, Health Sciences and Human Development, 2: Maia Institute of Higher Education (Maia, Portugal), 3: Centre of Research, Education, Innovation and Intervention in Sport, Faculty of Sport, University of Porto (Porto, Portugal) Introduction Physical Education (PE) classes comprise regular supervised physical activity aiming to improve physical fitness, among other purposes. Although there is some information regarding the intensity of PE classes, intensity assessments aren't regularly performed, particularly considering if small-sided games or analytical exercises are mainly used. Thus, the purpose of this study was to characterize students' cardiovascular strain during PE classes according to the level of education, gender and type of exercises. Methods One hundred and sixty heart rate (HR) recordings of 24 male and 24 female Portuguese students from the 1st (6 to 10 yrs old), 2nd (10 to 12 yrs old) and 3rd (12 to 15 yrs old) levels of education were registered during PE classes using Polar Team System. Maximal HR was determined during the yo-yo intermittent recovery test-level 1 (Bangsbo, 1994), except in children ages 6 to 10 years old, where maximal HR was estimated (220 bpm-age). Resting HR was determined according to Fairclough & Stratton (2005) and physical activity intensity levels were determined according to Stratton (1996). Results The 2nd and 3rd level students spent more than 50% of effective class time in intensities equal to or above moderate-to-vigorous physical activity. The 3rd level of education students spent a higher percentage of effective class time in vigorous physical activity (VPA) ( $29.2 \pm 20.76\%$  vs.  $19.9 \pm 17.56\%$  and  $10.5 \pm 10.47\%$ ;  $p < 0.05$ ) compared to 1st and 2nd levels of education, respectively. Students spent a higher percentage of time in VPA in small-sided games than in analytical exercises ( $32.4 \pm 31.23\%$  vs.  $18.6 \pm 22.61\%$ ;  $p < 0.05$ ). Boys spent a higher fraction of effective class time in VPA than girls ( $23.8 \pm 21.07\%$  vs.  $16.9 \pm 14.61\%$ ;  $p < 0.05$ ). Discussion Only 2nd and 3rd level PE classes seem to achieve the international recommendations regarding classes' intensity, which depends on students' level of education and gender. These results are in accordance with previous studies (Fairclough & Stratton, 2005). 1st level results may be due to the teacher characteristics, insufficient infrastructural and material conditions of schools, and curriculum, which focuses on coordination activities performed at low intensity. Small-sided games provide a better method for achieving higher intensity levels than analytical exercises. References Bangsbo, J. (1994). Fitness Training in Football: A Scientific Approach. Bagsvaerd: HO & Storm. Fairclough, S., & Stratton, G. (2005). *Health Educ Res*, 20(1), 14-23. Stratton, G. (1996). *Pediatr Exerc Sci*, 8(3).

### EFFECT OF SHORT-TERM HIGH-INTENSITY INTERVAL TRAINING AND CONTINUOUS TRAINING ON LACTATE KINETICS PARAMETERS IN ADOLESCENT GIRLS

Saremi, A., Shavandi, N., Khanjari, M.

Arak university

Introduction Training-induced adaptations have been extensively studied in adults, and some exercise scientists have recommended similar training programmes for young people. However, the subject of the response to training of children and adolescents is controversial. The purpose of this study was to compare the effects of short-term high-intensity interval training (HIIT) and continuous training (CT) (matched for total work) on lactate kinetics parameters in adolescent girls. Methods Twenty-two recreationally active adolescent girls (age:  $13.21 \pm 2.34$  year; height:  $161.25 \pm 8.63$  cm; mass:  $52.81 \pm 5.42$  kg) were randomized to either HIIT ( $n = 11$ ;  $8 \times 2$  min at 90% Vo2peak) or CT ( $n = 11$ ; 40 min at 50% Vo2peak) 4 times per week for 4 weeks. Before and after training, all participants performed an incremental exercise test to assess maximal oxygen uptake (Vo2peak) and a 3 min 90% Vo2peak exercise followed by 15 minutes of passive recovery to determine an individual blood lactate recovery curve fitted to the biexponential time function:  $[La](t) = [La](0) + A1(1 - e^{-\gamma1 \cdot t}) + A2(1 - e^{-\gamma2 \cdot t})$ . Results After training, both groups had significant improvements in Vo2peak ( $P < 0.05$ ), with no significant differences between HIIT and CT ( $P > 0.05$ ). Both training groups also had significant improvements in lactate exchange ( $\gamma1$ ), lactate removal ( $\gamma2$ ), and half-time of the blood lactate ( $t_{1/2} - [La]$ ) ( $P < 0.05$ ), with no significant differences between them. There were no significant changes in peak blood lactate concentration ( $[La]_{peak}$ ), time to reach  $[La]_{peak}$  ( $t - [La]_{peak}$ ), and blood lactate concentration at the beginning of recovery ( $[La](0)$ ) after the training period ( $P > 0.05$ ). Discussion These results indicate that short-term CT and HIIT are equally effective in terms of lactate kinetic improvement in adolescent girls. The present data expand on the principles of exercise prescription for adolescent girls by demonstrating that HIIT elicits substantial training effects, which are similar in magnitude to those produced by CT at half the exercise intensity but double the exercise time. ### THE EFFECT OF COMBINED MARTIAL ART AND WEIGHT TRAINING IN ATHROPOMETRIC CHARACTERISTICS AND STRENGTH VARIABLES IN ADOLESCENT BOYS

Ferunaj, P.F., Kavaja, G., Kuvarati, S., Skenderi, D.H., Erindi, A.

University of Sports of Tirana

Introduction Many adolescent boys are highly concerned about their body image perception and combined martial arts and weight training are preferred by them to improve muscle strength. Pubescent boys have presented a higher arm and thigh circumference in relation to prepubescent boys, and this fact may be explained due to the higher increase on the muscular mass in this maturational

stage(I). However, there are controversial data determining the ratio of predominant factor for this change, growth age or physical training. Methods In the study 9 volunteer adolescents (mean age  $17 \pm 0.23$ ) undertook the 3 days per week, 1.5 hour per session, 16 weeks of mixed training, combination of taekwondo (45 minutes) and progressive weight training (45 minutes). We have measured the body mass, anthropometric traits (Chest, biceps, leg girth) and body fat percentage (%BF) via skin fold thickness (SKF) method (2). The maximal and endurance strength for major muscle groups was measured before and after training using 1 RM and 75% of 1RM, respectively. Results Body mass was increased from  $73.77 \pm 13.28$  kg to  $77.43 \pm 13.98$  kg and interestingly, body fat decreased from 18.43 % to 16.75 %. The decrease in body fat was parallel combined with anthropometric changes. Thus, pectorals girth increased from  $87.8 \pm 4.32$  cm to  $90.35 \pm 5.82$  cm, biceps girth from  $30.2 \pm 2.45$  cm to  $32.17 \pm 2.61$  cm, leg girth from  $56.92 \pm 7.07$  cm to  $59.25 \pm 7.86$  cm. Maximal strength in back squat, dead lift and bench press was increased 23 %, 26 % and 18 %, respectively, whereas endurance strength 19 %, 22 % and 17 %. Discussion The major finding of this study was that martial arts and weight training was effective to improve maximal strength and anthropometric traits in adolescent boys. However, data from our study suggest that body weight status is not influenced by concurrent training. But despite of high intensity training, there was no decrease in body mass. Although we did not measure muscle mass, considering the increase in body mass and other anthropometric traits let us conclude that dominant factor for this change is the physical training and not age status. Furthermore, strength is clearly more closed to muscle size (3). However, the weak point of our study is the lack of control group. References 1. Hansen L, Bangsbo J, Twisk J, Klausen K. 1999. ### PREDICTIVE VALIDITY OF PREDICTORS IN A NEW TALENT IDENTIFICATION PROGRAMME BY THE GERMAN HANDBALL FEDERATION

Schorer, J., Strauß, B., Pabst, J., Büsch, D.

*University of Muenster, Institute of Applied Training Science Leipzig*

Introduction The German Handball Federation conducts a talent identification programme (TIP) with female (15-16 years) and male (16-17 years) youth handball players every year. In 2008, the DHB launched a modified TIP with anthropometric, motor and psychological tests (Elferink-Gemser et al., 2005; Lidor et al., 2005; Mohamed et al., 2009) with the aim to improve the predictive validity of the talent identification. This study evaluates the modified TIP in general and especially the predictive validity of the different tests. Methods Youth handball players from 20 regional selection handball teams (N = 542, 259 female and 283 male, 14 to 16 years) performed a series of tests. The number of items for the following analyses was reduced to eight potential predictors by ratings. Nomination by the national coaches was the outcome variable. First, a multivariate analysis of variance with the factors nomination and gender was conducted. Results The results showed significant main effects for nomination (Wilks' Lambda = .87, F(6, 169) = 4.39,  $p < .001$ ,  $\eta^2 = .14$ ) and for gender (Wilks' Lambda = .21, F(6, 169) = 101.37,  $p < .001$ ,  $\eta^2 = .78$ ), but no interactions between both. Therefore stepwise discriminant analyses were carried out separately for each gender. For boys, 30-m sprint is mainly responsible for a large explained variance (55.9%). For girls, this is the 30-m sprint, ball throwing velocity, and achievement motivation (67.6%). Discussion The results indicate that singular tests differentiate between nominated and not-nominated female or male youth handball players (Mohamed et al., 2009) but the predictive validity is quite low. The predictors are just not sensitive and specific enough (Lidor et al., 2005). Therefore, TIP will be expanded by tactical tests (Elferink-Gemser et al., 2004) with open skills assuming that an increase of the predictive validity will occur. Additionally, a longitudinal study will be conducted to test long-term effects. References Lidor R, Falk B, Arnon M, Cohen Y, Segal G, & Linder Y. (2005). *J Strength Cond Res*, 19(2), 318-325. #### PP-PM55 Health & Fitness: Physical Activity 2

##### CHANGES OF SELECTED SOMATIC PARAMETERS OF CZECH SENIOR POPULATION

Hrebickova, S., Sedlacek, J., Cacek, J., Grasgruber, P., Ondracek, J., Hrazdira, E., Vilim, M.

*Faculty of Sports Studies Masaryk University, Brno*

Introduction Nowadays in the life of human being the movement activities play all the time more and more important role. The purpose of any recreational movement activity is the health increase and prolonging of active life. During last several decades changed fundamentally the way of human living. On one side there was step by step minimized the movement activity and on the other side extremely increased the emotion and psychological load and parallel was worsened the quality of life environment. The care of individual health is a first-rate duty of each man. To keep needed level of health and movement performance all the life is a very difficult task. It needs systematic effort, self discipline, endurance and strong willing. At present is stated that the way of living can influence health from about 50%. There are relatively many researches about school population parameters of health and physical fitness. Researches about adults are more rarely. In this contribution there are presented results of 569 Czech adult people (273 males and 296 females) older than 18 years. There are presented and discussed results in 5 somatic parameters: body height, body weight, BMI, fat tissue percentage and waist hips rate. Methods These parameters were measured in Czech Republic during second half of year 2011. There was used special machine apparatus Inbody 720 plus anthropometric parameter body height. Authors compare and discuss trends and changes in groups of decades after 18 years of age. Results and discussion Presented results confirm negative trends that are very often presented by similar researches. Body height trend changes from positive to neutral both in groups male and female, when the oldest groups (over 49) are the lowest, while those under 49 are taller and in each decade they do not differ so much like those older. Like negative can be also considered decade changes in another watched parameters. The lowest body weight is among youngest probands and it also seems, that more progressive negative changes become in age over 59 years of age, both in groups of male and female. Body weight of course influence negatively all watched parameters (BMI, fat tissue percentage and waist hips rate), that are getting worse with getting

older. Males are already from 29 years in zone of overweight, females after 59 years; with it also correspond fat tissue percentage and waist hips rate, too. The project 'Creating a research team for the purpose of determining the level of physical activity (inactivity) in selected age groups of the population of men and women in the Czech Republic' (CZ.1.07/2.3.00/20.0044) is financed by the European Social Fund and the state budget of the Czech Republic. ### PHYSICAL ACTIVITY AND CARDIOVASCULAR RISK FACTORS IN SCHOLARS

Brito, L., Moser, D.C., Titski, A.C.K., Mascarenhas, L.P.G., Góes, S.M., Lazarotto, L., Carvalho, H.M., Coelho-e-Silva, M.J., Leite, N.

*Federal University of Parana and CAPES*

Introduction Physical activity is part of human life; however, with the gradual changes in lifestyle, daily movements decreased in both children/adolescents and adults (Neri, 2003). These modifications result in chronic diseases related to sedentary lifestyle and increase cardiovascular risk factors (Andersen et al., 2011). The aim of this study was to investigate the historical of physical activity and risk factor cardiovascular in scholars. Methods Cross-sectional epidemiological study was conducted with 1325 scholars (591 boys and 734 girls) from five schools in Curitiba-PR-Brazil. Height, body mass, waist circumference, blood pressure (BP) and the self-reported maturational stage by Tanner criteria were measured. The cardiorespiratory fitness was assessed by Leger test. The physical activity history (PAH) was measured by the 3-day record (3DPAR). Student's t-test for independent sample, Chi-square test and Pearson's partial correlation were performed. These statistical procedures were calculated with significance set at  $p < 0.05$ . Results Boys showed a higher age, height, SBP, DBP,  $VO_2\text{máx}$  and maximum heart rate average compared to girls ( $p < 0.05$ ). Considering the PAH under 300 min/week, scholars exhibited overweight (boys: 30.8%; girls: 37.1%), visceral obesity (boys: 22.6%; girls: 35.9%) and hypertensive levels (boys: 16.4%; girls: 17.2%). There were no significant differences between genders when cardiovascular risk factors and PAH were analyzed. Discussion In this study the frequencies of CVD risk factors were similar between physically active and sedentary, both girls and boys. This might be occurred due to an increased physical activity practice, as an alternative treatment, among children and adolescents previously identified with cardiovascular risk factors (Escrivão, 2000). ### FIGHTING AGAINST LOWER PHYSICAL ACTIVITY IN PREGNANCY WITH BODY COMPOSITION CONTROL

Robic, T., Benedik, E., Bratanić, B., Fidler Mis, N., Rogelj, I., Golja, P.

*Biotechnical Faculty*

Introduction Regular physical activity maintains optimal body composition and wellbeing, but in some cases, i.e. pregnancy, its levels are often insufficient. Consequently, body mass during pregnancy can increase not only due to fetal and gestational tissue growth, but also due to accumulation of additional maternal body fat. This alters body composition and can lead to pregnancy diabetes or high blood pressure. Precise determination of body fat content in pregnant women is challenging, as for safety reasons several routine techniques can not be used and only a few specific anthropometric equations for the assessment of body composition have been developed. Therefore, our aim was to compare anthropometric methods for the evaluation of body fat content in pregnant women to select optimal methodology. Methods This study is part of a wider project entitled "The role of human milk in development of breast fed child's intestinal microbiota" (project N° J4-3606) supported by Slovenian Research Agency and approved by the Slovenian Ethics Committee. 150 pregnant women volunteers provided information on their age, gestational week, and pre-pregnancy mass. Body height, mass, six skinfolds, wrist, and upper arm circumference were measured in the (mean (SD)) 32nd (3) week of pregnancy. Their body mass was also noted a few days before and after delivery. Body mass index (BMI) and percentage of body fat tissue according to thirteen different existing anthropometric equations were calculated. Body composition data were analyzed with one-way repeated measures ANOVA and level of 0.05 was adopted as statistically significant. Results Body mass gain was 10.3 (3.8) kg up to the 32nd week of pregnancy, and 14.4 (4.7) kg just before the delivery. During pregnancy, BMI increased from 22.6 (3.7), 26.2 (3.8), and 27.8 (4.0) kg/m<sup>2</sup> for pre-pregnancy, 32nd week, and pre-delivery, respectively, and decreased to 24.7 (3.8) kg/m<sup>2</sup> after delivery. Body composition results differed largely according to the anthropometric method used and ranged from 12 (4) % to 37 (7) % for the same sample of pregnant women during the same period of pregnancy. Discussion Increased BMI after pregnancy, as compared to pre-pregnancy, reflected general changes in body composition. Precise assessment of changes in body composition with anthropometric methods, however, was not reliable due to wide ranging of results. To determine body fat content correctly, it is thus important that the reliability of the existing methods for the assessment of body composition in pregnancy is thoroughly examined. Only so, assessments of body composition can be used as feedback information of health status, adequate physical activity, and the effectiveness of potential targeted exercise programs for pregnant women.

### SUBJECTIVE CHARACTERISTICS, ACTIVE PARENTS, ATTITUDE OF THE PHYSICAL EDUCATION TEACHER AND MOTIVATIONS TO THE PHYSICAL ACTIVITY IN ADOLESCENTS

Zito, V.1, Fischetti, F.1, Moretti, B.1

*University of Bari in Italy*

Introduction: This survey provides data on physical characteristics of young adolescents, family environment and correlations with their Physical Education teachers connected to the interests and motivations towards motor and sports practice. The data is valuable in identifying priorities for action and define strategies to improve young people's health and to prevent further health risks. Methods: We studied 1,250 high school students living in southern Italy city (M:F=712:538, mean age 16±1 yrs, range 15-19) according to BMI, physical activity, parents lifestyle and opinions regarding their physical education teachers. The anonymous questionnaire were made up of 19-items custom designed closed answers and multiple choice. Results: Obese, overweight, lean, and underweight subjects were: 25.5%, 8.7%, 64.5%, 1.3% (M) and 7.3%, 8.4%, 80.3%, 4% (F). Physical activity was more frequent in M (71%) than F (60%). Percentage of subjects practicing at least 2-3 times/wk PA was higher in lean than obese M (66% vs. 51%) and F (63% vs. 33%). 50% of active students appreciate the ability of the physical education teacher to establish positive relationships with pupils compared to 12.7% of active students who do not admire anything. 39.2% students wearing the tracksuit during the hours of physical education because it is necessary to do all the exercises and not only because the professor expects (7.2%). 65.4% of adolescents practice a sport to be fit and 60.2% to feel well. 28.2% of

students are no active mostly because they have no time and 22,8% because they are lazy. 85.2% of students who practice a sport have parents who are physically active, the percentage drops to 61.8% with inactive parents. 39.2% of parents, advised their children to practice a sport. Discussion: Of note, the research showed that a fit body together a positive family environment and a well-delivered PE class can contribute to let students be more active. These data give also the opportunity to develop integrated training programs among the various educational systems such as school, family and teachers to increase the level of physical activity in young adolescents revaluing the role of the family beyond that of teacher. ### LIFE QUALITY IN RUNNERS, A BRAZILIAN EXPERIENCE

Benetti, M., Sierra, A., Assumpcao, B.P., Gabriel, E.A., Bastos, F.C., Kiss, M.A.P.D., Martini, J.S.C., Cortez, J.A.A.  
*University of Sao Paulo*

The matter of life quality has been intensely discussed nowadays, and its concept incorporates, in its theoretical construction, a multidimensional nature, as does the definition of health by the World Health Organization. The components of life quality can be divided into eight concepts: physical functioning (PF), role physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role emotional (RE), mental health (MH). The eight concepts are hypothesized to form two distinct higher-ordered clusters due to the physical and mental health variance that they have in common. This research aims at checking the life quality score in runners of Ecorrida de Revezamento (relay race) in São Paulo. Methods: 122 runners, 98 men and 24 women, aged between 19 and 57 years (35.6±9.2 years). They had filled the SF36 Questionnaire, Portuguese version. The group was divided by age and compared in the eight concepts evaluated. For the analysis we established a raw scale (0-100) for each concept; t-Student test to compare the groups and Pearson correlation for practicing time. Results: Concepts - average±STDEV PF - General (G)- 94.87±12.6; Women (W)- 96.87±5.06; Men (M)- 94.38±13.81 RP - G - 85.86±26.5; W - 88.54±23.29; M - 85.2±27.3 BP - G - 77.41±17.78; W - 70.42±9.45; M - 69.98±12.65 GH - G - 70.06±17.78; W - 70.42±9.45; M - 69.98±12.65 VT - G - 74.3±15.01; W - 72.5±16.28; M - 74.74±14.73 SF - G - 81.35±19.43; W - 79.69±19.09; M - 81.76±19.59 RE - G - 84.15±27.84; W - 81.94±31.05; M - 84.69±27.14 MH - G - 77.67±14.7; W - 74±14.78; M - 78.57±14.61 Concepts by age (years) - average±STDEV PF - 19/29 years - 96.3±5.9\*; 30/39 years - 96.8±5.9; 40/49 years - 91.8±16.8\*; 50/57 years - 90±28.3\* RP - 19/29 years - 83.3±27.1; 30/39 years - 89.8±21.8; 40/49 years - 83±32.7; 50/57 years - 86.4±25.9 BP - 19/29 years - 77.8±17.1; 30/39 years - 75.3±17.1; 40/49 years 78.9±19.6; 50/57 years - 80.7±19.8 GH - 19/29 years - 68.3±14.5; 30/39 years - 71.5±11; 40/49 years - 69.6±10.3; 50/57 years - 71.9±11.2 VT - 19/29 years - 68.8±16.1; 30/39 years - 75.4±14.4; 40/49 years - 77.3±13.8; 50/57 years - 81.4±11.8 SF - 19/29 years - 80.4±18.3; 30/39 years - 81.5±21.3; 40/49 years - 80.4±19.4; 50/57 years - 86.4±17.2 RE - 19/29 years - 76.9±31.7\*; 30/39 years - 84.8±28.3; 40/49 years 92.8±16.6\*; 50/57 years - 84.8±31.1 MH - 19/29 years - 74.7±15.1\*; 30/39 years - 75.6±15.1\*; 40/49 years - 82.6±12.6\*; 50/57 years - 84±14.2 \*P<0.05 Pearson Correlation between the concepts and the practice time PF = -0.02; RP = +0.02; BP = +0.24; GH = +0.21; VT = +0.33; SF = +0.12; RE = +0.25; MH = +0.34 Conclusion: We found life quality score greater than 70 for all of the concepts in all sub-groups. It had statistical difference between the age band for: physical functioning (19/29, 40/49, 50/57), role emotional (19/29 and 40/49), and mental health (19/29, 30/39, 40/49). The correlation was positive in all concepts except physical functioning.

### HABITUAL PHYSICAL ACTIVITY IN OPERA ENSEMBLE OF CROATIAN NATIONAL THEATRE

Rupcic, T., Nedic, A., Mejovsek, M.  
*Faculty of Kinesiology*

Introduction There are many scientific evidences linking physical activity to numerous health improvements and substantial benefits that can be gained. Regular physical activity greatly reduces the risk of dying from coronary heart disease. It reduces the risk of developing diabetes, hypertension, and even colon cancer. Physical activity fosters strong muscles, healthy bones and joints and may favourably affect body fat distribution and prevent obesity. In older adults it helps maintain function and greater quality of life. The aim of this study is to establish the level of habitual physical activity in the employees of the opera ensemble of Croatian National Theatre in Zagreb. Methods The sample comprises 110 members (57 males and 53 females) of the opera ensemble of Croatian National Theatre in Zagreb. The level of their habitual physical activity was determined by Baecke questionnaire. The obtained data were analysed by standard statistical procedures, with statistical software package STATISTICA for Windows. Basic descriptive statistical parameters were calculated for the whole sample Results and discussion The answers from Baecke questionnaire are the grounds for the calculation of three basic indices: sport index (SI), leisure index (LI) and work index (WI). The highest possible value of the index was 5.0 and it indicates the highest physical activity, while the lowest physical activity was indicated with the value of indices of 1.0. Male members of the ensemble had significantly higher values of sport index, their experience of work load is slightly higher, while female members had slightly higher leisure time index. In comparison with average population in Croatia work index was, as expected, lower for the members of ensemble, while they results in LI and SI are significantly higher than in average Croats. This data suggests that, both male and female, ensemble members understand the benefits of physical activity for their health. When comparing orchestra members, soloists and chorus, work index is the highest for the soloists, although according to Manchester (2012) musicians spend more energy while playing than singers while singing. The soloists have the highest level of sport activity, while musicians were the most active in their leisure time. References Baadjou VAE, et al. (2011). Med Probl Perform Art, 26(4), 218-222. **14:45 - 15:45****Poster presentations****PP-PM56 Training & Testing 11****NORMALIZATION OF PHYSICAL TESTS' RESULTS CAN ATTENUATE THE RELATIVE AGE EFFECT IN YOUNG SWISS ALPINE SKIERS**

Gorski, T.1, Hoppeler, H.1, Rosser, T.1, Beltrami, F.G.2, Vogt, M.1

*1: University of Bern (Bern, Switzerland), 2: University of Cape Town (Cape Town, South Africa)*

**Introduction** The occurrence of the relative age effect (RAE), characterized by an over-representation and/or better performance of athletes born in earlier year quarters (Q) of the competitive calendar in comparison to those born in later Qs, has been reported in several sports. Recently, we demonstrated the occurrence of the RAE in young Swiss alpine skiers. This study analyses the effect of normalizing results in physical tests to weight and height on the occurrence of RAE in Swiss alpine skiers between 11 and 19 years old. **Methods** The Swiss Ski Power Test includes anthropometric data assessment, endurance (Cooper test, high-box jump), strength (one-leg and two-legs 5-hop, standing long jump, push-ups), and speed and coordination (two circuits containing obstacles) tests. Data of 6996 tests carried out with 1031 female and 1438 male athletes between 2004 and 2010 were analyzed, with athletes being divided according to sex and category (K1: 11-12 years old, K2: 13-14 years old, JUN1: 15-16 years old, JUN2: 17-19 years old). One-way ANOVAs were used to assess differences between athletes born in different Q for non-normalized results and results normalized to height and weight for each test of each category and sex. Significance level was set at  $p < 0.05$ . **Results** Significant differences in performance between athletes born in different Q (i.e., RAE) were found in several tests for different categories, with RAE occurring in a higher number of tests in categories K1 (male) and K2 (female) in comparison with other categories. For female and male athletes, normalization to height, but not to weight, reverted RAE in most cases. In female athletes, normalization to height, but not weight, was able to revert RAE in all tests of all categories in which RAE was present but the Cooper test of JUN2 athletes. Nevertheless, in male JUN2 skiers normalization to weight seemed to be more adequate than normalization to height. Reverting the RAE using normalization was not possible in some tests (mainly strength tests) of male K2 and JUN1 athletes. **Discussion** Normalization of performance in physical tests to height – and, in some cases, to weight – seems to be a possibility of attenuating RAE occurrence in young alpine skiers. Generally, normalization to height reverted more RAE cases than normalization to weight. RAE cases not reverted by normalization highlight the role played by other factors than anthropometric variables in the development of RAE. Based on these results, normalization to height is recommended when such tests are used for comparisons between athletes born in different Q or talent selection, for example.

**ROWING PERFORMANCE AND ROWING TECHNIQUE OF GERMAN JUNIOR WOMEN IN THE EIGHT FROM 2001-2011**

Mattes, K.1, Manzer, S.1, Boehmert, W.2

*1 University Hamburg*

**Introduction** For several years, regularly in June / July 2000-m race tests in the eight (8+) were performed with the best athletes of each year in preparation for the World Junior Championships (WJC). The data represent the individual rowing technique and the transformation of the motor abilities into rowing performance under the specific conditions of big boats. The cross-sectional data show what kind of medium-term development was completed from 2001-2011 in order to show trends for the junior women as well as for setting a benchmark for powerful rowers. **Methods** Each year two 8+ with junior women ( $N = 156$ ; body height  $1.79 \pm 0.05\text{m}$ , body mass  $70.2 \pm 5.8\text{kg}$ ) were measured over 2000-m races on the same regatta course in "Berlin Gruenau". The race boat was equipped with a mobile measuring system (Boehmert & Mattes, 2003) that captured the inboard handle force as the oar bending moment, with a strain gauge (resolution 0.25N), and the oar angle with a high-resolution magnetic field sensor that is attached to the gate pin (resolution 0.1°). Based on the data, the inboard handle power per stroke (Pih) and its components force (Fih), velocity (vih) and stroke length (sl) were determined. The 2000-m race time from the finals of the WJC in the 8+ was taken as external criteria. For the evaluation a linear regression analysis was calculated. On the basis of the results, different performance groups were formed. **Results** The race times of the winner and the German crews at WJC in the 8+ decreased approximately 1.5s/year during the period studied. The decrease in the body height of the German junior women was not significant in comparison to the body mass. At the same time the stroke rate remained comparable, however a significant increase in the Pih (1.1W/year) and the Fih (1.2N/year) with significant decrease of the sl (-0.2°/year) was found. Based on Pih six performance groups from international level ( $225 \pm 6\text{W}$ ) until national level ( $164 \pm 2\text{W}$ ) were formed. **Discussion** The positive development of the external criteria (race time) corresponds with the increase of the Pih over the 2000m. Since performance development is based on cross-sectional data, various reasons are responsible for it. The trend can be attributed to an improved rowing technique and a more effective transformation of motor abilities in rowing performance, but without making a clear distinction between current exercise-induced effects or selection effects. The individual rowing power can be better assessed on the basis of the new performance groups. **References** Boehmert, W. & Mattes, K. (2003). **EFFECT OF THIGH MUSCLE GROWTH ON BALL KICKING PERFORMANCES DURING PRE AND POST ADOLESCENCE IN MALE**

Teshima, T., Tanaka, S., Tsunoda, N.

*Kokushikan University*

**Introduction** The purpose of this study was investigated the effect of thigh muscle growth on ball kicking performance during pre and post adolescence in Japanese male soccer players. **Methods** Participants of this study were 303 Japanese male soccer players. The participants were classified into 4 chronological groups (10-12G, 13-15G, 16-18G, 19-22G). The height, weight, and body composition parameters such as fat-free mass (FFM) were measured using the body impedance analysis method. Muscle thickness of the thigh was measured using the B-mode ultrasonic method in dominant leg. The ball distance (BD) was measured with a tape. The ball velocity (BV) was measured using a radar gun. **Results** Muscle thickness of thigh anterior was obtained significantly difference among the age groups. And also,

FFM such as whole body muscle growth was significantly increased with chronological age. However, Relative muscle thickness (muscle thickness of anterior / FFM1/3) was obtained significantly difference between 13-15G and 19-22G. Ball kicking performances were observed significant difference in each year. Relative muscle thickness of thigh anterior was significantly correlated to BV and BD in 13-15G. And also, these relationships did not show a significant correlation in the 16-18G and 19-22G. Discussion In specific soccer training, repetition of the ball kicking movement, sprint and jump might be occurring muscle growth. However, There is no denying the natural growth in adolescence. Especially, muscle thickness of thigh was affected on ball kicking performance during adolescence. However, muscle thickness of thigh was not correlated to the ball kicking performances after post adolescence. Therefore, the ball kicking performance may vary depending on differences in skill level after the post adolescence. From these results, it was suggested that the ball kicking performance is probably affected by not only the thigh muscle growth but also the individual's ball kicking skills after post adolescence. ### **CORRELATION BETWEEN MAXIMUM STRENGTH OF THE LOWER LIMBS AND BODY COMPOSITION IN DIFFERENT MATURATIONAL STAGES IN BOYS.**

Portella, D.I., Arruda, M., Cossio-Bolanos, M.A.

*USCS University of São Caetano do Sul*

Correlation between maximum strength of the lower limbs and body composition in different maturational stages in boys. Portella, D.I., Arruda, M., Cossio-Bolanos, M.A. 1: USCS (São Caetano do Sul, Brazil), 2: UNICAMP (Campinas, Brazil) Introduction In human growth and development, the maturation is a factor that generates interference in those aspects. Body composition and physical capacity are influenced by the advent of maturity. However, in course of the maturation the relationship of the body composition and physical capacity change. The aim of this study was to identify the correlation between maturation, components of body composition and maximum isometric strength and their correlations during the maturational process in young boys. Methods Young boys soccer players (N=207, 14.09 age  $\pm$ 1.54, 162.74cm  $\pm$ 11.86, 54.77kg  $\pm$ 13.26). The measurement and classification of maturation (MAT) were obtained from the peak height velocity (PHV) calculated by the model proposed by Mirwald et al (2002). To measure the maximum isometric strength (MIS) was used a load cell coupled to a horizontal leg press and the individual positioned with the knees at 90 degrees. For body composition measurement was used DEXA (Discovery I, Hologic, USA) and the protocol used was the Whole Body. The variables were lean leg mass (LLM), Leg bone mineral content (LBMC), leg bone mineral density (LBMD) and leg bone area (LBA). Used the Pearson linear correlation ( $p < 0.01$ ) Results The maturation correlation between body composition and MIS were very strong (MATxLLM=.855; MATxLBMC=.879; MATxLBMD=.859; MATxLBA=.806; MATxFMI=.872). The correlations between MIS and the body composition were strong (FMIxLLM=.775; FMIxLBMC=.781; FMIxLBMD=.807; FMIxLBA=.689). The correlation of the MIS with the LLM, LBMC, LBMD and LBA across maturational stages, observed an increase in the strength of correlation between all variables in the advancement of the maturation process. Discussion Just as the maturation generates positive influence on physical performance in young athletes (Malina, Bouchard & Bar-Or, 2004) the positive influence of body composition in the performance of athletes was also observed in this study. Regarding the MIS and its relations with the bone component, Vicente-Rodriguez et al (2003) identified a similar pattern to the current study, very strong correlation between the MIS and the components in young athletes. The correlations between MIS and body composition suggest the importance not only of muscle mass to better performance, but also components of bone. References Malina R, Bouchard C, Bar-Or, O (2004). ### **TEN YEARS OF A FITNESS ASSESSMENT PROGRAMME FOR HIGH-LEVEL JUNIOR BADMINTON PLAYERS**

Hughes, M.G.1, Andrew, M.2, O'Donoghue, P.1, Stembridge, M.1

1: Cardiff Metropolitan University (Cardiff, UK), 2: Badminton England (Milton Keynes, UK)

Introduction English Badminton has a well-established programme of fitness assessment designed to provide feedback for the optimisation of fitness development in its junior players. Here, some key conclusions from the first ten years of this testing programme are presented. These findings may inform the development of similar testing programmes in other sports and may educate about fitness development in this population. Methods Since the year 2001, the most talented English junior players (n = 95 females; n=118 males; age range of 10 to 18 years) in this Olympic sport have performed fitness testing twice a year. Many of these players have gone on to become senior international players ('future elite players'; n=29). The tests include anthropometry and performance tests of jumping (vertical jump and standing long jump) and movement speed (sport-specific speed and lateral movement speed). Results Mean performance test data between males and females were similar across the age groups until the age of 13 years, after which male players showed increasingly superior performance; a pattern which persists into adulthood. Regarding test validity, for the future elite players the movement speed results of both male and females were superior to non-elite age-matched peers. Similarly, jump performance also discriminated between future elite and non-elite in females only (e.g., vertical jump, 50.4 $\pm$ 6.2 vs. 46.7 $\pm$ 5.2 cm, respectively;  $P < 0.05$ ). Neither mean stature nor body mass were different between groups. However, the broad distribution of the data shows that future success can not be predicted from test results alone. Across the ten years of the programme, there was evidence that age-matched players during the more recent tests (2007-10) were significantly fitter during some activities than players from earlier years (2001-3, 2004-6). Finally, and in keeping with many other similar reports, the players displayed a relative age-effect, with those born in the last third (Sep-Dec) of the selection year (Jan - Dec) significantly under-represented (17.5%) compared with those from the other thirds (Jan-Apr, 45%; May-Dec, 37.5%). Discussion The testing programme has provided valuable information on the development of fitness for this sport. The governing body has amended its selection policy to account for any relative age effect. The data have allowed for the establishment of fitness targets for the players who are implementing increasingly advanced fitness development programmes to optimise their likelihood of future success in the face of rule changes and increased international competitiveness. The trend for higher fitness in the recent players may reflect improved physical preparation or preferential selection of fitter junior players.

## FACTORS THAT IMPACT ON TALENT DEVELOPMENT WITHIN A TALENT DETECTION PROGRAM

Morley, E.

*Australian Institute of Sport/Victoria University*

Elissa J. Morley 1,2, Jason P. Gulbin 1, Juanita R. Weissensteiner 1, Clare MacMahon 2. 1. Australian Institute of Sport, Canberra, Australian Capital Territory, Australia 2. Victoria University, Melbourne, Victoria, Australia Introduction Talent detection is a form of talent identification that identifies athletes from outside the sport of interest as distinct from talent selection which selects athletes from within the sport (Vaeyens et al., 2008). Systematic talent detection and development (TDD) programs have become increasingly prevalent in recent years however their viability has not been well established in the literature. Therefore, the aim of this study was to examine the characteristics of a successful TDD program and to investigate why some talent detection athletes transition successfully into high performance sport, while others do not. Methods A case study approach was adopted using talent detected flatwater kayakers. Athletes were matched in pairs with the key differentiating factor being their highest level of achievement in kayaking with one athlete reaching Australian team representation and the other unable to reach this benchmark. Athletes (n=14) and their coaches (n=4) participated in semi-structured interviews and completed questionnaires based on Gagne's (2009) Differentiated Model of Giftedness and Talent. Additionally, on water and off water performance data was collected prospectively and analysed. Results Coaches, successful athletes and underachieving athletes raised a variety of contrasting explanations for performance. Coaches emphasised the importance of athletes' natural ability, intrapersonal characteristics including determination and 'coachability', and environmental and process factors such as the importance of early and ongoing success and a satisfying social setting. Successful athletes attributed their achievements to environmental provisions such as quality training programs and international competition, influential others including parents and coaches, and intrapersonal factors such as motivation and perseverance. The impact of poor injury management, competing priorities, performance plateaus, and ambiguous expectations were highlighted as consequential by underachieving athletes. Discussion Factors found to facilitate and constrain successful athlete development within a TDD setting will be presented. Discussion will focus on theoretical insights gained and recommendations for improving current TDD practices and maximising athlete retention. References Gagne, F. (2009). ## MEASURING CORE STABILITY: THE FEASIBILITY OF THE MCGILL CORE ENDURANCE PROTOCOL IN YOUNG FEMALE ATHLETES

Verschueren, J., De Pauw, K., Meeusen, R.

*Vrije Universiteit Brussel*

Introduction: Recent studies have shown that a lack of core stability can be an intrinsic risk factor for sport injuries, not only in sports with a high load on the spine, but also in young female athletes (4). The ability to sustain a muscle contraction for a prolonged period of time is of great importance to core stability (1). McGill published a test protocol for core endurance and reported a good reliability (3). The goal of our study is to examine the reliability of the McGill test protocol in young female athletes. Methods: 19 young female hockey players (age  $12.7 \pm 1.6$ ) participated in the study. An a-priori power measurement determined the sample size. The McGill test protocol consists of four tests in which the instruction is to maintain the position for as long as possible. The four tests are the flexion endurance test, left side bridge test, right side bridge test and the Biering-Sørensen extension test. Participants performed the McGill test protocol on 3 consecutive days, the only difference being the observer on day 2. Statistical analysis was performed following the method of Hopkins (2) using SPSS and the spreadsheets on sportssci.org. Results: The ICC for the flexion endurance test was 0.56, 0.45 for the Biering-Sørensen extension test, 0.67 for the right side bridge test and 0.60 for the left side bridge test, indicating a moderate reliability of the test protocol. The test-retest reliability of the flexion endurance test was poor to moderate for the flexion endurance test ( $R = 0.46 - 0.74$ ), the Biering-Sørensen extension test ( $R = 0.29 - 0.64$ ), the right side bridge test ( $R = 0.33 - 0.70$ ) and the left side bridge test ( $R = 0.17 - 0.58$ ). Conclusions: Given the moderate to poor reliability, we do not recommend the McGill test protocol in a population of young female athletes. Other protocols to measure core endurance should be developed. References: 1. Biering-Sørensen F. ## AGE AND GENDER RELATED DIFFERENCES OF THE RELATIONSHIP BETWEEN ANAEROBIC POWER PRODUCTION CAPACITY AND SKATING PERFORMANCE IN JAPANESE JUNIOR SPEED SKATERS

Kumagawa, D., Tanaka, S., Tsunoda, N.

*Japan Institute of Sports Sciences*

Introduction It is well known that the muscle force and power generation capacities are improved by speed skating training (Nemoto et al. 1990, de Koning et al. 1991). And also, these muscle functional characteristics are closely relation to the short-distance skating performance. However, it is not clear whether the effects of age and gender on the strength of relationship between anaerobic power and skating performance. Therefore, this study investigated the age and gender related differences of the relationship between anaerobic power production capacity and skating performance among Japanese male and female speed skaters aged 10-20 years. Methods Body compositional parameters for body height, body mass, and fat-free mass of the whole body were measured using the body impedance analysis method. Maximal anaerobic power (MANP) generation capacity was determined using a bicycle ergometer. In addition, the mean 500m skating velocity (SV), calculated from recently attained individual best times, was used as a measure of athletic performance. Furthermore, the subjects (both males and females) were divided into ten groups according to chronological age, and the correlation coefficients between MANP and SV were examined, respectively. Results MANP and SV values increased with chronological age in both males and females. The MANP of male skaters was significantly higher than that of female skaters after 13 years of age. SV greatly improved from 11 to 14 years in both male and female skaters, and gender-related differences in SV were observed in all ages except at 11 years. MANP were significantly correlated with SV in all the age groups. The 12-17-year-old groups among the males and the 10-14-year-old groups among the females showed the high correlation coefficients in terms of the relationships between MANP and SV. However,

significant correlations were not found in any other age groups. Discussion From these results, it was considered that the growth tendency of anaerobic power and 500m skating velocity were almost the same. However, it was cleared that the contributions of anaerobic power production capacity to speed skating performance may differ with age and gender. ### PHYSIOLOGICAL PERFORMANCE TESTS IN TRACK AND FIELD ATHLETES AGED 15 TO 18 YEARS

Gürol, B.1, Kale, M.1

*anadolu university health sciences institution*

PHYSIOLOGICAL PERFORMANCE TESTS IN TRACK AND FIELD ATHLETES AGED 15 TO 18 YEARS Gürol, B.1, Kale, M.1 1: School of Physical Education and Sports, Anadolu University, Turkey Introduction Physiological performance tests offer some insight into the factors contributing to success and to describe how physiological and technical performance evolves in young track and field athletes. The purpose of this study was to determine the differences in physiological performance test results related to ages in young track and field athletes. Methods Nineteen young female athletes (15-16 age group; height: 165.03±5.73cm, body weight: 55.85±9.04kg, 17-18 age group; height: 163.65±5.71cm, body weight: 54.18±5.98kg), and twenty-two young male athletes (15-16 age group; height: 172.95±8.18cm, body weight: 56.73±8.97kg, 17-18 age group; height: 176.15±5.15cm, body weight: 59.47±4.89kg) were volunteered to participate the study. Sit and reach test, squat jump, counter movement jump, standing long jump, medicine ball throw, 20m shuttle run test, 10m, 20m, 30m, and 40m sprint tests were performed. Unpaired sample t test was used to analyze the differences in two age groups (15-16 year and 17-18 year) both female young athletes and male young athletes. Results There were statistical significant differences in sit and reach test, squat jump, counter-movement jump, horizontal jump, and medicine ball throw in two young female athlete groups ( $p < .05$ ). There was a statistical significant difference in medicine ball throw between two young male athlete groups ( $p < .05$ ). Discussion In conclusion, there were more significant differences between 15-16 ages and 17-18 ages in young female athletes than young male athletes. ### EFFECTS OF A REPEATED SPRINT ABILITY TRAINING PERIOD ON CARDIO-RESPIRATORY FITNESS IN ADOLESCENT TENNIS PLAYERS

Moya, M.1, Sarabia, J.M.1, Guillén, S.1, Fernández-Blasco, M.J.1, Aracil, A.1, Torres-Luque, G.2

1.- *Research Group on Healthy Physical Conditioning, Centro de Investigación del Deporte, Universidad Miguel Hernández de Elche, Spain*  
2.- *UJAEN (Universidad de Jaén, Spain)*

Introduction Repeated and brief explosive movements separated by short recovery periods are very common during a tennis match. Consequently, training this intervallic form of exercise should be considered when designing tennis training schedules. Therefore, the present study was carried out in order to exclude any detrimental effect of the addition of a repeated sprint ability (RSA) training period on cardio-respiratory fitness adaptations in young tennis players. Methods Twenty-two male tennis players (age: 14±1,3 years) were included after parental informed consent. All of the subjects followed a similar training schedule before starting the study. For the study, subjects were divided in three training groups: a) a control group (C; n=6) that continued the previous training schedule; b) a first experimental group (E1; n=7) that continued the previous training schedule, and in addition performed one RSA training session per week; and c) a second experimental group (E2; n=9), similar to E1, but that performed two RSA training sessions per week. The intervention period lasted six weeks. Before and after the intervention period the subjects were subjected to a maximal stress test on a treadmill with continuous monitoring of the cardio-respiratory function. Mean  $\dot{V}O_{2max}$ , HR<sub>max</sub>, HR and  $\dot{V}O_2$  at VT1 and VT2 were compared among the three groups as well as intra-group before and after the intervention period. The statistical analysis was performed in a simple masked fashion. Results The three groups were comparable in age and in general anthropometric measurements. No statistical differences were found in the  $\dot{V}O_{2max}$  among the groups neither before (C=48,5±1,5; E1=50,04±3,3; E2=52,2±1,1 mL/Kg/min; ANOVA) and after the intervention (C=49,9±1,4; E1=51,9±1,7; E2=53±1,6 mL/Kg/min; ANOVA). Similarly, no differences were noted among the groups in the  $\dot{V}O_2$  and HR at both VT, as well as in HR<sub>max</sub> before the intervention. After the intervention: a)  $\dot{V}O_2$  and HR at VT1 were significantly higher in group E1, in comparison with C but not with E2 ( $p < 0,05$ , ANOVA); and b) HR at VT1 was significantly higher in E1 in comparison with the other groups ( $p < 0,05$ , ANOVA). No statistical differences were noted among the groups in the other variables. Discussion Our results support the idea that adding up to two sessions per week of RSA training to the regular training schedule during six weeks does not interfere with the cardio-respiratory fitness adaptation in adolescent male tennis players.

### THE EFFECTS OF ROPE JUMP TRAINING ON SPRINT, AGILITY, JUMP AND BALANCE TESTS IN YOUNG BASKETBALL PLAYERS

Boccolini, G., Costa, N., Alberti, G.

*UNIVERSITÀ DEGLI STUDI DI MILANO, ITALY*

INTRODUCTION Rope jumping has been a major training tool for many sports like boxing and tennis. In recent years, it has also been a favourite training tool for basketball players in addition to many other training options. Studies in the literature have demonstrated that the rope jump training is a valid training method for volleyball players [1], and that weighted rope jumping is a viable alternative to high impact plyometric exercises [2]. The aim of this study is to evaluate the effects of rope jump training on sprint, agility, jump and balance tests in young basketball players. METHODS The study was conducted on 28 amateur basketball players of two different team. The players were randomly divided into two groups: Rope Group (RG; n=14; 14.0±0.0 yr; height 169.6±11.1; weight 59.1±11.3) and Control Group (CG; n=14; 14.0±0.0 yr; height 164.1±8.3; weight 52.0±10.0). In this way, and (19.1±4.8 yr; height 176.8±5.8; weight 69.6±7.8). RG received a technical training program and in addition a rope jump training twenty minutes per session, three times a week, for four weeks. Rope training consisted always in jumps forwards. The control group followed only a technical training program for the same duration. Before and after four weeks, sprint test on 10m (SpT), lane agility drill test (LADT), stiffness test (StT), counter movement jumps test (CMJ) and balance test (BaT) have been performed. CMJ and BaT have been performed on one and two legs. All subjects performed 3 trials for each tests. The data were analyzed using paired T-test using SPSS software v. 17 (SPSS Inc, Chicago, IL). The significant level was set up to  $p < .05$ . RESULTS Following rope jump training, the RG obtained significant improvement in SpT ( $p < .001$ ), LADT ( $p < .001$ ), StT ( $p < .001$ ), CMJ with right leg ( $p < .05$ ) and BaT ( $p < .05$ ) for 3.76%, 3.07%, 6.29%, 7.24% and 13.37% respectively. Regarding the CG, there were no signifi-

cant increases in any of the variables analyzed. **DISCUSSION** These findings indicate that rope jump training is a valid method to improve the sprint capacity on 10m, the agility test, the stiffness and balance ability with two legs. We suggest to use rope jump training during warm-up and also strength and coordinative trainings. **REFERENCES** [1]Duzgun I et al. The effects of jump-rope training on shoulder isokinetic strength in adolescent volleyball players. *J Sport Rehab* 19:184-199, 2010. [2]Masterson GL and Brown SP. ### **EFFECTS OF THE SPORT-SPECIFIC TRAINING BACKGROUND ON SEATED MEDICINE BALL THROW IN YOUNG BASKETBALL AND VOLLEYBALL PLAYERS**

Battaglia, G.1,2, Bellafiore, M.1,2, Caramazza, G.2,3, Palma, A.1,2

*School of Sports Science, University of Palermo*

**Introduction** A sport-specific training background (SSTB) based on the nature of sport might affect explosive power of upper limbs in athletes (Izquierdo et al., 2002). However, there have been no attempts to study this in young female players from different ball games background. Therefore, the purpose of this study was to evaluate the effects of sport-specific training background on explosive power of upper limbs in basketball [BP] and volleyball players [VP]. **Methods** In the present study, thirty one short-limbed girls (Scelic Index  $\geq 54.6$ ) of which 11 age-matched control sedentary subjects [SS] (age: 15.00 $\pm$ 0.52 years, BMI: 21.10 $\pm$ 2.09, SI: 55.45 $\pm$ 1.45, sedentary life: 3 years); 10 basketballers (age: 15.60 $\pm$ 1.34 years, BMI: 22.67 $\pm$ 3.13, SI: 54.70 $\pm$ 1.37, SSTB: 3 years) and 10 volleyballers (age: 14.50 $\pm$ 0.97 years, BMI: 22.17 $\pm$ 1.87, SI: 55.29 $\pm$ 2.12, SSTB: 3 years), performed seated backward overhead ball throw (SBOBT) and seated chest pass throw (SCPT) using a 3-kg rubber medicine ball. All tests were performed for three times but only the best performance was considered. All data were compared using non-parametric test of Kruskal-Wallis and statistical significance was determined using a probability level of  $P < 0.05$ . **Results** Players showed higher performances than sedentary subjects in SBOBT and SCPT. However, we found only a significant difference ( $P < 0.05$ ) in the comparison between BP and SS during SCPT; instead, in SBOBT test, basketballers' performance was lower than volleyballers' one ( $P > 0.05$ ). **Discussion** These results showed that sport-specific training backgrounds affect the seated medicine ball throw performance. Indeed, basketball training background appears to affect much more the explosive power of upper limbs than volleyball training background in SCPT. For these reasons, in agreement with Izquierdo M et al. (2002) we suggest that the magnitude of the sport-related differences in explosive power output by upper limbs may be explained by sport-specific neuromuscular adaptations. **Reference:** Izquierdo M, Häkkinen K, Gonzalez-Badillo JJ, Ibañez J, Gorostiaga EM. (2002). *Eur J Appl Physiol*, 87(3), 264-71.

#### **SEASONAL VARIATION IN ANTHROPOMETRIC AND PERFORMANCE CHARACTERISTICS OF ELITE HURLING PLAYERS**

Collins, D.K.1, Morton, J.P.2, Reilly, T.P.2, Doran, D.A.2

*ITT Dublin (Ireland) 1, LJMU (UK) 2*

**Introduction** The seasonal change in anthropometric and performance characteristics is well documented in many team sports though no data are available on elite hurlers. The information may be useful in identifying effectiveness of training regimen. Therefore the aim of the current study was to examine the seasonal variation of anthropometric and performance characteristics of elite hurling players. **Methods** Twenty-three male competitive hurlers (age 23  $\pm$  3 yrs; height 183.5  $\pm$  6 cm) underwent anthropometric and performance assessment on three separate occasions during the competitive season (January; March; June). The anthropometric variables of body mass, sum of 5 skinfolds ( $\Sigma$ SKF) (Reilly, Maughan and Hardy, 1996) and body-fat percentage (BF%) (Durnin and Womersley, 1974) were determined. The performance measures of broad jump, countermovement jump (CMJ), linear sprint speed over 5, 10, and 20 m; and estimated VO<sub>2</sub>max were determined. A one-way ANOVA with a Tukey post-hoc test was used to identify significant change. **Results** The anthropometric variables of body mass (83.4  $\pm$  9.5; 81.7  $\pm$  8.4; 81.1  $\pm$  8 kg),  $\Sigma$ SKF (43  $\pm$  10; 39  $\pm$  6; 39  $\pm$  6 mm) and BF% (12.9  $\pm$  2.9; 12.2  $\pm$  2; 12.4  $\pm$  2.1 %) showed little seasonal change. Significant seasonal change were evident in broad jump (2.3  $\pm$  .3; 2.4  $\pm$  .2; 2.5  $\pm$  2 m) ( $p = .006$ ) and sprint speed over 5- (1.06  $\pm$  .03; .99  $\pm$  .04; .99  $\pm$  0.4 sec) ( $p < .01$ ), 10- (1.84  $\pm$  .05; 1.78  $\pm$  .04; 1.78  $\pm$  .04 sec) ( $p < .01$ ) and 20-m (3.16  $\pm$  .08; 3.03  $\pm$  .06; 3.04  $\pm$  .07 sec) ( $p < .01$ ) from January to March. The performance measures of CMJ (43.6  $\pm$  5.6; 45.7  $\pm$  6.3; 47.3  $\pm$  6.3 cm) and estimated VO<sub>2</sub>max (53.1  $\pm$  3.5; 54.3  $\pm$  3.1; 54.8  $\pm$  2.7 mL.kg<sup>-1</sup>.min<sup>-1</sup>) showed little seasonal variation. **Discussion** Anthropometric characteristics show little change over the course of the season. The broad jump and sprint speed performance improved significantly from January to March (pre-season). As a measure of seasonal adaptation to training, estimated VO<sub>2</sub>max seems to lack the required sensitivity for elite hurlers. Future research should consider if the YOYO test is sensitive to seasonal adaptation to training within a hurling population. **References** Durnin, J., Womersley, J. (1974) *Br J Nutr*, 32, 77-97. #### **EFFECTS OF RHYTHMICAL AND EXTRA RHYTHMICAL MUSICAL QUALITIES ON SPINNING PERFORMANCE**

Iuliano, E., Aquino, G., Moffa, S., Fiorilli, G., Giombini, A., Di Cagno, A., Calcagno, G.

*University of Molise*

**Motivational music benefit** has been found to improve sport performance. The aim of the present study was to evaluate ergogenic effects of rhythmical and extra-rhythmical qualities of the music on Spinning performance. **Methods** Twenty health adults, 8 males and 12 females, aged 25.70  $\pm$  3.97, volunteered this study and performed three 50 min-spinning sessions, under each of the three conditions: LOW-BPM music tracks, with a tempo in the range 120-150 BPM, HI-BPM music tracks with a tempo in the range 150-180, and RHYTHMICAL BASE, using only bass and drums, without melody, with a tempo in the range 150-180 BPM. Heart Rate (HR) and fatigue rate perception were monitored during the tests (Lopez-Minarro and Muyor Rodriguez, 2010). **Results** MANOVA revealed a significant difference for the parameter 'time to 75% MTHR' (time taken to reach the 75% of the Maximum Theoretical HR) ( $F_{3,20} = 3,811$ ;  $P < 0,05$ ). Post hoc analysis

showed that the 'time to 75% MTHR' in LOW-BPM session, was significantly longer than in the HI-BPM and RHYTHMICAL BASE sessions ( $p < 0,05$ ), while no significant differences were found between HI-BPM vs. RHYTHMICAL BASE sessions. After reaching the 75% MTHR, in the RHYTHMICAL BASE session, the HR showed a trend of reduction, not founded on the LOW-BPM and HI-BPM sessions. Discussions The BPM of music influenced the HR, such as a 'pacemaking' effect (Karageorghis et al., 2007), more in the first phase of Spinning performance (start of session - reaching of 75% of the MTHR), than in the second one (reaching of 75% of the MTHR - end of session) (Karageorghis et al., 2010). In the second phase, the extra rhythmical effect of the music, as melody, influenced the spinning performance, probably increasing the participant ability to sustain the effort. M. *Science sports* (2010) 25, 238-224 Karageorghis C.I., Jones L., Low D.C. *Research Quarterly for Exercise and Sport* (2007) 77,2, pp.240-250

### THE INCIDENCE OF RULE CHANGES ON PHYSIOLOGICAL CHARACTERISTICS OF MALE AND FEMALE CANOE SLALOM PADDLERS: A 14-YEAR LONGITUDINAL STUDY.

Tremblay, J.1, Cormery, B.2,3, Frechengues, E.2, Paillard, T.2, Marcil, M.M.3, Bouvard, M.3

1:Université de Montréal, 2:Université de Pau, 3:Hôpital de Pau

**Introduction** The sport of competitive canoe slalom has greatly evolved within the last fifteen years and this brought changes in the physiological demands placed on the paddler. A reduction in boat length (4.0 to 3.5 m), race duration (~30%) and a greater number of events to reach the finals in international competition are some of the significant changes introduced after the 2000 Olympics that might have altered the athlete's training in order to prepare for competition. **Methods** A total of 31 men and 22 women were studied, all were elite french canoe slalom paddlers (125 and 56 maximal tests completed, respectively). The human ethics committee of Pau's hospital approved all procedures. All maximal tests were conducted on a calibrated ergometer adapted for seated arm cranking. Maximal oxygen consumption ( $VO_{2max}$ ) was measured using an automated gas analysis system during an incremental test to volitional exhaustion. Ventilatory threshold (VT) and respiratory compensation point (RCP) were also determined. A 6s all-out force-velocity test was used to measure maximal power ( $P_{max}$ ) for the upper limbs (Vandewalle, 1987). Statistical analyses (ANOVA) were carried out to determine the interaction between the gender and the effect of the change in rules (since 2000) on the physiological characteristics of the paddlers ( $p < 0.05$ ). **Results** Significant main effects of "before" vs. "after" rule changes were found for maximal and submaximal  $O_2$  consumption in men, which increased by 9.9% at VT ( $32.5 \pm 0.8$  to  $36.1 \pm 0.8$  mL.min<sup>-1</sup>.kg<sup>-1</sup>), 11.1% at RCP ( $39.2 \pm 0.7$  to  $44.1 \pm 0.7$  mL.min<sup>-1</sup>.kg<sup>-1</sup>) and 7.6% at  $VO_{2max}$  ( $48.4 \pm 0.7$  to  $52.4 \pm 1.1$  mL.min<sup>-1</sup>.kg<sup>-1</sup>). Changes in women were only found at VT ( $25.9 \pm 1.3$  to  $28.3 \pm 1.6$  mL.min<sup>-1</sup>.kg<sup>-1</sup>, 8.4%). Maximum power in the force-velocity test remained stable between the two periods for both men and women ( $1152.1 \pm 20.9$  and  $563 \pm 21.9$  W, respectively). **Discussion** While force-velocity characteristics stayed constant during the last decade, the changes in boat length, competition rules and race duration since 2000 might have contributed to a modification of the physiological profile of paddlers, by generally increasing their level of fitness. It is well accepted that an increase in the volume of high-intensity training, even for short repeated bouts of a few seconds, can significantly improve fitness level (Gibala, 2008). In the present study, results might be indicative of an improvement in the general conditioning of athletes allowing them to support a greater training volume at a higher quality. ### RESPONSE TIMING AND MUSCULAR COORDINATION IN FENCING: A COMPARISON OF ELITE AND NOVICE FEMALE EGYPTIAN FENCERS

Aboalmaty, H., Alreni, A.

Tanta University

**Introduction** Although the coordination and control of fencing lunge were investigated in many Egyptian reports, numerous of fundamental questions concerning response organisation and accuracy still unanswered. Therefore, this study was undertaken. The effects of choice on response timing, the differentiation of levels of skill, the effects of different lengths of lunge and the nature of neuromuscular coordination of elite and novice female Egyptian fencers were the main concern of this study. **Methods** Three recent female Egyptian champions formed the elite group. They were ranged in age between 20 to 24 years with at least 5 years of high level of active training and competition. The three novice subjects were in their second year of active training and competition at the Muslim Youth Club team in Tanta (Egypt). They ranged in age between 17 to 21 years. Statistical procedures included ANOVA (program DMPD 4F), chi-square and Pearson product-moment correlation were used. The accuracy of elite and novice subjects was examined in three levels of target choice (single, two, and four targets) with three variations of movements distance (short, medium and long lunge). In addition, electromyographic activity (EMG) of selected upper and lower limb muscles was used to compare the two groups. **Results** The elite subjects reported higher level of accuracy; also they were faster for reaction time and total response time. The hypothesis that increasing choice would cause increases in reaction time was not upheld, except for some differentiation between the short and the two longer distances. The effects of distance movement were not marked. Qualitative and quantitative analysis of EMG revealed the high consistency of response patterns within subjects and highlighted the synergistic roles of selected muscles in distinguishing between elite and novice fencers. **Discussion** The findings of this study confirm that differences in the technical skill of fencers can be distinguished in the laboratory through a combination of response timing measures in association with measures of muscle action. They also draw attention to practical implication for individual skill assessment and training. Analysis of pre-movement muscle activity provided moderate support for the hypothesis that it was part of a single control process and indicates that a dual process can involve both the maintenance of postural stability and the generation of movement. It is also suggested that different movement contexts can lead to different levels of coordination between the system controlling posture and that controlling movement. References Ahmed M. (1992), Effect of A Proposed Training Programme For Developing Speed of Motor Response of Fencers, H.U. Egypt. Dsouky M. ## DETERMINATION OF CLIMBING SPECIFIC MAXIMAL OXYGEN UPTAKE DURING CLIMBING WITH INCREASING INCLINATION AND CONSTANT SPEED

Balas, J., Panackova, M., Strejčova, B., Kalab, M., Kodejska, J.

*Faculty of Physical Education and Sport*

**Aim** The aim of the study was to determine climbing specific maximal oxygen consumption (VO<sub>2</sub> max) during climbing with increasing inclination and constant speed. **Methods** Twenty six climbers volunteered to perform the climbing test on an incline wall and running test on a treadmill until exhaustion. The climbing test started with submaximal climbing on a known climbing circuit at 90° and 105° (15° overhang) and speed 25 movements•min<sup>-1</sup>. Rest of 4 minutes followed before the maximal test on the second climbing circuit. The less advanced climbers started with 95° (more advanced 105°) and after every 3 minutes, the wall was inclined by 10°. The test finished by the fall of the climber. Respiratory analysis was undertaken during the whole test. **Results** The VO<sub>2</sub> and heart rate (HR) significantly correlated with climbing ability during the submaximal test at 90° (VO<sub>2</sub>,  $r = -0.82$ ; HR,  $r = -0.66$ ) and at 105° (VO<sub>2</sub>,  $r = -0.84$ ; HR,  $r = -0.78$ ). The attained inclination at the moment of exhaustion was the strongest predictor ( $r = 0.89$ ) of climbing performance. There was a plateau of climbing specific VO<sub>2</sub> with mean  $40.3 \pm 3.5 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$  (68 % for the running test) independent of climbing ability. Maximal ventilation was  $74.9 \pm 4.9 \text{ l} \cdot \text{min}^{-1}$  (54% for the running test). **Discussion** Climbers with higher climbing ability demonstrated lower VO<sub>2</sub> and HR during easy climbing and, therefore, greater economy of movement. The maximal VO<sub>2</sub> during climbing corresponded to the peak values of de Geus et al. (2006) during top-rope climbing and bouldering at self-selected speed and near-maximal difficulty ( $41.3 \pm 4.9 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ). However, Magalhaes et al. (2007) stated peak oxygen uptake during self-paced lead climbing of near-maximal route at only  $33.4 \pm 2.1 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ . The discrepancy might be explained by the lower speed during lead climbing. The role of speed on oxygen uptake was stated by Booth et al. (1999) who used increasing speed, instead of inclination, on a motorized climbing treadmill to determine VO<sub>2</sub> max. The climbers achieved values of  $43.8 \pm 2.2 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ , slightly higher than our study. Lower speeds and overhanging climbing involve considerable static contractions of the upper limb which can deteriorate the pulmonary ventilation and therefore, transport of oxygen. It seems that the climbing test with increasing inclination until exhaustion is suitable for controlled training status, but maximal specific oxygen uptake may not be achieved. **References** Booth J, Marino F, Hill C, Gwinn T (1999). *BJSM*, 33, 14-18. ## ANALYSIS OF CARDIO-RESPIRATORY AND METABOLIC VARIABLES MEASURED DURING LABORATORIAL AND SPORT-SPECIFIC INCREMENTAL TESTS FOR TABLE TENNIS PERFORMANCE PREDICTION

Papoti, M.2, Dos Reis, I.G.M.3, Gobatto, C.A.3

*1: UFMS (Campo Grande, Brazil), 2: UNESP (Presidente Prudente, Brazil), 3: Unicamp (Limeira, Brazil)*

**Introduction** The aerobic energy system is very important in table tennis performance. It enables generation of repeated powerful strokes, rapid on-court movements, and ensures fast recovery for the next effort during the match (Lees, 2003; Zagatto et al, 2010). However, the procedures used to estimate aerobic aptitude for table tennis are not well documented in literature. The purposes of this study were: i) to compare physiological responses measured during a specific table tennis incremental test with physiological responses measured during cycling, arm crank, and treadmill running tests; and ii) to verify the accuracy of table tennis performance prediction based on the physiological responses from these tests. **Methods** Eleven national level male table tennis players participated in the study performing four graded exercise tests (GXTs): cycle ergometer, arm ergometer, treadmill, and specific table tennis exercise. Oxygen uptake (VO<sub>2</sub>), heart rate (HR), blood lactate concentration ([La]) and rate of perceived effort (RPE) were measured in all GXTs. Parameters were estimated at peak intensity and respiratory compensation point intensity (RCP). Table tennis performance was defined as the ranking position obtained during a simulated tournament between participants. **Results** VO<sub>2</sub> peak during specific table tennis test ( $39.9 \pm 1.5 \text{ ml/kg/min}$ ) was similar to cycling ( $41.2 \pm 1.4 \text{ ml/kg/min}$ ), but statistically lower than treadmill ( $43.9 \pm 1.5 \text{ ml/kg/min}$ ) and higher than arm crank ( $26.6 \pm 1.5 \text{ ml/kg/min}$ ). At RCP intensity, [La] ( $2.8 \pm 0.4 \text{ mM}$ ,  $4.6 \pm 0.5 \text{ mM}$ ,  $3.9 \pm 0.3 \text{ mM}$  and  $3.7 \pm 0.4 \text{ mM}$ , respectively) and RPE ( $13.3 \pm 1.1$ ,  $15.1 \pm 0.7$ ,  $14.4 \pm 0.8$  and  $14.5 \pm 1.0$ , respectively) were not statistically different between ergometers; however, arm crank VO<sub>2</sub> and HR at RCP ( $18.0 \pm 1.1 \text{ ml/kg/min}$  and  $130.7 \pm 3.1 \text{ bpm}$ ) were lower ( $p < 0.05$ ) than the other ergometers ( $35.2 \pm 2.2 \text{ ml/kg/min}$  and  $180.8 \pm 5.7 \text{ bpm}$  from specific table tennis;  $33.8 \pm 1.5 \text{ ml/kg/min}$  and  $169.3 \pm 3.7 \text{ bpm}$  cycle ergometer; and  $37.7 \pm 1.7 \text{ ml/kg/min}$  and  $178.9 \pm 5.0 \text{ bpm}$  treadmill). Stepwise multiple regression analysis revealed significant correlation between table tennis performance (TTP) and [La] at RCP and RPE at RCP during cycling ( $r = 0.89$ ,  $p < 0.05$ ); the prediction equation is described below.  $\text{TTP} = (-2.139 \times [\text{La}] \text{ at RCP}) + (0.675 \times \text{RPE at RCP}) + 5.492$  **Conclusion** The significant differences between the specific and laboratory ergometers highlighted the need for a specific test to measure physiological parameters in table tennis, whereas both RPE and [La] at RCP measured during cycling showed good correlations with table tennis performance. **References** Lees A. (2003). Science and the major racket sports: a review. *J Sports Sci*, 21(9), 707-732. Zagatto AM, Morel EA, Gobatto CA. (2010). ## EFFECT OF EQUITATION ON BODY COMPOSITION AND CARDIORESPIRATORY FITNESS OF HORSEBACK RIDERS.

Faludi, J., Virág, A., Komka, Zs., Trájer, E., Bosnyák, E., Udvardi, A., Zsidegh, M., Tóth, M.

*Semmelweis University*

**Background** Limited information exists on analyzing equitation as a training strategy to develop the fitness level of young and adult equestrians. In fact, horses' performance referred to as a crucial determinant of competitive performance in all equestrian disciplines. It is therefore rare in the horse riding disciplines to analyse body constitution and conditional capabilities of riders. The aim of the study was to quantify the effects of regular equitation training programs on body dimensions and cardiorespiratory fitness of young and adult equestrians. **Methods** Fourteen young female horseback riders of olympic disciplines (vaulting, dressage and jumping), 12 horseback archers and 20 jockeys were observed. They took part in the investigation on a voluntary basis. For estimation of body composition, percentages of bone, muscle, fat and residual was applied. All of methods were accepted by the International Biological Program. (Weiner and Lourie 1969) Conventional cardiorespiratory parameters were measured while running on a treadmill applying all out testing protocol. Data of VO<sub>2</sub>max, VE, O<sub>2</sub>P and physical performance (duration of running and estimated power output) were applied as an estimation of aerobic fitness. Predicted values of VO<sub>2</sub>max, VE, O<sub>2</sub>P of each participant served as a control (Wasserman et al. 1994). Group differences between the measured and predicted values were analysed by independent samples t-tests. Level of significances in each case was 5%. (\* =  $p < 0.05$ ) **Results** Fat proportion of young equestrians was near to threshold of overweight ( $23.88 \pm 4.71\%$ ), while their

muscle proportion was relatively low (40,12±2,07). Data of VE, VO<sub>2</sub>max, O<sub>2</sub>P of young riders were similar to predicted values of normal population. Archers and jockeys had higher proportion of muscle mass, lower proportion of fat mass, and greater values of VE, VO<sub>2</sub>max, O<sub>2</sub>P, than predicted values of their non athletic counterparts. Conclusion In spite of the fact, that young equestrians met ACSM criteria for aerobic activity (5days/week >30 min) no significant improvement in parameters of cardio-respiratory function and body composition were found. Riding a horse is not an adequate to improve fitness for young equestrians. Riders for olympic disciplines should participate in supplemental training sessions consisting of aerobic exercises and strengthening, which also help to avoid injuries. ### **RUNNING PERFORMANCE DURING A COMPETITIVE MATCH OF THE GERMAN NATIONAL RINK HOCKEY TEAM**

Baumgart, C., Hoppe, M.W., Freiwald, J.

*Research Center for Performance Diagnostics and Training Advice, University of Wuppertal (Germany)*

Introduction: Rink hockey is an indoor team sport played with roller skates, hockey sticks made of wood and a hard rubber ball towards two goals. The playing field has a size of 20x40 m and is surrounded by bounds. A rink hockey team consists of four field players and one goalkeeper. At the present, there is no study which assessed the running performance during rink hockey matches. The knowledge of these informations (e.g. distance and speed) can be used to design training programs and to evaluate players' performance during matches (Carling et al., 2008). Methods: Eight field players of the German national team (mean ± SD: age 24.1 ± 5.0 years, body mass index 24.3 ± 1.8 kg/m<sup>2</sup>) were analysed during a 2x20 min match against the actual European Champion (Spain) with the help of a two 25 Hz video system (720x480 pixel). Each camera covered approximately one half of the field and was calibrated using the field dimensions (9 points). Players were tracked by one person manually. Running speed of the players was calculated with the coordinates given by the video system. The following parameters were analysed: total distance, mean and maximum speed as well as relative time and distance in seven speed categories (<5, <9, <13, <17, <21, <25, >25 km/h). Results: Elite rink hockey players cover a total distance between 1252-5970 m with a playing time between 469-2322 s during a competitive match. The assessed values for mean and maximum speed of all players were 9.2 ± 0.68 km/h and 29.2 ± 2.0 km/h. The relative time which was spent in each speed category was 27%, 28%, 20%, 14%, 8%, 3% and 1%. Moreover, the relative distance which was covered in the speed categories was 8%, 22%, 24%, 22%, 15%, 7% and 2%. Furthermore, the mean time which was spent in the defined speed categories ranged from 0.87-1.9 s. Discussion: The results of the present study revealed that running performance of elite rink hockey players during competitive matches is highly intermittent similar to other team sports (Carling et al., 2008; Ziv et al., 2009). Therefore, training programs should notice the assessed running performance. Also rink hockey specific performance tests can be designed on the basis of the present findings. ### **THE COMPARISON OF BALANCE, REACTION TIME AND SOMATOTYPE PROFILES OF TENNIS AND BADMINTON PLAYERS**

Kılınç, H., Babayigit Irez, G., Saygın, O.

*Mugla University*

The Comparison of balance, reaction time and somatotype profiles of Tennis and Badminton players Hilal Kılınç, Gonul Babayigit Irez, Ozcan Saygın Mugla University, School of Physical Education and Sports, Mugla, Turkey Introduction In racket sports some physical fitness components are important. This can determine success level of players (Omesagaard, 1996). Badminton and tennis requires quick anticipation and response time (Mahoney and Sharp, 1995) and balance (Mantis, 1998). Methods A total of 40 university team tennis players (N=10 women, N=10 men) and badminton players (N=10 women, N=10 men) participated in this study. The Heath-Carter formula was used to determine the somatotype profile. Dynamic balance was measured by using Lafayette balance device and Nelson reaction time technique was used for measuring Reaction time. Results An independent sample of t-test was (SPSS 16 statistical package) used comparing group differences. As a result, There were no significant differences in reaction time (p>0, 05) and somatotype profiles (p>0, 05) between tennis players and badminton players although there was significant difference (p<0, 05) in dynamic balance measurements. Discussion Reaction abilities and balance (Omesagaard, 1996) seem to be valuable in racquets sports as in other sports (Mori, 2002). In this study, it was found these are important skills and when compared with each other, there was differences in their balance ability rather than reaction time. Singh and Singh, (2011) studied a comparison of somatotypes of tennis and badminton players. The Tennis players in their study were highest in their mesomorphic components while in our study can not found any significant differences although tennis players have high endomorphic components. ### **EFFECT OF SPEED OF MOVEMENT DURING CLIMBING IN FEMALE CLIMBERS**

Panackova, M., Balas, J., Strejčova, B., Kalab, M., Kodejska, J., Bunc, V., Kalabova, M.

*Charles University*

Introduction Climbing is a fast expanding sport in the recreational and performance area. Watts (2004) counts sport climbing among activities with moderate energy expenditure. The average oxygen consumption is around 20-34 ml•kg<sup>-1</sup>•min<sup>-1</sup> and maximum oxygen uptake is around 30-45 ml•kg<sup>-1</sup>•min<sup>-1</sup>. Up to now published studies were focused on men or mix population. For the assessment of adaptation to climbing, it can be used comparison with the activities, where it can expect the highest adaptation, which is run. We observed oxygen consumption given to specific activity. The aim of this study was to determine the effect of speed on VO<sub>2</sub> during climbing specific test until exhaustion. Methods Nine female climbers (aged 17-29 years) volunteered to participate in the study. Climbers were

divided according to their actual climbing performance into recreational (5/7- UIAA) and performance (7+/9- UIAA) climbers. They undertook maximal specific climbing test and maximal test on the treadmill. Climbers climbed a route in shape of ring in slightly overhanging profile (105°). They climbed 3 minutes according to their own speed. Then the speed was determined by the metronome. The starting speed was 20 movements•min<sup>-1</sup> (movement means a move of body from one hold to next hold) and increasing every 3 minutes by 5 movements until individual exhaustion. Results Relationship between the performance and the speed of climbing was the highest ( $R = -0.65$ ) at submaximal loads (30 movements•min<sup>-1</sup>). Maximal consumption ( $VO_{2peak}$ ) on the treadmill was  $55.0 \pm 0.82 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$  in recreational climbers, while the performance climbers was  $VO_{2peak} 51.6 \pm 2.51 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ . Specific consumption ( $VO_{2spec.peak}$ ) was  $34.2 \pm 7.03 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$  ( $62.2 \pm 12.78\%$  of running value) in recreational climbers and  $VO_{2spec.peak} 42.3 \pm 3.44 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$  ( $81.4 \pm 6.67\%$ ) in performance climbers during climbing. The climbers with higher performance reached higher speed of movement ( $R = 0.94$ ). Discussion Differences of  $VO_2$  between recreational and performance climbers were the highest in 30 movements•min<sup>-1</sup>. Female climbers with high climbing performance (over 7+ UIAA) use from 80% to 90%  $VO_{2peak}$  during climbing, while climbers with low climbing performance only from 49% to 77%  $VO_{2peak}$ . We agree with Booth et al. (1999) who reached  $VO_{2spec.peak} 43.8 \pm 2.2 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$  on climbing ergometer in climbing protocol with increasing speed. Climbing experience was confirmed by a higher percentage of consumption. In the current study, it was showed that speed of climbing in female climbers is determining factor in oxygen consumption. ## TRUNK MUSCLE VOLUME AND POSTURAL STABILITY IN JAPANESE FEMALE DANCERS AND NON-DANCERS

Kuno-Mizumura, M., Yokohata, E., Yoshida, Y., Kumagawa, D., Tsunoda, N., Ikegawa, S.

*Ochanomizu University*

Introduction Stability of the trunk, often referred to as core stability, has gained attention recently. Core stability training has become major element of training programs for dancers as well as for the athletes. Several studies have indicated that better balance control in dancers than in control groups (Mouchnino et al 1992, Crottes et al 1996, Golomer et al 1997). In addition, recent studies have suggested that trunk muscle such as psoas muscles would contribute to attain better balance and mobility (Suri et al 2009, 2011). The authors hypothesized that trunk muscle attributes would be closely linked to postural stability and dancers would show high postural stability compared with the controls. So the purpose of this study was to investigate trunk muscle volume by MRI images and postural stability by COP trajectory during standing in Japanese female dancers and non-dancers. Methods Subjects were seven female dancers with ballet training more than ten years as the dance group and nine female university students as the control group. Control subjects had no experience of any dance training and no regular exercise in past three years. This study was divided into two testing. For evaluating muscle volume of the trunk, MRI images were prepared using a 1.5 T MRI scanner (TOSHIBA EXCELART Vantage). Contiguous transverse images with 1.0cm slice thickness were obtained from the seventh thoracic vertebra to the hip joint. Cross sectional area were digitized for psoas major muscle, abdominal rectus muscle, erector spinae muscle, external oblique muscle, and quadratus lumborum muscle. For evaluating postural stability, subjects stood barefoot on the force platform (Kistler) for 20 seconds in six different conditions. Results There was no significant difference in all trunk muscles between two groups. Total trajectory of COP in six different standing conditions were significantly shorter in dancers than those in controls. Significant correlations between total trajectory of COP during eye-opened two-legged standing and muscle volume of psoas major muscle and that of external oblique muscle were obtained only for dancers, while significant correlations between COP and muscle volume of abdominal rectus muscle and that of erector spinae muscle only for controls. Discussion From the results of this study, it is indicated that long-term dance training would induce stable posture, while there was no significant difference in muscle volume of the trunk. It is also speculated that trunk muscle volume might contribute to maintain stable posture.

### IS-PM12 Benefits of High Intensity Intermittent Training (HIIT) in Untrained and Diseased People (\*)

#### APPLICATION OF HIIT TO CLINICAL POPULATIONS AND EFFECT ON MARKERS OF DISEASE RISK

Gibala, M.

*McMaster University*

High-intensity interval training (HIT) can serve as an effective alternate to traditional endurance-based training, inducing similar or even superior physiological adaptations in healthy individuals and diseased populations, at least when compared on a matched-work basis. While less well studied, low-volume HIT can also stimulate physiological remodeling comparable to moderate-intensity continuous training despite a substantially lower time commitment and reduced total exercise volume (1). For example, as little as six sessions of HIT over 2 wk, totaling ~15 min of "all out" cycle exercise within a total training time commitment of ~2 h, increases the maximal activity of mitochondrial enzymes and improves performance during tasks that rely heavily on aerobic energy provision. These data suggest that HIT may be a potent and time-efficient strategy to induce skeletal muscle metabolic adaptations that are linked to improved health. Many low-volume HIT studies have employed relatively extreme variable-load exercise interventions (e.g., repeated Wingate Tests) that may not be safe or well tolerated by certain individuals. Recent work has shown that short-term training using a more "practical" model of HIT (e.g., 10 x 1 min repeats at ~90% maximal aerobic work capacity, interspersed by 1 min of recovery) increased muscle oxidative capacity and improved endurance performance (2). Low-volume HIT studies in persons who might be at risk for cardiometabolic disorders or patients with chronic disease are very limited. However, it was recently demonstrated that low-volume HIT was effective and well tolerated in people with type 2 diabetes (3). Two weeks of HIT reduced average 24-h blood glucose concentration and postprandial glucose excursions, measured via continuous glucose monitoring under standardized diet but otherwise free-living conditions. Given that "lack of time" is the most commonly cited barrier to regular exercise participation, it is tempting to speculate that low-volume HIT may represent a time-efficient alternative to traditional endurance training. While the preliminary evidence from small, short-term studies are intriguing, large-scale studies are clearly needed to resolve whether low-volume HIT is a realistic, time-efficient exercise alternative to improve health and reduce the risk of cardiometabolic disease. **THE EFFECTS OF HIIT ON THE ABILITY TO OXIDIZE FAT IN HUMAN SKELETAL MUSCLE**

Spriet, L.

*University of Guelph*

It is now well established that models of high intensity intermittent training (HIIT) produce robust increases in mitochondrial volume. Mitochondrial biogenesis occurs rapidly with this training model with increased mitochondrial protein content observed after as little as 3-4 training sessions in humans. The HIIT models ask subjects to perform short bouts of exercise anywhere from ~90% VO<sub>2</sub>max for 1-4 min to all out sprints at power outputs as high as 300% of what is needed to elicit VO<sub>2</sub>max for 30 sec. These workouts are usually completed every other day. The ability to exercise at high aerobic intensities (~90% VO<sub>2</sub>max) is not surprisingly drastically improved following HIIT. Interestingly, when subjects are asked to exercise at ~60-65% of the pre-training VO<sub>2</sub>max following HIIT, the reliance on fat as a fuel is also increased. This is similar to what is seen following the classical endurance training protocols where subjects exercise for 1-2 hours/day at ~60% VO<sub>2</sub>max, 5 times a week. These results demonstrate that the HIIT exercise stress is able to activate the molecular machinery to produce the many proteins needed to increase mitochondrial volume and capacity. Numerous studies have assessed these adaptations by directly measuring either the activity and/or the protein content of enzymes and intermediates involved in the major mitochondrial pathways, including citrate synthase from the TCA cycle, cytochrome IV from the electron transport chain, beta-hydroxyacyl dehydrogenase from the beta-oxidation pathway, enzymes of the electron transport shuttle into the mitochondria, and pyruvate dehydrogenase or regulatory elements of this complex. An impressive aspect of these adaptations is how rapid they occur where increases have been shown after as little as 3 HIIT workouts. HIIT also increased the amount of mitochondrial and plasma membrane fat transport proteins in human skeletal muscle. Hormone sensitive lipase activity was increased by 13% and the use of intramuscular triacylglycerol was increased by 35% during 1 hour of submaximal exercise, but these changes were not significant. The important conclusion seems to be that the high intensity exercise bouts during HIIT maximally or near-maximally activate the aerobic system at the onset of exercise and also the various molecular signals that lead to increased production of mitochondrial fat-metabolizing proteins. This leads to rapid upregulation of the pathways that metabolize fat resulting in an increase in the capacity to oxidize fat during submaximal exercise following HIIT.

**MOLECULAR MECHANISMS UNDERPINNING RAPID MITOCHONDRIAL ADAPTATIONS TO HIIT**

Perry, C.G.R.

*University of Guelph, Guelph, Ontario*

Contraction signals a plethora of genomic events designed to increase the efficiency by which muscle responds to future energetic challenges. Central to this improved metabolic regulation is an increase in mitochondrial content described by Holloszy 45 years ago. This mitochondrial biogenesis is linked to lower substrate phosphorylation, carbohydrate sparing and increased fat oxidation, all of which contribute to improved endurance performance. Furthermore, Dudley et al demonstrated in the 1980's that the rate and magnitude of mitochondrial protein accumulation during training is proportional to the training intensity. Multiple breakthroughs were then made ~15-20 years ago establishing nuclear genomic expression as the critical link between contraction and improvements in glucose uptake which later led to similar nuclear/mitochondrial genomic links for exercise-induced mitochondrial biogenesis. Initial explorations into contraction/exercise-induced gene expression by Neuffer, Wasserman and others were followed by an explosion in research into the regulation of contraction-induced gene expression by transcription factors and co-activators. Most notably, the discovery of the PPAR, NRF, and PGC1 family of transcriptional regulators (and others) drastically improved our understanding throughout the last ~15 years of exercise-induced transcriptional regulation of mitochondrial biogenesis. In the past ~5 years, these same questions have been applied to HIIT in human muscle. We now possess a detailed understanding that the fast increases in mitochondrial content in human muscle during HIIT are likely mediated by multiple transcriptional regulators. Several groups have demonstrated that HIIT activates a variety of signaling cascades sensing specific signals generated during exercise which then activate transcription factors (PPARs, NRFs, etc) that are likely co-ordinated by co-activators (eg. PGC1s). These transcriptional regulators also increase in content at a rapid rate which precedes increases in mitochondrial proteins. This process requires repeated exercise sessions in order to accumulate sufficient genomic messages (mRNA) to drive translation of mitochondrial proteins at a level that sustains a greater mitochondrial content. Future studies should examine if the balance between net transcriptional repression (RIP140, etc) and activation (PGC1 regulators, etc) determines 1) the rate of mitochondrial biogenesis and 2) the onset of plateaus in protein content and performance improvements during training, with no single factor being essential but rather all cooperating to maximize the rate of adaptation. It is now clear that HIIT invokes rapid improvements in muscle energy homeostasis via a coordinated expression of multiple transcriptional programs controlling substrate uptake and catabolism. These molecular responses underscore the impressive efficacy of HIIT as a tool to stimulate robust increases in endurance performance and metabolic health in humans.

**16:05 - 17:35****Oral presentations****OP-SH07 Sport Psychology 3****ASSESSING MOOD STATE, STRESS AND RECOVERY IN ENDURANCE RUNNERS WEARING COMPRESSION SOCKS**

Welman, K., Venter, R., Terblanche, E.

*Stellenbosch University*

Introduction Adequate training and recovery are both important factors to enhance endurance performance and to avoid overtraining. Recovery and stress are also dynamic in nature and sport specific (Nicolas et al., 2011). A recent survey reported that compression garments are the most popular recovery intervention amongst endurance athletes (Nusser & Senner, 2010). Still limited scientific evidence support these anecdotal claims. This study set out to investigate distance runners' perception of stress and recovery following an ultramarathon race while wearing compression socks. Methods Psychological states were assessed in 40 runners (42±8years) before and for 72 hours after a 56km race. Participants were men who participated in regular endurance races over the past 3 years. Runners were

randomly divided in either an experimental group (CS), wearing knee-high compression socks (20–30mmHg), or a control group (C) wearing knee-high sport socks (<5mmHg). Runners completed the Recovery-Stress-Questionnaire for Athletes (RESTQ-Sport) twice, Stel-lenbosch Mood Scale (STEMS) five times and five muscle damage and energy level questionnaires. To quantify muscle damage myoglobin (Mgb) was assessed. Results The CS ran 13 minutes faster than the C ( $P>0.05$ ;  $ES=0.32$ ). Results revealed significant changes in all variables in both the C and CS after the race, which recovered in both groups by 72 hours. The CS demonstrated less anger at 24 hours after the race ( $P=0.01$ ;  $ES=0.58$ ). C were more confident when wearing the control sock compared to the CS ( $P=0.06$ ), specifically directly after the race ( $P=0.04$ ;  $ES=0.49$ ). CS reported 25% and 75% less fatigue directly ( $P=0.03$ ;  $ES=0.44$ ) and 48 hours after the race ( $P=0.03$ ;  $ES=0.61$ ). Runners wearing control socks stated to have less energy on average compared to the CS ( $P=0.03$ ). C perceived 37% more total stress at 72 hours after the race compared to CS ( $P=0.05$ ;  $ES=1.97$ ). Even though Mgb was 46% more reduced directly after the race compared to C ( $P=0.04$ ;  $ES=0.67$ ), the CS did not perceive a faster recovery rate. Discussion The results suggest that an ultra-endurance race induces perceived stress and leads to subsequent changes in perceived recovery. In addition, CS seems to contribute to an improved perception in fatigue, energy levels and reduces stress, but not necessarily improved perception of recovery and confidence. Conclusions This investigation added to our knowledge of the use of compression socks as a recovery technique, which may form part of a balanced training program for optimal performance. In addition, the results give us insight to the psychological challenges of a demanding distance running event. References Nicolas M, Banizette M, Millet GY (2011). *Psychol of Sport and Exerc*, 12(4), 368–374 Nusser M, Senner V (2010). *Procedia Engineering*, 2(2), 2845-2850.

### **‘YES, WE CAN!’: PERCEPTIONS OF COLLECTIVE EFFICACY SOURCES IN VOLLEYBALL**

Fransen, K., Vanbeselaere, N., Exadaktylos, V., Vande Broek, G., De Cuyper, B., Berckmans, D., Ceux, T., De Backer, M., Boen, F.

*KU Leuven (University of Leuven)*

Introduction ‘We have to believe that we can make it as a team!’ Coaches, players and other sport enthusiasts routinely talk about the importance of team confidence. Psychologists refer to this concept as collective efficacy, defined as ‘a group’s shared confidence that they will successfully achieve their goal’. Previous research findings revealed that teams with a strong sense of collective efficacy set more challenging goals, exert more effort, and are ultimately more likely to succeed. Nevertheless, little is known about the sources contributing to the development of collective efficacy. Therefore, in this study we examined which behaviours and events are perceived as sources of collective efficacy beliefs in volleyball. Study 1 In Study 1, volleyball coaches from the highest volleyball leagues ( $n=33$ ) in Belgium indicated the most important sources of collective efficacy. This list was then adapted based on the literature and on feedback given by an expert focus group, resulting in a 40-item questionnaire. Study 2 In Study 2, coaches and players from all levels of volleyball in Belgium ( $n=2,365$ ) rated each of these sources on their predictive value for collective efficacy. A principal component analysis revealed that the 40 sources could be divided into eight internally consistent components. Positive supportive communication (e.g. enthusiasm after making a point) was identified as the component most predictive for positive collective efficacy beliefs. The component referring to negative emotional reactions of players (e.g. discouraged body language) was most predictive for negative efficacy beliefs. Discussion Previous research has focused on sources of collective efficacy that take place before the game. Within that perspective, past performance was found to be the strongest source of efficacy beliefs. By contrast, in the present study, positive supportive communication, including sources during the game, was rated even more predictive for collective efficacy. Until now, collective efficacy has never been measured during the game. One of the reasons for this research lacuna is the fact that in most team sports it is not possible to interrupt a player repeatedly during a game to measure his or her collective efficacy beliefs. Observational data might provide a viable alternative for these self-report measures. It is therefore noteworthy that in the present study the sources that were most predictive for positive collective efficacy as well as those most predictive for negative collective efficacy are clearly observable behaviours during the game. These sources may thus offer a starting point for the design of a continuous measure of players’ collective efficacy beliefs through observation.

### **A COMPARISON OF FOOTBALL PLAYERS’ SPORT CONFIDENCE AND SELF-EFFICACY BELIEFS IN TURKEY**

Kocaeksi, S.2, Koruc, Z.1, Bozkurt, O.1, Arsan, N.1

*1) Hacettepe University, School of Sport Sciences and Technology, Ankara, TURKEY, 2) Anadolu University, School of Physical Education and Sport, Eskişehir, TURKEY* Introduction

Most sport psychology researchers, applied consultants, coaches, and athletes agree that confidence is an essential contributor to optimal sport performance. Research has identified confidence as a characteristic that clearly distinguishes between successful and unsuccessful athletes. Self-efficacy as defined by Bandura is an individual’s belief that she / he has the necessary skills to produce the desired outcome. Self-efficacy is considered as a situation-specific issue. Vealey applied these ideas of Bandura to the sport domain and developed sport confidence. Sport confidence is the athletes’ certainty that they have the ability to be successful in their sport (Manzo et al., 2005). The purpose of the present study was to examine the sport confidence and self-efficacy beliefs in football players participating in either super league or second league. Methods Super league ( $N=48$ ) and second league ( $N=53$ ) football players were participated in this study. Athletes completed the TSCI, SSCI, and SES. Data collection was carried out by researchers, and participant requirements and basic information about the nature of the research were explained. Data were analyzed by using descriptive statistics, Pearson Moment Correlations, MANOVA, and linear regression. Results Pearson Moment Correlation results indicated a positive significant relationship between SSCI and SES ( $r = .492, p < .05$ ), TSCI and SES ( $r = .493, p < .05$ ), and SSCI and TSCI ( $r = .766, p < .05$ ) of the Super League players. Results also revealed a non-significant relationship between SSCI and SES ( $r = .227, p > .05$ ), and a positive significant relationship was found between TSCI and SES ( $r = .271, p < .05$ ) and SSCI and TSCI ( $r = .787, p < .05$ ) of the Second League players. MANOVA analyses revealed significant differences between the Super League and Second League players’ self-efficacy beliefs ( $F(1,99) = 7.188, p = .009$ ). The linear regression results revealed that for both the Super League and Second League players, trait sport-confidence predicted state sport-confidence and self-efficacy. Discussion Positive correlations between the self-efficacy measures and positive effect. For performance, only the correlation between outcome confidence and place was statistically significant (Martin, 2002). All athletes compared themselves to someone who played at or above their level, except for college females, who sometime compare themselves to high school athletes. In general, the higher the comparison athlete, the lower the confidence score (Schultz&Short, 2006). Finally, it was revealed that the super league and second league football players were similar with regard to sport confidence, whereas, they had different self-efficacy beliefs. ## INTERRELATIONSHIPS BETWEEN TEAM COHESION, COACHING ENVIRONMENT, NEED SATISFACTION, AND WELL-BEING IN HOCKEY PLAYERS.

Merrett, C.K., Duda, J.L.

*University of Birmingham*

Interrelationships between team cohesion, coaching environment, need satisfaction, and well-being in hockey players. Introduction In their work involving basketball players and grounded in Basic Needs Theory (BNT; Deci & Ryan, 2002), Blanchard and colleagues (Blanchard, Amiot, Perrault, & Vallerand, 2009) found perceived team cohesion to positively predict players' basic need satisfaction, which in turn, predicted greater satisfaction in basketball and positive emotions. A perceived controlling coach climate negatively impacted on feelings of autonomy. Extending their work, this study considered both controlling and autonomy-supportive features of the coach-created environment and distinguished between task- and social cohesion. Further, both positive and negative indicators of athletes' well-being were taken into account. The interplay between the variables was examined in both an elite and recreational sample of hockey players. More specifically, the present research: i) determined the links between player perceptions of task and social cohesion, the coaching climate (both controlling and autonomy-supportive features), BN satisfaction, and reported indicators of well-being (i.e. subjective vitality) and ill-being (i.e., emotional and physical exhaustion), and ii) as assumed in BNT, tested for invariance in these relationships between elite and non-elite hockey players. Method Elite and non-elite (school/club level) (M age =17.59 years) field hockey players completed a multi-scale questionnaire pack assessing the targeted variables. Results Structural equation modeling supported the hypothesized models for elite (CFI= .91, TLI= .90, RMSEA= .06, Chi-squared= 1209.8, df 606 p< .01) and non-elite (CFI= .90, TLI= .90, RMSEA= .07, Chi-squared= 1184.1, df 606, p< .01) hockey player samples. The overall hypothesized structural models were invariant albeit some specific paths between variables were significantly different between elite and non-elite models. Most notably the paths between social cohesion and the three basic needs were variable between the two models. Discussion Findings support the assumed universality of BNT across elite and non-elite hockey samples but highlights variance in specific relationships between variables within the BNT framework. The theoretical and applied implications of these results are discussed. References Adie, J.W., Duda, J.L., & Ntoumanis, N. ## SMALL-SIDED FOOTBALL GAMES: INFLUENCE OF PLAYERS' NUMBER ON PERCEIVED SOCIAL LOADING, STATE OF FLOW AND ENJOYMENT

Bondarev, D.

*Lund University*

Introduction. Game-based approach using small-sided football games (SSGs) to develop various fitness aspects has become popular among recreational population. Previously, it was found that changing variables, such as the pitch area, player number, coach encouragement, training regimen (continuous vs interval training), rules, has an influence on physiological responses of the participant. At present, there is relatively little information regarding how variations of these factors affect psychological variables. Therefore the aim of this study is to explore how perceived social loafing, state of flow and enjoyment might be affected by variations of players' number in SSGs performing with recreational athletes. Methods. Twenty four recreational athletes participated in a series of SSGs of varying player number (three-, four-, five- and six-a-side games) with a goalkeeper. The heart rate, rating of perceived exertion (RPE), perceived social loafing, anticipated effort reduction, state of flow and enjoyment were assessed for each different SSG format. Results. For the variable "perceived social loafing" there was a statistically significant increase between different SSGs format ( $P < 0.05$ ). HR and RPE were greater in three-a-side game compared to six-a-side game. There was no effect of player number on state of flow and enjoyment ( $\beta = .08, P < 0.05$ ). However, the effect of perceived social loafing on enjoyment ( $\beta = -.34, P < 0.05$ ) and anticipated effort reduction ( $\beta = .25, P < 0.05$ ) has been found. Discussion. The results indicate that perceived social loafing may indirectly contribute to decreasing training stimuli when players' number increases. Furthermore, perceived social loafing may affect motivation and lead to frustration with regards to the team's achievement. Further researches needed to clarify how achievement goals of participants contribute to the social loafing in recreational football.

### OP-PM35 Rehabilitation 1

#### EFFECTIVENESS OF AN INTEGRATIVE BIOPSYCHOSOCIAL REHABILITATION PROGRAM FOR THE INPATIENT REHABILITATION OF CHRONIC LOW BACK PAIN

Pfeifer, K.1, Hofmann, J.1, Buchmann, J.2, Meng, K.2, Vogel, H.2, Faller, H.2, Bork, H.

*(1) Institute of Sport Science and Sport, University of Erlangen-Nuremberg, (2) Rehabilitation Sciences Unit, University of Würzburg (3) Rehab Centre. St. Josef Stift. Sendenhort*

Introduction In chronic low back pain (clbp), intensive biopsychosocial rehabilitation programs are effective in the short term (van Middelloop et al., 2011). The long-term effectiveness of such programs in Germany has yet to be proven. Besides, the practice of rehabilitation rarely includes a goal-oriented combination of interventions which are directed towards knowledge, behavior and physical activity. In this context, we developed and implemented the integrative rehabilitation program PASTOR. The attempt was to foster self-management in patients with clbp and to evaluate the program compared to inpatient standard-rehabilitation (usual care, UC). Methods A quasi-experimental study with control group design was conducted (three points of measurement: directly before and after rehabilitation, 12 months follow-up). The sample consisted of 537 patients with non-specific clbp (women: 51%; mean age  $49 \pm 8.4$ ). UC was ana-

lyzed in three rehabilitation clinics (n=270). Afterwards PASTOR was implemented as the new program and evaluated (n=267). PASTOR consists of five modules and was delivered in closed groups (48 hours altogether, comparable to UC). Subjective function was analyzed as primary outcome besides various secondary outcomes: e.g. pain, pain-directed cognitions, physical activity, health-related quality of life. ANCOVA was used for statistical analysis. Results After 12 months data of 382 patients (71%) can be analyzed. There is a significant, small effect for function in favor of PASTOR ( $\eta^2=0.036$ ;  $p<0.001$ ) as well as small to medium effects for most secondary outcomes (e.g. pain ( $\eta^2=0.012$ ;  $p<0.032$ ), amount of sports activities ( $\eta^2=0.015$ ;  $p=0.024$ ), mental distraction ( $\eta^2=0.080$ ;  $p<0.001$ ). Discussion PASTOR had small to medium long-term effects regarding function, pain and multiple other outcome variables compared to standard rehabilitation. Therefore, we strongly recommend the implementation and dissemination of interdisciplinary and especially integrative rehabilitation concepts for patients with chronic low back pain. A recent review on multidisciplinary rehabilitation in clbp did not find evidence for long-term effects on function and pain (van Middelkoop et al., 2011). The effects of PASTOR in comparison demand further research to identify the key factor(s). References van Middelkoop, M., Rubinstein, S.M. et al. (2011). A systematic review on the effectiveness of physical and rehabilitation interventions for chronic non-specific low back pain. *European Spine Journal* 20: 19-39.

## EXERCISE TRAINING AS TREATMENT OF NECK PAIN AMONG FIGHTER PILOTS

Murray, M.1, Lange, B.1,2, Andersen, H.C.1, Sjøgaard, G.1

*1 Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Odense C, Denmark*

Introduction Neck and shoulder pain is a common complaint among fighter pilots and a growing aero-medical concern. Unfortunately, previous intervention studies have been unsuccessful in relieving such pain within this occupational group. The aim of this study was to investigate if an exercise intervention could reduce the high prevalence of neck pain among fighter pilots. Methods F-16 pilots were randomized in a controlled intervention trial, to either an exercise-training-group (ET, n=27) or reference-group (REF, n=28). ET underwent 24 weeks of strength, endurance, and coordination training, 3 times a week, targeting deep and superficial neck muscles (see: [www.sdu.dk/f16pilots](http://www.sdu.dk/f16pilots)). REF received no training but was scheduled for corresponding training 6 months later. Main outcome: Three months prevalence of neck pain assessed on a ten point visual analog scale, VAS (0 corresponded to "no pain" and 10 to "pain at worst"). Compliance was evaluated by training diary as mean training sessions completed per week, and by questionnaire on a six-step scale, 1) regular, 2-3 times a week, 2) less regular, 1-2 times a week, 3) irregular, but > 4 times a month, 4) very irregular, 2-3 times a month, 5) seldom, trained but stopped, 6) no participation at all. Maximal Voluntary Isometric Contraction (MVC) and Rate of Force Development (RFD) for cervical flexion and extension were measured by strain-gauge transducers. Results Prevalence of neck pain was significantly reduced in ET from baseline (mean  $\pm$  SD)  $2.0 \pm 0.4$  to follow-up  $1.0 \pm 0.2$ , change  $-1.0 \pm 0.4$  ( $P = 0.01$ ), but not in REF from  $2.1 \pm 0.4$  to  $2.3 \pm 0.4$  ( $P = 0.80$ ). Comparison between groups found the reduction significant ( $P = 0.01$ ). Compliance for ET according to the training diary was  $1.9 \pm 0.6$  times per week, and according to questionnaire 58% participated more than once a week (scale 1+2). Compliance according to the questionnaire correlated with registrations in the training diary ( $r = -0.745$ ,  $P < 0.000$ ). MVC measures for cervical flexion and extension at baseline in ET were  $183.6 \text{ N} \pm 47.1$  and  $286.5 \text{ N} \pm 48.0$ , and in REF  $160.7 \text{ N} \pm 51.4$  and  $265.2 \text{ N} \pm 60.8$ , respectively. No significant differences were found between groups at follow-up for cervical flexion or extension. RFD for cervical-flexion increased significantly in ET from  $866.6 \text{ N/s} \pm 263.5$  at baseline to  $968.9 \text{ N/s} \pm 295.9$  at follow-up ( $P = 0.04$ ), but not in the REF group, from  $807.0 \text{ N/s} \pm 286.2$  to  $867.8 \text{ N/s} \pm 274.3$  ( $P = 0.33$ ). No difference was found between groups at follow-up. Discussion The exercise intervention reduced neck pain among F-16 pilots with a modest effect size. Compliance according to the questionnaire correlated well with participation based on the training diary, but only 58% of the training group trained regularly once or more a week. Higher compliance may be requested to attain strength gain and larger effect size. The intervention incorporated deep neck muscle training, which may be an important factor in the success of the training regime.

## BENEFICIAL EFFECTS OF LIFE-LONG PHYSICAL EXERCISE ON BRAIN FUNCTIONS OF AGED RATS

Nyakas, C.

*Semmelweis University Budapest*

BENEFICIAL EFFECTS OF LIFE-LONG PHYSICAL EXERCISE ON BRAIN FUNCTIONS OF AGED RATS Nyakas C.1,2, Marosi K.1, Kobor-Nyakas DE.2, Mehra RD.3, Radak Z.1, Luiten PGM.2 1: Research Institute of Sport Sciences, Semmelweis University, Budapest, Hungary, 2: Institute of Molecular Neurobiology, University of Groningen, The Netherlands, 3: All India Institute of Medical Sciences, Department of Anatomy, New Delhi, India Introduction Accumulating evidence shows that long-term physical exercise may interfere with the symptoms of brain aging under both normal and pathological conditions in human (Tierney et al., 2010) and animals (O'Callaghan et al., 2009). The aim of present experiments was to study how long-term, regular and moderate intensity physical exercise does interfere with the functional decline of aging brain in the light of behavioural, cellular and molecular mechanisms of action in rats. Methods In male rats the moderate intensity treadmill exercise started either in the young age of 3-months and in the advanced age of 18-months. The physical training was continuous until the age of 24 months in both groups. The cognitive behaviour of trained and control aged rats were measured at the end of exercise training: open-field activity, novel object recognition (NOR) to measure attention, and Morris water maze spatial learning ability. Biochemical and morphological analyses were performed in the hippocampus. The phosphorylation of Akt (protein kinase B), and that of AMP kinase (AMPK), brain derived neurotrophic factor (BDNF), acetylcholine synthesizing enzyme (ChAT), and glucose transporter 1 (Glut1) levels were measured with Western blot technique. Morphologically immune-cytochemical technique was used to measure the cholinergic (ChAT positive) fibre and the Glut1 positive capillary densities, and the neuronal expression of BDNF in the hippocampus. Results The results showed that contrary to the 6 months long exercise training, the life-long training (LLT) increased attention (NOR) in the age of 24 months. The Morris water maze learning was also positively influenced but only by the LLT. The life-long training markedly increased pAkt and pAMPK levels, as well as Glut1 and BDNF concentrations. The ChAT positive cholinergic fibre density, capillary Glut1 and neuronal BDNF levels were also increased by the LLT. Discussion It was concluded that the life-long exercise is much more powerful for interfering with the age related decline in cognitive and neurobiological markers in the brain of aged rats as compared to the long-term moderate exercise started only at the beginning of aging. The energy providing neuronal capacity is increased markedly which was supported by enhanced neurotrophic and glucose transport processes. Supported by Neuropeptide Foundation and by NWO 'bezoekersbeurs' in The Netherlands References O'Callaghan RM, Griffin EW, Kelly AM. (2009). *Hippocampus*, 19, 1019-1029. ## THE EFFECTS OF PRESCRIBED PHYSICAL ACTIVITY ON PATIENTS WITH SCHIZOPHRENIA

Curcic, D.J.1, Radivojevic, N.2, Dikic, N.2, Vukasinovic-Vesic, M.2, Andjelkovic, M.2, Antic, T.2, Baralic, I.2, Djordjevic, B.2  
*Special Hospital for Mental Disorders "Dr Laza Lazarevic", Belgrade 1, Sports Medicine Association of Serbia2*

**Introduction** Schizophrenia is a chronic, severe, and disabling mental disease. It has negative influence, not only on psychological functions, but also on physical state of patients. People with schizophrenia are overall less physical active than the general population. Unfortunately, no general concept for a therapeutic application of physical exercise has been developed so far. The purpose of this study is to examine the effects of 12 weeks of prescribed physical exercise on mental states, quality of life and side effects of drugs on individuals with schizophrenia. **Methods** Pilot study involved eight patients, and they were split into two groups, one exercise group (4 patients), and control group (4 patients). There were no personal differences such as gender, age, disorder duration and medication use between groups. Twelve weeks program of physical activity (45 minutes four times per week) were made for every patient, and their target heart rate (HR) were controlled by Polar F4 monitors (between 65-75% of max HR). Functional ability (VO<sub>2</sub>max) as an indicator of aerobic endurance has been obtained by ergospirometric test on a treadmill. Mental state data were collected by using Positive and Negative Symptoms Scale (PANSS) and World Health Organization Quality of life Scale (WHOQOL-BREF). Side effects of drugs were measured by Clinical Global Impression Scale (CGI). All tests were repeated after 8 and 12 weeks. T test and Wilcoxon test was used for statistical analysis. **Results** After 12 weeks, subjects in exercise group showed significantly increases of VO<sub>2</sub> max ( $p=0.004$ ), and significantly higher level of VO<sub>2</sub> max compared to the control group ( $p=0.032$ ). The results also showed significant difference between two groups in scores on PANSS Scale ( $p=0.044$ ) and in scores on WHOQOL-BREF Scale ( $p=0.037$ ) after 12 week of programmed physical activity. CGI score was significantly higher in exercise group ( $p=0.041$ ), which means that index of treatment efficacy was better in subjects who exercised. **Discussion** These results suggest that prescribed physical exercise significantly improves aerobic capacity, and also is effective adjunct treatment for patients with schizophrenia. Prescribed physical exercise is effective for decreasing psychiatric symptoms and side effects of drugs, and for increasing quality of life in people with schizophrenia. This is just preliminary results and the total number of patients will be much bigger at the end of study. **References** Meyer T, Brooks A (2000) Therapeutic impact of exercise on psychiatric diseases. *Sports Medicine* 30(4):269-79 Holley J, Crone D, Tyson P, Lovell G (2011) The effects of physical activity on psychological well-being for those with schizophrenia A systematic review. *British Journal of Clinical Psychology* 50:84-105

## THE INFLUENCE OF A 4-WEEK TREADMILL TRAINING USING UNSTABLE SHOES IN PATIENTS WITH LOW BACK PAIN

Stegen, C., Schellendorfer, S., Bauer, C., Kool, J.  
*Zurich University of Applied Sciences*

**Introduction** Low back pain (LBP) is one of the major health and socio-economic problems in western countries (Hoy et al. 2010/12), generating an enormous amount of direct and indirect costs for health care systems (Hoy et al. 2010/4). The working-age population is frequently affected. Lifetime prevalence is between 60-80% (Krismer and Tulder 2007). Unstable shoes, such as MBT shoes, claim to have the potential to stimulate muscle activity. LBP reduction after wearing MBT shoes was shown in a study with golf players suffering from LBP (Nigg et al. 2009). The purpose of this study was to investigate the effect on pain and disability of a four week treadmill training comparing jogging in unstable shoes and sport shoes in patients with LBP. **Methods** A randomized controlled trial in 22 patients suffering from LBP was conducted. Subjects were randomly assigned to two training groups. Both groups received the same supervised treadmill training sessions, two times a week for four weeks. One group wore unstable shoes during the training, as well as during daily activities; the other group performed the training with normal sport shoes. Outcomes were disability (Roland Morris Questionnaire, RM) and individual main complaints (patient specific functional scale, PSFS). We used SPSS 19 and analysed within group differences before and after treatment with the Wilcoxon-test, and between group differences with the Mann-Whitney-U-test. Alpha was set at 0.05. **Results** A significant reduction in disability (RM) was shown after the training in both groups. The individual main complaints (PSFS) showed a significant improvement and less pain. Differences between groups were not significant. **Discussion** High intensity aerobic training alleviated pain, disability and psychological strain in patients with chronic LBP (Chatzitheodorou et al. 2007). Treadmill training could influence pain reduction in patients with non-specific LBP positively. The non-significant between group differences might be caused by insufficient power in this pilot study. An alternative explanation is that the effect of treadmill training is much stronger than the effect of the unstable shoes. Further investigations are needed to evaluate the effect of wearing unstable shoes on pain reduction in patients with LBP. **References** Chatzitheodorou, D., Kabitsis, C., et al.(2007). *Phys Ther* 87 (3): 304-312. ## IS BLOOD FLOW-RESTRICTED EXERCISE SAFE FOR PATIENTS WITH ISCHEMIC HEART DISEASE?: A PILOT STUDY ON MARKERS OF COAGULATION AND INFLAMMATION

Madarame, H., Kurano, M., Fukumura, K., Fukuda, T., Nakajima, T.  
*The University of Tokyo*

**Introduction** Since resistance exercise with blood flow restriction (BFR) increases muscle size and strength with relatively low intensity, it might be a feasible method of cardiac rehabilitation for patients with ischemic heart disease (IHD). Although previous studies with healthy subjects showed relative safety of low-intensity resistance exercise with BFR (Madarame et al., 2010; Clark et al., 2011), we cannot exclude the possibility of unfavorable effects in IHD patients. We therefore investigated the effects of low-intensity resistance exercise with BFR on markers of coagulation and inflammation in IHD patients. **Methods** Nine stable IHD patients (aged 49-70 yr) who were not taking anticoagulant drugs performed leg extension exercise with and without BFR at an intensity of 20% 1RM. Two exercise sessions were separated at least for 1 week, and the order was randomly assigned. In each exercise session, one set with 30 repetitions was followed by 3 sets with 15 repetitions. Blood samples were taken before, immediately after and 1 h after the exercise. Fibrin degradation products (FDP) and D-dimer were measured as markers of coagulation, whereas white blood cell counts (WBC) and high-sensitive C-reactive protein (hsCRP) were measured as markers of inflammation. The data were analyzed with a two-factor (condition x time) repeated measures ANOVA. **Results** Neither a condition x time interaction nor a main effect of time was observed for FDP. For D-dimer, WBC and hsCRP, there was a significant main effect of time but no condition x time interaction. D-dimer, WBC and hsCRP increased significantly after the exercise independent of the condition. **Discussion** There was no statistical difference between the conditions (with and without BFR) for markers of coagulation and inflammation. This result, which is in line with previous studies with healthy subjects (Madarame et al., 2010; Clark et al.,

2011), suggests that low-intensity resistance exercise with BFR would be relatively safe not only for healthy individuals but also for IHD patients, at least for coagulation and inflammatory responses. It should be noted, however, that two patients in this study showed an apparent increase in FDP after the exercise with BFR (one of them showed increases in both conditions), though the values were within a clinically normal range. In addition, this is only a pilot study with a small number of stable IHD patients. Therefore, it should still be cautious to prescribe BFR to IHD patients. #### OP-PM36 Reliability and Validity of testing procedures

##### RELIABILITY OF CARDIORRESPIRATORY PARAMETERS DURING CYCLING EXERCISE PERFORMED AT SEVERE DOMAIN IN ACTIVE INDIVIDUALS

Barbosa, L.F.1, Montagnana, L.1, Denadai, B.S.1, Greco, C.C.1

HPL - UNESP - Univ Estadual Paulista

**Introduction** Exercise intensity domains (i.e., moderate, heavy and severe) have been defined based on the oxygen uptake (VO<sub>2</sub>) and blood lactate responses to constant-work rate cycling exercise (Gaesser and Poole, 1999). Studies have proposed that the reliability of the VO<sub>2</sub> kinetic parameters may be influenced by the exercise intensity (Ozyener et al., 2001) and that the amplitudes of the VO<sub>2</sub> response were more robust than the temporal parameters (time constants and time delay) (Carter et al., 2002). Limited data related to the reliability of cardiorespiratory parameters during exercise performed at severe domain have been published. Thus, the purpose of this study was to determine the test-retest reliability of the cardiorespiratory parameters during cycling exercise performed at severe domain in active individuals. **Methods** Thirteen active males (24.5 ± 4.5 yr; VO<sub>2</sub>max = 42.9 ± 6.1 ml.kg<sup>-1</sup>.min<sup>-1</sup>) performed the following tests: 1) An incremental test to determine VO<sub>2</sub>max and the intensity associated with VO<sub>2</sub>max (IVO<sub>2</sub>max), and; 2) 4 repetitions of square-wave transitions from rest to a power corresponding to 95%IVO<sub>2</sub>max to determine parameters of VO<sub>2</sub> kinetics and time to exhaustion (Tlim). **Results** While the two measures of Tlim were moderately related (ICC = 0.78; p < 0.01; CV = 9.6%), Tlim from the second test (545.2±103.1 s) was significantly higher than that of the first (492.5±100.9 s; p = 0.02). Moderate to high reliability (ICC = 0.76-0.93) for the amplitudes of the VO<sub>2</sub> kinetics responses was found. Poor reliability, however, was found for time constants and time delays of the VO<sub>2</sub> kinetics responses. **Discussion** To our knowledge, this is the first study that used multiple transitions to examine the reproducibility of the VO<sub>2</sub> kinetic response during severe cycling exercise. In non-familiarized individuals, Tlim shows a relatively low within-subject coefficient of variation. However, the second score in a series of two Tlim tests may be significantly greater than the first. Additionally, the amplitudes of the VO<sub>2</sub> response have significantly moderate to high reliability. The time-based parameters, however, present an important day-to-day intra-individual variation. Therefore, multiple transitions are recommended to increase confidence of data. **References** Carter H, Jones AM, Maxwell NS, Doust JH. (2002). *J Sports Sci*, 20, 901-909. Gaesser GA, Poole DC. ##### PERCEIVED FUNCTIONAL ABILITY RELATES TO LABORATORY AND FIELD MEASURES OF EXERCISE CAPACITY IN CANCER PATIENTS

Schmidt, K., Vogt, L., Thiel, C., Banzer, W.

Goethe-University Frankfurt a. M.

**Introduction** Cardiopulmonary exercise testing (CPET) and the 6-minute walk test (6MWT) have found widespread acceptance for the evaluation of functional capacity in chronic diseases. Self-rating instruments may be more economic and sufficiently precise to estimate fitness in the everyday clinical setting or in large clinical trials. However, in cancer patients it is unknown how such scales relate to results derived from CPET and 6MWT. Therefore the present study in cancer patients compared the results of a self-rating instrument to assess perceived functional ability (PFA) with the gold standard in both, laboratory and field exercise testing. **Methods** Fifty cancer patients (36 f, 14 m; 57.4 ± 10.2 years; BMI: 25.3 ± 4.2; during (56%) or after (44%) treatment) rated their PFA on an adapted 13-point scale (George et al. 1997) by estimating the walking or running velocity they could keep up for 1 mile. Subjects also performed a 6MWT and, after sufficient rest, a CPET to assess peak oxygen consumption (VO<sub>2</sub>peak). Test-retest reliability of the PFA was determined in a subsample (n = 26) by repeated measures within 2-7 days. **Results** Participants' VO<sub>2</sub>peak was 21.2 ± 4.8 ml•kg<sup>-1</sup>•min<sup>-1</sup>, and mean distance covered during the 6MWT 593 ± 81m. Their PFA averaged 7.1 ± 2.6 points, corresponding to a self-estimated speed of 6.1 km•h<sup>-1</sup> to cover 1 mile. PFA was significantly (p < .001) correlated with VO<sub>2</sub>peak (r = .62) and 6MWT distance (r = .65). Grouped for PFA estimated walking or running velocity (≤ 5; >5-7; > 7 km•h<sup>-1</sup>) ANOVA and Scheffé's post hoc tests revealed significant differences in VO<sub>2</sub>peak (17.7 ± 3.7; 21.6 ± 4.1; 26 ± 4.9 ml•kg<sup>-1</sup>•min<sup>-1</sup>) and 6MWT (538 ± 62; 598 ± 72; 687 ± 60 m). The intraclass-correlation coefficient (2,1) for test-retest reliability was .879 (95%CI: .748 - .944) (p < .001). **Discussions** The present findings in cancer patients revealed linear relationships between PFA and VO<sub>2</sub>peak/6MWT which are almost comparable to the correlation established between field and laboratory outcome measures (r = .67). From sub-group analyses it emerges that different grades of PFA seem to be able to distinguish between varying levels of exercise capacity. Future studies might evaluate the responsiveness of PFA to intervention-induced exercise capacity changes. **References** George JD, Stone WJ, Burkett LN (1997). **HIGH PREVALENCE OF FALSE-POSITIVE PLATEAU PHENOMENA DURING VO<sub>2</sub>MAX TESTING IN ADOLESCENTS.**

Beltrami, F.G.1, Wong, D.P.2, Noakes, T.D.1

1: UCT (Cape Town, South Africa), 2: The Hong Kong Institute of Education

Background: It is believed that a plateau in oxygen consumption (VO<sub>2</sub>) at the end of an incremental exercise test identifies the upper limits of cardiovascular capacity. We investigated how the choice of different mathematical criteria used to define a plateau influences the frequency with which the "plateau phenomenon" is detected and the prevalence at which "false" plateau phenomena occur during submaximal exercise. Methods: We employed six different criteria to identify the "plateau phenomenon" from a single data set comprising 63 incremental exercise tests in adolescent soccer players. Tests were performed on a motorized treadmill set at 5.5% grade, and had a initial speed of 7km.h<sup>-1</sup> for four minutes and subsequent increases of 1km.h<sup>-1</sup> every minute thereafter until participants could no longer tolerate the running speed. The different criteria were based on either absolute or relative stage-to-stage VO<sub>2</sub> differences for the individual or group. All criteria were tested using the highest sampling intervals of 15s, 30s or 1min within each stage for comparison with the previous stage, thus totalizing 18 different criteria. A single criterion (less than half of expected stage-to-stage change in VO<sub>2</sub> for the specific subject) was also used to detect the incidence of the plateau phenomena at any point of a test (except the linear portion between minutes two and four). If a plateau was identified during a test but VO<sub>2</sub> increased on a subsequent stage the plateau was deemed to be "false". The prevalence of secondary criteria based on Heart Rate within 10 beats of age-predicted maximum (HR) and respiratory exchange rate (RER) in excess of 1.1 were also measured. Results: The plateau phenomenon was detected in 16-83% of the tests depending on the criteria used, and only 3 different criteria produced an identical prevalence (49%). The single criterion method identified the presence of 103 "plateau phenomena" but 73 (70.9%) of these occurred during submaximal exercise and so were "false". False plateau were verified by one or both secondary criteria in 15.5% of cases. Subjects reached the HR and RER secondary criteria for determining a maximal test after 83.6 ± 11.7 % and 81.9 ± 18.1 % of total test duration, respectively. Conclusion: The wide range in the percentage of plateau phenomena detected by different criteria in the same data set could indicate that this phenomenon maybe is a calculation artifact rather than an indicator of an absolute limitation in oxygen delivery to or use by the exercising muscles. The high rate (71%) of "false" plateau phenomena further supports this interpretation. Secondary criteria can be reached early in exercise and often identifies "false" plateau phenomena as "true".

**THE USE OF HEART RATES AND GRADED MAXIMAL TEST VALUES FOR DETERMINING POSITIONAL DIFFERENCES IN RUGBY UNION GAME INTENSITIES**

Sparks, M., Coetzee, B.

*North West University*

Introduction In order to construct sport and position specific training regimens for players, the physiological demands players of different positions experience during match play have to be available (Duthie, Pyne & Hooper, 2003a). Therefore, the purpose of this study was to determine the positional differences in tertiary institution rugby game intensities, using heart rates and graded maximal test values. Methods In the weeks between three rugby matches ten forwards and eleven backs performed a standard incremental maximal oxygen uptake (VO<sub>2</sub>max) test to the point of exhaustion. The test was used for determining two ventilatory threshold points by which the low, moderate and high-intensity heart rate zones were categorized for each of the players (Chicharro, Hoyos & Lucia, 2000). Results The telemetry heart rate values recorded during each of the matches revealed that forwards spent significantly more (P < 0.05) time in the high-intensity zone compared to the backs (54.6% vs. 32.7%), whereas the backs spent significantly more time in the low-intensity zone during the match compared to the forwards (34.2% vs. 11.3%). Also, the mean duration of high-intensity bouts also lasted longer for the forwards than for the backs (1min:51s versus 38s) when the matches were analyzed as a whole. Discussion Sport scientists and conditioning coaches should construct different training programs for the two positional groups, concentrating more on frequent high-intensity activities lasting more or less 40 s for the backs and more or less 111 s for the forwards. In conclusion, this is the first study to make use of heart rate and graded maximal test values to show that significant differences exist with regard to the game time spent in the different heart rate intensity zones between rugby union forwards and backs. **METHODOLOGICAL ISSUES IN THE DETERMINATION OF THE OPTIMAL LOAD TO OBTAIN ANAEROBIC MAXIMAL PEAK AND MEAN POWER**

Santos, A.M.C.1, Lopez, R.1, Correia, C.1, Fontes Ribeiro, C.A.1,2

*Universidade de Coimbra*

Introduction The majority of studies have used the Wingate Anaerobic Test (WANT) to determine peak power in any 1 or 5 s period but it is well documented that the resistance typically applied - 75 g.kg<sup>-1</sup> - may not be optimal for eliciting true peak power. The Force Velocity test (FVT) circumvents this problem by determining individual force-velocity curves from which optimal peak power (OPP) may be derived. Although WANT is the anaerobic evaluation test over known and applied. In this investigation we attempt to verify if the optimum load determined, by force-velocity test can be the optimal load for WANT anaerobic mean and peak power. We also want to check that the values obtained in the WANT mean and peak power are sensitive to variations in 0.010 Kg.Kg body mass<sup>-1</sup> in the applied loads. Methods The subjects performed a WanT and FVT on a calibrated Monark cycle ergometer ( Monark model 824 E), that was individually adjusted for seat-saddle height and equipped with toe-clips to secure the feet to the pedals. The test preceded with a standardised warm-up, for both tests, that consisted of four minutes of constant pedalling at 60 rpm against a minimal force, interspersed with three all-out intensity sprints of 3-5s at the test applied force. Subjects were then taken through a two-minute series of standardised stretches for the quadriceps and hamstring group of muscles. The WanT commenced from a rolling start of 60 rpm and the subjects were verbally encouraged to cycle as fast as they could against an applied force that was set equivalent to 0.74 N.s<sup>-1</sup>. The 1s interval peak power (PP) and mean power over 30s of the test (MP) were derived from the WanT. The FVT consisted of 4 to 6 sprints on a Monark cycle ergometer lasting 5 to 8 s against a range of randomly presented resistances (30 to 95 g.kg<sup>-1</sup>) selected according to age and sex. Each sprint commenced also from a rolling start of 60 rpm. OPP was determined according to the procedures described by Winter et al., 1996. Results Subjects were 19 boys aged 21.3 ± 1.6 y, and 14 girls aged 20.3 ± 1.4 y, mass and stature were 76.79 ± 10.33kg and 174.43 ± 6.42 for boys and 56.07 ± 6.63 kg and 160.89 ± 4.72 cm for girls. The results indicate that peak power (PP) and mean power (MP) Obtained with optimal

load (OL) were significantly greater than those achieved with the standardized load (75 g.kg<sup>-1</sup>) We also found that determination of PP and MP with the WANT protocol is sensitive to variations of 0.010 Kg.Kg MC-1, both for heavy and light loads. Discussion The data suggest that to accurately determine the PP and MP using the want, it is necessary to determine in advance the OL of each subject, rather than a standardized load. We suggest that FVT can be used to determine the OL. This study suggests also that the OL for PP is the same for MP. ### CONCURRENT VALIDITY OF INERTIAL MEASUREMENT UNIT FOR THE ASSESSMENT OF COUNTERMOVEMENT JUMP IN YOUTH SOCCER

Cortis, C.1, Picerno, P.2, Pesce, C.3, Capranica, L.3

1: University of Cassino (Italy), 2: Sensorize motion sensing technology (Rome, Italy), 3: University of Rome "Foro Italico" (Italy)

Introduction Countermovement jump (CMJ) is considered a suitable test to determine muscle power, a good indicator of functional performance and a relevant index in soccer (Wisloff et al., 2004; Holsgaard et al., 2007), reflecting the players' ability to perform stretch-shortening cycle activities. In field conditions, CMJ measurements are usually performed by means of optical cells and contact mats, which can only be used on a flat surface, limiting the ecological validity of the evaluation when investigating athletes who compete on different surfaces (i.e., clay, artificial turf, natural grass). Thus, the aim of this study was to evaluate concurrent validity and reliability of wearable accelerometers with photocell system measurements for measuring flight time, thus estimating vertical jump height. Methods After obtaining parental, club and coach informed consent forms, 14 young elite ("Esordienti" team of the Italian first league S.S. Lazio Club) soccer players (age: 12±1 years; body mass: 40.3±9.1 kg; height: 151.9±11.8 cm; BMI: 19.1±1.3) were asked to perform maximal countermovement jumps (CMJ). To evaluate concurrent validity, athletes' CMJ flight times were recorded by means of an inertial measurement unit (IMU, FreePower Jump Module, Sensorize, Italy) wore on the trunk at the level of L5 and, at the same time by means of Optojump photocells (Microgate, Italy) considered as a gold standard (Glatthorn et al., 2011). To investigate test-retest reliability of the IMU, athletes participated in two experimental sessions separated by one week. Repeated measures ANOVA (p<0.05) was used to evaluate differences in experimental sessions. Intra-class correlation coefficients (ICCs) were used to evaluate validity and reliability. Results No differences emerged between experimental sessions (Test: Optojump = 0.448±0.027 s; IMU = 0.471±0.021 s; Retest: Optojump = 0.455±0.026 s; IMU = 0.478±0.022 s). High (p<0.001) ICCs were found between measurement systems for both experimental sessions (test = 0.891; retest = 0.959). Furthermore, IMU system showed an excellent test-retest reliability (ICC = 0.976). Discussion The IMU system demonstrated good concurrent validity and excellent test-retest reliability for the measurement of flight time in young soccer players. Therefore, this tool can be used as a valid method to measure CMJ flight time to estimate jump height in field settings, independently from testing surface, thus improving the ecological validity of the measurement. References Glatthorn et al *J Strength Cond Res* 2011:556-560 Holsgaard et al *Scand J Med Sci Sports* 2007:43-53 Wisloff et al *Br J Sports Med* 2004:285-288

##### MUSCLE DAMAGE PROTECTIVE EFFECT BY LOW-INTENSITY ECCENTRIC EXERCISE IN THE ELDERLY

Trevor, C.1, Hsin-Lian, C.1, Jui-Hsin, L.1, Wei-Chin, T.1, Guan-Ling, H.1, Kou-Wei, T.2, Kazunori, N.3

1NCYU (Taiwan), 2TPEC (Taiwan), 3ECU (Australia)

Introduction A bout of eccentric exercise with a light (10%) dumbbell that does not change any muscle damage markers attenuates muscle damage in the subsequent maximal eccentric exercise (MaxECC) of the elbow flexors (EF) performed 2-14 days later in young men (1). It is unknown whether such effect is evident for knee extensors (KE) of elderly individuals. Since KE are less susceptible to eccentric exercise-induced muscle damage than EF (2), and are used and perform low-intensity eccentric contractions in daily activities, it might be that the protective effect by a low-intensity eccentric exercise is minimum. Thus, the present study investigated whether an initial low-intensity (10%) eccentric exercise of the KE would reduce muscle damage induced by MaxECC of the same muscle performed 7 days later by elderly men. Methods Twenty-six untrained elderly men (66.4 ± 4.6 y) were assigned to two groups (n=13 per group); Group A performed 6 sets of 10 MaxECC (30°.s<sup>-1</sup>) of the KE using non-dominant leg, and Group B performed 6 sets of 10 light eccentric contractions of the KE by lowering a weight (10% of maximal voluntary isometric knee extension strength) on a leg extension machine (10%ECC) 7 days prior to MaxECC. Changes in maximal voluntary isokinetic (30°.s<sup>-1</sup>) concentric (MVC) strength, optimum angle (OA), range of motion (ROM), leg girth, muscle soreness (SOR), plasma creatine kinase activity (CK) and myoglobin concentration (Mb), and echo-intensity of the B-mode ultrasound images before to 5 days following MaxECC were compared between the groups by a two-way repeated measures ANOVA. Changes in the variables following the 10%ECC were analysed by a one-way repeated measures ANOVA. Results The 10%ECC did not change any variables. Changes in all variables except for OA following MaxECC were smaller (P<0.05) for Group B than Group A. For example, maximal changes in MVC strength (Group B: 18 ± 2 % vs Group A: 28 ± 2 %), ROM (6 ± 1 vs 8 ± 1 °), leg girth (4.6 ± 0.6 vs 5.9 ± 0.6 mm), SOR (8 ± 2 vs 14 ± 3 mm), CK (879 ± 285 vs 1822 ± 626 IU/L), and Mb (126 ± 19 vs 265 ± 86 ug/L) following MaxECC were reduced (P<0.05) by performing 10%ECC (Group B). Discussion The results suggest that non-damaging KE eccentric exercise conferred protection against muscle damage induced by MaxECC of the KE for the elderly, which is in line with the results shown by the previous study using the EF of young men (1). Preconditioning muscles by low-intensity eccentric contractions can be used as a strategy to minimise the magnitude of muscle damage in resistance training for both young and elderly individuals. **INFLUENCE OF PRIMING EXERCISE ON MUSCLE DEOXY[Hb+Mb] DURING RAMP CYCLE EXERCISE**

Boone, J., Bourgois, J.

*Ghent University*

**INTRODUCTION** The aim of the present study was to get a better insight into the mechanisms underpinning the sigmoid pattern of deoxy[Hb+Mb] during incremental exercise by assessing the changes in the profile following prior high-intensity exercise. **METHODS** Ten physically active students performed an incremental ramp (25 Watt.min<sup>-1</sup>) exercise preceded on one occasion by an incremental arm (10 Watt.min<sup>-1</sup>) and on another occasion by an incremental leg exercise (25 Watt.min<sup>-1</sup>)(RT) until exhaustion. Deoxy[Hb+Mb] was measured at the M. Vastus Lateralis throughout the exercises by means of near-infrared spectroscopy. Deoxy[Hb+Mb] was set out as a function of work rate (% peak power) and compared between the different exercises. **RESULTS** These procedures showed that the sigmoid pattern provided the best fit for the pattern of deoxy[Hb+Mb] during the RT and also when the incremental exercise was preceded by the arm exercise. However, when the incremental exercise was preceded by the leg exercise (RT), deoxy[Hb+Mb] started to increase immediately from the onset of the ramp exercise and thus the sigmoid model no longer provided a good fit to the data. **CONCLUSIONS** In the present study it was observed that the sigmoid pattern of deoxy[Hb+Mb] was disturbed when the ramp exercise was preceded by a high-intensity leg exercise but not by a high-intensity arm exercise. This observation suggests that the sigmoid pattern of deoxy[Hb+Mb] is probably related to the sequential recruitment of different muscle fibre types.

**PROTECTIVE EFFECT CONFERRED BY MAXIMAL ISOMETRIC CONTRACTIONS AT A LONG MUSCLE LENGTH**

Nosaka, K.1, Chen, T.C.2, Lin, M.J.3, Chen, C.H.4, Chen, H.L.2

*1: Edith Cowan University (Australia), 2: NCYU (Taiwan), 3: CCU (Taiwan), 4: NTU (Taiwan)*

**Introduction** The magnitude of muscle damage induced by maximal eccentric contractions is reduced by preconditioning exercise consisting of light eccentric contractions (1) or maximal isometric contractions (2) that do not change indirect muscle damage markers. In the last ECSS conference, we reported that only 2 or 10 maximal voluntary isometric contractions of the elbow flexors performed at 20° elbow flexion (MVIC) attenuated the magnitude of muscle damage induced by 30 maximal eccentric contractions (MaxECC) performed 2 days later (2). However, it is unknown whether the protective effect is still conferred when 2MVIC are performed immediately before MaxECC, and how long the protective effect lasts. The present study investigated whether the magnitude of muscle damage induced by MaxECC would be reduced when 2MVIC were performed immediately before, or 2, 4 or 7 days prior to MaxECC. **Methods** Sixty-five untrained young men were assigned into one of the five groups (n=13 per group) based on the timing of the 2MVIC performed prior to MaxECC; immediately before (0d), 2 (2d), 4 (4d) or 7 days (7d), and no 2MVIC (control). The subjects in the 0d, 2d, 4d, and 7d groups performed 2MVIC on a Biodex dynamometer before performing 5 sets of 6 maximal isokinetic (60°/s) eccentric contractions of the elbow flexors using non-dominant arm. Changes in maximal voluntary isokinetic (60°/s) concentric contraction strength, optimum angle (OA), range of motion, upper arm circumference, muscle soreness, plasma creatine kinase activity and myoglobin concentration, and ultrasound echo-intensity following 30 MaxECC were compared among the groups by a two-way repeated measures ANOVA. Changes in the variables following 2MVIC were also analysed by a one-way repeated measures ANOVA. **Results** No significant changes in any of the variables were evident following 2MVIC. The 2d and 4d groups showed smaller (P<0.05) changes in all variables following MaxECC when compared with the control, 0d and 7d groups. The 2d group showed smaller (P<0.05) changes in all variables except for OA when compared with the 4d group. The changes in the variables were similar amongst the control, 0d and 7d groups. **Discussion** The results suggest that non-damaging isometric contractions performed within 4 days prior to maximal eccentric contractions attenuated the magnitude of muscle damage, but no such effect was conferred if the isometric contractions were performed immediately before or 7 days before the eccentric contractions. It appears that some time lag is necessary for the protective effect to be implemented, and the effect is relatively short-lived. **References** 1) Chen et al. (2012). *Eur J Appl Physiol*, 112, 555-565. 2) Chen et al. (2012). *Appl Physiol Nutr Metab*, under review.

**THE EFFECTS OF EXERCISE-INDUCED MUSCLE DAMAGE ON INCREMENTAL TREADMILL PERFORMANCE**

Twist, C.1, Burt, D.1, Magalhaes, J.2, Ascensao, A.2, Highton, J.1

*1University of Chester, UK; 2University of Porto, Portugal.*

**Introduction** Exercise-induced muscle damage (EIMD) is known to alter the physiological and perceptual responses during sub-maximal running at fixed intensities (Chen et al. 2007). However, the effects of EIMD on incremental running to exhaustion are yet to be elucidated. Therefore, this study sought to investigate the effects of EIMD on the physiological, perceptual and performance characteristics of incremental treadmill exercise to exhaustion. **Methods** Nine physically active participants performed measurements of perceived muscle soreness, isokinetic strength and creatine kinase (CK) before performing an incremental treadmill test to exhaustion. The treadmill test commenced with participants walking at 5 km/h against a gradient of 1%, increasing by 1 km/h every 2 minutes until volitional exhaustion. Participants then performed muscle-damaging exercise comprising 100 barbell squats against a load corresponding to 80% of body mass. Measurements of muscle soreness, isokinetic strength and creatine kinase were repeated at 24 h and 48 h after muscle-damaging exercise. The incremental treadmill test to exhaustion was repeated at 48 h. **Results** Reductions in peak torque and increases in muscle soreness and CK (all P < 0.05) confirmed the presence of EIMD at 24 and 48 h. Oxygen uptake, heart rate, minute ventilation and blood lactate concentration at all submaximal speeds of the incremental test remained unchanged between trials (all P < 0.05). Although unchanged at slower treadmill speeds, RPE at 11 and 12 km/h was increased 48 h after squatting exercise (P < 0.05). Reductions in time to exhaustion (1333 +/- 205 c.f. 1211 +/- 198 s, P < 0.05) and peak running speed (14.9 +/- 1.8 c.f. 14.0 +/- 1.6 km/h, P < 0.05) accompanied lower peak values for blood lactate concentration (11.6 +/- 2.5 c.f. 8.2 +/- 2.1 mmol/l) and heart rate (198 +/- 7 c.f. 192 +/- 10 b/min) at 48 h after squatting exercise. However, peak oxygen uptake (48.3 +/- 6.9 c.f. 47.4 +/- 7.2 ml/kg/min), peak minute ventilation (128.7 +/- 34.9 c.f. 126 +/- 31.3 l/min) and peak RPE (19.9 +/- 0.3 c.f. 19.8 +/- 0.4) were unchanged between trials. **Discussion** The reduction in exercise tolerance and lower peak running speeds observed after muscle-damaging exercise are not explained by impaired oxygen delivery. Instead it is proposed that performing incremental treadmill exercise with weaker and painful muscles increases perceived effort that leads to a premature termination of the exercise. **Reference** Chen TC, Nosaka K, Tu J-H (2007). *J Sports Sci*, 25, 55-63.

**16:05 - 17:35****Invited symposia****IS-SH07 Role and Competences of PE Teacher and Coaches****SPORT AND EXERCISE PEDAGOGY: THE PROFESSIONAL LEARNING FOUNDATION FOR PE TEACHERS AND SPORT COACHES**

Armour, K.

*University of Birmingham*

Sport and exercise participants have not been served well by the professional structures that exist to support them. In the case of children and young people there are numerous examples to support this claim. For example: (i) Historically, physical education and sport – and teaching and coaching – have been viewed as opposites rather than as points on a shared continuum of professional practice. (ii) School curricula have been designed around specific activities to be taught, coached or delivered, with a lesser emphasis on diagnosing the specific learning needs of children. (iii) Academics in sport and exercise sciences produce discipline-based knowledge that might be of excellent quality, but is often fragmented – and too specialist – to readily inform practice; (iv) Professional development opportunities for teachers and coaches are rarely adequate to support their progressive and essentially inter-disciplinary learning needs over a career. In other words, it can be argued that there is a degree of pedagogical dissonance at the heart of these structures. This paper discusses the need for the development of a stronger interdisciplinary theoretical foundation to inform the practices of teaching and coaching. Drawing on the work of Hodkinson et al (2008); Kirk, Macdonald, and O'Sullivan (2006); Lee (2010); Shulman (2000); Tinning (2010); and Wathne, (2011) this paper will present a case for the development of 'Sport and Exercise Pedagogy' as the mechanism to ensure that knowledge developed in Sport & Exercise Sciences is made available to practitioners and, as a result, to participants. It is argued that this new, interdisciplinary knowledge should form the basis of professional learning and development in both teaching and coaching. Hodkinson, P., Biesta, G., & James, D. (2008). **VALUE EDUCATION IN SCHOOLS**

Naul, R.

*University of Duisburg-Essen*

VALUE EDUCATION IN SCHOOLS Naul, R. WGI-UDE (Essen, Germany) Introduction The term value education seems to be an essential part of the teaching domain in school based physical education and school sport around the world (cf. Siedentop, 1994; Pühse & Gerber, 2005; Naul, 2010). Today, however, values in PE, school sports and daily life are somewhat differently assessed, experienced and realized, by teachers, pupils and coaches at school in physical education, physical activities and in extra-curricular school sports (cf. Goncalves 1998; 2007). Methods The paper will address three items which will be discussed and pointed out on the basis of a qualitative literature review: 1. What means value education and what is it about to achieve in a local school setting? 2. What means value education in the context of the subject of physical education and school sports (PESS)? 3. Finally, in how far value education in physical education and school sports is linked with "active Olympism" or "Olympic value education programmes" (OVEP) for school aged children and youth? Results Traditionally, values are embed in individual physical activities, in team sports related social interactions, and in mental gathering of the "spirit" of games and sports inside and outside curricular based physical education and extra-curricular sport activities. Discussion Experiences of values in physical education, physical activities and sports are not limited to any type/concept of physical education, any kind of organized sports or unorganized physical activities and sports. However, some research underpin: the more competitive sports children and youth experience and exercise in life the more moral attitudes and social value grounded behavior patterns seem to be omitted (cf. Bockrath & Bahlke, 1996; Shields & Bredemeier, 1995). References Bockrath, F. & Bahlke, S. (1996). *Moral und Sport im Wertebewußtsein Jugendlicher*. Köln: Strauß. Goncalves, C. (1998). **THE INTERNATIONAL SPORT COACHING FRAMEWORK: IMPLICATIONS FOR SPORT COACHES IN SCHOOL AND COMMUNITY CONTEXTS**

Duffy, P.

*Leeds Metropolitan University*

The International Council for Coach Education (ICCE) and the Association for Summer Olympic International Federations (ASOIF) have established a Joint Project Group to develop the International Sport Coaching Framework (ISCF). ISCF, to be published in its first version at the Global Coaches House in London 2012, will provide a reference point for national organisations, International Federations and other agencies, for the education and development of sport coaches. A key feature of the Framework, supported by recent research on coaching expertise and coaching as a profession, is the proposal that coaching as a 'blended professional area' consists of both participation

and performance oriented occupations. Within these occupations there are a number of coaching domains that are linked to the orientation of key participant groups. One of these domains is Coaching Children. The emphasis on children's coaching highlights the need to identify the specific capabilities required by coaches working in the 5-15 age range. The implications for the role, education and qualification of coaches operating within school and community contexts are examined in this paper. These include the need for clearer role definitions for children's coaches at each stage of participant development and their relationship between the work of these coaches and others working in the field, particularly teachers and physical education teachers. In addition, the importance of recognising the social and organisational context for this work is outlined. This includes recognition of coaching status and whether coaches act in volunteer, part-time paid and full time paid roles. The significance of 'pre-coaching' roles played by parents and others in the children's sport context is also addressed. Finally, the presentation summarises the process to date and further steps in its evolution.

### IS-BN08 Biomechanics and Optimizing Performance in Elite Sports

#### BIOMECHANICS FOR PERFORMANCE OPTIMIZATION IN ELITE CROSS-COUNTRY SKIING

Stöggl, T.

*University of Salzburg*

Cross-country skiing (XCS) demonstrates a large variety in a) skiing techniques (skating and classical as basic technique categories with up to five sub techniques) that use both the upper and lower body to various extents for propulsion, b) race distances in the World Cup ranging from ~1k up to 90k (Vasaloppet), and c) competition modes (single start, sprint, team sprint, pursuit). Altogether, XC skiing is determined by a multiplicity of factors such as aerobic and anaerobic capacity, power, strength, speed, technical level, equipment, etc. This variety in XC skiing constitutes a challenge for athletes, coaches and scientists, and gives wide scope for research to study and enhance performance. Biomechanics can serve for detailed technique description, to determine performance predicting variables, to develop test concepts in diagnostics and provide input data for sport equipment analysis and development. Applied methods reach from simple stationary 2D video analysis up to complex measures combining pole/plantar forces, EMG, 3D measurements and positioning data. Associated with this, recent studies proposed new strategies in the double poling technique (Holmberg et al 2005), the double-push (Stöggl et al 2008,2010), and the running diagonal stride (Stöggl&Müller 2009) and characterized modern technique by high peak forces and force impulses combined with enlarged recovery phase and cycle length. By application of a dGNSS system combined with 2D video analysis, absolute skiing speeds, technique use and tactical skills during a sprint competition were determined (Andersson et al. 2010). Furthermore, based on biomechanical findings, new test concepts for XCS diagnostics were established, demonstrating that short duration maximal skiing speed together with general and specific maximal and explosive strength tests were shown to be good predictors of XCS performance (Stöggl et al. 2007, Andersson et al. 2010, Sandbakk et al 2010). Biomechanical data further allows for analysis of skiing equipment e.g. pole behaviour (Stöggl&Holmberg 2011) or the clap skate (Stöggl&Lindinger2006). Goals for XCS biomechanics are improvements in measurement technology towards a single measure and data collection unit for collection of pole/plantar forces, EMG, 3D, etc., with low weight and size, wireless data transmission over large distance at high sampling rate. As a consequence subject preparation, data collection and data analysis might be greatly accelerated, and allow for greater sample sizes and larger measurement area in the field. #### THROWING PERFORMANCE IN ELITE TEAM HANDBALL

Wagner, H., von Duvillard, S.P., Müller, E.

*University of Salzburg*

THROWING PERFORMANCE IN ELITE TEAM HANDBALL Wagner, H.1, von Duvillard, S.P.2, Müller, E.1 1: US (Salzburg, Austria), 2: UTAD (Oslo, Norway) In team-handball, the objective of the game is to score goals. To succeed in scoring goals, team-handball players utilize different throwing techniques to maximize throwing precision and ball velocity. When comparing elite vs. low level players in the team-handball jump throw, it was shown that team-handball players, who were taller and weigh more, achieved a higher ball velocity in the jump throw. In addition, an increase in trunk flexion and rotation angular velocity improves the performance in team-handball jump throw that results in an increase in ball velocity (Wagner et al., 2010b). No significant differences were found in the throwing precision, we therefore conclude that there is no speed-accuracy trade-off in team-handball throwing. In the over-arm movements with high endpoint-speed, an optimal transfer of momentum from proximal to distal is important to improve performance. In team-handball throwing a specific proximal-to-distal sequence of the joint movements was found (Wagner et al., 2012), where the elbow flexion occurred before the shoulder internal rotation. This specific proximal-to-distal sequence was found in elite, experienced and highly experienced players; however, length of playing experience resulted in a delayed start of the trunk flexion. In team-handball competition, 73-75% of all throws during the game constitute jump throws, followed by the standing throw with run-up (14-18%), penalty throw (6-9%), diving throw (2-4%) and direct free throw (0-1%) (Wagner et al., 2008). Comparing different throwing techniques in team-handball, it was shown that depending on the floor contact (standing vs. jump throws), elite players used two different strategies (lead leg braced the body vs. opposed leg movements during flight) to accelerate the pelvis and trunk to yield differences in ball velocity (Wagner et al., 2011). However, elite players were able to adapt to differences in the lower body and trunk movements that enable similar movements of the throwing arm. These similar movements of the throwing arm were also found when comparing team-handball throws with different arm positions; however, trunk movements and ball velocity was significantly different (Wagner et al., 2010a). **GOLF SPORTS SCIENCE SERVICES - BIOMECHANICAL CONCEPTS AND CHALLENGES**

Wallace, E.S.

*University of Ulster*

GOLF SPORTS SCIENCE SERVICES - BIOMECHANICAL CONCEPTS AND CHALLENGES WALLACE, E.S. SPORT & EXERCISE SCIENCES RESEARCH INSTITUTE, UNIVERSITY OF ULSTER The purpose of the golf drive is to propel the ball a large distance with a degree of accuracy to optimise the playability of the next shot. The pioneering work of Cochran and Stobbs (1968) proposed a double pendulum model of the down-swing to explain the basic mechanics and showed that the combined effect of inertia and centripetal force acting on the lower lever can create a well-controlled swing. Since then there have been a plethora of studies on the biomechanics of the golf swing (leg kinematics, kinetics, EMG) yet less than a decade ago it was claimed that our understanding of golfer's interaction with the club is still too crude to fit clubs to people properly. Betzler et al., (2008) provided a comprehensive review of existing biomechanical models and simulations of the golf swing in order to progress the design of future modelling and simulation studies. Over the last couple of decades we aimed to gain a better understanding of not only the biomechanics of the golf swing but also the effect of golf equipment on the swing and ultimately how we can translate this knowledge to the coaching process. The method by which the coach achieves technical improvements has been illustrated for gymnastics as a conceptual model of technique and performance by Irwin and Kerwin (2007). The most widely measured kinematic parameters related to golf performance outcomes are hip and shoulder rotations and in particular, the resulting X-factor (Horan et al., 2010). Wallace et al. (2007) studied the effects of shaft length on driving performance and showed a significant difference in initial ball launch speed due to a main effect of club length, a significant difference between participants, but no difference between the intra-subject trials. Betzler et al. (2012) showed greater variability in a range of clubhead presentation variables for lesser skilled golfers compared to highly skilled players, while in a study focussing on elite female golfers, Brown et al. (2011) showed there was no common technique for optimal performance and the need remains to focus on individual aspects. Ball and Best (2006), using a cluster analysis method, identified 2 centre of pressure patterns which were associated with both highly skilled players and lesser skilled players and highlighted the importance of identifying different movement strategies before evaluating performance measures (Ball and Best, 2007). **16:05 - 17:35****Oral presentations****OP-BN08 Sports Biomechanics 3****OPTIMAL FORCE-VELOCITY PROFILE FOR EXPLOSIVE PERFORMANCES: THEORETICAL AND EXPERIMENTAL EVIDENCES**

Samozino, P., Edouard, P., Gimenez, P., Morin, J.B.

*Universités de Savoie et de Saint-Etienne*

OPTIMAL FORCE-VELOCITY PROFILE FOR EXPLOSIVE PERFORMANCES: THEORETICAL AND EXPERIMENTAL EVIDENCES Samozino P, Edouard P, Gimenez P, Morin JB Laboratory of Exercise Physiology, University of Savoie (Le Bourget-du-Lac, France) Laboratory of Exercise Physiology, University of Lyon (Saint Etienne, France) Explosive performances have been shown to directly depend on power capabilities of lower limb neuromuscular system (e.g. Yamauchi et al. 2007). Recently, through an integrative model, Samozino et al. (2012) put forward that jumping performance was mostly determined by lower limb maximal power (Pmax), but also by their mechanical force-velocity (Fv) profile describing the balance between force and velocity capabilities. For each individual, an optimal Fv profile maximises performance, while unfavourable Fv balances leads to performance alterations up to 30%. Even if the model was validated through experimental data, contributions of both Pmax and Fv profile to explosive performances have not been experimentally reported yet. This study aimed to bring experimental supports to the effect of F-v profile on jumping performance, independently from the effect of Pmax. Jumping performance, Pmax, Fv profile and lower limb extension range (Hpo) were measured in 33 high-level soccer players and athletes (including a sub-10 s sprinter). Subjects performed maximal squat jumps with different additional loads from 0 to 100% of body mass. During each jump, mean force, velocity and power output were measured using flight time in a simple computation method (Samozino et al. 2008). Individual linear Fv relationships were obtained to determine Fv profile and Pmax values for each subject (Samozino et al. 2012, Yamauchi et al. 2007). The optimal Fv profile was computed (Samozino et al. 2012) and used to determine Fv imbalance as: 1-(Fv profile / optimal Fv profile). Based on the recent model, a multiple regression analysis was performed with unloaded jump height as dependent variable and Pmax, Fv imbalance and Hpo as independent ones. The multiple regression presented a high adjustment quality ( $r = 0.977$ ,  $r^2 = 0.955$ ,  $P < 0.001$ ,  $SEE = 0.013$  m) and showed high significant contributions of the three independent variables to explain interindividual differences in jumping performance ( $P < 0.001$ ). Regression coefficients were positive for Pmax and Hpo and negative for Fv imbalance. This experimentally confirmed the theoretical predictions obtained from the integrative biomechanical model recently proposed (Samozino et al. 2012). Jumping performance depends on Fv profile independently from the large effect of Pmax: a Fv imbalance induces lower performances for a given Pmax. Moreover, for given Pmax and Fv profile, individuals with higher Hpo presented higher performances. ## **BODY-WEIGHT SUPPORTED SPRINT RUNNING – AN EFFECTIVE METHOD TO GENERATE REDUCED GROUND CONTACT TIMES IN WELL TRAINED SPRINTERS**

Kratky, S., Müller, E.  
*University of Salzburg*

Introduction Time on the ground is the crucial part of sprinting as the available time frame to apply force to the ground diminishes with increasing running velocity (Mero et al. 1992; Weyand et al. 2000). Data of elite sprinters indicate that faster athletes realize shorter ground contact times compared to slower individuals (Mann 2010). The aim of this study was to investigate effects of body-weight support during full-effort sprints and overspeed sprints on kinematic stride parameters and especially ground contact time in 19 Austrian male elite sprinters. Methods A kite with a lifting effect combined with a towing system to erase drag was utilized. Subjects performed flying 20m-sprints under three conditions: (1) free sprint; (2) body-weight supported sprint – normal speed (BWS-NS); and (3) body-weight supported sprint – overspeed (BWS-OS). Sprint cycle characteristics were recorded during the high-speed phase by an optical acquisition system. One-way analyses of variance for repeated measures were used to determine differences between sprinting conditions and partial Eta-squared was used to determine effect-size (ES). Results Compared to the free sprint, running velocity, step length, and step frequency remained unchanged during BWS-NS, while ground contact time decreased (-5.80%,  $p < 0.001$ ,  $ES = 0.85$ ) and air time increased (+5.79%,  $p < 0.001$ ,  $ES = 0.79$ ). Throughout BWS-OS ground contact time (-7.66%,  $p < 0.001$ ,  $ES = 0.85$ ) was reduced, whereas running velocity (+2.72%,  $p < 0.001$ ,  $ES = 0.91$ ), air time (+4.92%,  $p < 0.001$ ,  $ES = 0.72$ ), step length (+1.98%,  $p < 0.001$ ,  $ES = 0.58$ ) and step frequency (+1.05%;  $p < 0.01$ ,  $ES = 0.39$ ) increased. Compared to BWS-NS, BWS-OS caused an increase in running velocity (+3.33%,  $p < 0.001$ ,  $ES = 0.94$ ), step length (+1.92%,  $p < 0.001$ ,  $ES = 0.62$ ), and step frequency (+1.37%,  $p < 0.01$ ,  $ES = 0.39$ ), while ground contact time was diminished (-1.97%,  $p < 0.001$ ,  $ES = 0.48$ ). Discussion In summary, sprinting with a body-weight supporting kite appeared to be a highly specific method to reduce ground contact times in well trained sprinters. The additional application of an overspeed condition led to a further reduction of ground contact time. Therefore, we recommend body-weight supported sprinting as an additional tool in sprint training. References Mann R (2010) The mechanics of sprinting & hurdling. ## **MINIMIZING VELOCITY FLUCTUATIONS IN ROWING IMPROVES PERFORMANCE IN CREW ROWING; BREATHING NEW LIFE INTO AN OLD IDEA**

Hofmijster, M.J., De Brouwer, A.J., De Poel, H.J.  
*Vrije Universiteit Amsterdam*

Introduction Competitive rowing performance is defined as the time to cover a certain race distance, usually 2000m. The power equation can be used to investigate rowing performance. It shows that power dissipation can be divided into useful power (i.e. power needed to overcome resistance) and wasted power, namely power lost during the push off and power lost to speed fluctuations (e.g. Hofmijster et al. 2007). From this perspective, a rowing crew can increase performance by either maximizing power output or by minimizing power losses. In the 1920's of the previous century, an interesting strategy was attempted to minimize speed fluctuation losses in an eight. By having pairs of the crew row in 90 degree antiphase, a more continuous boat run was achieved and checking of the boat was minimized. Nevertheless, the strategy was not successful and subsequently abandoned for being "too difficult". We reinvestigated this idea of "syncopated rowing" using a less complicated strategy where we had pairs of rowers perform in phase and in 180 degree antiphase on a set of coupled free floating ergometers. Ergometer motion was resisted using a linear damper to introduce power losses to velocity fluctuations (see also Hofmijster et al. 2008). We hypothesized that velocity fluctuations would be much smaller for antiphase rowing, resulting in higher efficiency. We also hypothesized that power output might be negatively influenced for the antiphase situation as antiphase rowing might be more difficult to execute. Methods Nine pairs of rowers performed a 2 minute in phase and a 2 minute antiphase maximum effort trial at 36 strokes/min. Kinematics of ergometers and both rowers were recorded as well as pulling forces on both handles. Useful power was defined as the power dissipated in both flywheels combined. Wasted power was defined as the power dissipated by the linear damper. Crew coordination accuracy was determined as the average absolute deviation from the intended phase difference between the rowers. Results All nine pairs easily managed to row in antiphase coordination, while one of the pairs showed a transition from antiphase to inphase coordination during the maximum effort trial. Although for antiphase rowing the interpersonal coordination was indeed less accurate, power production was not affected. Importantly, in antiphase rowing the decreased power loss to velocity fluctuations resulted in more useful power being transferred to the ergometer flywheels, hence in better performance. Conclusion The results imply that antiphase coordination indeed improves rowing performance, even without any experience with the antiphase technique, thereby encouraging further study exploration of (on-water) antiphase crew rowing. ## **A COMPARISON OF ELLIPTICAL ZONE AND 3D SCANNING CALCULATING METHODS OF ESTIMATING SWIMMER'S BODY SEGMENT VOLUMES**

Machtsiras, G., Sanders, R.  
*The University of Edinburgh*

A COMPARISON OF ELLIPTICAL ZONE AND 3D SCANNING CALCULATING METHODS OF ESTIMATING SWIMMER'S BODY SEGMENT VOLUMES Machtsiras, G. 1, 2, & Sanders, R. 1 1:UoE (Edinburgh, UK), 2:ENU (Edinburgh, UK) Introduction In swimming, anthropometric data are combined with three-dimensional motion analysis techniques to compute the centre of mass (CM) location of the body segments and whole body (WBCM). Kinematics and kinetics of the body motion can then be derived. For this reason high accuracy is necessary to identify the location of the WBCM precisely. The 'e-Zone' software developed by Deffeyes and Sanders (2005) is a modified version of the elliptical zone method (Jensen, 1978) enabling the identification of the location of the segment CMs and subsequently the WBCM. The body is divided into segments and each segment is modelled as a series of elliptical cylinders whose volume is computed and summed to make the volume of the whole body (WB). The aim of the current study is to assess the accuracy of the e-Zone software by comparing directly the volume of each body segment measured by 3D scanning. Method A national level swimmer volunteered to participate in the study. The volume of the head, neck, thorax, abdomen, right upper limb and right lower limb segment was measured when standing in

the anatomical position with the use of the e-Zone software and also with the use of 3D body scanning techniques. Symmetry in the sagittal plane was assumed and only the right upper and lower limbs were measured in both cases. A front and side view photograph was taken simultaneously for the requirement of the e-Zone method and the radii of each elliptical cylinder was measured from the photographs with manual digitizing. The digitizing process was repeated five times to establish reliability. In parallel, a 3D laser scanner (Hamamatsu®) was employed to create an accurate 3D representation of the swimmer's body. The model was then edited and segmented with the use of Rhinoceros® software whereas the segment volumes were measured with the use of the Magics® software. Results The volume of the WB was computed to be 74230.90 cm<sup>3</sup> with the eZone method and 76613.90 cm<sup>3</sup> with the 3D scanning technique. The head and neck volume was overvalued by 3.7% whereas the core, the right upper and lower limb were undervalued by 3%, 2.7% and 4.5% respectively. Discussion The findings of this study demonstrate that the volume of the full body was undervalued. These findings suggest that the estimates of segment mass and the location of the WBCM could have been affected. Further investigation of the accuracy of the e-Zone method with a greater number of participants and of both genders is necessary to draw a safe conclusion. Also, the effect of the WB volume measurement error in the location on the WBCM should be investigated. References Deffeyes J & Sanders R, (2005). ### SPRINT RUNNING MECHANICS: A CASE STUDY OF A WORLD-CLASS ATHLETE

Morin, J.B., Bourdin, M., Edouard, P., Peyrot, N., Samozino, P.

*Laboratoire de Physiologie de l'Exercice*

SPRINT RUNNING MECHANICS: A CASE STUDY OF A WORLD-CLASS ATHLETE Morin, JB.1, Bourdin, M.2, Edouard, P.1, Peyrot, N.3, Samozino, P.4 1: LPE, University of Lyon (Saint Etienne, France), 2: LBMC, University of Lyon (Lyon, France), 3: DIMPS, University of La Réunion (Le Toupon, France), 4: LPE, University of Savoy (Le Bourget du Lac, France) Introduction To date very few experimental data have been obtained directly on world-class sprinters. The recent validation of a sprint instrumented treadmill (Morin et al., 2010) allowed us to introduce the concept of effectiveness of force application throughout sprint acceleration and to show its relationship with 100-m performance in non-specialists (Morin et al., 2011). We tested here our recent hypothesis that the forward orientation of the resultant force onto the ground was better related to sprint performance than its magnitude, in a population including a sub-10 s individual. Methods The biomechanics and field 100-m performance of a world-class sprinter (WCS, 2011 best times of 9.92 s and 19.80 s on the 100-m and 200-m, respectively) were tested and compared to those of three national-level sprinters (NLS), and nine physical education students (PE). Subjects performed 6-s sprints on an instrumented treadmill during which horizontal, vertical and resultant ground reaction forces (GRF), and belt velocity were continuously recorded and used to compute linear force-velocity relationships. An index of the force orientation effectiveness (DRF) was also computed as the slope of the linear relationship between the decrease in the ratio of contact-averaged horizontal-to-resultant GRF and the increase in velocity (Morin et al. 2011). A 100-m field sprint was also performed with performances were recorded with a radar. Results WCS differed by more than 2 SD from the NLS and 2 to 4 SD from the PE for the slope of his force-velocity relationship (~25 % more oriented towards velocity muscular qualities), his ability to orient the resultant GRF forward during acceleration (~43 % better DRF) and his step frequency (~5 % higher, resulting only from a lower contact time). Contrastingly, he did not differ from NLS and some of the PE for the magnitude of resultant force produced. Discussion The main mechanical determinants characterizing this WCS were (i) a "velocity-oriented" force-velocity profile, likely explained by (ii) a higher ability to apply the resultant GRF vector with a forward orientation over the acceleration. Despite similar resultant force capabilities compared to NLS and PE, the WCS showed a better forward orientation of the resultant force onto the ground during acceleration, which confirmed our recent hypothesis that what matters to acceleration and sprint performance is more the orientation of the resultant force than its magnitude. ### STRONG POSITIVE CORRELATIONS WERE FOUND BETWEEN MUSCLE ACTIVATION AND BREASTSTROKE SPEED MEASURED WITH 3D AUTOMATIC TRACKING

Olstad, B.H., Zinner, C., Cabri, J., Haakonsen, D., Kjendlie, P.L.

*1: NSSS (Oslo, Norway), 2: GSU (Cologne, Germany), 3: VUC (Toensberg, Norway)*

Introduction A limited number of studies have investigated the muscle activation during breaststroke swimming through the use of surface electromyography (sEMG). No previous studies have investigated kinematic variables in human swimming using motion capture (mo-cap) 3D with automatic tracking (AT). The aim of this study was therefore to investigate the relationship between muscle activation in eight different muscles and swimming velocity at five different efforts. Methods Four swimmers (one male, world championship medalist and three females, one Olympic medalist, one national medalist and one national finalist) performed one trial of 20m breaststroke at the speeds of 60%, 70%, 80%, 90% and 100% of maximum effort. During each trial the velocity of the swimmers right trochanter major and the muscle activation in biceps brachii, triceps brachii, trapezius (pars descendens), pectoralis major (pars clavicularis), rectus femoris, biceps femoris, tibialis anterior and gastrocnemius were recorded over three stroke cycles. Each stroke cycle started when the heels were fully pulled up, flexed and ready to kick. 3D images with AT were recorded from ten underwater mo-cap cameras (Oqus Underwater, Qualisys, Gothenburg, Sweden). The cameras recorded spherical markers (diameter of 19mm) fixed to the swimmers suit using cyan LED light. The muscle activity was recorded using waterproof electrodes and active sensors from (Plux Ltda, Lisbon, Portugal) and recorded according to (Olstad et al., 2011). Results Pearson's correlations was used to assess the relationship between the average velocity of trochanter major (representing hip speed) at the five different velocities with the average sEMG during the three stroke cycles. Strong positive and significant relationships were found for tibialis anterior  $r=.756$  ( $p<0.001$ ), biceps femoris  $r=-.666$  ( $p<0.001$ ), pectoralis major (pars clavicularis)  $r=.666$  ( $p<0.001$ ), biceps brachii  $r=.641$  ( $p<0.002$ ), triceps brachii  $r=-.622$  ( $p<0.01$ ). Positive but insignificant relationship was found for rectus femoris  $r=.448$ . Moderate positive and insignificant relationships was found in gastrocnemius  $r=.311$ . In trapezius (pars descendens) weak and insignificant relationship was found,  $r=-.028$ . Discussion The study showed a strong and significant relationship between muscle activation in five different muscles and average swimming velocity over five different speeds. It showed that velocity can be tracked using 3D AT and therefore opens up new possibilities for conducting kinematic analysis in swimming with 3D AT combined with measuring muscle activity through the use of sEMG. #### COMPARATIVE STUDY OF ENERGY EXPENDITURE MEASURED BY DIFFERENT DEVICES IN A CIRCUIT RESISTANCE TRAINING

Furukawa, M., Peinado, A.B., Benito, P.J., Zapico, A.G.

*Universidad Politécnica de Madrid*

COMPARATIVE STUDY OF ENERGY EXPENDITURE MEASURED BY DIFFERENT DEVICES IN A CIRCUIT RESISTANCE TRAINING Furukawa, M1; Peinado, AB1; Benito, PJ1; Zapico, AG2 1: Universidad Politécnica de Madrid, Spain; 2: Universidad Complutense de Madrid, Spain. INTRODUCTION Physical Activity (PA) is recommended by major health and sports medicine organizations to maintain good health[1]. The use of monitors of PA to measure energy expenditure (EE), such as accelerometers (AC), is a common practice in PA research studies because it is practical, relatively inexpensive and an easy-to-use method to estimate EE. However, the accuracy of the real EE measured by AC has been questioned. The aim of this study was to compare the accuracy of different devices of EE during a circuit resistance training (CRT). METHODS Six overweight subjects (body mass index  $27.02 \pm 2.75$  kg/m<sup>2</sup>) participated in this study. Each subject had to perform three sets of 15 maximum repetitions in a combined circuit training (strength and aerobic exercises) at 70% of their maximum weight load (strength exercises) and at 70% of their maximum heart rate (aerobic exercises). EE was measured by indirect calorimetry with the portable system Oxycon Mobile (OM) and with two ACs: Sense Wear Armband (SWA) 2-axis accelerometer and the MTI Actigraph single axis accelerometer (AG). The differences between the EE measurements were evaluated with an ANOVA. The significance level was set at 0.05. RESULTS The measured EE was  $364.83 \pm 95.96$  kcal for OM,  $337.40 \pm 98.52$  kcal for SWA and  $212.17 \pm 60.22$  kcal for AG. An underestimation of EE in kcal was found when we compared AG vs OM ( $p < 0.05$ ). Differences between SWA vs OM and SWA vs AG were not found ( $p > 0.05$ ). OM showed  $4.5 \pm 0.7$  METs, SWA  $3.2 \pm 0.7$  METs and AG  $3.3 \pm 0.21$  METs. Differences in METs were found comparing OM vs SWA and AG ( $p < 0.01$ ). There was no difference between SWA vs AG ( $p > 0.05$ ). CONCLUSION Our study found that AG underestimates EE during CRT. However, some studies such as Schmidt et al[2] and Strath et al [3] have reported overestimation. Drenowatz[4] reported that SWA does not accurately estimate EE at intensities above ten METs. However, futures studies are needed to improve the accuracy of SWA and AG. REFERENCES 1. Garber, C.E., et al., *Med Sci Sports Exerc*, 2011. 43(7): p. 1334-59. 2. Introduction A disproportionate enlargement with bigger individuals is obvious, both in shape and composition and in particular in obese children and adolescents. There is a great interest on physical activity interventions for health related benefits. The available information about size relationships with peak oxygen uptake (VO<sub>2</sub>max) in obese adolescents is limited as well as their trend of change in response to training exposure. Hence, the aim of this study was to examine the peak oxygen uptake responses to aerobic training in obese males aged 10-16 years from an allometric perspective. Methods Thirty obese adolescent males ( $12.5 \pm 1.7$  yrs) were measured in the pre- and post 12 weeks of multidisciplinary training program. Stage of pubic hair development was assessed at clinically. Body mass (BM) was measured and fat-free mass (FFM) was estimated by bioelectrical impedance (Biodynamics®). VO<sub>2</sub>max was assessed (Balke protocol) on treadmill using a calibrated breath-by-breath monitoring system (Parvo Medics, True Max 2400, Utah, USA). The training program consisted on physical exercise sessions, nutritional intervention and three educational meetings. Nonlinear allometric modeling was used to partition variation in body size on VO<sub>2</sub>max in beginning and after 12-week training program. Proportional allometric model incorporating the chronological age within an exponential term in addition to the body size components to accommodate both mass (or BM or FFM), age when modeling VO<sub>2</sub>max was also used. We also investigated the effect of maturity status, but it was not significant in all the proportional allometric models. Results Values of VO<sub>2</sub>max significantly increase with training program [pre-training:  $2.41$  (0.67) L/min; post-training:  $2.65$  (0.65) L/min,  $p < 0.01$ , ES =0.38]. The estimates for size exponents (95% CI) from the separate allometric models for VO<sub>2</sub>max before vs after training program were, respectively: BM  $1.01$  (0.67–1.36) vs  $0.82$  (0.48–1.15), FFM  $1.11$  (0.84–1.37) vs  $1.05$  (0.81–1.28). Estimates for size exponents (95% CI) from the separate proportional allometric models for VO<sub>2</sub>max before and after training program were, respectively: BM  $0.62$  (0.21–1.03) and age  $0.07$  (0.02–0.12) vs  $0.48$  (0.13–0.83) and  $0.07$  (0.03–0.11), FFM  $0.87$  (0.48–1.27) and age  $0.04$  ( $p > 0.05$ ) vs  $0.88$  (0.47–1.21) and  $0.03$  ( $p > 0.05$ ). Discussion/Conclusion The results showed a change in the VO<sub>2</sub>max–BM relationship as response to a 12-week training program. The relationships of VO<sub>2</sub>max with BM and FFM in obese adolescent were differently affected by the responses to training. VO<sub>2</sub>max–body size relationships in response to training in adolescent obese males do not appear to be influenced by inter-individual variability in maturity status.

#### VERIFICATION OF THE SENSEWEAR® PRO ARMBAND TO ESTIMATE ENERGY EXPENDITURE OF LOW-INTENSITY, DAILY ROUTINE ACTIVITIES BY DIFFERENT BODYWEIGHT GROUPS

Eckert, K., Lange, M., Hermsdorf, M., Wagner, P.

*University of Leipzig*

Introduction Assessing low-intensity physical activity (PA) accurately is a major challenge in sport science. Each of the current methods of assessing PA and energy expenditure (EE) has limitations. Spirometry is regarded as a very precise measure of EE for physical activity (Jakicic et al., 2004), but this technique is not feasible for studies in the field. The aim of our investigation was therefore to evaluate, how accurate the SenseWear Pro Armband (multisensory device) (SW) measures low-intensity, daily routine activities depending on BMI (WHO classification) compared to portable spirometry MetaMax® 3b (Cortex, Germany) (MM) by normal, overweight and obese participants. Methods We were able to include 47 participants to our study (♀=31, ♂=16). Mean age was 70,5 (standard deviation sd=4,9) and mean

BMI 27,42 (sd=3,3). All participants were asked to perform the following activities under standardized conditions: sitting, walking (3,2 km/h), vacuuming, cycling (50 watt) and stair stepping for three minutes each with a resting time of six minutes in between. Data were taken by SW and MM to measure EE for each activity. T-tests, ANOVA and Pearson correlations were used for calculation. Results Our findings show that the measurements of four out of five activities with the SW are significant lower than those with the MM. Only sitting reached higher results. Looking at different BMI groups (BMI: <25, n=13; ≥25 to <30, n=21; ≥30, n=13), it can be observed that these differences become taller with increasing BMI. It is also noticeable that especially the activities cycling ( $p<.001$ ,  $t=15,88$ ) and vacuuming ( $p<.001$ ,  $t=5,67$ ) have been quantified clearly different between the measurement devices. Overall, interclass correlations for sitting, walking and vacuuming ( $p<.001$ ) proved to be moderate with correlation coefficients between  $r=.648$  to  $.741$ . Discussion This study supports existing literature that body mass strongly impacts EE during a given PA (LeCheminant et al., 2009). For further studies in this field, it would be important to investigate whether the SW can recognize and define more specifically the transition from resting levels to light activities. ### **HORMONAL, ANTHROPOMETRIC AND BIOCHEMICAL CHANGES IN OBESE SUBJECT SUBMITTED AT RESISTANCE TRAINING PROTOCOL: A HEALTH PROMOTION MODEL**

Pimenta, L.D.1, Neiva, C.1,2,3, Guimaraes, B.R.1, Verardi, C.E.L.2, Furukawa, M.3, Zaia, J.E.1

1: UNIFRAN (Franca, Brasil), 2: UNESP (Bauru, Brasil), 3: UPM (Madrid, España)

Introduction Obesity can currently be defined in a simplified way. That is an illness characterised by excessive storage of fat, as a consequence of positive energetic balance. Thus, it causes health issues with significant losses in both quality of life and life expectancy of obese individuals. Endocrine-metabolic, biochemical and anthropometric alterations are ordinarily observed in obese women. Therefore, evidence allows us to affirm that excessive weight plays an important role in relation to the appearance of degenerative diseases, which are increasingly detected in women. Physical exercise causes alteration in the rhythms or levels of secretions of certain hormones, such as Growth Hormone (GH), Triiodothyronine (T3), and insulin, and they, in turn, are directly involved in controlling and treating obesity. As a result, resistance exercise protocols and weight training exercise have shown effective results in obese individuals not only with the increase of bone mass, strength and muscle mass, but also in the loss of fat mass. Thus, the aim of this research was to study the effects of a strength training protocol on obese women's hormonal, biochemical and anthropometric variables and their impact on these individuals' health promotion. Methods Seventeen obese women from 24 to 56 years of age submitted themselves to the resistance muscular training oriented protocol in the percentage of 15RM, performed in circuit form, for 8 weeks in three weekly sessions lasting 50 minutes each. Additionally, pre- and post-applications of training were carried out on the selected women, as well as anthropometric, hormonal, and biochemical evaluations. Results After 8 weeks of training, results showed the efficiency of the training protocol in reducing TG values, and in significantly improving ( $p<0,01$ ) the levels of this biochemical variable on the investigated group. With reference to T3, the results after applying the protocol also showed a statistically different reduction ( $p<0,05$ ) regarding the values of this hormone, which can be explained by negative regulation of their blood concentrations, regarding an improvement of its performance and significant raising of its metabolic rate. When it comes down to the other investigated variables (GH, insulin, IMC and RCQ), the protocol did not show any significant alterations. Discussion The regular practice of the physical training protocol can contribute to reducing TG rates on obese adult women, which can produce favourable metabolic alterations observed by variation of tri-iodine ironia blood centralisation, even if anthropometric alterations are not noticed. This result is an important indicative of promotion of these individuals' health.

### **PHYSICAL ACTIVITY PATTERNS OF OBESE CHILDREN AND THEIR PARENTS**

Sartor, F., de Groot, K., Boughorbel, S., Breebaart, J., van Mil, E.

*Philips Research*

Introduction Child Obesity is a worldwide spread epidemic, in 2010 it was estimated that 43 million children are overweight and obese and 92 million are at risk of overweight (de Onis 2010). The etiology of child obesity is multifactorial, however the environmental component is of paramount importance (unlimited food availability & low physical activity). Parents should and can provide a healthy environment that minimizes exposure to temptations (Golan 2011), and help to promote healthy behaviors, such as healthy eating, and regular physical activity. The aim of this study was to monitor objectively physical activity in obese children undergoing a lifestyle change coaching program, and their parents to see whether these are correlated. A secondary aim was to monitor the adherence to wear an unobtrusive physical activity monitor. Methods Eighty-three participants took part in this study (46 females and 37 males), which consisted of 28 families, 32 obese children (16 boys and 16 girls) and 46 parents (25 mothers and 21 fathers). Those families took part in a lifestyle coaching program, provided by the local Hospital. One physical activity monitor (TracmorD, Philips) was given to each participant. The observation period lasted 3 months. Wearing time was analyzed only if the activity counts were above 500 counts/min. The activity data were considered for correlation analysis only if they were above 1000 counts/min. PAL conversion was done using Bonomi's et al. formula (2010). Results The total wearing time for children was 16.1% (including day and night), whereas total wearing time for mothers, fathers and coaches was 15.0%, 16.0%, 24.0% respectively. Children had an average PAL of  $1.70 \pm 0.18$ , mothers of  $1.55 \pm 0.13$ , fathers of  $1.51 \pm 0.11$  and coaches of  $1.58 \pm 0.12$ . The Pearson's correlation between obese children PAL and their parents' PAL was  $r = 0.271$ ,  $t(19) = 1.226$ ,  $p$ -value = 0.235. Discussion We observed that physical activity of obese children was not correlated with the physical activity of their parents. Wearing time over 3 months observation period in the obese children and in their parents was rather low. The higher PAL in children than in their parents could be due to their anthropometric differences. However, children's PAL in this study was similar to non-obese children's PAL (Ekelund et al 2004). **THE CONTRIBUTION OF MUSCLE HYPERTROPHY TO INTER-INDIVIDUAL VARIABILITY IN THE STRENGTH RESPONSES TO ELBOW FLEXOR RESISTANCE TRAINING**

Erskine, R.M.1, Fletcher, G.2, Folland, J.P.2

*(1) Manchester Metropolitan University, UK; (2) Loughborough University, UK.*

**Introduction** Although maximum force generation is proportional to muscle size, there is surprisingly little evidence to suggest that training-induced gains in human muscle strength are related to hypertrophy. Therefore, we aimed to determine the contribution of muscle hypertrophy to the inter-individual changes in isometric and isoinertial strength in response to 12-wk elbow flexor resistance training (RT). **Methods** Thirty-three previously untrained, healthy men (18-30 yr) completed 3-wk elbow flexor RT, followed by 6-wk no training, and then 12-wk RT. The initial 3-wk RT provided extensive familiarisation and facilitated neural adaptations that might confound muscular responses to the subsequent 12-wk RT, which was performed 3 x per wk with unilateral and bilateral preacher curls [2-3 sets of each exercise; 8-10 repetition maximum (RM)]. The following assessments were made pre and post 12-wk RT: muscle strength [isometric maximum voluntary force (MVF) at an elbow joint angle of 120° (180° = full extension) and unilateral preacher curl 1-RM]; total agonist muscle volume (Vm) and sum of maximum anatomical cross-sectional areas of agonist muscles ( $\Sigma$ ACSAmax), both assessed with 1.5T MRI; agonist muscle fascicle pennation angle, measured with ultrasound; muscle activation [EMG at MVF and during the 1-RM normalised to Mmax (agonists) or maximum EMG during maximum isometric elbow extension (antagonists) or during maximum isometric bench press (stabilisers)]. **Results** Following 12-wk RT, there were increases in Vm ( $15.9 \pm 6.0\%$ ,  $P < 0.0005$ ),  $\Sigma$ ACSAmax ( $15.9 \pm 5.8\%$ ,  $P < 0.0005$ ) and pennation angle ( $16.2 \pm 7.5\%$ ,  $P < 0.0005$ ), and the relative gains in pennation angle correlated with % increases in both Vm ( $R^2 = 0.184$ ,  $P = 0.013$ ) and  $\Sigma$ ACSAmax ( $R^2 = 0.215$ ,  $P = 0.007$ ). MVF and 1-RM increased by  $13.2 \pm 9.1\%$  ( $P < 0.0005$ ) and  $41.6 \pm 19.9\%$  ( $P < 0.0005$ ), respectively, and these strength gains correlated with the % increase in Vm (MVF,  $R^2 = 0.28$ ,  $P = 0.002$ ; 1-RM,  $R^2 = 0.23$ ,  $P = 0.005$ ). However, strength gains were unrelated to changes in pennation angle ( $R^2 \leq 0.04$ ;  $P \geq 0.25$ ). Furthermore, there were no changes in normalised agonist EMG ( $P \geq 0.167$ ) or stabiliser EMG ( $P \geq 0.058$ ) when measured at MVF or during 1-RM. **Conclusion** We have shown for the first time that, following 12-wk elbow flexor RT in young men, muscle hypertrophy explains ~28% and ~23% of the inter-individual variability in isometric and isoinertial strength changes, respectively. This provides clear evidence that the individual hypertrophic response does influence the functional adaptations that occur with RT. **Acknowledgement** This study was sponsored by GlaxoSmithKline Nutritional Healthcare UK.

**DYNAMIC OUTPUT OF TWO TYPES OF VERTICAL JUMPS PERFORMED WITH POSITIVE AND NEGATIVE LOADING**

Suzovic, D.1, Pasic, M.1, Markovic, G.2, Jaric, S.3

*1Faculty of Sport and Physical Education, Belgrade, 2Faculty of Kinesiology, University of Zagreb, 3Department of Health, Nutrition, and Exercise Sciences, University of Delaware, Newark, DE*

**Introduction** The aim of this study was to evaluate the effects of positive and negative external loading on mechanics of the two types of vertical jumps (Markovic, Jaric, 2007). We hypothesized that the muscular mechanical output could be higher under no-load conditions than in the presence of either positive or negative external loads (Jaric & Markovic 2009; Leontijevic et al. 2012), as well as that the output would be lower for the counter movement jump performed without (CMJ) than with the arm swing (CMJWA). **Methods** Thirteen physically active physical education students (age: 21.2 (1.3) yr, body mass: 79.5 (10.8) kg, height: 1.84 (0.06) m; mean (SD)) performed CMJ and CMJWA on a force plate while a pulley system exerted a constant vertical force upon the body simulating either increase or decrease of body weight (BW) within the range from 0.6BW to 1.4BW. **Results** Both the mean (Pavg;  $P < 0.03$ ) and peak power output (Ppeak;  $P < 0.03$ ) calculated from the ground reaction force and the velocity of the center of mass revealed a significant main effect of load (Pavg;  $P < 0.001$ ) and (Ppeak;  $P < 0.001$ ) with the maxima in the vicinity of 1.0BW (i.e., no loading applied), as well as a higher output in CMJWA than in CMJ ( $P < 0.01$ ), and no interaction. **Discussion** The findings observed from two different vertical jumps consistently revealed the data in line with our previous studies (Jaric & Markovic 2009; Markovic & Jaric 2007). These findings not only provide additional support for the 'maximum dynamic output hypothesis' (Jaric & Markovic 2009), but could also be of importance for optimizing the athletic training procedures aimed towards maximizing the muscle power output. **References** Leontijevic B., Pazin N., Bozic P., Kukolj M., Ugarkovic D., Jaric S. **ANTAGONIST FORCES ARE UNDERESTIMATED WHEN ASSESSED USING EMG-TORQUE RELATIONSHIP**

Simoneau, E.M., Longo, S., Seynnes, O.R., Narici, M.V.

*Université de Valenciennes*

**Introduction** Antagonist force production cannot be calculated directly in vivo and is usually estimated by using the relationship between surface EMG activity and exerted torque of the antagonist muscles, while they act as agonists (Maganaris et al., 1998; Mademli et al., 2004; Kellis et al., 1997). An implicit assumption of this method is that during an isometric contraction, the relationship between the level of EMG activity and the mechanical output is the same when a muscle is acting either as an agonist or as an antagonist. If this were the case, one would expect changes in EMG to match changes in architecture (Hodges et al., 2003) in both conditions. Therefore, the aim of this study was to investigate whether the behaviour of Gastrocnemius Medialis muscle (GM) - as assessed by its architecture - would be identical during isometric agonist and antagonist contractions at equal level of EMG activity. **Methods** Torque, architecture (pennation angle and fiber length) and EMG activity of GM were obtained while 8 young healthy males performed ramp isometric contractions in dorsi-flexion (DF) and plantar-flexion (PF) up to maximal voluntary contractions (MVC). **Results** At a given EMG activity, GM fiber length was significantly shorter while performing a sub-maximal PF contraction than during DF MVC (-18%;  $p < 0.001$ ). Similarly, pennation angle during sub-maximal PF was significantly larger than during DF MVC (+28 %;  $p = 0.014$ ). **Discussion** At a given level of GM EMG activity,

architectural parameters were significantly different when the muscle acted as agonist or antagonist: fiber length was longer, and pennation angle was smaller during antagonist than during agonist isometric contractions. These findings indicate that GM elicits a higher mechanical output while acting as an antagonist when EMG activity is matched. This means that estimation of antagonistic force using the common method based on the EMG/net torque relationship yields underestimated values. ### **ANKLE DESTABILISATION DEVICE FOR INJURY PREVENTION OR REHABILITATION IN SPORTS.**

Paizis, C.I, Fautrelle, L.2, Guinet, S.1, Lheraud, C.1, Ballay, Y.2, Babault, N.1

*University of Burgundy*

Introduction Numerous epidemiological studies demonstrated that lateral ankle sprain (LAS) seemed to be a recurrent problem in athletes (Hootman et al. 2007). Further to LAS, residual symptoms could arise and about 70% of the athletes who suffer acute LAS develop chronic ankle instability (Herel 2002). At the muscular level, the evolver muscles strength appeared as an essential factor in order to ensure ankle stability (Wilkerson et al. 1997). In this study, we proposed to investigate the modulation of the EMG activities of 6 ankle muscles (on the right and left leg) in response to an ankle destabilisation device (ADD) when walking, in normal or constrained conditions, and jumping. We hypothesized that such device should significantly modify the amplitude parameters of the EMG pattern of the ankle muscles, especially in the peroneal muscles. In such case, such ADD would then be use in ankle injury prevention or rehabilitation to improve the functional stability of the ankle joint. Methods Twelve healthy sport sciences students without previous history of neuromuscular disease or acute LAS volunteered for the experiment. Subjects were required to normally walk, walk along a straight line or realize horizontal jumps, with or without the ADD. The ADD was a device mounted under the heel of the shoes which induces subtalar joint destabilization. Kinematics and surface electrical activities were recorded on the both sides of the subjects in six muscles (twelve as a whole), namely the tibialis anterior, the peroneus longus, the peroneus brevis, the gastrocnemius lateralis, the gastrocnemius medialis and the soleus. For each muscle, the EMG activities recorded during the experimental conditions were normalized by the EMG activities recorded during a maximal voluntary isometric contraction. Results Our electromyographic investigations on these twelve ankle muscles showed a significant effect of the ADD when subjects have to realize horizontal jumps. Indeed in this condition, our statistical analyses clearly demonstrated a significant increase (17%,  $P < 0.05$ ) of the amplitude of the EMG activities in the left and right peroneus brevis and longus. Discussion Our finding evidenced that horizontal jumps with ADD generated a significant increase in electromyographic activity of both peroneus and are therefore a valuable resource in the functional strength training and sensory- motor rehabilitation and prevention of the ankle. ### **BAREFOOT TRAINING IMPROVES PHYSICAL PERFORMANCE IN NETBALL PLAYERS**

Venter, R., De Villiers, J.E.

*Stellenbosch University*

BAREFOOT TRAINING IMPROVES PHYSICAL PERFORMANCE IN NETBALL PLAYERS Venter, R., De Villiers, JE. Stellenbosch University (Stellenbosch, South Africa) Introduction Recent research on barefoot running has focused mainly on lower-limb and spatio-temporal kinematics, its influence on kinetics of running, as well as running economy. Little is known about the effect of barefoot training on physical performance in team athletes. The aim of this study was to determine the effect of barefoot training on speed, agility, power and single-leg stability in netball players. Methods Twenty women netball players (age:  $20 \pm 2$  years) were randomly assigned to a barefoot ( $n=10$ ) and a shod group ( $n=10$ ). Both groups performed the same drills during 20 training sessions over a period of eight weeks. Time spent training barefoot gradually increased to 40 minutes in the final session. Speed, agility, vertical jump height and single-leg stability were measured pre- and post-intervention. Results Players in the barefoot group showed significant improvements in agility to the left ( $P < 0.05$ ;  $ES=0.74$ ) and the right ( $P < 0.05$ ;  $ES=0.42$ ). A large practical significant difference was found between barefoot and shod players for 10-m speed ( $ES=1.01$ ) and 20-m speed ( $ES=0.80$ ). The barefoot group showed significant improvements in single-leg stability for the right leg in the anterior/posterior plane ( $P=0.01$ ;  $ES=0.22$ ), the medial/lateral plane ( $P=0.04$ ;  $ES=0.27$ ), as well as overall stability ( $P=0.01$ ;  $ES=0.25$ ). A small practical significant difference was found for the left leg in the medial/lateral plane ( $ES=0.24$ ) and overall stability ( $ES=0.17$ ). No significant differences were found between the two groups with regard to vertical jump height. Discussion Barefoot training improved speed, agility and single-leg stability in netball players. The novelty of this study makes it difficult to compare our results with previous research. Higher step frequencies and reduced contact time during barefoot running in habitually shod runners have been reported previously (Braunstein et al., 2010; Divert et al., 2008; Smith et al., 2010). It has also been suggested that barefoot training could strengthen small muscles crossing the ankle joint (Nigg, 2009) and improve proprioceptive ability (Jenkins et al., 2011). Although we did not analyse kinematic data or assess muscle strength in this study, the abovementioned aspects associated with barefoot training could have played a role in the improved performance of the barefoot group. Future longitudinal studies could determine the effect of barefoot training on prevention of ankle injuries in netball players. References Braunstein B, Arampatzis A, Eysel P, Brüggemann, GP. ## IS-PM09 Mechanism in Sarcopenia

**SARCOPENIA: MECHANISMS AND FUNCTIONAL SIGNIFICANCE**

Narici, M.V.

*University of Nottingham*

Sarcopenia, the age-related loss of muscle mass, has a prevalence of 20% in individuals aged 60- to 70-years, approaching 50% in those over 75 years. Between the 2nd and 7th decades, about 20% of muscle mass is lost during the normal ageing process. The associated decrease in muscle strength and power actually exceeds that of muscle size, indicating a deterioration of muscle quality (1). Decreased single fibre specific tension, changes in muscle architecture, alterations in tendon mechanical properties and in neural drive, contribute this phenomenon. Sarcopenia has a multifactorial origin, involving neuropathic processes leading to loss of motor units, oxidative stress leading to cellular damage, mitochondrial dysfunction and apoptosis, hormonal alterations impacting upon protein turnover, immunological changes involving inflammation-mediated cytokines release, activating proteolytic pathways and cellular apoptosis, and lifestyle changes (e.g. nutrition, physical activity, stress) leading to stable gene expression alterations (epigenetics) (1). A reduction in muscle regenerative capacity also contributes to sarcopenia (2). Basal protein synthesis and breakdown show little changes in old age, however, blunting of the anabolic response to feeding and exercise, particularly in older women, and of the anti-proteolytic effect of insulin are observed (3,4). Further understanding of the mechanisms of sarcopenia also requires disentangling of the effects of ageing alone from those of disuse and disease. Regular resistive exercise is by far the most effective intervention for combating sarcopenia. Evidence exists that it may also afford protection against the loss of motor units, as suggested by observations on master athletes (5). These benefits afforded by chronic exercise involve not only maintenance of muscle mass through the anabolic action of muscular exercise but likely also through a reduction of inflammation (6). Among the various pharmacological treatments for preventing sarcopenia, the use of anti-myostatin antibodies (7), of  $\beta$ -hydroxy- $\beta$ -methylbutyrate (HMB) (8) and of Omega-3 polyunsaturated fatty acids (9) seem particularly worthy of attention. **LOSS OF SKELETAL AND CARDIAC MUSCLE REGENERATIVE CAPACITY WITH OLD AGE**

Ellison, G.M.

*Liverpool John Moores University*

Organ ageing is characterised by a decline in the ability of its tissue-specific stem cells to repair damage and regenerate functional tissue. This decline in regenerative capacity involves both intrinsic molecular changes in the stem cells themselves and/or alterations in their aged environment. Proliferation of mammalian cells, including human, is dependent on having functional telomeres. Adult somatic stem cells, like embryonic stem cells, are self-renewing. Most express telomerase which restores telomere length after each cell replication and prevents 'replicative senescence'. However, haematopoietic stem cells have a finite lifespan and develop a senescent phenotype (Beerman et al. 2010, *Curr Opin Immunol.* 22:500). Telomere shortening in the absence of telomerase activity is one of the major causes of loss of proliferation in mammalian cells (Bodnar et al. 1998, *Science.* 279:349). Telomere attrition occurs with age and as a consequence of oxidative stress and it is proposed to be a cause of replicative cell aging. Progressive loss of telomere sequences like in telomerase knockout mice, *Terc*<sup>-/-</sup>, eventually leads to loss of organism viability after 3-6 generations (Herrera et al. 1999, *EMBO J.* 18:2950). We have found that in 22 month old mice, c-kit positive endogenous cardiac stem cells (eCSCs), are susceptible to the physiological aging process, characterized by impaired proliferation, p16INK4a expression, telomere shortening, 'permanent' withdrawal from the cell cycle (putatively senescent) and increased apoptosis. The senescence of eCSCs with age results in the development of cardiac dysfunction and failure. Interestingly, this progression is altered favourably in IGF-1 transgenic mice (Torella et al. 2004, *Circ Res* 94:514). Here, I will present our recent data on the molecular pathways and mechanisms regulating cardiac and skeletal muscle-derived stem cell fate and regeneration, and how these are affected by ageing. Specifically, I will show that it is possible to rejuvenate the 'aged' stem cell population by stimulating their growth with extrinsic cues or reverting their phenotype into self-renewing and therefore overcome the loss of the tissue-regenerative potential with age. It will be a better understanding of the biology of the processes regulating stem cell fate which will pen-ultimately lead to developing realistic and clinically applicable strategies, utilising the proper stimulation of these cells and leading to meaningful and functional cardiac and skeletal muscle regeneration.

**ROLE OF REACTIVE OXYGEN SPECIES AND INFLAMMATION IN SARCOPENIA**

Jackson, M.J., Vasilaki, A., Kayani, A., Pearson, T., Sakellariou, G., McArdle, A.

*University of Liverpool*

Chronic loss of skeletal muscle mass and function is a major contributor to frailty and weakness in the elderly. The major cause of age-related loss of muscle mass is a decrease in the number of skeletal muscle fibres associated with atrophy and weakness of the remaining fibres. The fundamental causes of loss of tissue function with increasing age are the subject of considerable research activity, but remain unclear. A large number of studies have reported a dysregulation of reactive oxygen species (ROS) homeostasis during ageing that may potentially lead to increased oxidative damage to tissues and/or to defective redox signalling. Skeletal muscle tissue from aged organisms contains increased amounts of oxidative damage, but whether this is the cause of age-related deficits in muscle or a consequence of ageing has been the subject of controversy. Studies from our group have examined the changes in ROS generation that occur

with ageing in man and experimental models and have also utilised a transgenic approach to modify ROS generation in model organisms. Data from these experiments support the hypothesis that aberrant ROS regulation plays a role in the deficits in skeletal muscle and motor neurons that occur during ageing, but also indicate this does not simply occur through increased oxidative damage to tissues. This research is supported by the Medical Research Council, Biotechnology and Biological Sciences Research Council and United States National Institute on Aging.

##### PACING STRATEGY AND PERFORMANCE DURING THE WORLD CHAMPIONSHIP MARATHON RACE

Renfree, A., St Clair Gibson, A.

*University of Worcester*

**PACING STRATEGY AND PERFORMANCE DURING THE WORLD CHAMPIONSHIP MARATHON RACE** Renfree, A.1, St Clair Gibson A.2 1: University of Worcester UK, 2: Northumbria University UK Introduction Optimal pacing is fundamental to successful endurance performance. Although there appears to be a common strategy characteristic of elite performance in distance running events (Tucker et al 2006), previous research has focused on strategies employed by successful or winning athletes. The present study analysed pacing strategies of successful and less successful athletes during a championship race. Methods Final and intermediate 5 km times of finishers (n=60) in the 2009 IAAF Women's Marathon Championship race were accessed via the championship website along with individual personal best (PB) times. Times were converted to mean speeds (m/s). Competitors were split into four groups with Groups 1,2,3, and 4 comprising the first, second, third, and fourth 25% of finishers. Mean speed maintained in PB performances and intermediate segments of the race were calculated for all groups. Relative speed (% of PB speed) was also calculated for intermediate segments. One way ANOVA was used to identify differences in performance times, and two way ANOVA followed by the Bonferroni post-hoc test was used to identify differences between groups in intermediate segments. Results Mean PB speed decreased from Group 1 to 4; other than between Groups 3 and 4, all differences were statistically significant ( $P < 0.05$ ). Speed maintained in the race was  $98.5 \pm 1.8\%$ ,  $97.4 \pm 3.2\%$ ,  $95.0 \pm 3.1\%$  and  $92.4 \pm 4.4\%$  of PB speed for Groups 1-4 respectively. Group 1 was fastest in all segments and displayed less variability in speed. Differences in speed between groups increased as the race progressed. Group 1 ran at a lower relative speed than other groups for the first two 5 km segments, but a higher relative speed from 35km onwards. Statistically significant differences ( $P < 0.01$ ) in the percentage of PB speed maintained were observed between Groups 1 and 4, and 2 and 4 in all segments after 20 km, and Groups 3 and 4 from 20-25 km and 30-35 km. Discussion Group 1 athletes displayed strategies that resulted in superior relative performances. It appears that Group 2, 3, and 4 athletes selected unsustainable initial speeds that resulted in losses of speed later in the race. Although it is only possible to speculate as to the mechanisms underpinning selection of initial work rates, it may be that psychological factors specific to a major competitive event influenced decision making by athletes. These poor decisions resulted in performances inferior to those that may have been expected based on PB times. Further research is warranted to examine the decision making process leading to selection of pacing strategies in competitive events. Reference Tucker R, Lambert M, Noakes T. (2006) An analysis of pacing strategies during mens world-record performances in track athletics. *Int J Sports Physiol Perform*, 1(3), 233-245

##### CHARACTERISTICS OF A SUCCESSFUL PROFESSIONAL ROAD CYCLING SPRINTER: A PERFORMANCE ANALYSIS CASE STUDY

Menaspà, P.1,2,3, Abbiss, C.1, Martin, D.T.1,2,3

*1: Edith Cowan University (Perth, Australia), 2: AIS Physiology (Canberra, Australia), 3: Cycling Australia (Adelaide, Australia)*

**Introduction** Many stages during grand cycling tours (GT; Giro d'Italia, Tour de France and Vuelta a Espana) are designed specifically for sprinters. Of the 79 GT stages won by sprinters within 2008-2011, 5 sprinters won 54 stages and 19 sprinters won remaining 25 stages. The primary aim of this investigation is to describe the sprint performances of a successful professional road cyclist in order to explore performance analysis methodology used for evaluating road sprints. We focused on comparing winning sprints to less successful efforts. **Methods** A the time of this study the subject was the highest international ranked professional male road sprint cyclist (age, 26; height, 175 cm; weight, 69 kg). Performances of this athlete during 2008-2011 GT stages were identified using public access web sites. Stages won by sprinters were classified into those in which he won (W) or lost (L) the sprint, or was dropped (D) from the front bunch prior to the sprint. In addition, video footage of 16 stages have been analyzed for sprint duration, position in the bunch at 60, 30, 10 s remaining and the number of lead-out team members (at 30s) to determine tactical differences between W and L. The total elevation gain (TEG) of 22 stages has been determined to examine its relationship with W, L and D. A descriptive analysis of head-to-head performances against the 2nd-5th most successful professional sprinters has also been conducted. **Results** Over 4 years, the cyclist started 52 GT stages (out of 79 won by sprinters) with 30 W (58%), 15 L (29%), 6 D (12%) and one crash. Video analysis of the sprints showed that sprint duration was similar between W and L sprints ( $10.9 \pm 1.8$  and  $10.0 \pm 3.6$  s, respectively). The position in the bunch was lower for W compared to L at 10s from the finish ( $1.8 \pm 0.4$  and  $4.7 \pm 3.3$ , respectively) but not at =20s. The number of team members was not significantly different between W ( $1.1 \pm 0.6$ ) and L ( $0.6 \pm 0.8$ ). TEG was significantly higher when the rider was dropped ( $1313 \pm 395$  m) compared to W and L sprints ( $478 \pm 266$  and  $524 \pm 324$  m, respectively). The cyclist's ability to reach the finish line in the first bunch (77%) was lower when compared with other successful sprinters (89%). However, the subject won over 60% of stages in which he was in contention to sprint, while his competitors won less than 15%. **Discussion** This study presents novel methodology for the analysis of the road cycling sprint performance. The detailed descriptive information describes performances of one of the most successful sprinters in cycling history. This cyclist demonstrates the ability to win professional road sprints with or without a team lead out, when the GT stage is performed over low elevation gain.

## VARIATION OF PHYSICAL ACTIVITY DURING CONGESTED AND NON-CONGESTED PERIODS IN TOP-CLASS EUROPEAN TEAM SEASON 2011-12.

Djaoui, L., Dellal, A., Pialoux, V., Hautier, C.  
*Université Claude Bernard Lyon 1*

Variation of physical activity during congested and non-congested periods in top-class European team season 2011-12. Djaoui L. (1), Dellal A. (2), Pialoux V. (1), Hautier C (1). (1) Sport Science University of Claude Bernard, Lyon, France; (2) Olympique Lyonnais FC (soccer) Introduction In modern elite soccer, the ability to recover from consecutive official match-play is considered as a key factor, especially during a congested period. However, to the best of our knowledge, no study has investigated how consecutive match-play influences the physical activity. Therefore, the aim of the present study was to examine the variation of physical activity of elite soccer players within a prolonged period of fixture congestion and non-congestion period (from August to December) in competitive season. Methods 16 international players ( $24.3 \pm 3.2$  years;  $178.1 \pm 4.2$  cm;  $76.9 \pm 4.3$  kg), classified into 6 positional roles were examined during French First League and Cup ( $n=10$ ) and UEFA Champion's League ( $n=4$ ) matches, in season 2011-2012 (central defenders: CD,  $n=3$ ; full-backs: FB,  $n=2$ ; central defensive midfielders: CDM,  $n=3$ ; wide midfielders: WM,  $n=3$ ; central attacking midfielders: CAM,  $n=2$ ; forwards: FW,  $n=3$ ). The total distance covered at light ( $<12$  km.h<sup>-1</sup>), moderate (18 to 21 km.h<sup>-1</sup>), high (21 to 23 km.h<sup>-1</sup>), very high (23 to 25 km.h<sup>-1</sup>), over high (25 to 27 km.h<sup>-1</sup>), and sprinting ( $>27$  km.h<sup>-1</sup>) intensity running were analyzed using a semi-automatic match analysis system (Amisco©). Results No differences between congested and non-congested period for the total distance covered in all the speed thresholds superior at 18 km.h<sup>-1</sup> were observed, whereas at light-intensity running, CD and CDM covered lower distance when playing 1 match/week (vs. 2 matches/week,  $p<0.05$ ). Moreover, no physical seasonal variation was found across all matches of the different periods analyzed from August to December. However, lower coefficient of variation were found concerning the overall distance and at light intensity (4.9-7.3%) in comparison with the others speed thresholds all across the playing positions. Furthermore, differences ( $p<0.001$ ) were found among positions for overall distance covered (CDM=CAM > others), sprinting (FB > CD=CDM=CAM and WM=FW > CDM), over high (FB > CD=CDM & WM=CAM > CDM), very high (FB=WM=FW > CD=CDM), high (FB=WM=CAM=FW > CD=CDM), moderate (CAM > FB=CD=WM > CD) and light (CD=CDM > FB=WM=FW) intensities. Discussion The present study reveals that the recovery time between two matches (72 to 96 hours) should not affect the physical performance during a prolonged period of fixture congestion in top-class soccer players. It could be suggested that post-match strategies (alternating legs' hot and cold water immersion, massage, diet and drink supplementation), and training including recovery and prevention session between matches, allow to reduce the apparition of fatigue and thus, to maintain sufficiently a high-level of physical performance within congested period.

## DIFFERENCES BETWEEN COMPETITION AND RECREATIONAL GAME PLAY IN SOCCER

Laura, T., Hermann, T., Bürgi, R., Heinzmann, P., Murer, K.  
*ETH Zurich*

Introduction The amount of recreational game play in childhood, in addition to official competition matches, relates positively with a child's chances of a successful career (Ford et al., 2009). It is, however, unclear whether this relationship is due to recreational play improving children's soccer skills by simply increasing the time spent on game play or by training different aspects of the game compared to competition game (CG) play. This study compares qualitative and quantitative aspects of recreational game (RG) and CG play. The analysis is on physical and tactical parameters. Methods 34 boys and one girl ( $10.3 \pm 1.3$  years) from different junior teams were assessed during one CG and one RG. The games were about 60 minutes in duration. The RG took place on hard surface (1280 m<sup>2</sup>), the CG on grass fields (1650 to 3332 m<sup>2</sup>). The number of players ranged from 6 to 9 per team. These numbers were different depending on the age based category. The physical parameters total distance covered, speed distribution (Castagna et al. 2009) and maximal velocity were extracted from GPS tracking devices (BT-Q1300S, Qstarz International Co., Taiwan) carried in an armband by all players. The tactical parameter number of one-on-one situations was extracted from videos of the games. Dependent t tests and Wilcoxon signed ranks tests were used to detect differences between RG and CG play. The significance level was set to 0.05. Results Significant differences between RG and CG play were detected in the conditional parameters. In RG the percentage of total distance walking (CG = 20.3% < RG = 23.7%) and jogging (CG=  $42.7 \pm 7.9\%$  < RG =  $46.6 \pm 4.6\%$ ) was higher, medium intensity running (CG=  $21.7 \pm 6.5\%$  > RG =  $17.6 \pm 4.8\%$ ) and high-intensity running (CG =  $9.3 \pm 3.6\%$  > RG =  $7.4 \pm 3\%$ ) was lower. Top speed differed significantly between CG and RG only during back checking (23.4 km/h and 21.3 km/h, respectively). No differences between games were found for the total distance covered. Finally, the total number of one on one situations was significantly lower in CG (CG =  $6.2 \pm 5$  < RG =  $14.7 \pm 8.5$ ). Discussion It seems that intensity during RG is lower than in CG. This can be explained by the fact that during RG children can chose the intensity they want. The freedom and relative insignificance of RG seems to trigger creativity and a willingness to initiate more offensive one-on-one actions. Relative to CG play, defensive work is slightly neglected. It thus seems that RG play more specifically targets the offense and one-on-one situations than CG play does. References Ford PR, Ward P, et al. (2009). High Ability Studies 20(1), 65-75. ## VARIABILITY AND PREDICTABILITY OF PERFORMANCE TIMES OF ELITE CROSS-COUNTRY SKIERS

Spencer, M., Losnegard, T., Hallén, J., Hopkins, W.G.  
*Norwegian School of Sports Sciences*

VARIABILITY AND PREDICTABILITY OF PERFORMANCE TIMES OF ELITE CROSS-COUNTRY SKIERS Spencer, M. 1, Losnegard, T. 1, Hallén, J. 1, Hopkins, W.G. 2 1: Norwegian Research Centre for Training and Performance, Norwegian School of Sports Sciences, Oslo, Norway, 2: Sport Performance Research Institute NZ, AUT University, Auckland, New Zealand Introduction The variability in performance of elite athletes between competitions provides useful information for research on factors affecting medal-winning performance (Hopkins et al., 1999). The aim of this study was to estimate the variability of performance of cross-country skiers in international competitions. Methods Official race times and course information were downloaded from fis-ski.com for individual-start races in World Cup, World Championship and Olympic competitions from 2001 to 2010. The eight events were classic and free versions of women's distance (10 km), men's distance (15 km), and men's and women's sprint qualification (prolog), each with a total of 410-569 athletes competing in 1-44 races at 15-25 venues. In analyses restricted to the top 10 from each race there were 55-107 athletes in 1-28 races. A linear mixed model of log-transformed race times for each event provided estimates of within-athlete race-to-race variability (the residual, expressed as a coefficient of variation, CV) after adjustment for fixed effects of snow conditions (6 levels), altitude (2 levels), and race length (simple numeric), with random effects (expressed as CV) representing differences in performance time arising from race terrain, athlete ability, and chang-

es in-athlete ability between seasons. Predictability of performance was expressed as an intraclass correlation representing the mean correlation between pairs of races within a season. Results Within-athlete race-to-race variability in performance time was similar for men and women in the various events for all athletes (CV of 1.5-1.8%), but for top-10 athletes men were a little less variable (0.68-0.73%) than women (0.88-1.0%). Observed effects of differences in snow conditions and altitude on mean performance time were substantial (up to ~2%) but mostly unclear, owing to extremely large effects of terrain (CV of 4-10% in top-10 analyses). Predictability of performance was extremely high (correlations of 0.90-0.96) for all athletes but only poor-moderate (0.09-0.46) for top-10 athletes. Discussion The race-to-race variability of the best skiers is similar to that of elite runners (Hopkins, 2005) and is therefore likely a consequence of irreducible variability in physiological power output, with little contribution from variability in pacing, skill, or environmental effects. Estimates of the smallest worthwhile performance enhancement (0.3x within-athlete variability) will assist researchers investigating factors affecting performance of elite skiers. ## ACCELEROMETER-DERIVED PHYSICAL ACTIVITY IN PRESCHOOLERS: A G-FORCE HISTOGRAM ANALYSIS

Laukkanen, A., Havu, M., Pesola, A., Sääkslahti, A., Finni, T.

*University of Jyväskylä*

ACCELEROMETER-DERIVED PHYSICAL ACTIVITY IN PRESCHOOLERS: A G-FORCE HISTOGRAM ANALYSIS Laukkanen, A.1, Havu, M.1, Pesola, A.1, Sääkslahti, A.2, Finni, T.1. 1: Department of Biology of Physical Activity, University of Jyväskylä, Finland, 2: Department of Sport Sciences, University of Jyväskylä, Finland Introduction Accelerometers have been seen as gold-standard objective tool for monitoring children's habitual physical activity. To become biologically meaningful, the activity levels have generally been estimated on the basis of cut-off points. However, there is a lack of general agreement on how to choose the cut-off points (Bornstein et al., 2011). The aim of this study was to describe habitual physical activity of preschool-aged children both by means of an acceleration histogram and the cut-off points (van Cauwenberghe et al., 2010). Methods The subjects were 4- to 6-year-old children attending all-day day-care in kindergarten (n = 17; 10 boys; mean age 5.5 ± 0.6 years). Physical activity was measured over 6 days (at least 1 weekend day) using triaxial Gulf Coast Data Concepts X6-1a accelerometers with a dynamic range of ±6g. The devices were carried in an elastic belt that was firmly worn on the subjects' waist (Finni et al. 2011). The direction of the acceleration was ignored. Magnitudes were band-pass filtered (0.25 Hz ... 11 Hz), and values below 0.05g were filtered out. Physical activity counts were calculated by summing over 15-second epochs and multiplying by a device-specific factor that was derived from simultaneous recordings with the X6-1a and ActiGraph GT3X. Results Physical activity was monitored for an average of 4.7 days (12.2 ± 2.5 hours/d). The average time children spent at acceleration level under 0.05g, between 0.05-2g and over 2g each day were 658.0 ± 133.3 (89.6%), 48.1 ± 12.1 min (6.6%) and 28.1 ± 12.2 min (3.8%), respectively. Mean total activity was 664 ± 295 counts per minute. Children participated on average 36.7 ± 14.6 minutes per day in light physical activity and 52.7 ± 35.4 minutes per day in moderate-to-vigorous physical activity. Discussion To our knowledge this is the first time to describe preschool-aged children's physical activity by g-force histogram using accelerometers. The g-force histogram conserves valuable raw data gathered and is thus promising tool for assessing both the amount and quality of preschool-aged children's physical activity. In further research, g-force histogram could be useful for assessing, for instance, physical activities' dose-response rate relating to children's bone and motor skill development. Further study is also needed to map behavioural meanings into g-force histogram values. References Bornstein DB, Beets MW, Byun W, McIver K. (2010). *J Sci Med Sport*, 14, 504-511. ### OP-PM40 Rehabilitation 2

#### IS THE INITIAL PERFORMANCE LEVEL RELATED TO EXERCISE RESPONSE IN ALLOGENIC STEM CELL TRANSPLANT PATIENTS?

Wiskemann, J.1,2, Jäger, D.2, Bohus, M.3, Nies, R.1, Huber, G.4, Dreger, P.5, Ulrich, C.M.1

1: NCT/DKFZ (Heidelberg, Germany), 2: NCT/University Clinic (Heidelberg, Germany), 3: CIMH (Mannheim, Germany), 4: ISSS (Heidelberg, Germany), 5: University Clinic (Heidelberg, Germany)

Introduction Before, during and after allogeneic hematopoietic stem cell transplantation (allo-HSCT) patients experience considerable physical, psychological and psychosocial distress. Besides GVHD and infections, particularly reduced physical performance and functioning as well as high levels of fatigue affect patient's quality of life negatively. Our recently published study in this field shows that a partly self-administered exercise program is beneficial for several treatment-related side-effects (Wiskemann et al., 2011). In this analysis we investigate the individual training response of the exercisers group depending on their baseline fitness level. Methods We analyzed physical performance data of 40 exercise intervention (EX) participants from a randomized-controlled trial. Patients trained in a home-based setting prior to hospital admission, during inpatient treatment and 6-8 weeks period after discharge (partly self-administered with an intervention manual and DVD). Physical performance was assessed via 6-minute walk test (6MWT) and handheld dynamometry (HHD). In order to analyze individual training response patients in the EX were categorized as 'fit' (>80% of their predicted fitness scores) or 'unfit' (<80% of their predicted fitness scores). Results Patients in the 'unfit' group declined about 1,7% in maximal voluntary isometric strength in knee extensor muscles over the entire study period whereas the 'fit' group lost 31,1% in average (p<0.05). Comparable differences between the "unfit" (improvement or maintenance) and "fit" (maintenance or loss) were observed for all other measured muscle groups. Similarly, the 6MWT distance showed a significantly greater improvement for the 'unfit' vs. the 'fit' group (+13,4% vs. -3,7%, p<0.05). Discussion The effect of exercise training on physical fitness in allo-HSCT patients differs by their performance level at baseline. Oncologists and exercise therapists should be aware of the importance of exercise in initially unfit patients in improving performance during allo-HSCT. Effects of a partly self-administered exercise program before, during, and after allogeneic stem cell transplantation. *Blood*, 117(9):2604-2613.

### **SPORTS CLIMBING ONCE A WEEK IMPROVES BALANCE, FATIGUE AND COGNITIVE FUNCTION IN MULTIPLE SCLEROSIS**

Kern, C.1, Tusker, F.2, Bischoff, C.3, Oberhoffer, R.1

*Technical University of Munich*

Purpose MS affects mainly young adults, still capable of working. Even though immunomodulating drugs slow down disease progression, the loss of functional capacity severely handicaps patients with MS. Although exercise reduces secondary complications in patients with MS, Motl (2005) has shown that MS patients are less physically active than non-disabled subjects. Sports Climbing (SC) is new in therapy of neurological patients and intrinsically highly motivating. Thereby, multidimensional skills in SC allow targeting various symptoms of patients with MS individually. This study aimed to investigate if SC once a week improves balance, fatigue and cognitive function in patients with MS. Patients and Methods We report on 27 MS-patients randomized into SC-group (n=12) and control-group (cg) (n=15) with an Expanded Disability Status Scale (EDSS) 1-6.5. The SC-program was performed over 20 sessions of two hours within 6 months on consecutive Saturdays. Criteria for exclusion are 'attendance less 18 sessions' or 'relapse during intervention'. Each session was adjusted individually and documented. Controlled top rope climbing and safety-standards in the SC-program were ensured. Data were collected for cognitive function (PASAT=Paced Auditory Serial Addition Test), dynamic balance (MFT S3Check [Multifunktionale Trainingsgeräte GmbH]), steady balance (COP=Center of Pressure [Kistler force platform]) and fatigue (WEIMuS=Würzburger Erschöpfungsinventar). Results EDSS decreased in SC-group (n=10) from 5.5 [IQR 2.8; 6.5] to 4.3 [2.6; 6.5], p=0.068 whereas we had no changes in cg (n=14) 4.0 [pre 2.5; 6.0; post 2.4; 6.0], p=0.157. Significant improvements were found in all mental and physical tests in the SC-group from pre- to post-test. WEIMuS totally decreased in SC-group from 36.0 [25.75; 46.50] to 17.5 [1.75; 32.50], p=0.011 whereas results in cg increased from 26.0 [5.75; 45.25] to 27.0 [15.25; 34.25], p=0.550. The PASAT ascended significantly in SC-group from 44.0 [27;50] to 50.5 [38.5;57.25], p=0.028; slightly in control-group from 46.0 [38;51] to 49.0 [42.5; 55.5], p=0.270. Steady and dynamic balance improved in SC-group; S3Check (n=7) revealed (pre / post) for stability index 5.8 [5.3; 6.4] / 5.6 [4.5; 6.6], p=0.046 and sensomotoric index 5.1 [4.4;6.3] / 4.6 [4.0;5.0], p= 0.051 vs cg stability index 5.0 [4.8;6.5] / 5.5 [4.5;6.4], p=0.752 and sensomotoric index 4.6 [3.7;5.6] / 4.3 [3.7;5.3], p=0.612. Conclusions SC-intervention improves or stabilizes mental as well as physical functioning in MS-patients. Regular sport participation, such as SC should be recommended to patients with MS.

### **EFFECT OF AEROBIC INTERVAL TRAINING ON PHYSICAL AND METABOLIC FITNESS IN OVERWEIGHT/OBESE ADOLESCENTS WITH INTELLECTUAL DISABILITY.**

Elmahgoub, S., Cambier, D., Gysel, T., Rombaut, L., de Wandele, I., Roman de Mettelinge, T., Calders, P.

*Arteveldehogeschool / Universiteit Gent*

INTRODUCTION: Aerobic interval training has the potency to improve physical fitness in adolescents with overweight/obesity without intellectual disability (Ingul CB 2011). Data concerning the effect on metabolic fitness are not available. In overweight/obese adolescents with intellectual disability no data are available. Therefore, the purpose of this study is to evaluate the effect of aerobic interval training on metabolic and physical fitness in adolescents with intellectual disabilities and overweight/obesity compared to endurance training and no training. METHODS: This study is a controlled trial with patients receiving either aerobic interval training (AET), endurance (END) or no training (C). 30 adolescents with intellectual disabilities (mean age: 17 (3,4), mean BMI-percentiles: 91 (4), mean IQ: 54 (8,3)) were recruited from two schools for special education (BUSO Ravelijn and BUSO De Varen, Brugge, Belgium). Subjects received either aerobic interval training (4 blocks of 10 minutes; alternating 2 minutes 80% peak heart rate (3x), 2 minutes 50% peak heart rate (2x); n=10) or endurance training (4 blocks of 10 minutes, continuous heart rate at 70% peak heart rate; n=10) twice a week for 40 minutes per session for 20 weeks or no training (n=10). After 10 weeks, intensity was increased to 90% of peak heart rate and 60% of peak heart rate in the interval group and to 80% of peak heart rate in the continuous group. Groups were matched for age, sex and intellectual disability. Before and after the training period body composition (length, weight and BMI), physical fitness (aerobic capacity, muscle strength), blood pressure (resting systolic and diastolic) and lipid profile (triglycerides, HDL, LDL and total cholesterol) were evaluated. RESULTS: Compared to no training, aerobic interval training has significant positive effects on peak VO<sub>2</sub>, ventilatory threshold (VO<sub>2</sub> and power output), muscle fatigue and six minute walk test. Compared to endurance training, aerobic interval training resulted in a significant better evolution of ventilatory threshold VO<sub>2</sub> (mean differences: +10% versus +4%), ventilatory threshold power output (+15% versus +5%), muscle fatigue (+5 sec versus 0 seconds), 6 minute walk test (+109m versus +68m). PeakVO<sub>2</sub> increased in both groups significantly with 5%. There was no significant effect on metabolic fitness in all groups. CONCLUSION: This study revealed a tendency towards more beneficial effects concerning physical fitness of aerobic interval training in overweight/obese adolescents with intellectual disability compared to endurance training. Concerning metabolic fitness no positive effects could be revealed. Reference: Ingul CB, Tjønnhaug AE, Stølen TO, Stølen A, Wisloff U. Impaired cardiac function among obese adolescents: effect of aerobic interval training. *Arch Pediatr Adolesc Med*. 2010 Sep;164(9):852-9

### **UNEXPECTED DISTURBANCE PROGRAM IN REHABILITATION OF HIGH PERFORMANCE ATHLETES.**

Teichmann, J.

*National Sport Institute of Malaysia*

Unexpected disturbance program (UDP) in rehabilitation of high performance athletes. Jörg Teichmann<sup>1</sup>, Dr Ramlan Bin Abd. Aziz<sup>1</sup>, Edin Suwarganda<sup>1</sup> Msc., Prof.Dr.Dietmar Schmidbleicher<sup>2</sup> and Dr Barry Wilson<sup>1</sup> <sup>1</sup>National Sports Institute of Malaysia, <sup>2</sup>Goethe-University Frankfurt-Germany Athletes recovering from anterior cruciate ligament (ACL) injury reached 75-85% of their pre injury level of performance (Haas et al., 2004). Exercises in proprioception training with voluntary corrective movements are widely accepted in post-surgical rehabilitation for ACL reconstruction of athletes. The UDP promotes exercises in response to so-called involuntary short to mid latency disturbances (Taube et al., 2006). A pre - post study design was used to investigate the effectiveness of UDP in the last 6 weeks of rehabilitation of 15 Malaysian national athletes. Tests included 20 m sprint, 1 RM single leg press, standing long jump, sway test and a psychological questionnaire. The rehabilitation consisted of two parts, general training and specific training. A total of 7 sessions per week of 90 minutes with 3 sessions allocated for 5-6 UDP exercises. Conditioning tests were measured with timing system (Brower), measure tape and observation on the outdoor track or in-house gym. Sway was measured as the centre of pressure movement in AP and ML directions, at 100 Hz for a period of 10-15 seconds, on a tri-axial force plate. Sway conditions were semi-randomized in a 3x3x3 design with

varying intrinsic, extrinsic conditions and each trial was repeated three times. The non-injured leg served as a control for the injured leg. Two-tailed paired t-tests were used for limited a-priori comparisons to examine differences. Significance level was set at  $p < 0.05$ . Significant improvements in average time by 3.6% (ES=0.42), strength by 21.6% (ES=1.49), distance jumped by 5.2% (ES=0.36) and ML sway (ES=0.96) were noted. Additionally athletes reported improved perceived confidence in their abilities. All athletes improved in each conditioning tests except for the long jump of two athletes. The ML sway decreased with 9 out of the 15 athletes for the injured limb. Group mean sway showed an overall increase for both the injured and non-injured limb. However, the injured limb increased significantly less in ML sway than the non-injured limb. The increase in sway due to the UDP was unexpected but may be due to athletes' increased ability to correct imbalances with active torque. The prevention training with UDP resulted in improved conditioning and seems to decrease ML sway. Continued research is needed to further confirm these observations. ## EXERCISE ADHERENCE AFTER AEROBIC INTERVAL TRAINING IN PATIENTS WITH CORONARY ARTERY DISEASE

Aamot, I., Karlsen, T., Dalen, H., Stoylen, A.

*Norwegian University of science and technology*

Introduction: Aerobic interval training (AIT) is shown to be superior in increasing aerobic capacity compared to moderate continuous training in coronary artery disease (CAD) patients (1). However, exercise adherence to high-intensity exercise is reported to be low (2). The aim of this study was therefore to assess exercise adherence one year after an AIT cardiac rehabilitation (CR) program. Methods: 47 CAD patients (41 men/6 women, mean age 58±8 years, body mass index 27±3) referred to CR due to myocardial infarction (n=30), acute coronary syndrome (n= 2) or coronary artery bypass graft (n=15) completed 12 weeks of AIT, twice a week. Exercise intensity was 85-95% of peak heart rate during the 4x4 minute intervals. They were encouraged to continue exercise after CR completion, and then the participants returned to retests 12 months later. Primary outcome measure was peak oxygen uptake (VO<sub>2</sub>peak). Secondary outcome measures were self-reported physical activity (PA) using International Physical Activity Questionnaire (IPAQ) short version last seven days and health-related quality of life with MacNew. All tests were performed at baseline (BL), after 12 weeks of AIT and after 15 months, analyzed with Repeated measures ANOVA with Bonferroni corrections for multiple analysis. Results: VO<sub>2</sub>peak at BL was 34.7±6.8 ml•kg<sup>-1</sup>•min<sup>-1</sup>, after 12 weeks of AIT 38.3±7.2 ml•kg<sup>-1</sup>•min<sup>-1</sup> (mean difference (md) 3.6, CI 2.7-4.5,  $p < 0.001$ ), and after 15 months 36.0±7.0 ml•kg<sup>-1</sup>•min<sup>-1</sup> (md from BL 1.3, CI 0.14-2.4,  $p = 0.023$ , md from 12 w 2.4, CI 1.2-3.5,  $p < 0.001$ ). Self-reported MET-minutes • week<sup>-1</sup> were 2109±1584, 2331±1794 and 2318±1712, for BL, 12 weeks and 15 months, respectively (differences non-significant). MacNew Global scores were 6.0±0.5 at BL, 6.2±0.5 at 12weeks (md 0.3, CI 0.09-0.45,  $p = 0.001$ ) and 6.2±0.6 at 15 months (md from BL 0.2, CI -0.1-0.5,  $p = 0.31$ , from 12 weeks 0.08, CI -0.4-0.2,  $p = 1$ ). Discussion: our results indicate that exercise adherence after AIT in CR is not optimal, though VO<sub>2</sub>peak at 15 months still were significantly above BL levels. In a study from Moholdt et al (2011) adherence to exercise after CR were higher after AIT than exercise at lower intensity (3). Exercise intensity per se is probably not the reason for decline in exercise participation. Thus, AIT is an optional exercise mode in cardiac rehabilitation. However, CAD patients seem to be in need of additional attention for a prolonged time to stay into exercise habits after CR completion. 1. #### IMMUNE RESPONSE EFFECTS OF A SWIMMING SESSION REMAIN FOR MORE THAN 24 HOURS

Morgado, J.I, Monteiro, C.P.I, Matias, C.2, Alves, F.1, Seixas, M.T.3, Alvim, M.3, Bourbon, M.3, Laires, M.J.4

1,2,4 - Faculty Human Kinetics, Technical University of Lisbon, Portugal; 3 - Unidade Laboratorial Integrada, Dpt Promoção da Saúde e Doenças Crônicas, Instituto Nacional de Saúde Dr Ricardo Jorge

Introduction The effect of exercise over the immune response along the recovery period has revealed inconsistent findings especially in swimming training. The purpose of this study was to evaluate the immune systemic response to a high intensity swim training session during a 24h recovery period. Methods A group of 36 Portuguese male swimmers (16 ± 0.4 yrs; 186 ± 12 cm; 65 ± 1.3 Kg) performed a selected swim training session with a high intensity main set at the end of the first macrocycle of the season. Blood samples were collected before (Pre), immediately after (Post), 2 h after (Post2h) and 24 h after (Post24h) the swimming session, by standard procedures for assessment of Haemogram and Leukogram (automated counter Beckman Coulter LH 750) and Lymphocytes subpopulations (FACS Calibur Becton, Dickinson and Company) including CD3+, CD4+, CD8+, CD16+ and CD19+. ANOVA for repeated measures with Bonferroni post-hoc test or Friedman test with pairwise comparisons were used for the assessment of exercise effects. Statistical significance was considered at  $p < 0.05$ . Results At Post, significantly lower values of haemoglobin, monocytes, eosinophils, total lymphocytes and all the subpopulations evaluated were observed. Platelets, neutrophils and CD4+/CD8+ ratio were elevated at Post but leukocytes did not change significantly. At Post2h, monocytes and platelets had return to Pre values; haemoglobin, eosinophils, continued to decrease; total lymphocytes, CD3+, CD4+, CD8+ and CD16+ maintained lower values; CD19+ increased significantly regarding Post but remained below Pre; neutrophils continued to rise, CD4+/CD8+ ratio maintained higher values and leukocytes increased. At Post24h, neutrophils, eosinophils, CD8+, CD16+ and CD4+/CD8+ ratio recovered to Pre levels; total lymphocytes, CD3+ and CD4+ augmented comparing to Pos2h but stayed above Pre; CD19+ remained lower than Pre while leukocytes and monocytes decreased to values below Pre. Discussion A demanding swimming session seems to provoke a significant acute depression of the Immune System suggesting that a 24h period is insufficient to attain total recovery. These findings support the idea that exercise induces immune suppression and increases susceptibility to infections after high intensity training sessions.

### SYSTEMIC CHANGES AFTER 4 MONTHS OF SWIMMING TRAINING

Monteiro, C.P.1, Morgado, J.1, Matias, C.2, Alves, F.1, Seixas, M.T.3, Alvim, M.3, Bourbon, M.3, Laires, M.J.4

1,2,4 - Faculty Human Kinetics, Technical University of Lisbon, Portugal; 3 - Unidade Laboratorial Integrada, Dpt Promoção da Saúde e Doenças Crônicas, Instituto Nacional de Saúde Dr Ricardo Jorge

**Introduction** In endurance sports such as Swimming the implementation of cycles of high training volume in order to optimize aerobic and movement economy adaptations can lead to transient imbalances between training loads and recovery contributing to the onset of fatigue and eventually illness in well trained athletes. An immunodepression state characterized by substrate depletion, hormonal and immune functions disturbances is usually the response to hard training periods. The purpose of this study was to evaluate the effects of a 4-month swim training macrocycle of preparation for the Winter Swimming National Championships over the resting systemic immunity. **Methods** Systemic immunity was assessed in 35 Portuguese male swimmers ( $15.8 \pm 0.32$  yrs;  $187 \pm 14.6$  cm;  $63.8 \pm 1.4$  kg) at the beginning of the training season (M1) and at the end of the winter National Championships (M2). This macrocycle was characterized by an aerobic training predominance and the progressive increase of training volumes and intensities in the first 3 months and for the maintenance of high intensities and progressive decrease of volumes in the last month. At the National Championships swimmers have accomplished at least one personal best time in the races they were enrolled in. Blood samples were collected by standard procedures for assessment of haemogram and leukogram (automated counter Beckman Coulter LH 750) and lymphocytes subpopulations (FACS Calibur Becton, Dickinson and Company) including CD3+, CD4+, CD8+, CD16+ and CD19+. Paired samples t test or Wilcoxon test was used to compare M1 and M2 resting values of each variable. The level of significance was set at  $p < 0.05$ . **Results** At M2 we observed significant higher resting levels of haemoglobin, haematocrit, red blood cells, and neutrophils. Contrarily, total lymphocytes (%) were significantly diminished. **Discussion** During this training cycle it was observed a stimulation of innate immunity (represented essentially by neutrophils) and a decline in the adaptive immunity (represented by total lymphocytes) that may be associated with the higher performance levels observed after a swimming winter macrocycle. These alterations may reflect the cumulative effects of aerobic training predominance suggesting that training load volume may be determinant for systemic change.

### HAEMATOLOGICAL CHANGES IN RECREATIONAL ENDURANCE RUNNERS DURING A MULTI-STAGE ULTRA-MARATHON CONDUCTED IN HOT AMBIENT CONDITIONS.

Gill, S.K.1, Teixeira, A.4, Rama, L.4, Morse, T.3, Cresswell, S.3, Godson, N.3, Scheer, V.6, Valero, E.6, Costa, R.J.S.1,2

Coventry University, UK; Coimbra University, Portugal; University of Heidelberg, Germany; Vinalopo Hospital, Elche, Spain.

**Introduction:** Endurance running in the heat has previously been linked with disturbances to haematological parameters. The aim was to monitor haematological responses in ultra endurance runners (UER) during a multi-stage ultra-marathon (MSUM) competition in hot ambient conditions ( $T_{max} 36.8 \pm 3.6^\circ\text{C}$ , RH 35%) conducted over five consecutive days (5 stages) totalling 230km. **Methods:** On each of the 5 stage days, whole blood samples were collected by antecubital venepuncture without venostasis pre-stage and immediately post-stage (UER  $n = 21$ ; Control (CON)  $n = 6$ ). Full blood counts, Hct, and Hb were analysed using an automated cell counter. Haematological indices were corrected for changes plasma volume. Data were analysed using a repeated measures ANOVA with post hoc HSD. **Results:** Pre-stage resting plasma volume in UER increased by Stage 3, and remained elevated thereafter ( $p < 0.01$  vs. pre-Stage 1;  $p < 0.05$  vs. CON). Leukocytosis was observed post-stage on all stages ( $p < 0.01$  vs. pre). Resting pre-stage leukocyte counts were higher on Stages 2, 3 and 5 compared with Stage 1 ( $p < 0.05$ ). Lymphocyte counts decreased post-stage on Stage 1 ( $p < 0.01$  vs. pre), but increased post-stage on Stages 2 and 3 ( $p < 0.05$  vs. pre). Post-stage lymphocyte counts were higher on Stages 2 to 4 compared with Stage 1 ( $p < 0.01$ ). Monocyte counts increased post-stage on Stages 1 to 3 ( $p < 0.01$  vs. pre). Resting pre-stage monocyte counts were higher on Stage 5, while post-stage monocyte counts were lower on Stages 4 and 5, compared with Stage 1 ( $p < 0.01$ ). Granulocyte counts increased post-stage on all stages ( $p < 0.01$  vs. pre). Resting pre-stage granulocyte counts were higher all other stages, while post-stage granulocyte counts were lower on Stage 5, compared with Stage 1 ( $p < 0.01$ ). UER presented higher monocyte and MCHC counts pre-Stage 5, and lower granulocyte counts pre-Stage 1 compared with CON ( $p < 0.05$ ). **Conclusion:** Extreme exertional-heat stress may contribute in transient haematological changes observed during MSUM, regardless of acute stress induced adaptations. Despite these changes, illness symptoms in UER was low ( $n=1$ ). Notably, haematological responses are influenced by nutritional and hydration status, it is therefore plausible that sufficient food and fluid intake throughout competition may have attenuated any further disturbances in these haematological parameters.

### EFFECTS OF PROGRESSIVE RESISTANCE EXERCISE INTENSITY ON OXIDATIVE STRESS IN RESISTANCE EXERCISE TRAINED AND UNTRAINED MEN

Cakır-Atabek, H., Özdemir, F., Colak, R., Sevil, G.

Physical Education and Sport 3: Physical Education and Sports School, Ardahan University, Ardahan, Turkey

**Introduction** Acute resistance exercise induce oxidative stress responses are conflicting and the relation between oxidative stress and some exercise components, e.g. "intensity" – "volume", is not clear. Therefore the purposes of this study were (a) to determine time-dependent effects of progressive intensity of resistance exercise (RE) on oxidative stress markers, (b) to determine time-dependent effects of progressive intensity of RE on oxidative stress markers in RE trained and untrained men, (c) to search possible threshold intensity required to evoke oxidative stress. **Methods** RE trained (RET gr:  $n=8$ , experience:  $5,31 \pm 3,40$  years, 1RM:  $137,4 \pm 19,9$  kg) and untrained (UT gr:  $n=8$ , 1RM:  $110,5 \pm 17,67$  kg) young men volunteered to participate to this study. To elicit blood oxidative stress all subjects performed the leg extension RE test at 5 different but progressive intensities: 1) 1x17 reps at 50% of 1RM; 2) 1x14 reps at 60% of 1RM; 3) 1x12 reps at 70% of 1RM; 4) 2x5 reps at 80% of 1RM; 5) 3x3 reps at 90% of 1RM, with 5 min rest between intensities and 90 sec rest between sets. The RE intensities were standardized for total volume. Blood samples were drawn before (PRE), immediately post each intensities (T50%, T60%, T70%, T80% and T90%) and after (30 min post = T30min, 60 min post = T60min and 24 h post = T24h) the RE in order to analyze LHP, AOPP, PCO, 8-OHdG, total GSH and SOD. **Results** In response to progressive intensity of RE; LHP significantly increased during the test and then significantly decreased in recovery period in both groups, the T24h LHP level was lower than PRE LHP level. During the test AOPP level decreased and later increased. In recovery period the T30min AOPP level was significantly lower than PRE and T24h AOPP level. PCO and SOD significantly increased in both groups however 8-OHdG and GSH were not affected by the RE intensity. The results indicated that there were no significant training status (group) x RE intensity (time) interaction for examined variables. **Discussion** Most of the studies used only one or two oxidative stress biomarker that makes it difficult to explain effects of RE on oxidative stress precisely (Dixon et al., 2006; Hoffman et al., 2007). On the other hand different RE intensities may affect biomarkers in contrast (Hudson et al, 2008).

Results suggest that for standardized exercise volume RE-intensity increased oxidative stress responses both in RE trained and untrained young men. References Dixon CB, Robertson RJ, Goss FL, et al. ### DOES AEROBIC TRAINING COUNTERACT CANCER-INDUCED SKELETAL MUSCLE WASTING?

Campos-Ferraz, P.L., Alves, C.R.R., Carnevali Jr, L.C., Lira, F.S., Rosa, F.O., Almeida, N.R., Brum, P.C., Seelaender, M., Gualano, B., Lancha Jr, A.H.

*University of Sao Paulo*

**Introduction:** It is currently unclear whether aerobic training can mitigate the skeletal muscle wasting in cancer-induced cachexia. The present study aimed to examine the impact of moderate-intensity aerobic training on skeletal muscle mass and oxidative stress in Walker 256 tumor-bearing rats. **Methods:** Male adults Wistar rats were randomly allocated into three groups: 1) control (CON; n=5), 2) Walker 256 (W; n=7) and 3) Walker 256 + aerobic training (WT; n=10). The WT group was submitted to 8 weeks of aerobic training 5 days a week; 60 min per session at 60 % of VO<sub>2</sub> max). After 6 weeks of aerobic training, WT and W groups were inoculated with Walker-256 tumor cells (2.10<sup>7</sup> for each rat). Subsequently, WT group were submitted to 2 additional weeks of aerobic training. All animals were killed by decapitation and gastrocnemius were isolated, weighed, and deep frozen for further analyses of lipid hydroperoxidation. Data are expressed as mean ± standard deviation. **Results:** Gastrocnemius weight was significantly higher in the CON compared to W and WT groups ( $p < 0.05$ ), but no significant differences were observed between the W and WT groups ( $p > 0.05$ ) (CON =  $2.03 \pm 0.37$  vs. W =  $1.46 \pm 0.33$  vs. WT =  $1.56 \pm 0.18$  g). Additionally, lipid hydroperoxidation were comparable in the W and WT groups (CON =  $22.9 \pm 6.3$  vs. W =  $32.2 \pm 27.2$  vs. WT =  $33.8 \pm 6.3$  nmol-mg<sup>-1</sup>;  $p > 0.05$ ). **Discussion:** Gastrocnemius mass was reduced in the W group, suggesting that Walker 256 tumour-bearing rats were in a cachexia process and skeletal muscle wasting. Lipid hydroperoxidation remained unchanged in both W and WT groups. Aerobic training did not affect either the skeletal muscle mass or the oxidative stress marker. **Conclusion:** These data suggest that therapeutic moderate-intensity aerobic training has no effect on muscle mass in an aggressive experimental model of cancer-induced cachexia. Further experiments are warranted to confirm these preliminary data, testing different types and intensities of exercises in a broad spectrum of cachexia stages. **References:** Dimeo FC, Tilmann MHM, Bertz H et al. ### CRITICAL POWER DOES NOT CORRESPOND TO MAXIMAL LACTATE STEADY STATE

Groves, E.M., Sasso, J.P., Aylwin, A.J.M., Neil, R., Smith, D.J.

*University of Calgary*

**Introduction** Critical power (CP) is often considered to be the threshold of aerobic energy production and the highest power output at which ventilatory and metabolic variables attain a steady state. However, the original study inaccurately defines steady state, which leads to a misinterpretation of maximal lactate steady state (MLSS) and its subsequent association with CP (Poole et al. 1988). The purpose of this research was to compare MLSS, defined as the highest power output where blood lactate (Bla) slope is 0mM/min, and CP. **Methods** Seventeen male subjects (29+/-5.8yrs, 74+/-7.8Kg, 178+/-4.9cm) participated in one incremental exercise test and 6 constant load rides of varying power outputs on an electronically braked cycle ergometer on separate days. Three rides were to exhaustion (ranging 3 to 15min) to determine CP and 3 rides were used to establish MLSS zero (MLSSz). Blood lactate was collected every 5min and the resulting slope was plotted against power output to determine MLSSz (Neupert et al. 2006). Subjects were blinded to all power outputs, elapsed time and times to exhaustion. **Results** Maximal oxygen consumption and power output were 48.3+/-3.5ml/Kg/min and 355+/-39W, respectively. Critical power (245+/-40W) was significantly higher than MLSSz (212+/-32W)  $p < 0.001$ . Interpolating to the maximum power output possible within the traditional 1mM change in Bla (i.e. a slope of 0.05 mM/min) resulted in an MLSS at 221+/-33W, which remained significantly lower than CP ( $p < 0.001$ ). Conversely, extrapolating the MLSSz model to CP resulted in a mean Bla slope of 0.185+/-0.072mM/min or an increase of 3.7mM over 20min at CP. **Discussion** The current results show that in active individuals, CP does not correspond to MLSSz or the broader traditional definition of MLSS. It is also in agreement with McLellan & Cheung (1992) who showed a significant difference between CP and the individual anaerobic threshold. This refutes the often-quoted paradigm that CP and MLSS represent the same physical intensity (Poole et al. 1988). The power-duration relationship provides a theoretical framework for understanding the physiology of exercise tolerance and is an accurate tool for predicting performance (Morton 2006). However, it is only a parametric model, and as shown here, CP does not represent the MLSS intensity it commonly purports to. **References** McLellan, T. M. and Cheung, K. S. (1992). *Med Sci Sports Exerc*, 24(5), 543-550. Morton, R. H. (2006). *Eur J Appl Physiol*, 96(4), 339-354. Neupert, E., Smith, D. J. and Norris, S. R. ### THE EFFECT OF DOMESTIC TRAVEL ON PERFORMANCE DURING AND RECOVERY FOLLOWING COMPETITIVE FOOTBALL MATCHES.

Duffield, R.

*Charles Sturt University*

THE EFFECT OF DOMESTIC TRAVEL ON PERFORMANCE DURING AND RECOVERY FOLLOWING COMPETITIVE FOOTBALL MATCHES. Duffield R.1, Fowler P.1, Vaile J.2 1. School of Human Movement Studies, Charles Sturt University, AUSTRALIA. 2. Performance Recovery Centre, Australian Institute of Sport, AUSTRALIA. **Introduction** Travel is a necessary demand for professional footballers, although there is little evidence

on the effect of domestic in-season travel on player performance and recovery. The aim of this study was to investigate the effect of domestic travel on the physiological, perceptual and performance responses to home v away matches in professional (Australian) football players. Methods Six male, football players from a professional A-League Club were recruited for this study. Following familiarisation, data was collected from 3 pairs of home and away games (n=6) involving the same three opposition teams (travel time = 5–8h). Data collection occurred on the 2 days prior, match day and 2 days following each match. Measures included urine specific gravity (USG) for hydration status, actimetry measures of sleep quantity and quality and subjective perceptions of sleep quality, fatigue, stress and muscle soreness. Match performance was determined from the result (win/draw/loss) and goal difference (goals for - goals against). Physical match load was determined via Global Positioning Satellite measures of movement demands, whilst technical performance was assessed from video coding of match technical outcomes (passes, tackles, possessions etc). Effect size analyses (Cohen's d) were used to determine the magnitude of effect of home v away matches on performance and recovery. Results Reduced match performance was evident during away matches with increased losses and goals conceded ( $1.2 \pm 2.2 \pm 0.8$  goals;  $d > 1.0$ ). Further, technical performance was reduced during away matches with fewer passes completed and increased turnovers, corners conceded and opposition attempts on goal ( $d > 1.2$ ). Physical performance during away matches resulted in an increased mean speed compared to home matches ( $119 \pm 8$  v  $111 \pm 6$  m.min<sup>-1</sup>;  $d = 1.6$ ), with trivial effects ( $d < 0.3$ ) for playing duration ( $81 \pm 9$  v  $84 \pm 7$  min) or high-intensity running distance. Pre-match USG did not differ ( $d < 0.3$ ), but was higher 2 days following away matches ( $d = 0.80$ ), while sleep duration was lower 2 days following away matches ( $465 \pm 88$  v  $384 \pm 82$  min;  $d = 1.3$ ). Subjective sleep quality, stress and muscle soreness did not differ between conditions ( $d < 0.3$ ), although perceived fatigue was increased 2 days following away matches ( $d = 0.9$ ). Conclusion Away matches resulted in inferior match outcomes, likely due to reduced technical performance alongside increased physical match loads; although, the domestic travel seems to have minimal physiological or perceptual effect to explain such outcomes. Following away matches, altered sleep patterns, hydration status and increased perceptions of fatigue were evident, suggesting an exacerbated post-match recovery, which may be of importance for ensuing weekly preparation cycles.

### HIGH INTENSITY INTERVALS WITH INCOMPLETE RECOVERY: COMPARING CYCLING TEAM PURSUIT RACE STRATEGIES

Bartram, J.2, Martin, D.T.2, West, N.2,3, Stephens, J.1, Michaels, S., Halson, S.L.1

1: AIS Performance Recovery (Canberra, Australia), 2: AIS Physiology (Canberra, Australia), 3: Griffith University (Gold Coast, Australia)

Introduction For aerodynamic reasons, a team pursuit cyclist riding at 60km.h<sup>-1</sup> will produce ~600W in the lead position but ~400W when drafting (Broker et al., 1999). The purpose of this study was to simulate two team pursuit race strategies varying the rate of positional changes. Strategies were simulated such that total time as the lead rider was consistent (1min), but with varied compositions (4x15s versus 3x20s). Methods Male competitive cyclists (n=31; 20.0±1.6yr, 70.2±7.0kg, 355±35W MAP; mean±SD) completed 37d of structured training. Training included daily rides of 2-8 h and cycle ergometer (Wattbike) sessions 3 d.wk<sup>-1</sup>. Included within an extensive ergometer session were two pursuit-specific interval sets (4x15s, 45s rec at ~250W; 3x20s, 60s rec at ~250W) simulating 1 or 1.5 lap changes in lead position. Both team pursuit interval sets resulted in 1min of high intensity work and 3min of incomplete recovery. Reliability of high intensity power produced during interval sets over one wk was calculated as typical error (TE). A priori planned contrasts (paired t-test) was used to compare each cyclist's best efforts of the two approaches, provided that corresponding incomplete recovery powers were comparable (±5W). Influence of within group cyclist ability was also explored by establishing two sub samples (Low, High) based on the magnitude of power increase from incomplete recovery to effort. Results TE for 1min of high intensity power for both interval sets was ~7% (37W). Best interval power for 1min of total work was similar for 1 and 1.5 lap strategies (577±116W vs 588±108W), a difference (mean±90% CI) of 1.4±1.6% (p=.14). Differences were similar for both sub samples (Low 1.9±2.2%, p=.14; high 0.9±2.7%, p=.56). Based on our testing conditions and a minimum worthwhile difference of 2% these differences could be considered "trivial" and "unclear". Discussion Cycling power during a simulated pursuit does not appear to be compromised by performing 3x20s efforts compared to 4x15s efforts with incomplete recovery. This finding was observed regardless of the magnitude of power production by the cyclists involved. Reducing interval number from 4 to 3 while increasing interval duration from 15-20s can be accomplished without a large decrement in work capacity within the conditions employed in this study. Further research with more reliable performance measures is required to evaluate the ~1.4% greater power produced during the 3x20s intervals. References Broker JP, Kyle CR, and Burke ER. Racing cyclist power requirements in the 4000m individual and team pursuits. *Med Sci Sports Exerc.* 1999. 31:1677-85.

### EFFECTS OF LIGHT EXERCISE ADDED TO CONTRAST-WATER IMMERSION ON RECOVERY AFTER AN EXHAUSTIVE INTERMITTENT EXERCISE.

DELEY, G., DENUZILLER, J., BABAULT, N.

*Faculty of Sport Sciences*

Effects of light exercise added to contrast-water immersion on recovery after an exhaustive intermittent exercise. G. DELEY, J. DENUZILLER, N. BABAULT Centre d'Expertise de la Performance Gilles Cometti, Dijon, France Introduction For athletes, the development of strategies that would optimize recovery and speed performance restoration is essential. Among them, contrast water immersion (CWI) is one of the most popular (Hing et al. 2008). Due to temperature changes, this technique is supposed to increase blood flow and enhance the removal of metabolic by-products, consequently speeding recovery (Vaile et al. 2008, Hing et al. 2008). However, it has been suggested that vaso-pumping induced by CWI might be insufficient to induce significant effects on blood flow (Wilcock et al. 2006). We hypothesized that adding light pedalling during water immersion might maximize the effects of recovery. The aim of the present experiment was therefore to investigate the efficacy of CWI associated with light pedalling to recover from an exercise inducing a great metabolic fatigue. Methods Thirty-three young healthy male subjects physically active participated in this study. They were randomly assigned to one of the three experimental groups: (i) passive contrast water immersion (CONTRAST), (ii) contrast water immersion with light pedaling (ACTIVE), and (iii) passive rest at room temperature (PASSIVE). Recovery was applied during 30 minutes after a fatiguing exercise composed of four Wingate Anaerobic Test (WANt) separated by 30 seconds of passive rest. Counter-movement jump, blood lactate concentration as well as peak power and mean power developed during a WANt were recorded before and immediately after the fatiguing exercise. Measurements were repeated after the 30-minute recovery intervention and after an additional 30-minute period of passive rest. Results After 30 minutes of the CONTRAST intervention, jump height was back to Pre values, whereas values were still depressed after 60 minutes in the other groups (P<0.05). Conversely, lactates were back to their initial values after 30 minutes of ACTIVE recovery (P<0.05), whereas 60 minutes and more were necessary for the PASSIVE and CONTRAST conditions. Performances to WanT were back to their initial values after 30 minutes of recovery, whatever the intervention. Discussion The present results are in favor of the utilization of CWI after an exhaustive exercise (as compared with passive). Surprisingly, we found that despite a greater clearance of blood lactate when light pedalling was added during CWI, jump performances returned faster to normal after passive immersion. These results suggest that the intervention to

be chosen depends on the aim of recovery (lactates elimination or subsequent performance). ### EFFECTS OF DOSE RESPONSE LOAD SQUAT JUMP TRAINING ON MUSCLE STRENGTH, STRUCTURE AND PERFORMANCE

Coratella, G., Annicchiarico, M., Trepin, M., Impellizzeri, F.M., Schena, F.

*University of Verona*

Introduction Squat jump training is a common method to improve athletic performance. The load that maximize power is around 30% of maximal dynamic strength, i.e. body weight only.(Cormie 2007) However, also weighted jump training has been proved effective to enhance jump or sprint(Mc Bride 2002) Few studies measured changes in muscle mass and architecture to better understand physiological mechanisms those lead to a better field performance. Aim or the study is to evaluate a dose response effect of weighted or un-weighted squat jump training on muscle strength, mass structure, jump and sprint ability. Methods Forty eight healthy students were randomly assigned to body weight only (BW), 25% body mass weighted squat jump training (WJ) and control group (CON).Isokinetic quadriceps strength(MVC), lower limbs total lean mass (DEXA), architectural adjustments (ultrasound), Squat jump (SJ), 30m dash, 20+20m shuttle and ability T test were assessed before and after 8 weeks of 60 maximal jumps, twice a week. All the dependent variables were analyzed after log transformation with ANCOVA using the baseline values as covariate and factor "group" as independent variable. Results No differences appeared in CON. Compared to baseline, BW improved MVC (23%,16 to 30,p<0,001), lean mass (2%,1 to 4 p<0,05), fascicle length (11%,7 to 16, p<0,001), SJ (10%,6 to 15, p<0,001), 20+20m(-3%,-5 to -1 p<0,05). Compared to baseline, WJ improved MVC(22%,15 to 29,p<0,001), lean mass(5%,3 to 7, p<0,001) fascicle length (5% 0 to 9,p<0,05), SJ(5%,0 to 10,p<0,05), 20+20m(-3%,-6 to -1,p<0,01), 30m(-3% -1 to -5,p<0,01). All parameters were significantly different from CON. BW had significant alterations in muscle architecture compared to WJ, while the latter improved 30m dash and T Test running test more than BW. Discussion Jump training improved task related quadriceps strength, also by an increment of lower limbs lean mass, that caused a power transfer in jumping and shuttle test. Greater velocity contractions in BW caused different architectural alterations(Blazevich 2003). Higher changing direction agility and sprint power could be related to increased strength expression in WJ. ### EFFECTS OF PULSED ELECTROMAGNETIC FIELD THERAPY ON SYMPTOMS ASSOCIATED WITH ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE

Banyard, H., Nosaka, K.

*Edith Cowan University*

EFFECTS OF PULSED ELECTROMAGNETIC FIELD THERAPY ON SYMPTOMS ASSOCIATED WITH ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE Banyard, H. 1, Nosaka, K. 1 1:Edith Cowan University (AUSTRALIA) Introduction Pulsed electromagnetic field therapy (PEMFT) sends magnetic waves to deep tissues to reduce pain and enhance injury recovery (1). It is expected that PEMFT is effective for alleviating symptoms associated with eccentric exercise-induced muscle damage (EIMD). One study (2) reported that 20-min PEMFT for 5 consecutive days after exhaustive eccentric contractions of the elbow flexors with a dumbbell significantly attenuated muscle soreness compared with a sham treatment. However other symptoms of muscle damage such as decreases in muscle strength, and blood markers (e.g., plasma creatine kinase activity: CK) were not examined in the study. The present study investigated the effects of PEMFT on several indirect muscle damage markers to test the hypothesis that PEMFT would be effective for EIMD. Methods Four men and seven women (24.1 ± 5.1 y) performed two bouts of 60 maximal isokinetic (30°·s<sup>-1</sup>) eccentric contractions of the elbow flexors on each arm separated by 4 weeks. In each eccentric contraction, the elbow joint was forcibly extended from a flexed (90°) to a fully extended position (0°). At immediately after and 1-4 days following the exercise, the exercised arm received either PEMFT or sham treatment by a device (E-cell®). The duration of the treatment was 30 min, but one with an active device and the other with a sham device that did not generate electromagnetic pulses. The arm dominance and the order of treatment conditions were randomised and counterbalanced amongst the subjects, and the study was conducted in a double-blinded manner. Dependent variables included maximal voluntary isometric contraction strength (MVC), range of motion (ROM), muscle soreness by a visual analogue scale (100 mm) and CK. Changes in the variables for 7 days following the exercise from baseline were compared between PEMFT and sham treatment conditions by a two-way repeated measures ANOVA. The changes in the variable from pre to post treatment were also analysed by a two-way repeated measures ANOVA. Results All variables changed significantly (P<0.05) following eccentric exercise such that MVC decreased to 55.3 ± 2.6% immediately post exercise and did not recover at 7 days post-exercise (85.2 ± 2.9% of baseline), moderate muscle soreness was induced (peak: 29.7 ± 4.4 mm), and CK increased (peak: 1705 ± 462 IU/L). However, changes in MVC, ROM, muscle soreness and plasma CK activity over time were not significantly different between conditions. No significant changes in variables were evident from pre to post treatment for any days for neither condition. Discussion The results did not support the hypothesis that the PEMFT could alleviate muscle soreness and enhance recovery from EIMD. References 1) Foley-Nolan et al. ## IS-SH08 Life-Style Sports and Youth Development

**DETTE ER MEKKA! LIFESTYLE SPORTS AND YOUTH'S LEISURE-SPORT LIFESTYLES IN NORWAY**

Green, K.

*University of Chester*

Based on quantitative data from the Norwegian Statistisk Sentralbyrå (Statistics Norway) study of Mosjon, Friluftsliv and Aktivlivstill (Vaage, 2009), this paper explores Norwegian youths' engagement with conventional and lifestyle sports via an examination of recent trends. Norway boasts some of the highest levels of sports participation and adults as well as young people. Indeed, young Norwegians are the quintessential sporting omnivores. Nevertheless, among the age group where regular participation peaks in Norway, 16-19-year-olds, the popularity of games declined while participation in lifestyle sports continued to increase over the decade 1997-2007 (Vaage, 2009). It seems that the particular mix of conventional and lifestyle sports that Norwegian youngsters favour has shifted within a generation, with lifestyle activities far more prominent in 2007 than they had been even a decade earlier. One particular area of sporting participation strongly associated with Norwegian culture – friluftsliv (outdoor life) – has undergone particularly marked changes in participatory terms among young people. The changes in participation in outdoor sports in general and friluftsliv in particular appear to represent a shift among Norwegian youth to sports and physical activities that offer alternative forms as well as types of participation to conventional sports. In conclusion, the paper will draw upon these findings in order to tentatively hypothesize developments in youth leisure-sport. Vaage, O.F. (2009). Mosjon, Friluftsliv og Kulturaktiviteter. Resultater fra Levekarsundersøkelsene fra 1997-2007. Rapport 2009/15. Oslo-Kongsvinger: Statistisk Sentralbyrå.

**LIFESTYLE SPORT, PUBLIC POLICY AND YOUTH ENGAGEMENT**

Wheaton, B.

*University of Brighton Trevin Towers*

Images of 'lifestyle sport' participants (e.g. parkour, skateboarding, and surfing) have focused on their reckless, hedonistic and anti-social behaviour (c.f. Wheaton 2004; Wheaton 2010). In this paper I consider a recent discursive shift, whereby lifestyle sports are being repositioned by civic authorities, educationalists and policy makers as tools of youth engagement. The paper will discuss the emergence of these non-traditional, informally-organised sports as tools for policy makers (e.g. Bradley 2010), and the potential role they can make in terms of encouraging youth engagement, physical health and wellbeing. My main case study will be the emergence and development of parkour (Gilchrist and Wheaton 2011), and its use in public policy debates and initiatives around youth, physical activity, and risk in England. I explore the potential of parkour to engage communities, particularly those traditionally excluded from mainstream sport and physical education provision, discussing how the perceived success of parkour in these different contexts is related to the culture and ethos of the activity which is, anti-competitive, more inclusive and less rule-bound than most traditional sports; and to its ability to provide managed risk-taking. The paper will therefore contribute to on-going debates about the (in)ability of traditional sports to meet government targets for sport and physical activity participation, and the need to put lifestyle sport on the policy radar (Tomlinson et al. 2005). **WHAT'S IN IT FOR ME? LIFESTYLE SPORT AND POSITIVE YOUTH DEVELOPMENT**

Säfvenbom, R.

*Norwegian School of Sport Sciences*

As an extension of relational developmental systems theories on human development (Overton, 2010), theories on Positive Youth Development (PYD) have grown during the last decade (Lerner, et al., 2011). PYD-theory is concerned about outcome variables indicating thriving adolescents, yet first of all emphasizes the developmental process in terms of developmental regulation across ontogeny, integrated actions, relative plasticity, and thus optimism. According to the theory, the potential for plasticity at both individual and contextual levels constitutes a fundamental strength of all human's development (Silbereisen & Lerner, 2007). Based on in-depth interviews with three young lifestyle activity practitioners (longboarding, tricking and skydiving) and their experiences from both organized, traditional sports promoted by local sports clubs and more-or-less self-organized lifestyle activities, lifestyle activity contexts are discussed as developmental assets for youth. According to the adolescents' reflections on the magnitude of relative plasticity in traditional sports versus lifestyle sports, it is argued that traditional sports and lifestyle sports reveal adolescents' potentials differently, and that traditional sports often conceal more than they reveal about human potential. The paper claims that (1) if policy makers are concerned with improving life chances (e.g. lifetime activity alignment) of diverse youth, youth has to be viewed as resources to be developed and not as problems to be managed (Silbereisen & Lerner 2007: 7) and (2) if we really want to see more happy adolescents involved in movement activities, contexts based on non-traditional, new, explorative, lifestyle activities should be supported and funded at the same level as traditional sports (Säfvenbom et al., in rev). ### IS-BN06 Biomechanics and Injury Prevention in Elite Sports (\*)

#### GENDER SPECIFIC JOINT LOADS IN SOCCER

Gehring, D., Gollhofer, A.

*University of Freiburg*

Female soccer players have by far higher incidence rates to suffer from anterior cruciate ligament (ACL) injury than males (Agel et al., 2005). Due to recent findings about the complex shoe-surface interaction in soccer, the aim of this presentation is to review the current state of ACL injury research with a specific focus on the female soccer player and the equipment used. Based on the phenomenon of the increased ACL injury rates in women, much effort was made to evaluate the underlying etiology. Recent research suggests systematic differences in joint specific loading and whole body biomechanics between genders. Factors like increased knee abduction angles and moments, differences in activation patterns of flexor and extensor muscles, alterations in trunk control and anatomical specifications are suggested to result in increased ACL load during soccer specific movements in women (Hewett et al., 2006a). Various injury prevention programs were developed based on these recent findings about the gender specific knee joint loading. Neuromuscular training programs, comprising muscle strengthening, balance training or technique feedback, were shown to reduce the number of ACL injuries effectively (Hewett et al., 2006b). Beside these interventions, which aim to improve intrinsic factors of the athlete, modifications of the athlete's equipment may additionally have an effect on the injury outcome. In this context a very special feature is the cleated soccer shoe, which provides the traction needed on natural or artificial grass (Sterzing et al., 2010). However, the traction provided in the complex shoe-surface interaction seems to be a crucial factor for ACL loading, as systematic modifications in shoe traction were shown to result in systematic modifications in knee joint loading (Stefanyshyn et al., 2010). In light of these findings, consequences for cleat construction and gender-specific soccer shoe design will be discussed. In particular, it will be shown that alterations in the weight of the soccer shoe can influence knee joint abduction moments especially in female soccer players. #### CHARACTERISTIC EMG PATTERNS IN ELITE X/C ATHLETES WITH A HISTORY OF ANTERIOR COMPARTMENT PAIN - IMPLICATIONS FOR EARLY DIAGNOSIS AND FOR INJURY PREVENTION STRATEGIES

Federolf, P.A.

*Norwegian School of Sport Sciences*

Pain syndromes are common signs of overuse injuries in running, cross country skiing and related sports. The nature and characteristics of many chronic injuries have been described in detail, however, strategies for their prevention remain largely unknown. Important first steps for the development of effective prevention strategies would be an early identification of athletes that may be at risk of developing overuse injuries or the identification of movements that may contribute to their development. The physiological changes that lead to the development of a chronic injury may be accompanied by adaptations in the neuromuscular control of an athlete's movement. Detecting such adaptations in surface electromyographic (sEMG) signals may therefore offer one avenue to the development of effective prevention strategies. The wavelet transformation of the EMG signal, as proposed by von Tscharnner (2000), presents a promising technique for the detection of changes in muscle activation patterns that may be indicative of neuromuscular adaptation processes. In a recent study we investigated a group of young elite cross country skiers with a high incidence rate of chronic anterior compartment syndrome (CACS). The objective was to determine if the muscle activation patterns of athletes with a history of anterior compartment pain (symptomatic group) differ from pain free athletes in the same group (reference group). A first observation of this study was that the EMG power spectrum of the affected muscle (tibialis anterior) differed between athletes in the symptomatic and in the reference group (mono-modal versus bi-modal frequency spectrum). It has been suggested that such spectral differences might indicate differences in fibre type recruitment (Wakeling et al., 2002; von Tscharnner, Goepfert, 2006). A second observation of this study was that the differences were most obvious in the gliding phase, when the subjects were supported only by the instrumented leg while the contralateral leg and the arms were in a swing phase. This suggests that the neuromuscular control of balance may play a role in anterior compartment pain and potentially in the development of CACS. Both of these results may prove to be clinically useful in the future. The first result might help develop an early indicator of athletes that are at risk of developing CACS. The second result might help to better understand what movements are critical for the development of CACS. This might help establishing prevention programs, for example, specific balance training exercises. References: von Tscharnner V. #### BIOMECHANICS AND INJURY PREVENTION IN ELITE ALPINE SKIING

Kröll, J., Spörri, J., Gilgien, M., Chardonens, J., Müller, E.

*University of Salzburg*

BIOMECHANICS AND INJURY PREVENTION IN ELITE ALPINE SKIING Kröll, J.1, Spörri, J.1, Gilgien, M.2, Chardonens, J.3, Müller, E.1 1: IFFB-US (Salzburg, Austria), 2: NSSS (Oslo, Norway), 3: EPFL (Lausanne, Switzerland) Introduction Data obtained by the International Ski Federation (FIS) Injury Surveillance System illustrated an alarmingly high injury risk for elite alpine ski racing (Florense et al, 2009). One of the main contributors to the injury situation seems to be the ski-plate-binding-boot system (Bere et.al. 2011, Spörri et al. 2010). Therefore the FIS launched a scientific project which should serve as a base for a new regimentation. The current presentation illustrates the process from a "qualitative interview survey" via "experimental prototype studies" to the "support of decision making units with scientific results" for giant slalom. Methods Based on existing knowledge (Bere et.al. 2011, Spörri et al. 2011) together with FIS and ski manufacturers a definition process for prototypes occurred. Limiting factors for the definition were technical (by ski manufacturers) so as controllability possibili-

ties (by FIS). The three prototypes (GS30, GS35, GS40) differed compared to the actually used equipment (GS27) in radius (>30m, >35m, >40m), minimum with (<65mm) and length (>195). Active and recently retired World Cup racers have tested the prototypes among several experimental conditions. During the biomechanical experiments athlete's kinetics (pressure insoles), kinematics (video based 3D reconstruction, GNSS, Time) and qualitative judgment in terms of safety aspects were captured. Results and Discussion The biomechanical analysis depicted no differences between GS27 and GS30. Comparing GS35 and GS40 with GS27 with respect to the occurring forces, differences in the order of 2% and 3.8% were found. Those numbers go in line with the findings for turn speed and run times. The force distribution among the turn alters in the way that towards turn end the forces seem to substantially decrease with GS40, which is with respect to specific ski racing injury mechanisms (Bere et al. 2011) of importance. The qualitative judgment of the not quantitative measurable parameters (e.g. aggressiveness of the Ski) for the prototypes with the substantially increased radius revealed a remarkable difference towards more safety. Consequently only radical changes will lead to substantial improvement in terms of safety. References Bere, T., Florenes, T. W., Krosshaug, T., Koga, H., Nordsletten, L., Irving, C., Bahr, R. (2011). #### THE OBSERVATION OF A SOCIAL INTERACTION SPECIFICALLY MODULATE HUMAN CORTICOSPINAL SYSTEM

Ippolito, D., Bucchioni, G., Cavallo, A., Matron, G., Castiello, U.

*University of Padova, University of Torino*

THE OBSERVATION OF A SOCIAL INTERACTION SPECIFICALLY MODULATE HUMAN CORTICOSPINAL SYSTEM Ippolito, D.1, Bucchioni, G.2, Cavallo, A.3, Marton, G.1, Castiello, U.2 1: DSB-UNIPD (Padova, Italy), 2: DPG-UNIPD (Padova, Italy), 3: DPT-UNITO (Torino, Italy) Introduction It is well known that when we observe another individual acting, we resonate with her action, as revealed by an enhancement of motor evoked potentials (MEPs) in muscles corresponding to those involved in the observed action (Fadiga et al. 1995). What remains unclear is if the viewer's motor facilitation varies depending on context. In the present study, we investigated whether facilitation of the corticospinal system (CS) during the observation of an action differs depending on the presence of a social interaction. Methods 23 right-handed volunteers were tested. All participants were free from any contraindication to transcranial magnetic stimulation (TMS) (Rossi et al. 2009). Two types of video representing individual action (i.e., throwing a ball) or social interaction (i.e., throwing a ball to a partner) were utilized as experimental stimuli. SpTMS and MEP recording were used to investigate CS excitability during the stimuli observation. TMS coil was placed over the left primary motor cortex corresponding to the area where the flexor carpi ulnaris, FCU and the abductor digiti minimi, ADM are cortically represented. MEPs from the right FCU and the right ADM muscles were acquired for each condition. Results The repeated measure ANOVA on normalized MEP amplitudes yielded a statistically significant main effect of type of action for both the FCU ( $P < 0.05$ ) and ADM ( $P < 0.01$ ) muscles. Post hoc comparisons indicated MEP amplitude for both the FCU ( $P < 0.05$ ) and ADM ( $P < 0.01$ ) muscles were greater for the social than for the individual condition. Discussion The results of the present study show that during the observation of an action performed in a social context, the mean amplitude of MEPs recorded from the FCU and ADM muscles was significantly greater than those recorded when observing the same action performed in a context which did not entail a social interaction. These findings are consistent with previous studies. For example Oberman et al. (2007) have demonstrated that the observation/execution matching system is sensitive to the degree of social interaction of the observed action. Moreover, activation of action observation system is stronger during observation of actions performed by an interacting partner than for the actions performed alone (Kourtis et al. 2011). Along these lines, our findings show that the human CS is modulated by the social nature of observed actions. #### VALIDATION OF A FIVE-ITEM NEIGHBORHOOD ENVIRONMENT SCALE: EVIDENCE FROM GREECE

Theodoropoulou, E., Karteroliotis, K.

*National and Kapodistrian University of Athens*

Introduction Recent studies have indicated that neighborhood environment has a positive impact on physical activity (Ishii et al., 2010). Despite its important role, there are not validated and reliable scales to assess perceived neighborhood environment in Greece. Therefore, the aims of the current study were to examine the factorial validity and reliability of the Greek version of a neighborhood environment scale, which presented satisfactory validity (Ishii et al., 2010). Methods Participants were 340 volunteers that attended the physical education classes at the University of Athens. To test the factorial validity, two samples were used. The first sample (N=150) were 77 men and 73 women (24.28±6.32 yrs), whereas the second sample consisted of 86 men and 64 women (22.85±5.64 yrs). An Exploratory Factor Analysis (EFA) was conducted with the first sample. The extraction method employed was principal axis factor followed by promax rotation (Russell, 2002). A Confirmatory Factor Analysis (CFA) (maximum likelihood method) was performed with the second sample to confirm the goodness of fit of the model found in EFA. The CFA was conducted using the AMOS 16.0 statistical software (Arbuckle, 2007). Assessment of model fit was based on  $\chi^2$ ,  $\chi^2/df$ , CFI, GFI, IFI, TLI and RMSEA indices (Kline, 2005). To test the internal consistency, the Cronbach's alpha ( $\alpha$ ) coefficient was used. To examine the test-retest reliability, 40 students, 21 men and 19 women (28.78±5.647 yrs), completed this scale twice with an interval of 15 days between the two assessments. Results The Kaiser-Meyer-Olkin (0.778) and the Bartlett Test of Sphericity ( $\chi^2=318.18$ ,  $df=10$ ,  $p=0.00$ ) were satisfactory. EFA yielded one factor accounted for 60.96% of the variance of the model (item factor loadings=0.52-0.86,  $\alpha=0.84$ ). Similarly, CFA showed that this model presented a good fit ( $\chi^2=3.441$ ,  $df=4$ ,  $p=0.487$ ,  $\chi^2/df=0.860$ , CFI=0.990, GFI=1.000, IFI=1.002, TLI=1.004, RMSEA=0.000, item factor loadings=0.66-0.81,  $\alpha=0.86$ ). The test-retest reliability

coefficient was 0.87. Discussion The results revealed that the neighborhood environment scale was a valid and reliable instrument. The aforementioned findings show that this scale is a useful tool for studies focusing on environmental factors, which may act as facilitators or barriers to physical activity. Additional research is needed to further the knowledge about its validity and reliability using other samples of Greek adults. References Ar buckle JL. (2007). Amos 16 user's guide. ### THE ROLE OF SELF-IDENTITY AS A COMPONENT OF THE THEORY OF PLANNED BEHAVIOR IN PREDICTING PHYSICAL ACTIVITY

Ries, F., Hein, V., Pihu, M.

*University of Seville - Faculty of Educational Sciences*

Among the variables proposed as useful additions to the structure of the Theory of Planned Behavior (TPB; Ajzen, 1991), there is evidence for the predictive usefulness of a measure of self-identity. The main purpose of this study was to test the hypothesis that self-identity is an independent predictor of physical activity (PA) intention and behavior in adolescents. School students (N = 397) from Estonia and Spain completed an initial questionnaire assessing the TPB constructs of attitude, subjective norms, and perceived behavioral control, as well as self-identity and intrinsic motivation in a leisure-time PA context. Four weeks later, participants completed a follow-up questionnaire that assessed self-reported PA during the previous four weeks. Several structural equation models were constructed. Self-identity had a direct effect on PA intention ( $\beta = .33$ ,  $p < .01$ ) and behavior ( $\beta = .31$ ,  $p < .01$ ). The hypothesized model accounted 67% of the variance of intention and 45% of PA behavior. To confirm the hypothesis that intention mediated the effect of self-identity on PA behavior the direct path from self-identity was fixed to zero. The effect of intention on PA behavior ( $\beta = .61$ ,  $p < .01$ ) increased indicating that partial mediation occurred. Overall, the results provide support for an extended version of the TPB incorporating self-identity.

### A MULTIDIMENSIONAL MEASURE OF CHILDREN'S WELL- AND ILL-BEING: INITIAL VALIDATION OF A NEW PSYCHOMETRIC TOOL.

Bracey, S., Qusted, E., Duda, J.L.

*University of Birmingham*

A MULTIDIMENSIONAL MEASURE OF CHILDREN'S WELL- AND ILL-BEING: INITIAL VALIDATION OF A NEW PSYCHOMETRIC TOOL. Bracey, S.J., Qusted, E., Duda, J.L. School of Sport and Exercise Sciences, University of Birmingham (Birmingham, UK) Introduction: Indices of subjective well-being and life satisfaction, commonly utilized to measure well-being in youngsters, were developed with adult populations. Moreover, existing measures of well-being tend to assess only positive indicators of functioning, not potential facets of experienced ill-being. Well- and ill-being are posited as independent albeit often inversely related constructs (Ryff et al., 2006). Addressing these gaps in the literature, a multidimensional measure of children's well- and ill-being was developed. Items were developed from children's qualitatively assessed conceptualizations of well-/ill-being as well as a consideration of item content contained within existing measures of emotional and physical health of children (Bracey et al., 2011). Extending this line of work, the present study tested the psychometric properties of the new multi-dimensional questionnaire. Method: Children (N=704) aged 7-11 years old (M = 9.33, SD = 1.16) comprising 387 males and 302 females (15 participants did not report gender) completed the 70-item questionnaire tapping multiple indicators of well- and ill-being. The questionnaire asked children to rate their well-/ill-being over the past month (e.g., 'I was full of energy...'; 'I felt like crying...') using a 5-point Likert scale (1 = never to 5 = always). Exploratory factor analysis with principal axis factoring (PAF) were conducted. Confirmatory factor analysis (CFA) will be conducted with an independent dataset. Factors were extracted with PAF and direct oblimin rotation. Results: A 43 item hierarchical structure with 6 second order dimensions (i.e., depression/anxiety, lethargy, physical ill-being, vitality, serenity, secure/inspired) was revealed. Cronbach's Alphas for all dimensions were acceptable to good: DEP/ANX .89; LET .73; PIB .76; VIT .85; SER .72; SEC/INS .61. Discussion: These findings support the perspective that children's well- and ill-being is multidimensional. Future work is required to confirm the factor structure and to examine the psychometric properties of the measure with different aged children. References: Bracey, S. J., Qusted, E., & Duda, J. L. ### OP-PM43 Health and Fitness: Youth population

#### INTERACTION OF SEDENTARY ACTIVITY, SPORTS PARTICIPATION, AND PHYSICAL FITNESS WITH BODY COMPOSITION IN CHILDREN

Drenowatz, C.1, Kettner, S.1, Kobel, S.1, Fischbach, N.1, Steinacker, J.M.1

*Ulm University*

1: Ulm University Medical Centre (Ulm, Germany) Introduction The increasing prevalence of childhood overweight and obesity warrants further research on the interaction of various behavioural and physiologic aspects. While the effect of single components contributing to weight gain have been addressed only limited research is available on the combined association of sports participation, physical fitness, and time spent watching TV with body composition; thus the purpose of this study. Methods Baseline data from a large school-based intervention in southern Germany funded by the Baden-Württemberg Stiftung was used. 1594 children (809 male; 785 female), 7.1±0.6 years of age with no reported chronic disease were included in the analysis. Height and weight was measured by trained technicians and BMI was calculated and converted to BMI percentiles (BMIPCT) to determine normal weight, overweight and obesity. Sports participation and time spent watching TV was assessed via parent questionnaire and fitness was determined based on the results of the DKT

fitness test (Graf et al. 2004). 2-way ANCOVA, controlling for age and sex, using tertiles for fitness and sports participation groups (high, medium, low) as well as 2 groups for TV time (up to 60 min/day; more than 60 min/day) were used to examine combined effects on BMIPCT. Continuous scores for sports participation, fitness, and TV time were also used in one-way ANCOVA to determine differences between normal weight, overweight and obese subjects. Results Prevalence of overweight and obesity was 8.5% and 5.4%, respectively. There was no difference between boys and girls in BMIPCT. No interaction effects of fitness, sports participation or sedentary behaviour on BMIPCT occurred but significant main effects were observed for fitness and TV time. Higher TV time and lower fitness scores were associated with higher body weight. Similar results occurred when examining the different weight categories. Only TV time and fitness differed significantly between normal weight, overweight, and obese subjects, while no difference was seen for sports participation. Discussion Time spent watching TV and physical fitness independently influence body weight, while no effect of sports participation on body composition in children was shown. The lack of significance may be due to subjective assessment but could also be a reflection of lower sports participation in children in relation to their habitual physical activity. Overall, more research using objective measurements is needed to examine the combined association of various behavioural and physiological components contributing to weight gain in children. ### ASSOCIATIONS BETWEEN WEIGHT STATUS AND MOTOR COORDINATION DURING CHILDHOOD

Lopes, V.P., Stodden, D.F., Rodrigues, L.P.

*Polytechnic Institute of Braganca*

Introduction Ordinarily the relationship between obesity, physical activity (PA) and motor coordination (MC) is analyzed having in mind that low levels of PA cause obesity and low MC. But MC was found to be predictor of both PA (Lopes et al. 2011) and adiposity (Lopes et al. 2011). The purpose of this study is to analyze the association between MC and weight status. Methods Participants were 6,625 children (boys n = 3,344; girls n = 3,281), aged 6 - 10 years. Body mass index (BMI) was calculated from height and weight. MC was evaluated using the body coordination test (KTK). A factorial ANOVA was conducted using BMI as dependent variable. A binary logistic regression using two weight status categories as the dependent variable was performed. The odds ratios were calculated for weight status and MC tertiles separately in boys and girls, controlling for age. Results BMI significantly increases across age groups (F (5, 6224) = 50.59; p < 0,001). Children with higher MC showed lower BMI levels (F (10, 6224) = 4.53; p < 0.001). The differences in BMI among MC tertile groups became larger across age (F (10, 6224) = 4.53; p < 0.001). Girls in the first and second tertiles of MC distribution had respectively 3.47 and 1.63 more chances of being overweight/obese than girls in the third tertile. Boys in the first and second MC tertiles had respectively 3.90 and 2.08 more chances of being overweight/obese than boys in the first tertile. Discussion The findings show that children with lower MC had higher BMI than children with higher MC, and this difference became larger across age. The risk of being overweight/obese is higher in children with lower MC. We suggest that the relationship between MC, BMI and PA changes with age. At very young ages, till 4 - 5 years, the levels of PA are extremely important to MC and skills development and to weight control (Bürgi et al. 2011). During subsequent years and until puberty, children's weight status across time may be indirectly affected (from the direct result of PA and fitness levels) via the development of MC throughout childhood. Children who continue to develop higher levels of MC throughout childhood will be able to successfully engage in more movement opportunities promoting a healthy weight status (Stodden, Goodway et al. 2008). ### REDUCED MOTOR SKILLS IN KINDERGARTEN CHILDREN WITH CONGENITAL HEART DISEASE IN COMPARISON WITH HEALTHY CHILDREN

Engelhardt, A.1,2, Hess, J.2, Hager, A.2

*Technische Universität München*

Objective: Motor competence is of major importance for the interactions of individuals with their environment. School children with congenital heart disease are known to have limitations even with minor defects. Data from kindergarten children are missing. This study was to compare the motor development of kindergarten children aged 4-6 years with congenital heart disease with healthy peers of the same age. Patients and methods: Motor development was investigated in 62 children (19 female, 43 male) with various forms of CHD and compared to 39 healthy children (22 female, 17 male). All subjects performed the motor development test (MOT 4-6), answered the Kiddy-KINDL® quality of life questionnaire (as well as the parents) and wore an accelerometer to capture daily activity for seven consecutive days. Results: The median [quartile1; quartile 3] motor quotient (MQ) in the CHD group (104 [96;113]) was significantly lower than in the control group (111 [104;116]; Mann-Whitney-U test p=0.005). Quality of life did not differ significantly (p=0.774, parents' questionnaire p=0.066), nor the minutes in moderate and vigorous physical activity (p=0.093). No correlation between the MQ and the other variables could be shown. Conclusion: Kindergarten children with CHD have a reduced motor ability in comparison with healthy children. This reduction seems not to be related to physical activity or quality of life.

### SALIVARY IGA AND UPPER RESPIRATORY SYMPTOMS IN PORTUGUESE YOUNG SOCCER PLAYERS

Rama, L., Leitao, R., Rosado, F., Teixeira, A.M.

*Faculty of Sport Sciences and Physical Education of Coimbra*

Introduction: In sportive adult population, intense training or competition can induce immune alterations, namely, a decrease of salivary IgA (sIgA), predisposing to upper respiratory symptoms (URS) occurrence (Gleeson, M., 2004). Fewer studies were conducted with children involved in sport participation, looking for mucosal immune response. In young gymnasts, the sIgA at rest seems to be not affected (Filaire, Bonis, & Lac, 2004). It is generally accepted that sport activity at youth, brings benefits to the health, related to the immune function, as it develops at that time (Bartlett, et al., 1998). Most studies shown that more active children had lower illness episodes (Cieslak, Frost, & Klentrou, 2003) The aim of this study was to compare de sIgA response in U-10 soccer players with a control group of teammates which are not involved in physical activity. Methods: 12 young soccer players (U-10 level), training twice a week, and 11 controls, that were not involved in regular physical activity (less than 1 hour/ week), participate in this study held during the first 15 weeks of the training season. Anthropometric measurements and the maturation status were controlled. The Salivary IgA concentration was calculated through ELISA assays (Salimetrics, UK). During the study the URS episodes were recorded. Descriptive, independent t-test and repeated

measures statistics were used to analyze data. Significance was placed at  $p < 0.05$ . Results: When compared, the athletes show always significant higher sIgA values than non-athletes ( $p < 0.05$ ). However no variation of sIgA values was found within each group during the study period. The occurrences of URS shown by the controls was slightly higher than that of the athletes Conclusion: Young soccer players show higher sIgA values than less active counterparts. Although not significantly different, non-athletes tend to be more affected by URS than athletes. The weekly training schemas of this U-10 soccer player's don't affect the sIgA concentration. ### INDIVIDUAL, SOCIAL, AND ENVIRONMENTAL FACTORS ASSOCIATED WITH WALKING TO AND FROM SCHOOL IN PORTUGAL.

Rodrigues, L.P., Teixeira, S.

*Instituto Politécnico de Viana do Castelo*

In the present days, children are often restricted in their mobility and autonomy, resulting in a more inactive and less healthier life style. Traffic danger and social safety concerns are pointed as causes for these restrictions. Among them, commuting to and from school has become a usual behavior, setting apart the more healthier and autonomous walking to and from school. In fact, studies show that children are progressively more being driven by car and that the age for autonomous journeys is increasing in western countries. Because walking to school can encourage children's autonomy and physical activity, there is the need to better understand the reality in order to promote changes. The aim of this study was to understand how children commute to school and back home, and what characteristics or settings can predict a healthier behavior. Methods Four hundred eighty nine students (247 boys, 242 girls) from two northern Portuguese school clusters (Viana do Castelo (urban) and Ponte de Lima (rural)), ranging from the 4th to the 9th grade, and living up to a one kilometer from school were inquired about their weekly (five days) commuting to school (to and from school). Their results were analyzed using a binary logistic regression, with sex, school year, school cycle, socioeconomic status, urban/rural gradient, and living distance, as independent predictors of the active behavior (walking to school). Results Results show that 47% of the children walked to school, while 62% walked back home. Significant relationships were found between active commuting and sex, school year, school cycle, socioeconomic status, and living distance. Using a binary logistic regression a significant odds ratio (OR) was found for belonging to an older school year (OR from 4.2 to 11.8); being economically disadvantaged (OR from 2.3 to 4.2); living less than 500 m from school (OR from 2.4 to 2.9); living in the more urbanized city of Viana do Castelo (OR=1.4); and being a girl (OR=1.3), as compared to their counterparts. Discussion Although traffic danger and safety concerns are usually pointed as the two main causes for walking to school restrictions, our data showed that girls, and children living in a urbanized area with an increased traffic flow, have a higher chance of walking to school by themselves (particularly in the morning). It looks like that parent's perceptions do not entirely match with their behaviors, when it comes to allow (or encourage) their children to walk to school. More studies are needed to better understand this complex behavior if we want children to become more autonomous and active on their daily route to and from school.

### MOTOR COMPETENCE IN CONTEMPORARY KINDERGARTEN CHILDREN IS GOOD, BUT REDUCED IN THOSE BEING OVERWEIGHT

Engelhardt, A., Müller, J., Schinzel, M., Hager, A., Oberhoffer, R.

*Institute of Preventive Pediatrics*

Objective: Perceptual and motor experiences determine not only the physical and motor development of children; they also affect the emotional, psychosocial and cognitive development of children. Since contemporary studies report on a diminished physical activity and a rising prevalence of overweight and obesity, this study aimed to evaluate the motor competence of kindergarten children and to determine the relation of obesity. Patients and methods: We studied 90 healthy kindergarten children (53 girls) aged  $5.5 \pm 0.6$  years with a median Body Mass Index Standard Deviation Score (BMI-SDS) of  $0.3 \pm 1.2$ . All children performed the MOT 4-6 from Zimmer designed to assess motor competence by 18 different exercise tasks. Task points were summed up to a score that is transformed to a motor ability index (MQ) according to the corresponding age-dependent reference value for boys and girls. Results: In general, current kindergarten children present a similar motor competence compared to the reference values from 1987 (MQnow: 98.6 vs. MQref: 100;  $p = .393$ ). MQ significantly decreased with higher BMI-SDS ( $r = -.503$ ,  $p < .001$ ). This difference also became especially obvious when comparing the 20 overweight children (BMI-SDS  $> 1$ ) with the normal weight subjects (MQnormal: 102 vs. MQoverweight: 87,  $p = .001$ ) Conclusions: Motor competence of kindergarten children is rather good. Overweight seems to be a risk factor for impaired motor competence.

### OP-PM44 Exercise Physiology 3

#### IMPROVEMENT OF IMMUNE RESPONSE TO VACCINATION IN ELDERLY PEOPLE AFTER PHYSICAL EXERCISE

Vaisberg, M.

*Federal University of São Paulo*

Introduction: Aging is a multifactorial phenomenon that also affects the immune system, leading to a higher susceptibility to infections and other diseases. Vaccination against influenza is a powerful strategy to protect this population against pulmonary diseases. However the efficacy of the vaccine is lowered by aging. Elderly people also show increase in the production of autoantibodies which actually is considered a natural antibody that acts as a protective mechanism. According to the literature regular moderate exercise is able to

attenuate some aspects of immunosenescence. The aim of this study was to evaluate the presence of autoantibodies, and the relation of these antibodies to the response of serum IgM and IgG specific to the influenza vaccine, comparing a group of sedentary people to a physically active group. Methods: The study population consisted of 78 elderly people aged between 60 and 85 years (mean age  $69,7 \pm 6,97$  years) living in the city of São Paulo. The volunteers recruited to the study kept to their usual routine and were divided in two groups: sedentary [SE,  $n=34$  (mean age  $70,4 \pm 6,9$  years)] and physically active [PA,  $n=44$  (mean age  $69,2 \pm 6,35$  years)] that performed a routine of physical activity (4-days a week - 1 hour each exercise session), at least for 12 months. The training program was constituted in aerobic exercises (60-70% of  $VO_2$  maximum) associated with resistance exercises. All volunteers received the same sample of influenza virus vaccine and none of the participants had liver, renal, inflammatory, cognitive, autoimmune or neoplastic diseases. Serum was collected at two different times: before and 30 days after the vaccination to determine the levels of immunoglobulin G produced in response to vaccine of influenza virus by ELISA. Anti-nuclear antibodies (ANAs) were determined by indirect immunofluorescence assay. Results: The results showed that the number of individuals' ANAs positive in the physical activity (PA) group was higher [ $n=20$  (45,45%)] than in the sedentary group [ $n=13$  (32,35%)], however no statistical difference was observed. Before the vaccination the serum IgG levels did not showed difference between the subgroups [SE,  $P=0.07(0.02-0.15)$  and  $N=0.17(0.10-0.38)$ ; PA,  $P=0.18(0.06-0.31)$  and  $N=0.22(0.13-0.37)$ ]. After the vaccination, in a comparison between the negative and positive individuals of SE and PA groups, only a significant statistical difference was observed in IgG levels of positive individuals of PA group [ $0.46(0.30-0.58)$ ] in relation to concentration observed in the positive individuals of SE group [ $0.15(0.10-0.40)$ ]. Discussion: We were able to demonstrate that a regular moderate physical activity increased the presence of autoantibodies and that this increase is correlated to an improvement in the immune response of elderly people as can be viewed by the higher levels of IgG antibodies against the virus of the influenza vaccine.

### EXERCISE-INDUCED FATIGUE AND HYPOGLYCAEMIA IMPAIR EYE MOVEMENTS BUT NOT VISUAL PERCEPTION

Gant, N., Duncan, S., Kuhn, G., Thompson, B.

*The University of Auckland*

Purpose Lowered substrate availability and exercise-induced fatigue are known to impair motor performance. It is currently unclear, however, whether the human visual system is also susceptible to this type of functional impairment. The aim of this study was to assess the extent to which the neural control of eye movements and cortical processing of visual information are susceptible to exercise-induced fatigue and hypoglycemia. This study examined visual performance after prolonged exercise and energy depletion. Methods Within a double-blind, randomized, cross-over design, 9 male cyclists (mean age 30.5 y and  $VO_{2max}$  61 ml/kg) consumed either placebo (fatigue + hypoglycemia condition) or carbohydrate (fatigue alone condition) solutions every 15 min during a 180 min cycling protocol. Exercise was performed after a 14h overnight fast at an intensity equivalent to 60%  $VO_{2max}$ . Visual acuity, binocular function, global motion perception and saccadic eye moments, were assessed using an established social attention eye movement paradigm, which was employed before and after the exercise protocol. Eye movements were recorded using an infra-red eye-tracker. Heart rate and perceived exertion were recorded throughout the protocol and venous blood samples were collected at routine intervals for assessment of plasma glucose and serum insulin. Results Fatigue alone or fatigue and hypoglycemia did not reduce visual acuity, binocular visual function, global motion perception or the effects of social attention on the latency of eye movements. There was, however, a significant reduction in the velocity ( $F(1,8) = 18.4, p = 0.003$ ) and accuracy ( $F(1,8) = 34.7, p < 0.001$ ) of saccadic eye movements for both the fatigue alone and fatigue + hypoglycemia conditions. Conclusion Neural processing of visual information is robust to exercise-induced fatigue and hypoglycemia, however ocular motor control is susceptible to the effects of prolonged and depleting exercise. Exercise-induced perturbations in homeostasis may impair the function of cortical areas governing ocular-motor control, whereas brain regions associated with sensory processing appear resistant to exertional and metabolic fatigue.

### EXERCISE-INDUCED BRONCHOCONSTRICTION IS VAGALLY MEDIATED AND CORRELATES WITH LUNG CLEARANCE INDEX IN ELITE SWIMMERS

Luke-Zeitoun, M., Wildman-Tobriner, B., Ghio, E., Hatamiya, N., Luke, A., Nielson, D., Lazarus, S., Gold, W.

*University of California San Francisco, San Francisco, California, United States of America*

Introduction: There is a high prevalence of exercise-induced bronchoconstriction (EIB) in elite swimmers. Elite athletes frequently report respiratory symptoms associated with exercise, but the diagnosis of asthma is often difficult to make because of the variability and poor specificity of the symptoms. Vagal activity has been shown to be increased in high level athletes and is known to promote bronchoconstriction. The lung clearance index (LCI) is a simple and sensitive measure of lung physiology, which has been used to detect early airway dysfunction in patients with asthma. The goal of this study was to determine the direct effects of vagal tone on airway responsiveness in elite swimmers and to evaluate the relationship of LCI to bronchial response to exercise challenge. Methods: Bronchial response to exercise was measured in 19 elite swimmers on 2 different occasions. To provoke EIB, the athletes exercised for 8 minutes on a cycle ergometer at 90% of their maximal heart rate while breathing dry air. In one of the visits, the athletes received intravenous saline (placebo). In the other visit, they received intravenous atropine (0.04 mg/kg), given in divided doses (0.01 mg/kg every 30 seconds) between minutes 8 and 10 of exercise to selectively achieve parasympathetic blockade by the end of the exercise challenge. Specific airway conductance (SGAW) was measured by body plethysmography before and 3, 6, 10, 15, 20 and 30 minutes after the exercise challenge. LCI was measured at rest using the multiple breath washout technique. Results: Post-exercise SGAW showed changes over time ( $p < 0.05$ ), differences among the 2 experimental conditions ( $p < 0.05$ ) and a condition x time interaction ( $p < 0.05$ ) in both asthmatics and non-asthmatics. Post-exercise bronchial response was significantly higher during the placebo trial than the atropine trial. 10 athletes met criteria for exercise-induced bronchoconstriction (EIB,  $>35\%$  decrease in SGAW), 5 of which had no history of asthma. There was a significant correlation between LCI and percent drop in SGAW after exercise challenge ( $p < 0.05$ ). Discussion: EIB is highly prevalent and underdiagnosed in elite swimmers and it can be prevented with parasympathetic blockade. Parasympathetic blockade leads to post-exercise bronchodilation in swimmers without EIB. These data suggest that vagal mechanisms play a major role in post-exercise airway response and possibly the development of exercise-induced bronchoconstriction in competitive swimmers. LCI correlates with post-exercise airway response in elite swimmers and may be helpful in predicting degree of EIB in this population.

### INDOOR CLIMBING TECHNIQUE ON A TRAVERSE ROUTE: EMG ACTIVITY AND BLOOD LACTATE CHANGES AFTER REPEATED TRIALS

Paoli, A.1, Petrone, N.2, Matteraglia, L.3, Marcolin, G.1

*University of Padova*

1: Department of Biomedical Sciences, University of Padova, Italy. 2: Department of Industrial Engineering, University of Padova, Italy. 3: Faculty of Exercise and Sport Science, University of Verona, Introduction Indoor climbing is becoming very popular both as fitness discipline and competitive sport. Scientific literature concentrated on the physiological demands of this discipline (Sheel 2004; Watts 2004) with particular attention to the forearm muscle fatigue and fingertip force (Macleod 2007). Therefore aim of the present work was to study the overall climbing technique on a route graded 6b measuring EMG activity of upper limbs, lower limbs and trunk. Then to investigate a possible effect of fatigue on the climbing technique after repeated trials on the same route. Methods The surface EMG activity of 16 muscles (forearms (4), arms (2), trunk (2), thighs (4), shanks (4)) was recorded by means of a PDA PocketEMG (BTS-Italy) at a sampling frequency of 1Khz synchronously to video recording from 1 commercial camera. Maximal voluntary contractions (MVCs) were performed for each muscle for EMG normalization. Six advanced climbers performed a 13 meters width traverse route for 6 times without rest time. Blood lactate was collected from the right earlobe before the first run, after the third and after the sixth one. EMG analysis was referred to the whole route but also to 5 specific sequences of movements. EMG signals were integrated, filtered and normalized with respect to MVCs. The ratio among normalized mean activity of upper limb and lower limb muscles was also calculated as well as the time of each performance. Results EMG analysis of the selected muscles showed consistent patterns among the repetitions of the same climber but different patterns among the 6 climbers. A greater activation of the upper limb muscles with respect to the lower ones was detected with an overall mean ratio of  $1.65 \pm 0.2$ . Blood lactate was respectively  $1.6 \pm 0.3$ ,  $2.5 \pm 0.7$  and  $3.7 \pm 2.2$  mmol/l. Discussion Results of the study showed how climbers of similar level exhibited subjective climbing technique with specific patterns of muscle activation. On the other hand the higher employment of the upper limb muscles with respect to the lower limb ones was recorded in all the climbers. The blood lactate increased during the 6 runs but values were index of a slight muscle fatigue. No substantial EMG changes were detected among climbers during the six repetitions. ### INSPIRATORY MUSCLE TRAINING IMPROVES SELF PACED WALKING PERFORMANCE IN OVERWEIGHT AND OBESE ADULTS.

Edwards, A., Maguire, G., Graham, D.

*James Cook University*

Title: Inspiratory muscle training improves self paced walking performance in overweight and obese adults. Authors: AM Edwards<sup>1</sup>, G Maguire<sup>2</sup>, D Graham<sup>3</sup>, Institute of Sport & Exercise Science, James Cook University, Cairns, Australia <sup>2</sup>School of Medicine and Dentistry, James Cook University, Cairns, Australia <sup>3</sup>Department of Psychology, James Cook University, Cairns, Australia Introduction: The effectiveness of exercise interventions for overweight and obese individuals is often limited by factors including premature sensations of fatigue [1]. As obesity leads to an increase in respiratory demands [2], it is possible that an intervention such as inspiratory muscle training (IMT) might improve respiratory compliance, exercise tolerance and the benefits of exercise training in this population group [3]. The purpose of this study was therefore to examine whether a programme of IMT improves accumulative distance of self-paced walking in overweight and obese adults. Method: A total of 15 overweight and obese adults were matched for body mass index and lifestyle characteristics before being randomized into experimental (EXP: n=8) and placebo (PLA: n=7) groups. Lung function, inspiratory muscle performance, 6-minute walking test and predicted maximal aerobic power were assessed prior to and following the 4-week IMT intervention. EXP performed 30 inspiratory breaths, twice daily using a proprietary inspiratory resistance device set to 55% of baseline maximal effort, while PLA performed the same inspiratory training procedure but at the minimum resistive setting. Results: Lung function was unchanged in both groups post-training; however inspiratory muscle performance was significantly improved in EXP (31.4 % mean gain;  $P < 0.01$ ) but did not significantly change in PLA. Predicted maximal aerobic power was unchanged in both groups but the distance covered in the 6-minute walking test was significantly greater for EXP (18.8 % gain;  $P < 0.01$ ) over the 4-week period. PLA did not significantly improve walking performance (6.1% non significant gain). The magnitude of performance gain was positively associated with BMI ( $r = 0.736$ ;  $P < 0.05$ ) Discussion: The present study suggests IMT provides a practical, minimally intrusive intervention to significantly augment both inspiratory muscle performance and walking distance covered by overweight and obese adults in a clinically relevant 6-minute walk test. The post-training gains observed in walking distance indicate that IMT may provide a useful priming (preparatory) strategy prior to entry in a physical training programme for overweight and obese adults. ### IS-PM10 Protein Turnover and Inactivity

---

#### PROTEIN SUPPLEMENTATION TO IMPROVE MUSCLE ADAPTATION IN ATHLETES

Phillips, S.

*McMaster University*

Muscle protein turnover encompasses the opposing processes of muscle protein synthesis (MPS) and breakdown (MPB). Interventions aimed at supporting optimal muscle adaptation generally target MPS since it is by far the more responsive of the two parameters and is a primary driver of muscle remodeling and hypertrophy. Available data suggest that various forms of resistive work, and to a lesser extent aerobic work, are able to stimulate MPS in a protein fraction-specific manner. Protein ingestion also stimulated MPS and, through insulin and potentially amino acids themselves, reduces MPB. The amino acid leucine has a position of prominence as the amino acid that 'turns on' MPS. Data from our lab suggests that more rapidly digested proteins, such as whey, that result in a rapid aminoacidemia and leucinemia are particularly effective at stimulating MPS. Strategies to enhance anabolism through synergistic combinations of exercise and nutrition will be discussed in the context of improving muscle adaptation.

#### PROTEIN TURNOVER OF CONNECTIVE TISSUES IN HEALTHY AND INJURED ATHLETES

Kjaer, M.

*Bispebjerg Hospital*

The connective tissue (extracellular matrix (ECM)) is present in many load bearing structures like bone, cartilage, skeletal muscle, ligaments and tendons. As an example of an ECM rich tissue, tendons are designed to withstand considerable loads and it is shown that mechanical loading of tendon results in an up-regulation of collagen expression and an increased synthesis of collagen protein that is likely regulated by strain of the fibroblast. In vivo, the exercise stimulated increase in collagen formation peaks around 24 hrs and remains elevated for about 3 days after exercise. The degradation of collagen proteins also rises after exercise, but appears to peak earlier. The increase in collagen synthesis of the ECM is regulated by growth factors like IGF-I, TGF-beta, estrogen and IL-6, most likely in an auto/paracrine fashion. This has been demonstrated both in vitro and in vivo. Fibroblasts from adult human tendon tissue are able – when isolated - to respond in an embryonic pattern to induce fibrillogenesis in vitro. In addition to changes in collagen turnover, exercise also influences cross linking in the tendon structure, and some of these reactions appear faster than structural changes in collagen fibrils. Finally, signaling for protein synthesis is in general upregulated with injury, but depending upon type of injury, the protein synthesis is either unchanged or elevated. Understanding how ECM adapts to mechanical loading will be the solution to unraveling the pathogenesis of connective tissue overuse and overload diseases like e.g. tendinopathy and ligament ruptures.

#### MUSCLE PROTEIN TURNOVER AND SUPPLEMENTATION AFTER SPORT INJURIES IN ATHLETES

Tipton, K.

*University of Stirling*

Injuries are an unavoidable aspect of participation in physical activity. Nutrition is important for optimal wound healing and recovery, but little information about nutritional support for injuries exists. Immediately following injury, wound healing begins with an inflammatory response. Excessive anti-inflammatory measures may impair recovery. Many injuries result in limb immobilization. Immobilization results in muscle loss due to increased periods of negative muscle protein balance from decreased basal muscle protein synthesis and resistance to anabolic stimuli, including protein ingestion. Oxidative capacity of muscle is also decreased. Nutrient and energy deficiencies should be avoided. Energy expenditure may be reduced during immobilization, but inflammation, wound healing and the energy cost of ambulation limit the reduction of energy expenditure. There is a theoretical rationale for leucine and omega-3 fatty acid supplementation to help reduce muscle atrophy. During rehabilitation and recovery from immobilization, increased activity, in particular resistance exercise will increase muscle protein synthesis and restore sensitivity to anabolic stimuli. Ample, but not excessive, protein and energy must be consumed to support muscle growth. During rehabilitation and recovery, nutritional needs are very much like those for any athlete desiring muscle growth. The most important consideration is to avoid malnutrition and to apply a risk/benefit approach.

08:00 - 09:30

### OP-SH10 Physical Education and pedagogics 1

#### ANALYSIS OF PHYSICAL ACTIVITY OF PRESCHOOL CHILDREN - COMPARISON OF DIFFERENT EDUCATION PROGRAMS

Roettger, K.1, Grimminger, E.1, Kreuser, F.2, Assländer, L.1, Korte, J.1, Wehrle, A.2, Korsten-Reck, U.2, Gollhofer, A.1

*University of Freiburg*

Introduction: Physical Activity-Participation at preschool-ages is vital to establish lifelong physical activity habits and could have a protective effect against weight-gain in later life (Herman, Craig, Gauvin, & Katzmarzyk, 2009). Due to the increasing out-of-home care for preschoolers these settings, their structures and education-programs are of emerging interest. Therefore we investigated the influence of country-specific education-programs on physical activity of preschoolers. Comparing the three countries France, Germany and Switzerland in the tri-national region "Upper Rhine" we aimed to identify parameters to enhance and promote physical-activity in early childhood. Methods: The pilot-study measurements were conducted in three cities of the tri-national region with similar population. N= 60 children (age: 5,6±0,59 years) of randomized chosen nursery schools in each city were measured by direct accelerometry for 7 consecutive days. Proxy-report diary and physical-activity questionnaire were completed by parents and caregivers. Anthropometrical data (weight, height, skinfold thickness) and socioeconomic data were obtained. Country-specific timetables and curricula were analysed. Results: Median daily activity was lower in French versus German and Swiss children ( $p < .01$ ). Direct accelerometry revealed no significant differences for physical activity between the children of all countries at the weekend. In the forenoon (9-12.00) French children were significantly more passive than German or Swiss children ( $p < .01$ ). In the afternoon (14-18.00) Swiss children are significantly more active than French or German Children ( $p < .01$ ). In all countries, physical activity was lower at the weekend compared to weekdays ( $p < .05$ ). Conclusion: Compared to the more unstructured system in Switzerland and Germany the regimented and highly structured French system leads to more inactivity in preschoolers on weekday especially in the forenoon. In conclusion, "open concepts" should be preferred for enhancing physical activity in contrast to desk-based teaching (Reilly, 2010). Finally, the overall higher activity of Swiss children and the gradient of PA between weekday and weekend show the importance of physical activity habits established in the family. #### DEVELOPMENT OF THE LEARNING STYLES QUESTIONNAIRE FOR CHILDREN

Cunliffe, D.

*Southampton Solent University*

Introduction It is the duty of the educator to ensure that children are developed to fulfil their potential in both academic success and physical well being. A key factor when educating others is to accommodate for differences between them, yet within the area of cognitive development, the notion that we all possess a preferred learning style, or trait, is somewhat of a taboo within sectors of academia (Coffield et al. 2004). Others accept the notion that perhaps we do not all learn in the same fashion, using one or many preferred methods (Beadle, 2010, Capel & Whitehead, 2010). The current literature of this nature is limited (Salter & Graham, 1985; Stevens-Smith & Bowling, 2002), therefore, the more we are able to understand about the different dimensions of a child's development and their approaches to learning, the easier it could be to teach them the complex techniques, skills and demands required for participation in physical activities. Methods Appropriate ethical clearance was granted from a University's Ethical Committee, and permission sought and granted to assess the preferred learning styles of pupils across school years 7-11 ( $n=1500$ ) from one state school within the UK. The initial phase centered on children's perception of what they had learnt, and involved focus group discussions before analysing the results into five key themes. The acquisition of general content was carried out in adherence to standard guidelines using a triangulation approach, as commonly used in the development of a questionnaire (Terry, Lane, Lane, & Keohane, 1999; Walker & Fraser, 2005). Once the items and answers had been established, to improve reliability, the LSQ-C was administered three times over a six week period, with the order of questions and respective answers changed to avoid any learned response. Results A panel of experts agreed that the five key themes (Functional, Personal, Educational, Psychological and Social Learning) were reliable and in line with child development. When assessed for face validity, content validity and comprehensibility for its use with children, using Cronbach's Alpha, the LSQ-C held a reliability score of .871. Discussion Whilst the results of this research support that the LSQ-C offers face validity, there is a need for additional research to assess whether the results are replicable, therefore, further research will see the project extending to other schools. #### THE TEACHING EFFECTIVENESS OF PBLTEACHING MODEL ON NURSING COLLEGE HEALTH PHYSICAL FITNESS PROGRAM

Wang, W.Y.1, Chou, C.C.2

*1:HSC(Taoyuan, Taiwan), 2:TPEC(Taipei, Taiwan)*

Introduction To facilitate nurse practitioner students critical thinking and problem-based learning, PBL teaching model was introduced into their PE course. The purpose of this study was to investigate the effects of Problem Based Learning (PBL) teaching model on health fitness knowledge, physical activities, self-directed learning of PE ability and social problems solving ability of a health fitness program for nursing college students. Methods Quantitative and qualitative methods were used. Quasi-experimental design with an experimental group (EG)

and a control group (CG) were adopted to investigate the effects on student learning. Two classes of nursing students volunteered to be the participants, one class was set as EG (n= 47) and another class CG (n=47). All participations finished 100minutes/week fitness program for 12weeks, EG was taught with the PBL teaching model: first 50minutes was discussion course through discussion sheets by teaching tutors and students, and the second 50minutes was physical activity course. The CG was taught by direct teaching method and physical activity, each for 50minutes respectively. Data were collected through quantitative and qualitative methods. Health-related fitness knowledge test (HRFK) , Self-directed learning readiness Scale-PE (SDLRS-PE) , Social Problem-Solving Inventory-Revised (SPSI-R) and pedometers were used to collect quantitative data. Which analyzed by descriptive statistics, one-way ANCOVA, while qualitative data was analyzed thought content analysis from interview, observation, journal and other related documents. Results (1) For HRFK test, PBL showed significant effects in all dimensions except flexibility, with high degree effect size of explanatory power ( $\eta^2= .219$ ). (2) For SDLRS-PE scales, PBL teaching model showed significant effects on love to learning, motivation, creative learning and total score with PBL had high degree effect size of explanatory power ( $\eta^2= .229$ ). (3) For SPSI-R test, PBL teaching model showed significant effects on negative problem orientation, impulse/careless style, escape style and total score with PBL had medium degree effect size of explanatory power ( $\eta^2= .120$ ). (4) EG students' physical activity and fitness knowledge performances indicated similar development trend, showing students could internalize the knowledge related to physical activity under PBL teaching method. Discussion Based on the above result findings, suggestions on PBL theory, teaching practice and future studies were proposed.

## PERCEPTIONS OF BODY SENSATIONS GENERATED BY PHYSICAL ACTIVITY IN RELATION TO ATTRIBUTION STYLE AND REPORTED PHYSICAL ACTIVITY

Sollerhed, A.C.1, Apitzsch, E.2

1. *Kristianstad University*. 2. *Lund University*

**Introduction** Low levels of physical activity (PA) in childhood can lead to implications for current and future health. Degenerative biological processes initiated in childhood increase the risk of the onset of chronic diseases later in life. PA can generate painful sensations such as breathlessness, stiffness, ache, and sore muscles during and after exercise. These sensations can be perceived in different ways and might be barriers for participation. Successes and failures can be explained by a variety of causes (attributions), which affect not only expectations of future success or failure but also emotional reactions and motivation. The aim of the study was to investigate relations between attribution style, perceived body sensations during and after exercise in relation to reported PA among 15 year-old adolescents. **Methods** A questionnaire including items about ways of living, attribution style, perceptions of body sensations during and after exercise, and self-reported PA was used. The sample was 659 teenagers in Sweden and New Zealand, 15-16 years old. The chi squared test and the Student's t-test were used in the statistical analyses, which were carried out by using PASW version 18.0. Results Teenagers who reported high levels of PA were higher in task-orientation (TO) (29.4 vs 26.8;  $p<0.000$ ) and ego-orientation (EO) (20.5 vs 18.1;  $p=0.001$ ) than sedentary peers. Physically active teenagers perceived being out of breath as normal and okay to a higher extent than inactive teenagers (93% vs 73%;  $p<0.000$ ). They also perceived sore muscles as okay to a higher extent (77% vs 46%;  $p<0.000$ ). Teenagers who thought it was okay being out of breath during exercise scored higher both in TO (28.7 vs 26.4;  $p<0.000$ ) and EO (19.8 vs 17.4;  $p<0.000$ ). Those who thought it was normal and okay with sore and stiff muscles during and after exercise scored higher in TO (28.1 vs 24.8;  $p<0.000$ ) and in EO (18.9 vs 17.2;  $p<0.001$ ). **Discussion** Teenagers with high PA levels seemed to be motivated for PA despite some troublesome body sensations. This could be explained by their high TO which is associated with willingness to make efforts. Active children and adolescents also develop a more robust body than those who are inactive. They develop hardiness and control and see challenges as standard and find them stimulating and do not care about temporarily pains. Overall they do not focus on the negative aspects of PA, they enjoy it and regard it as a positive investment for themselves. The reverse could be seen among physically inactive teenagers who perceive the body sensations from PA as emotionally negative, which together with low TO could be strong barriers for effort, and substantially reduce the willingness of all PA especially the strenuous PA.

## EXPLORING CHILDREN'S MOTOR DEVELOPMENT

Saunders, J., Williams, M., Wilson, C.

*Australian Catholic University*

**Introduction** Current research into children's physical activity has focused largely on obesity. Interest in quantifying activity levels has generally related to physiological status. However, recent research by our motor development group in Melbourne suggests the need to be worrying about more than just declining physiological status. Movement-ABC data from a sample of children (255 males: 249 females) aged between 5 and 12 used the 15th percentile or below as the criterion to screen for DCD and found 35% (83 Males: 92 Females) of children fitted this criterion - a prevalence alarmingly greater than that generally cited in the literature. Fifteen years ago a group of researchers (Walkley, J., Holland, B., Treloar, R., & Probyn-Smith, H. 1993) used the notion of Fundamental Movement Skills to provide the basis for physical education curriculum initiatives in Victoria. Yet little success in enhancing children's motor ability seems to have occurred to date. **Method** Applying readily available biomechanical techniques of kinetic and kinematic analysis, our research group has been exploring two of the fundamental movement skills – locomotion and jumping. Wilson examined the locomotion of 218 children aged between 4-12 and Williams examined the vertical jump performance of 124 children. **Results** The major finding from the Wilson study was that children's fundamental locomotor skill was still developing as late as aged twelve. Velocity, cadence, step length and base of support all showed significantly greater variability for children even with the 11-12 year old sample when compared with young adults. The Williams study identified coordination error as the critical difference in performance between normal children and those identified with lower levels of motor ability. Differences were attributable to a greater loss of VCOM and a lower shank angular velocity at take off resulting in a longer elapsed time from the instant of peak VCOM to take off. **Discussion** The increasing availability of reliable biomechanical techniques for the evaluation of movement provides the means of developing greater understanding of child motor development processes. Findings from studies such as those reported here can prove particularly valuable not only in providing effective individual remediation strategies but also for practice in our motor development and physical education programs in schools at both primary and secondary levels. **References:** Walkley, J., Holland, B. **RELATIONSHIP BETWEEN BODY IMAGE AND PHYSICAL ACTIVITY ON SPANISH CHILDREN**

Dorado, M., Chinchilla, J.L., Carnero, A.

*University of Malaga, Spain*

**Introduction** A disturbance of body image should be related with some adolescence body composition-related disorders, which has a behavioral etiology, where body shape self-perception should one important risk factor. Some surveys have suggested that physical activity (PA) would be a positive co adjuvant to promote a better body self-perception. However, there is not enough evidence about what is the relationship between body composition, different patterns of PA and body shape on adolescents. To explore the relationship between body shape perception, body composition and PA. **Methods** 265 healthy students were examined (107 boys and 158 girls; 14.6 ± 1.1 years; body mass index, 22.2 ± 4.0 kg/m<sup>2</sup>). Body composition was estimated using bioelectric impedance and anthropometry. Body shape assessed with the body shape questionnaire (BSQ). Daily PA and out-of-school PA (OPA) were determined by a validated physical activity questionnaire for Spanish adult children (PAQ-A). Pearson's correlation coefficient was used to explore the relationships between variables. Independent sample T-test was carried out to compare body image perception between adolescents with and without OPA. **Results** A significant relationship between body image and FFM was found ( $r = 0.32$ ,  $p < 0.001$ ). No significant relationship was found between BSQ score and PA ( $r = -0.07$ ,  $p > 0.05$ ). BSQ score was significantly different between adolescents with OPA and without OPA (59.9 ± 24.4 vs. 71.0 ± 29.5). **Discussion** Our main finding was that adolescents, which had performed OPA showed an improved body shape perception. However, PA was not related with BSQ score. Also, in accordance with other studies on adults the higher FFM better BSQ score. These results suggest that some characteristics of the OPA should help to improve body self-perception; however more research is necessary in order to clarify this relationship. **References** Furnham, A., Badman, N. & Sneade, I. **08:00 - 09:30****Oral presentations****OP-PM45 Sports Medicine: Game Injuries****MUSCLE LESIONS AND INFLAMMATION IN FUTSAL PLAYERS ACCORDING TO THEIR TACTICAL POSITIONS**

Hatanaka, E.

*Cruzeiro do Sul University*

**Muscle lesions and inflammation in futsal players according to their tactical positions** Hatanaka E1, de Moura, NR1, Santos VC1,2, Bortolon JR1, Borges LS1, Cury-Boaventura MF1, Curi R2, Pithon-Curi TC1 1Institute of Physical Activity Sciences and Sports, Cruzeiro do Sul University (São Paulo, Brazil), 2Department of Physiology and Biophysics, University of São Paulo (São Paulo, Brazil). **Introduction.** Depending on the tactical function during the match, the loads imposed on the metabolism, muscles and immune system may differ among players, thus requiring differentiated adaptations. A less harmful inflammatory profile that is well adjusted to the tactical position may increase the athlete's performance during the match. Thus, the aim of this study was to characterize muscle lesion and inflammation in futsal players according to their positions in a competitive match. **Methods.** The participants in this study were five goalkeepers (23 ± 1.2 years old, body mass 74 ± 2.5 kg, height 178 ± 3.2 cm, body fat 13 ± 2%, VO<sub>2</sub> max 40 ± 2 mL.kg<sup>-1</sup>), eight defenders (21 ± 1 years, body mass 69 ± 2 kg, height 174 ± 1 cm, body fat 10 ± 2%, VO<sub>2</sub> max 42 ± 1 mL.kg<sup>-1</sup>), eight wingers (22 ± 1 years, body mass 68 ± 2 kg, height 169 ± 3 cm, body fat 11 ± 2%, VO<sub>2</sub> max 48 ± 1 mL.kg<sup>-1</sup>), and eight pivots (25 ± 2 years, body mass 71 ± 2 kg, height 173 ± 2 cm, body fat 10 ± 2%, VO<sub>2</sub> max 46 ± 2 mL.kg<sup>-1</sup>). Blood samples were collected from the participants before and immediately after a match. Muscle damage was detected based on CK and LDH activity. The inflammatory status was evaluated by determining CRP, TNF-α, IL-1β and IL-6, IL-10 and IL-1ra. **Results.** LDH activity in goalkeepers was 5.0-fold higher than in defenders, and 1.6-fold higher than in wingers. There was no variation in the concentrations of CRP, TNF-α, IL-1β, IL-8, IL-10 and IL-1ra among tactical positions. However, the IL-6 level in goalkeepers was 17.7-fold higher than in defenders and 14.2-fold higher than in pivots. The goalkeepers showed lower VO<sub>2</sub>max (40 ± 2 mL.kg<sup>-1</sup>) than defenders (42 ± 1 mL.kg<sup>-1</sup>), wingers (48 ± 1 mL.kg<sup>-1</sup>) and pivots (46 ± 2 mL.kg<sup>-1</sup>). Additionally, the goalkeepers presented a higher percentage of body mass (74 ± 2.5 kg) and body fat (13 ± 2%) than defenders, wingers and pivots. **Conclusion.** Goalkeepers showed higher LDH and IL-6 than players occupying other tactical positions, leading to the conclusion that the tactical position of futsal goalkeeper causes more inflammation and muscle damage than other positions. Moreover, this position is usually occupied by athletes with higher body mass and percentage of body fat and lower VO<sub>2</sub> max than players in the other positions. **References.** [1] de Moura NR, Cury-Boaventura MF, Santos VC, Levada-Pires AC, Bortolon JR, Fiamoncini J, Pithon-Curi TC, Curi R, Hatanaka E. **USE OF TENSIOGRAPHY FOR EARLY DETECTION OF MUSCLE INJURIES**

Zupet, P., Zorko, M., Rozman, S., Djordjevic, S.

*University medical center Ljubljana*

**USE OF TENSIOGRAPHY FOR EARLY DETECTION OF MUSCLE INJURIES** Petra Zupet<sup>1</sup>, Martin Zorko<sup>1</sup>, Sergej Rozman<sup>2</sup>, Srdjan Djordjevic<sup>2</sup> 1 Sports medicine unit, University Medical Centre Ljubljana, Slovenia 2 TMG-BMC Ltd., Ljubljana, Slovenia **BACKGROUND** Injuries of the hamstring muscles are the most common type of injury in sports where running is the basic movement pattern (1). There is a high rate of reinjury of 15-30% (1-4). Early diagnosis with determination of the injury level is very important. One of the major factors for determination of skeletal muscle strain level is the ability of injured muscle to contract. While most diagnostic methods allow us to observe macroscopic structure changes of an injured tissue, tensiomyography (TMG) can measure contractile properties (5-6) of the injured skeletal muscle. **AIM** The aim of our study was to verify, whether TMG can be used as an independent diagnostic tool in early stages after muscle injury. **METHODS** 11 athletes (4 female, 7 male; age 24 ± 9, 7) were treated in Sports Medicine Unit for hamstring injury. The protocol included obtaining medical history of present injury, clinical examination, paraclinical (imaging) methods and TMG measurement. Three parameters for evaluation of TMG signal were determined: Td (delay time), Tc (contraction time) and Dm (displacement of muscle belly during

contraction). Results are presented in a form of mean value  $\pm$  standard deviation. For a statistical analyzing of differences between injured and non-injured hamstring muscle Student's t-test was used. RESULTS We found a statistical significant difference in TMG signal in all injured subjects ( $T_c = 25,32 \pm 10,0$  non injured vs.  $T_c = 37,1 \pm 8,8$  injured ( $p < 0,006$ )). DISCUSSION Subjects were examined in different time periods after injury (2 - 10 days). In previous studies it was shown that the  $T_c$  parameter highly correlates with percentage of slow twitch fibers type I and heavy chain myosin type composition (5). Our study group was heterogeneous, included athletes from different sport types (chronic training adaptation). This and genetic differences caused relatively high differences in  $T_c$  values. CONCLUSION Contractile property changes after strain injury of hamstrings are detected as changes of  $T_c$  and  $D_m$  parameters in TMG signal. This was confirmed by clinical examination and standard imaging methods. There are further studies needed to verify the exact correlation between the injury grade and TMG parameters. References: 1. #### DATA QUALITY CONTROL IN SPORTS INJURY SURVEILLANCE STUDIES: AN EXAMPLE ON DISTANCE RUNNERS

Genin, J.I, Urhausen, A.2, Theisen, D.1

*1Sports Medicine Research Laboratory, CRP-Santé (Luxembourg), 2Centre de l'Appareil Locomoteur, de Médecine du Sport et de Prévention (Luxembourg)*

Introduction Sports injury surveillance studies relying on information technology sometimes report poorly on data quality control (2). The aim of this study was to present a data quality algorithm for sports injury epidemiology and to apply it in an analysis of running-related injury (RRI) incidence in novice and experienced runners. Method This study consists in a 24-week follow-up of 301 recreational runners. They were asked to run at least once a week and to upload their training data for running (duration, surface, intensity, mileage) plus any other sport activity on an internet-based diary. They were also asked to self-report all injuries (RRI or not). To ascertain for high-quality data, three inclusion criteria were applied before statistical treatment: uploading compliance was conformed when the athlete's status (training, at rest, injured, sick) was known for  $\geq 75\%$  of the weeks. Uploading delay was conformed when  $\geq 75\%$  of the sessions were uploaded within 15 days after the session was achieved. Self-assessed compliance evaluated monthly was conformed when the participant reported to have uploaded  $\geq 75\%$  of the actually performed sport sessions. In addition, two criteria assessing for the regularity of the running training were applied: the minimum average running training, evaluated throughout the observation period or until RRI occurrence, was set to 1 session/week, and there could be no period of 4 consecutive weeks with no running. Results From the initial 301 logged-on runners, 100 did not comply with the 3 data quality criteria. Another 24 participants were excluded from the final analysis after applying the two running training criteria. The demographics were not different between excluded and included participants. From the 177 runners retained, 43 (27%) sustained a total of 60 RRI; 75% were due to overuse, and the most frequently injured location was the knee (27%). RRI incidence was 14.2 and 4.7 RRI/1000 running hours in novice and experienced runners, respectively. Novice runners were 3.0 times (95% CI: 1.75-5.18) more at risk of sustaining a RRI than experienced ( $\chi^2 = 17.3$ ,  $p < 0.001$ ). Discussion Applying the present quality algorithm reduces the bias caused by lack of reporting and recall in the presented results. However, a selection bias due to this algorithm cannot be excluded. The fact that novice runners are more at risk than experienced is an important finding considering the high prevalence of RRI (1). (1) Buist I, Bredeweg S, Lemmink K, van Mechelen W, Diercks R. (2010). Am J Sports Med, 38, 273-80. (2) Jacobsson J, Timpka T, Ekberg J, Kowalski J, Nilsson S, Renstrom P. (2010). Br J Sports Med, 44, 1106-11.

#### INFRAPATELLAR STRAP REDUCES PAIN IN ATHLETES WITH PATELLAR TENDINOPATHY

Boetje, J., Zwerver, J., van den Akker-Scheek, I.

*University of Groningen*

Infrapatellar strap reduces pain in athletes with patellar tendinopathy (jumper's knee) Boetje J. MD; Zwerver J. PhD; van den Akker-Scheek I. PhD Center for Sports Medicine; University Center for Sport, Exercise and Health; University Medical Center Groningen; University of Groningen; Hanzplein 1, 9700 RB Groningen, The Netherlands OBJECTIVE: To determine if an infrapatellar strap reduces pain in athletes with patellar tendinopathy during functional loading of the patellar tendon. METHODS: 53 adult male ( $n=39$ ) and female ( $n=14$ ) athletes (mean age 28.5 (range 18-48) years) with patellar tendinopathy were included in this study. The mean VISA-P was  $55.0 \pm 14.5$ . The median duration of symptoms 24 (range 3-300) months. The athletes performed ten single leg decline squats and a maximal jumping test without and then with an infrapatellar strap (Push Med Patella Brace, Vivomed Downpatrick UK). Recruitment of participants took place on the Center of Sports Medicine of the University Medical Center Groningen, the Netherlands. Pain after each functional patellar tendon loading tests was recorded on a visual analogue scale. Additionally, the athletes used the strap for a week during training sessions and games and were asked for satisfaction with and side effects of the strap. RESULTS: Pain reported differed significantly when performing ten single leg decline squats without and with a strap,  $4.2 \pm 2.4$  and  $3.3 \pm 2.2$  respectively ( $p < 0.001$ ) and when jumping three times on one leg,  $3.0 \pm 2.6$  and  $2.6 \pm 2.2$  respectively ( $p = 0.02$ ). Sixty percent of the athletes reported that the strap reduced their pain during and after their sporting activities. The only side effect reported was a feeling of compression in the popliteal space due to the strap. DISCUSSION: This study showed that an infrapatellar strap reduces the pain during functional patellar tendon loading tests and sports activities. Generalization of these results might be hampered by the fact that there are many different straps available. Furthermore, little is known about the long-term effects of using an infrapatellar strap on the progression of patellar tendinopathy. CONCLUSION: An infrapatellar strap can reduce pain experienced by athletes with patellar tendinopathy during patellar tendon loading and sports activities.

#### INCIDENCE AND SEVERITY OF COMPETITION INJURIES IN AUSTRALIAN AMATEUR TAEKWONDO ATHLETES: A TWO-YEAR PROSPECTIVE STUDY

Lystad, R.P., Graham, P.L., Bonello, R.

*Macquarie University*

Introduction: There is a seeming paucity of prospective data on injury severity and risk factors for injury in Olympic-style taekwondo, particularly among amateur taekwondo athletes (Lystad et al., 2009). The main purposes of this study were to determine the injury incidence and severity in Australian amateur taekwondo athletes, and to investigate potential risk factors for injury in competition taekwondo. Methods: Data were collected prospectively at New South Wales (Australia) State Taekwondo Championships during 2010

and 2011 seasons. Injuries were diagnosed by tournament sports medicine personnel and recorded according to the Orchard Sports Injury Classification System, version 10. Injury severity was recorded by conducting post-tournament follow-up of injured athletes to determine the actual number of days lost from full participation. Injury incidence rates were calculated per 1,000 athlete-exposures (IIR\_AE) and per 1,000 minutes of exposure (IIR\_ME). All injury incidence rates, rate ratios and relative risks were computed with 95% confidence intervals (CIs) using standard methods. Results: The combined data revealed an overall IIR\_AE of 59.93 (CI: 51.16, 69.77). The lower limb was found to be the most common injury location, the contusion to be the most common type of injury, and receiving a blow to be the most common mechanism of injury. One third of injuries were found to result in more than one week of lost or restricted participation. There was no significant difference between the genders. Children were found to have a significantly lower IIR\_AE compared to their older age groups, and black belts to have a significantly higher IIR\_AE compared to yellow belts. However, none of these differences were present after accounting for the duration of exposures (i.e. comparing IIR\_ME). The proportion of upper limb injuries resulting in fractures was significantly higher than lower limb injuries resulting in fractures (relative risk: 9.90 [CI: 2.12, 46.20]). Discussion: Although significant differences in IIR\_AE were detected within belt ranks and age groups, no significant differences could be demonstrated after accounting for the exposure-time. This highlights the importance of reporting injury incidence rates with the duration of exposures factored into the denominator. Contrary to what has previously been suggested, the current data indicated that as many as one third of injuries resulted in more than one week of restricted participation (Pieter, 2009). Relative to the lower limb a disproportionate number of upper limb injuries were found to result in fracture. References: Lystad, R. P., Pollard H., Graham P. L. (2009). ### OP-PM46 Neuromuscular Physiology 3

#### COMPARISON OF M-WAVE AND TWITCH RECRUITMENT CURVES RESULTING FROM MUSCLE VS. NERVE STIMULATION OF THE QUADRICEPS MUSCLE

Place, N., Rodríguez, J., Maffioletti, N.A.

*University of Geneva*

COMPARISON OF M-WAVE AND TWITCH RECRUITMENT CURVES RESULTING FROM MUSCLE VS. NERVE STIMULATION OF THE QUADRICEPS MUSCLE Place N.(1), Rodríguez J.(2), Maffioletti N.A.(3). (1) ISMMS, Faculty of Medicine, University of Geneva, Switzerland (2) Departement of Electrical and Electronical Engineering, Public University of Navarra, Spain (3) Neuromuscular Research Laboratory, Schultthess Clinic, Zurich, Switzerland Introduction Surface electrical stimulation can be performed by using electrodes placed over the muscle (muscle stimulation) or over a major motor nerve (nerve stimulation). The purpose of the present study was to compare electrical (M-wave) and mechanical (twitch) properties of the quadriceps muscle evoked by single pulse delivered via muscle vs. nerve stimulation of increasing intensity. We hypothesized that motor unit (MU) recruitment will differ between the two stimulation modes. Methods Twenty two healthy subjects (16 men and 6 women, 29±2 yrs) were recruited for this study. They were seated with a knee angle of 90°. Electrodes were placed over the femoral nerve (diameter: 5 cm) and on the gluteal fold (10 x 5 cm) for nerve stimulation. For muscle stimulation, large electrodes (15 x 9 cm) were located 5–10 cm below the inguinal crease and 5–10 cm above the superior border of the patella. Peak twitch amplitude (Pt) and time to peak twitch (TPT) as well as M-wave amplitude from the vastus lateralis (VL) and vastus medialis (VM) muscles were obtained for stimulus of increasing intensity using muscle and nerve stimulation. The resulting recruitment curves and discomfort (visual analogue scale from 0 to 10) associated to maximal stimulation intensity (defined as the intensity where a plateau in M-wave and twitch responses was obtained) were analysed. Results Muscle and nerve stimulations resulted in similar Pt (57.3 ± 16.8 N vs. 60.6 ± 15.8 N, P>0.05) and similar M-wave amplitude for VL and VM muscles at maximal stimulation intensity. However, some differences between the two stimulation modes were found at submaximal stimulation intensities for both mechanical and electrical responses. TPT decreased (P<0.05) with increased stimulation intensity for both stimulation modes with no difference between stimulation modes. At maximal stimulation intensity, muscle stimulation resulted in a lower discomfort than nerve stimulation (3.2 ± 1.4 vs. 5.6 ± 1.6; P<0.001). Conclusion The shape of the recruitment curves showed some discrepancies between the two stimulation modes, suggesting that MU activation pattern differed. However, the reduction in TPT with increasing intensity suggest that Mus were orderly recruited with both stimulation modes, which is in contrast with the hypothesis of MU random activation with muscle stimulation (Bickel et al. 2011). Maximal M-wave amplitude and Pt were similar with muscle vs. nerve stimulation, suggesting that the use of muscle stimulation with large electrodes might be an alternative to nerve stimulation as it results in less discomfort. #### SHORTENING OF MUSCLE REFLEX LATENCIES WITH PRIOR KNOWLEDGE OF UPCOMING PERTURBATION

Shinya, M., Kawashima, N., Nakazawa, K.

*University of Tokyo*

Introduction Although postural reflexes are involuntarily triggered, higher cognitive functions such as prior knowledge of an upcoming perturbation contributes to the reflexes. For example, anticipating a perturbation during walking shortens muscle reflex latencies compared to latencies in which the subjects were completely naive to the possibility of the perturbation (Shinya and Oda, 2010). Prior knowledge includes two distinct elements: spatial (i.e. direction of perturbation) and temporal (i.e. timing of perturbation). The purpose of this study was to investigate how each of these two elements of prior knowledge for the perturbation contributes to shortening of muscle reflex latencies during walking. Methods Eleven healthy male participants walked on a split-belt treadmill and were perturbed by accelerating or decelerating the right belt at right foot contact. The perturbations were imposed with and without spatial and temporal prior knowledge. Spatial prior knowledge was informed to participants by instructing the direction of the belt perturbation (e.g. only acceleration perturbations would occur in this session). Temporal prior knowledge was given by auditory cue at right foot contact during preceding 3 strides before the perturbation. Muscle reflex latencies were calculated from electromyographic signals measured by surface electrodes placed on the right sides of the gastrocnemius, soleus and tibialis anterior muscles. Results In response to the acceleration

perturbations, reflexive muscle activities were observed in the gastrocnemius and soleus muscles. Gastrocnemius latency was shorter when the participants knew the timing of the perturbations (with prior knowledge:  $58 \pm 8$  ms, without prior knowledge:  $72 \pm 10$  ms). Soleus latency was not different between temporal prior knowledge conditions (with prior knowledge:  $45 \pm 12$  ms, without prior knowledge:  $44 \pm 8$  ms). There was no difference in latencies in any muscle tested between spatial prior knowledge conditions. Discussion The results demonstrated that temporal but not spatial prior knowledge of the upcoming perturbation played a critical role in muscle reflex latencies. The latency observed in the gastrocnemius muscle was consistent with reflex latencies that are mediated by multiple synapses in the spinal cord, subcortical and/or cortical brain area. Neural activity levels in these area might be enhanced when one anticipated the timing of the perturbation. The absence of the effect on soleus may be due to the reflex being mediated by a monosynaptic pathway. References Shinya M and Oda S. (2010). *Exp Brain Res*, 203(2), 437-446

### ACUTE POSTURAL MODULATION OF THE SOLEUS H-REFLEX AFTER ACHILLES TENDON VIBRATION

Lapole, T., Canon, F., Pérot, C.

*Université de Technologie de Compiègne*

Introduction After prolonged vibration exposure, it has been reported H-reflex depression (Ushiyama et al., 2005). Among the parameters susceptible to affect H-reflex responses, it was hypothesized that presynaptic inhibitory mechanisms largely contributed to explain the after-effects of vibration on the H-reflex. Indeed, it has been well reported that during vibratory exposure, the H-reflex is suppressed due to presynaptic inhibitory mechanisms (Gillies et al., 1969). To confirm presynaptic inhibition as main contributor to H-reflex changes after one bout of prolonged vibration, we analyzed the acute changes in postural modulation (standing vs. sitting) of soleus (SOL) H-reflex after a vibratory prolonged exposure. Indeed, postural modulation of the SOL H-reflex has been reported to inform on the level of presynaptic inhibition exerted on Ia afferents (Koceja et al., 1995). Methods Maximal SOL H-reflex (Hmax) and M waves (Mmax) were measured in both sitting and standing positions before and after 1h of Achilles vibration (frequency:50Hz) applied in sitting position (Vibration group, n=11) or before and after 1h of sitting position only (Control group, n=6). Hmax and Mmax were expressed by their amplitudes and Hmax was expressed in % of Mmax. Furthermore, in order to quantify presynaptic inhibition induced by prolonged vibration, an index of SOL H-reflex postural modulation was calculated as the standing Hmax/Mmax ratio relative to the sitting one. Results After 1h of vibration, a significant decrease in the SOL Hmax/Mmax ratio was observed both in sitting and standing positions. However, the decrease was more pronounced in the standing position, leading to a significant decrease of the index of SOL H-reflex postural modulation, while this index remained unchanged for the Control group. Discussion Since the level of presynaptic inhibition of Ia afferents is known to be greater in the standing position than in the sitting one (Katz et al., 1988), we hypothesized that the vibration-induced H-reflex depression would be posture-dependant. In both postures, the H-reflex was depressed after prolonged Achilles tendon vibration. However, the greater depression in the standing position confirms that the vibration-induced H-reflex depression may be largely mediated by presynaptic inhibition mechanisms, originated from Ia afferents, over-activated during the vibratory exposure. ### RECURRENT INHIBITION OF SYNERGISTIC MUSCLES DURING MAXIMAL VOLUNTARY ANISOMETRIC CONTRACTION

Duclay, J., Amarantini, D., Martin, A.

*University Paul Sabatier*

RECURRENT INHIBITION OF SYNERGISTIC MUSCLES DURING MAXIMAL VOLUNTARY ANISOMETRIC CONTRACTION Duclay, J.1, Amarantini, D.1, Martin, A.2 1: PRISSMH (Toulouse, France), 2: INSERM U-1093 (Dijon, France) Introduction In a previous study (Duclay et al., 2011), we reported that changes in corticospinal excitability observed for lengthening compared with shortening maximal voluntary contractions (MVC) depends mainly on pre- and postsynaptic inhibitory mechanisms acting at spinal level. However, this specific modulation of the spinal excitability differs between synergistic muscles, i.e. the Soleus (SOL) and the Medial Gastrocnemius (MG). We previously suggested that the reduction of the SOL spinal excitability during lengthening MVC can, at least partly, be linked to an increase in recurrent inhibition. The present study was designed to compare changes in recurrent inhibition during anisometric MVC between synergistic muscles with different sensitivity to spinal inhibitory mechanisms. Methods Experiments were performed on 8 healthy men. Maximal H reflexes (Hmax) and M-waves (Mmax) were evoked in SOL and MG at an ankle angle of 90° during shortening and lengthening MVC (20°/s). During MVC, maximal H reflex with no direct M-wave response was also recorded as reference H-reflex (H1). The paired H reflex technique proposed by Hultborn and Pierrot Deseilligny (1979) was used to record test H reflex (H') to assess recurrent inhibition. The Hmax/Mmax and H'/H1 ratios were computed to investigate the modulations of spinal excitability and recurrent inhibition, respectively. Results Preliminary results indicate that the SOL amplitudes of H' and H1 were by 34.5% and 18.4% lower ( $P < 0.05$ ) during lengthening than during shortening MVC, respectively. Both SOL Hmax/Mmax and H'/H1 ratios were smaller ( $P < 0.05$ ) during lengthening MVC ( $0.49 \pm 0.08$  and  $0.58 \pm 0.09$ , respectively) compared with shortening MVC ( $0.61 \pm 0.05$  and  $0.74 \pm 0.08$ , respectively). In contrast to SOL, no muscle contraction type effect was observed for both MG Hmax/Mmax and H'/H1 ratios ( $P > 0.05$ ). Discussion The main finding was that both Hmax/Mmax and H'/H1 ratios were reduced during lengthening MVC for the SOL but not for the MG, suggesting that neural adjustments at spinal level differ for two synergistic muscles of the triceps surae during lengthening MVC. Furthermore, the larger decrease in H' than in H1 for the SOL during lengthening compared with shortening MVC indicates a change in post synaptic inhibition (Hultborn and Pierrot-Deseilligny, 1979). These results further indicate that the relative contribution of recurrent inhibition to the modulation of the spinal excitability may depend on the muscle being investigated. References Duclay J, Pasquet B, Martin A, Duchateau J. (2011). *J Physiol* 589:2901-16 Hultborn H, Pierrot-Deseilligny E (1979). *J Physiol* 297:229-251

### CO-CONTRACTION OF LOWER LIMB MUSCLES DURING WALKING IN FOUR YEARS OLD CHILDREN

Plevnik, M., Gerzevic, M., Bogerd, C.P., Marusic, U., Pisot, R.

*University of Primorska*

Introduction Co-contraction, or simultaneous activation of agonist and antagonist muscles during the execution of a task, occurs to a limited extent in many activities requiring motor co-ordination and joint stability, including walking and running (Frost et al., 1997). During maturation and skill development, inhibition of antagonist muscle groups is thought to be progressively learned until an efficient movement pattern is obtained (Ford et al., 2008). The goal of this study was to analyse the co-contraction of eight major lower limb muscles

during walking in healthy four-year-old children. Methods 48 four-years-old children walked 4 times for 13 m at their self-selected comfortable walking speed. EMG was continuously obtained from: m. tibialis anterior, m. soleus, m. rectus femoris, and m. biceps femoris, for both the left and right leg. After typical EMG post processing, co-contraction indexes (CCI) were calculated according to Rudolph et al., 2001 and Lewek et al., 2004, for two muscle pairs for both legs: TA-SO and RF-BF. Paired-samples t-test and Spearman's correlation were used for analysis. Results CCI (Mean  $\pm$  SE) for the left and right TA-SO pairs were  $14.9 \pm 2.7$  and  $19.9 \pm 1.6$ , respectively during the contact phase ( $p=0.082$ ) and  $28.8 \pm 2.3$  and  $13.7 \pm 0.7$ , respectively during the swing phase ( $p<0.001$ ). For the left and right RF-BF pairs, CCI during the contact phase ( $p<0.001$ ) were  $11.2 \pm 0.9$  and  $6.5 \pm 0.4$ , respectively and  $8.5 \pm 0.8$  and  $4.4 \pm 0.3$ , respectively during the swing phase ( $p<0.001$ ). Spearman's correlation indicated significant interactions during the contact phase for the left and right TA-SO pairs ( $r=0.39$ ;  $p=0.006$ ) as well as for the left and right RF-BF pairs ( $r=0.36$ ;  $p=0.011$ ). Discussion Very few studies addressed the topic of co-contraction during child's fundamental motor patterns' development (Ford et al., 2008). In this paper, preliminary results were presented and further analysis will be done to verify and better understand the meaning of co-contraction in child's gait pattern development. The purpose is to further investigate how muscle co-ordination is changing with age and what is the role of different factors on co-contraction and other muscle activation patterns. Such factors will include, physical activity, lifestyle, anthropometrics, among others. Ultimately, these results will lead to a better understanding of the role of lifestyle on motor development. ### **INFLUENCE OF MUSCLE LENGTH AND LOAD CONDITIONS ON THE OCCURENCE OF PRE-MOTOR SILENT PERIOD DURING BALLISTIC ACTIONS**

Richartz, C., Duchateau, J.  
*Université Libre de Bruxelles*

Influence of muscle length and load conditions on the occurrence of pre-motor silent period during ballistic actions Richartz,C.,Duchateau, J. Laboratory of Applied Biology, Université Libre de Bruxelles, Belgium Introduction Ballistic muscle contractions performed from different initial conditions are very common in sports. If a submaximal static contraction precedes the ballistic action (STABAL) an electromyographic silent period (SP) may be observed during the transition of the two actions (Mortimer et al., 1987; Van Cutsem and Duchateau, 2005). The occurrence of SP is inconsistent from subject to subject (Mortimer et al. 1987; Aoki et al., 1989) ranging between 5% and 60% of the contractions. The aim of this study was to analyse the effect of ankle position and load condition on the occurrence of SP. Methods Nine healthy subjects performed STABAL dorsiflexions from 3 different ankle angles: neutral (0°), plantarflexion (+10°) and dorsiflexion (-10°). For each angle, 3 different loads were applied: 10%, 20% and 30% of maximal voluntary contraction (MVC) torque. Electromyographic activity (EMG) was recorded in the tibialis anterior (agonist muscle) and soleus, gastrocnemius medialis, gastrocnemius lateralis (antagonist muscles) by means of surface electrodes placed over the muscle belly. Ankle range of movement (°) was recorded by an electronic goniometer and angular velocity (°/s) was obtained by computing the first derivation of angular movement. Results The results indicate that SP occurrence was significantly greater when movements departed from a lengthened muscle condition (12,92% at +10° vs 8,37% at -10°;  $p<0.05$ ). SP occurrence depended also of the preload level (13,72% at 10% MVC and 8,17% at 30% MVC;  $p<0.01$ ). Furthermore the trials that presented a SP showed a greater angular velocity than those without SP ( $p<0.05$ ). The normalised average EMG activity (aEMG) during the first 50 ms following the onset of EMG activity was significantly higher in the trials presenting SP compared to those without SP ( $p<0.05$ ). Discussion It has been suggested that SP could be responsible for a non-refractory state of the motoneurons prior to the ballistic action, which supposedly allows a better synchronization of the motor units discharges at the onset of the contraction leading to a greater movement velocity (Van Cutsem and Duchateau, 2005; Richartz et al., 2010). The increased aEMG observed in the early stages of the ballistic action for movements with SP compared to movements without SP confirm this hypothesis. The new finding of this study is that the occurrence of SP depends on the initial conditions under which the movement is performed. #### **BRAIN CORTICAL CHARACTERISTICS OF SKILLED SENSORIMOTOR PERFORMANCE**

Mierau, A.1, Hannemann, M.1, Hülzdünker, T.1, Karamanidis, K.2, Sueptitz, F.2, Mierau, J.1, Strüder, H.K.1  
*German Sport University*

Athletes can achieve striking sensorimotor skills after years of extensive training. So far, only little is known about the neural mechanisms underlying such skilled performance. Recent electroencephalographic (EEG) studies compared athletes with non-athletes and/or high with low performance within a sample of subjects. These studies showed that activity in the alpha (7-12 Hz) and beta (13-30 Hz) frequency band (e.g. Del Percio et al. 2009) as well as frontal midline theta (4-7 Hz) band activity (e.g. Doppelmayr et al. 2008) are related to attention based sensorimotor performance. However, the available literature provides strong evidence that motor behavior is characterized not only by changes in alpha and beta but particularly in gamma band activity. Moreover, it has been shown that during motor behavior the topographical patterns of gamma and beta activity were more discrete, somatotopically more specific and more consistent with the traditional maps of sensorimotor functional anatomy (Crone et al. 1998) Therefore, the present study should extend previous research by further considering the power in the gamma-1 (30-35 Hz) and gamma-2 (35-40 Hz) bands over the primary motor cortex contralateral to the aiming arm/hand during air pistol shooting in experts and novices for high and low scores, respectively.

As compared to novices, experts showed significantly higher shooting scores and significantly less anterior-posterior fluctuations of the center of pressure immediately prior to the shot. Both, gamma-1 and gamma-2 power were significantly lower in experts compared to novices 3 sec prior to the shot. Furthermore, gamma-2 power was significantly lower in high compared to low scores 1 sec prior to the shot. Our findings suggest that gamma oscillations over the primary motor cortex are related to sensorimotor performance. Higher gamma power values in novices as well as in low score shots may reflect increased compensatory motion of the aiming arm/hand as a result of reduced dynamic stability. References: Crone, N. ### APPROACHING EFFECTIVE CONNECTIVITY MEASURES IN EXERCISE NEUROSCIENCE

Schubert, M., Hansmeier, T., Koutsandr ou, F., Reinecke, K., Wei , M., Baumeister, J.

*University of Paderborn*

Perception, evaluation and optimal reaction within sub seconds are of great interest in many kinds of sport and daily living activities. It requires sensory integration and evaluation in specific brain areas, which interact effectively. This information flow can be measured from the EEG using the concept of granger causality (GC) [3]. This approach will add information about brain network dynamics in sports and exercise. Aim of this study was to demonstrate the feasibility of effective connectivity estimation (ECE) in a standardized test paradigm. Six male subjects performed an oddball-task with 10% target and 10% distractor stimuli. During the task EEG was recorded from 60 scalp positions. Preprocessing included down sampling, zero-phase shift filtering, epoch extraction and baseline correction. Artifacts were either rejected or corrected with independent component analyses (IC analysis). Functional ICs were selected to calculate multivariate autoregressive models. After model validation, connectivity estimation using renormalized partial directed coherence (rPDC) [5] was calculated between components for every subject and stimulus type according to the processing pipeline of the SIFT toolbox for EEGLAB [2] [4]. A significant bidirectional information flow ( $p \leq 0.025$ ) between parietal and frontal located ICs appears between 100 ms and 500 ms after the stimulus for both types (target and distractor) in five subjects. Difference maps show higher amount of information flow after the distractor stimulus. EEG using the concept of GC is able to analyze ECE within the fronto-parietal network, which is recruited by tasks that involve attentional control processes during target detection [6]. Our results are consistent with findings in [1], where bidirectional information flow in the fronto-parietal network was found from fMRI signals in a similar setup. Especially the flexibility of EEG systems and its high temporal resolution allow an insight to network dynamics in more complex tasks and could gain the understanding of sensorimotor control mechanisms in sports and exercise. ### ANTERIOR CINGULATE CORTEX ACTIVATES 24 HOURS AFTER EXERCISE.

Fujimoto, T., Chiba, N., Tashiro, M., Nagamatsu, T., Sensui, H., Masud, M.M., Ishii, K., Gondoh, Y., Nagatomi, R.

*Tohoku University*

After a few days of consecutive exercise, people often feel positive psychological changes not only immediately but also the next day after exercise, despite their fatigue not recovering completely. Our purpose was to study a part of the mechanism of this positive psychological change. We observed the change in regional brain activities 24 hours after four days of consecutive exercise using positron emission tomography (PET) and 18Fluorine-fluoro-deoxy-glucose (18F-FDG). Subjects were nine healthy male volunteers (age,  $21.2 \pm 1.9$  years, means  $\pm$  SD). PET scans were performed two times, before the exercise period and 24 hours after the exercise. During the exercise period, subjects pedaled a bicycle ergometer for 90 minutes two times a day (180 minutes total) at workloads of 55%  $VO_{2max}$ . Subjects' results were recorded on the Mood checklist-short form 2 (MCL-S.2), visual analogue scales (VAS) as a subjective index and critical flicker fusion frequency (CFF). Normalized FDG uptake of the left anterior cingulate cortex (ACC) was significantly higher 24 hours after exercise than before the exercise period (uncorrected,  $p < 0.001$ ). The fatigue VAS was significantly elevated on the 3rd and the 4th exercise days compared with the value before the exercise period ( $p < 0.01$  and  $p < 0.05$ ). Fatigue VAS, 24 hours after exercise recovered to the level before the exercise period. Pleasure score declined significantly from 2nd to 4th exercise day as compared with that of before the exercise period ( $p < 0.05$ ), and it recovered 24 hours after exercise. CFF of the 4th exercise day was significantly lower than before the exercise period ( $p < 0.05$ ), and CFF 24 hours after exercise had declined more. These results demonstrated that subjects would be tired at least neurophysiologically (CFF decrease), but they would not feel much fatigue or stress psychologically 24 hours after exercise. This discrepancy on recovery between the recovery of CFF, the pleasure score, and fatigue VAS level might be related to the ACC function.

### PHYSICAL EXERCISE AND POSTNATAL BRAIN DEVELOPMENT

Arida, R., Gomes da Silva, S., Unsain, N., Masc , D.H., de Almeida, A.A., Amorim, H.A., Ara jo, B.H.S., Sim es, P.S.R., Naffah-Mazzacoratti, M.G., Mortara, R.A., Scorza, F.A., Cavalheiro, E.A.

*Universidade Federal de Sao Paulo*

PHYSICAL EXERCISE AND POSTNATAL BRAIN DEVELOPMENT Arida RM1, Gomes da Silva S1, Unsain N2, Masc  DH2, de Almeida AA1, Amorim HA3, Ara jo BHS3, Sim es PSR3, Naffah-Mazzacoratti MG3, Mortara RA4, Scorza FA3, Cavalheiro EA 3. 1: Universidade Federal de S o Paulo (S o Paulo, Brazil), 2: Universidad Nacional de C rdoba (C rdoba, Argentina), 3: Universidade Federal de S o Paulo (S o Paulo, Brazil), 4: Universidade Federal de S o Paulo (S o Paulo, Brazil) Introduction There is a great deal of evidence showing the capacity of physical exercise to enhance cognitive functions, to reduce anxiety and depression, and to protect the brain against neurodegenerative disorders. Although the effects of exercise are well documented in the mature brain (Cotman et al., 2007), the influence of exercise in the developing brain has been poorly explored. Therefore we investigated the morphological and functional hippocampal changes in adult rats submitted to daily treadmill exercise during the adolescent period. Methods Male Wistar rats aged 21 postnatal day-old (P21) were divided into two groups: exercise group (n=27) and control group (n=27). Animals of the exercise group were submitted to daily exercise in the treadmill between P21 and P60. Running time and speed gradually increased during the subsequent days, until reach 18

m/min during 60 min. After the aerobic exercise program (P60), histological and behavioral (Morris water maze) analyses were performed. Results Physical exercise program during the postnatal development increased the mossy fibers density and hippocampal expression of parvalbumin, brain-derived neurotrophic factor and its receptor tropomyosin-related kinase B, reduced cannabinoid receptor type 1 expression, improved spatial learning and memory, and enhanced the capacity to evoke spatial memories in later stages (when measured at P96). It is important to point out that while physical exercise induces hippocampal plasticity, degenerative effects could appear in undue conditions of physical or psychological stress. In this regard, we also showed that the exercise protocol used here did not induce inflammatory response and degenerating neurons in the hippocampal formation of developing rats. A significant increase in the hippocampal levels of pro- and anti-inflammatory cytokines was observed only when they were submitted to higher intensity of exercise between P40 and P50. Discussion Our findings demonstrate that a moderate exercise program during postnatal development may result in positive structural and functional changes for the hippocampal formation, a highly plastic region of the brain important for memory, learning and emotional processes. ### CEREBRAL/MUSCLE HEMODYNAMIC AND NEUROMUSCULAR RESPONSES DURING INTERMITTENT BICEPS BRACHII CONTRACTIONS AT DIFFERENT INTENSITIES

Bhambhani, Y.1, Fan, J.L.2, Place, N.2, Rodriguez, J.3, Kayser, B.2

1. University of Alberta; 2. Université de Genève; 3. Public Univ. Navarra

Introduction Numerous activities are performed with the upper extremities which elicit static muscle contractions of varying intensities. This study examined the cerebral and muscle hemodynamics and neuromuscular responses during intermittent static contractions of biceps brachii at 25%, 50% and 75% of the maximal voluntary contraction (MVC). We hypothesized that there would be: 1. significant differences between the three intensities for the hemodynamic and neuromuscular responses, and 2. concordance between hemodynamic and neuromuscular responses at the three intensities. Methods Eleven volunteers performed three MVCs against a biceps dynamometer (elbow angle 90°), followed by M-wave axillary nerve stimulation. They completed 2 min of intermittent isometric contractions (12/min) at 25%, 50% and 75% MVC, interspersed with 3 min rest. M-waves were evoked after the 1st, 12th and 23rd contractions and voluntary EMG was recorded during submaximal contractions. Near infrared spectroscopy (NIRS) was used to record oxyhemoglobin (HbO<sub>2</sub>) and deoxyhemoglobin (HHb) from left prefrontal cortex and right biceps brachii. Doppler ultrasound was used to measure middle cerebral artery velocity (MCAv). Force and EMGrms/M-wave amplitude ratio (RMS/Mmax) were expressed relative to the respective MVC of initial value and averaged over 24 contractions. Results Cerebral HbO<sub>2</sub> and total Hb (index of blood flow) increased while HHb decreased during contractions with significant differences being observed between 75% vs 50% and 25% contractions ( $p < .05$ ). MCAv increased from rest but was not different between three intensities ( $p > .05$ ). Muscle HbO<sub>2</sub> decreased while HHb increased during contractions with differences being observed between intensities ( $p < .05$ ). Muscle total Hb increased from rest at 25% MVC ( $p < .05$ ), but was not higher at 50% and 75% ( $p > .05$ ). RMS/Mmax increased with intensity and was significantly different between intensities ( $p < .05$ ). Discussion Increases in cerebral HbO<sub>2</sub> with concomitant declines in HHb are associated with enhanced neuronal activation (Rasmussen et al., 2007) while increases in muscle HHb with concomitant declines in HbO<sub>2</sub> imply enhanced oxygen utilization (Felici et al., 2009). Increases in RMS/Mmax imply enhanced neuronal activation (Millet et al., 2011). The current hemodynamic and neuromuscular findings indicate that the increases in force output at all three intensities were attained by enhanced neuronal and peripheral muscular activation. Since there was no difference in MCAv between intensities, we speculate that increases in neuronal activation and force output were not accompanied by increases in cerebral blood flow. The increase in RMS/Mmax at the three intensities suggested enhanced central drive (Millet et al., 2011) and was supported by the increase in cerebral HbO<sub>2</sub> measured by NIRS. References Felici et al, (2009). *J Electromyogr Kinesiol* 92:e1-11 Millet et al, (2011). *Eur J Appl Physiol* 111 :2489-500 Rasmussen et al, (2007). *J Cereb Blood Flow Met.* 27:1082-93

### NEURAL MECHANISMS IMPLICATION IN ELECTRICALLY INDUCED FATIGUE

Papaiordanidou, M., Billot, M., Varray, A., Martin, A.

Aix-Marseille University, Faculty of Sports Science

Electrical Stimulation (ES) induces important fatigue development, which has been shown to comprise both neural and muscular mechanisms (Boerio et al, 2005). Studies seeking to find the ES protocol that would minimise fatigue development classically use constant frequency (CFTs) and variable frequency (VFTs) trains (Binder-Macleod and Russ, 1999). Taking under consideration the fact that, when ES is applied in the periphery, neural structures are solicited (Collins et al, 2001) and that electrically induced fatigue may differ according to the stimulation parameters used (Darques et al, 2003), we aimed at comparing the nature of the developed fatigue by these two stimulation paradigms. Ten healthy males received the two protocols, which were randomly assigned to the left or right lower limbs. ES was applied over the triceps surae and protocols consisted of 450 trains (167ms on/500ms off, 30Hz) at an intensity evoking 30% of Maximal Voluntary Contraction (MVC). A doublet (100Hz) was used in the beginning of each train for the VFTs protocol. Torque and electromyographic activity of the soleus muscle were continuously recorded. Neuromuscular tests were performed before and immediately after each ES protocol. Changes in muscle characteristics (excitability and contractile properties) were evaluated by analysis of the muscle compound action potential (Mwave) and associated twitch torque (Pt), while the H reflex and Motor Evoked Potential (MEP) were studied in order to assess spinal and cortical excitability. All parameters were obtained during rest and MVC. MVC significantly decreased to the same extent after the two protocols ( $P < 0.05$ ), giving evidence of similar neuromuscular fatigue development. Mwave amplitude (at rest and superimposed to MVC) and Pt significantly decreased after both ES protocols ( $P < 0.01$ ), demonstrating alterations of the excitation-contraction coupling. Spinal excitability was decreased only during rest ( $P < 0.05$ ) while the ratio MEP/M remained unchanged after both protocols. The results indicate that the two stimulation paradigms gave rise to equivalent neuromuscular fatigue development both quantitatively and in terms of implicated mechanisms. This fatigue was the result of alterations taking place at the muscular level while spinal excitability was decreased at rest. The fact that, during MVC, cortical and spinal excitability remained unchanged shows a modified corticospinal command to cope with the increased presynaptic inhibitions observed at rest. ## IS-SH09 The Integrative Role of Sport in Multicultural Societies: From Research to Practice

**ETHNIC AND CULTURAL IDENTITY: A WORKING FRAMEWORK FOR THE INTEGRATIVE ROLE OF SPORT.**

Hatzigeorgiadis, A.1, Kouli, O.2, Elbe, A.3, Ries, F.4, Pappous, A.5, Sanchez, X.6

*1: University of Thessaly; 2: Democritus University of Thrace; 3: University of Copenhagen; 4: University of Seville; 5: University of Kent; 6: University of Groningen*

**Introduction** The multicultural character of contemporary societies is progressively growing and the issue of integration is therefore particularly important. Sport has been recognized as an important socializing agent; nevertheless, sport is also likely to reinforce existing differences. Thus, organized attempts are required towards the goal of social integration, through the development of appropriate sport environments. The purpose of this project is to explore the role of sport in promoting integration among youngsters with different ethnic-cultural background in five European countries. The ethnic and cultural identity approach for the social integration in multicultural groups (Ting-Toomey et al., 2000) was adopted in this project. The purpose of this presentation is to provide evidence for the conceptualization of the adopted framework. **Methods & Results** The Ethnic-Cultural Identity Salience questionnaire, as adapted by Kouli and Papaioannou (2010) for young students, was used. The instrument, which assesses two dimensions of Ethnic Identity (Ethnic Belonging and Feelings of Fringe) and two dimensions of Cultural Identity (Assimilation and Lack of Interaction), was translated into the different languages. The psychometric properties of the instrument were tested through confirmatory factor analysis (CFA) over two multicultural samples. In the first occasion, participants were 1350 young individuals from five countries; Denmark, Germany, Greece, Spain, and UK. The CFA for each subsample provided preliminary support for the validity of the instrument, and gave indications regarding alteration that could improve the fit of the model across the 5 subsamples. Accordingly, the questionnaire was edited in each language and re-administered. In the second occasion, participants were 1260 young athletes. The CFA provided support for models tested for the total sample and the five subsamples; additionally, multi-sample analysis supported the invariance of the model across the samples. **Conclusions** Overall, the ethnic-cultural identity salience approach seems to provide a useful framework for the study of multicultural integration through sport. The development and the psychometric support for the ethnic-cultural identity questionnaire could facilitate research towards this direction. **References** Kouli, O., & Papaioannou, A. (2009). *Psychology of Sport & Exercise*, 10, 45-51. Ting-Toomey, S., Yee-Jung, K.K., Shapiro, R.B., Garcia, W., Wright, T.J., & Oetzel, J.G. (2000). *International Journal of Intercultural Relations*, 24, 47-81.

**THE INTEGRATIVE ROLE OF SPORT IN MULTICULTURAL GROUPS: PERSONAL, MOTIVATIONAL AND TEAM FACTORS.**

Elbe, A.1, Sanchez, X.2, Ries, F.3, Kouli, O.4, Pappous, A.5, Hatzigeorgiadis, A.6

*1: University of Copenhagen; 2: University of Groningen; 3: University of Seville; 4: Democritus University of Thrace; 5: University of Kent; 6: University of Thessaly*

**Introduction** The sport environment is considered a suitable setting for the development of social and moral values in young athletes. Nevertheless, sport participation per se does not guarantee the desired outcomes. The presentation focuses on the examination of sport factors related to the ethnic and cultural identity of young athletes with non-dominant ethnic-cultural background. **Methods** Participants were 175 young athletes (147 males and 28 females) from Greece ( $n = 80$ ) and Spain ( $n = 95$ ) with a mean age of 15.91 ( $\pm 1.27$ ). Among them 41 were individual sport athletes and 134 were team sport athletes. In addition to ethnic and cultural identity, personal-demographic, motivational and team factors were considered. Participants completed measures of motivational climate, autonomy supportive and controlling coaching behavior, and team cohesion. **Results** Analyses of variance showed that female athletes and team sport athletes showed a more integrative profile, compared to male and individual sport athletes, characterized by higher scores on assimilation and lower scores on lack of interaction. In addition, considerable differences in the dimensions of ethnic and cultural identity were identified between the subsamples from Greece and Spain. Subsequently, separate regression analyses were conducted for the two subsamples to identify the degree to which motivational and team factors could predict ethnic and cultural identity. The analysis for the sample from Greece showed that the predictor variables could make a significant prediction for lack of interaction, predicting 34% of the total variance ( $p < .01$ ), and a prediction that approached significance for feelings of fringe, predicting 14% of the total variance ( $p = .07$ ). The analysis for the sample from Spain showed that the predictor variables could not significantly predict any of the ethnic-cultural identity dimensions. **Conclusions** For the sample from Greece, the results supported that appropriate sport environments can promote integrative patterns of cultural identity. The lack of significant findings for the sample from Spain can be attributed to the heterogeneity of this sample, as some of the athletes shared the same native language with the dominant sample, whereas other did not. Overall, the study provides valuable evidence regarding the role of sport participation and the sporting environment towards the goal of integration in multicultural societies.

**IMPROVING INTERGROUP RELATIONS IN YOUNG ATHLETES FROM DIFFERENT ETHNIC AND CULTURAL BACK-GROUNDS: TOWARDS THE DEVELOPMENT OF AN INTERVENTION PROGRAM.**

Pappous, A., Ries, F., Stathi, S., Kouli, O., Elbe, A.M., Sanchez, X., Hatzigeorgiadis, A.

*University of Kent., University of Seville., University of Greenwich., Democritus University of Thrace., University of Copenhagen., University of Groningen., University of Thessaly*

This presentation will focus on a research project aiming to test the effectiveness of established social psychology interventions in improving attitudes in young athletes from different ethnic and cultural backgrounds. The prospective intervention programme will be based on the theoretical framework of the Intergroup Contact Theory which is an approach that has focused on reducing intergroup bias, and has become one of the most influential theories in the field of intergroup relations. In this study it is planned to take part 60 participants, randomly allocated to one of the three conditions: positive contact, direct contact and control condition (20 participants per condition). The students will take part in the interventions 3 times per week for 3 weeks. In all conditions participants will be given a short questionnaire asking various questions about their views on young people from different ethnic and cultural backgrounds. In the Imagined

Contact condition participants will be asked to imagine positive interactions with people for different ethnic background. In the Direct contact group participants from different ethnic backgrounds they will engage in a physical activity following instructions from Pettigrew & Tropp (2000) who identified five factors which are considered to be essential for optimal bias-reducing contact: equal status between majority and minority groups; a shared goal between members of both groups; a cooperative, rather than competitive, framework for accomplishing the common goal; institutional support for the interactions between members of each group; and minority members who moderately disconfirm the prejudicial stereotypes about their group. The participants that will form part of the control group will perform an unrelated imaginary scenario. One week after the final intervention session, a questionnaire containing the dependent measures will be administered. These will be measures of prejudicial attitudes, stereotyping, and empathy and indented behaviour.

#### IS-BN07 Core Stability and Injury in Sports (\*)

##### TRUNK MOTOR CONTROL AND ITS INFLUENCE ON LOWER EXTREMITY MECHANICS

Chaudhari, A., Jamison, S., Best, T.

*The Ohio State University*

Previous research has demonstrated that activity-based interventions can be effective for knee injury prevention and rehabilitation, but has not elucidated the key mechanisms that reduce knee loading in vivo during sports-related dynamic motion. Anecdotal data throughout the scientific literature and popular press advocate for improved trunk motor control or "core stability" for injury treatment and, more importantly, prevention of injury involving the lower extremity as well as low back and upper extremity. Despite this widespread assertion that "you need to work on your core," a critical barrier to progress in the prevention of musculoskeletal injuries is the lack of understanding of the mechanism by which trunk motor control could modulate known biomechanical predictors of injury risk. This talk will discuss the current evidence that exists to define the role of trunk motor control in lower extremity mechanics, as well as future research directions to improve our understanding of lower extremity injury mechanisms and accelerate development of more efficient and effective injury prevention programs.

##### WHAT ARE CURRENT TRAINING PROGRAMS LACKING? TOWARDS HEALTHY TRAINING...

Verhagen, E.

*EMGO-Institute/VU University medical center*

Regular participation in physical activity and sports is beneficial for health. Thereby, safety in sports and physical activity is an important prerequisite for continuing participation in sports, as well as maintenance of a healthy physically active lifestyle. However, injuries are side effects of otherwise healthy activities and should not be neglected. The consistent findings that relative inactive individuals are at increased risk for injury pose an important issue in regards to public health and injury prevention. It is this part of the entire population that is encouraged through various channels to become more active for health reasons. Based upon current sports injury prevention research paradigms, one would expect that thus established activity level injury difference would have led to specific prevention programs. However, injury preventive behaviors and safety message are based upon research in more active sporting populations. As such, the main risk factors of injuries are for a large part not targeted in this important population at risk. This implies there is much to gain by studying and targeting the true injury causing factors in the larger part of low level and novice athletes.

##### CORE TRAINING TO PREVENT INJURY

Best, T.

*The Ohio State University*

Popular scientific and lay press advocate for core training and injury prevention and rehabilitation. Despite these assertions, limited well-conducted, controlled studies provide a direct link between core training and an alteration in primary and secondary injury risk prevention. In this session, we will review recent studies from our laboratory and others involving core training that delineate specific strategies to mitigate biomechanical risk factors for lower extremity injury. The goal is to develop consensus from the current literature and to formulate evidence-based questions that can move the field forward regarding core training and injury prevention/rehabilitation.

#### OP-BN09 Sports Biomechanics 4

##### PITCHER AGING AFFECTS THROWING SHOULDER BIOMECHANICS AND PROPRICEPTION: THE ITALIAN EXPERIENCE

Pegreff, F.1, Vittori, L.1, Foschi, E.1, Latessa Maietta, P.1, Paladini, P.2, Campi, F.2, Pellegrini, A.2, Porcellini, G.2, Tentoni, C.2  
*University of Bologna*

Introduction: Baseball is a sport increasingly practiced in Italy. The pitcher is at risk from repetitive stress on the dominant upper arm. Because of this, pitchers train far more on the dominant arm leading to asymptomatic biomechanical changes. The purpose of this study

was to compare shoulder intra/extra rotational power and shoulder motor skill in young and senior athletes. Methods: Twenty right-hand healthy pitchers playing for at least four years were recruited : Group A (12±2yrs) and Group B (24±1yrs). Subjects with a history of shoulder dislocation, shoulder surgery or structural injuries to the shoulder complex were excluded from the study. Isokinetic tests (IT) were performed to evaluate intra/extra rotational power, and shoulder motor skill test (SMST) to evaluate proprioception. Results: Performing IT, we have found in both groups a significant higher external rotation compared to internal rotation in the throwing shoulder (TS), while in the contralateral shoulder (CS) the balance was preserved ( $p < 0.003$ ). In Group A, SMST was 4±2 points (TS) and 4±1 points (CS),  $p = n.s$ . In Group B, SMST was 9±1 points (TS) and 4±2 points (CS),  $p < 0.005$ . Discussion and Conclusion: Italian pitchers demonstrated a higher external rotational power in the throwing shoulder after only four years of practicing baseball. Motor skill ability seems to develop later in the dominant shoulder. This study suggests that a baseball training program, especially for young pitchers, should include not only exercises to restore internal/external rotation balance but also motor skill exercises, to improve throwing ability, limit the number of throws, prevent shoulder injury over time.

### **EXERCISE OF MECHANISMS OF DYNAMIC STABILITY IMPROVES THE STABILITY STATE AFTER AN UNEXPECTED GAIT DISTURBANCE IN ELDERLY**

Bierbaum, S.1, Arampatzis, A.2

1: University of Stuttgart, 2: Humboldt-University of Berlin

Introduction Elderly individuals are more challenged in their dynamic stability by unexpected changes during gait than young persons. This is represented in a reduced recovery performance in response to obstacles and unexpected perturbations (Tseng et al., 2009; Galna et al., 2009). However, the adaptive potential of elderly persons seems to be preserved and therefore the training of the mechanisms of dynamic stability as well as the contribution of muscle strength may improve the dynamic stability after unexpected perturbations. Methods 37 persons in the age from 65-75 years participated in the study divided in two experimental groups (SG: n=14; MG: n=13) and a control group (CG: n=10). SG- and MG-group performed a training of exercises which included the mechanisms of dynamic stability. MG-group exercised additionally muscle strength. Exercise volume and intervention duration was equal for both groups (14 weeks, two times a week and ~1.5h per session). Prior to the intervention and afterwards, subjects performed a gait protocol in which they experienced an unexpected perturbation. Dynamic stability was analyzed according to the concept of the extrapolated center of mass (Hof, 2008). Results Margin of stability after an unexpected perturbation during gait has been increased significantly after the intervention in the SG-group indicating an improvement in stability state (pre: -30.3±5.9cm; post: -24.1±5.2cm). Further, after the intervention, both intervention groups showed an increase of the base of support after the perturbation (SGpre: 90.9±6.6cm, SGpost: 98.2±8.5cm; MGpre: 91.4±6.2cm, MGpost: 97.9±12.7cm). Control group showed no difference between pre and post measurement. Discussion The exercise of the mechanisms of dynamic stability led to a better application of these mechanisms after an unexpected perturbation during gait. Both experimental groups increased the base of support after the intervention as an important mechanism to regain balance after a gait perturbation. However, a clear improvement in the stability state (i.e. margin of stability) during the disturbance has been achieved only in the SG-group. Therefore we suggest that the repeated exercise of the mechanisms of dynamic stability contributes adequately to the accomplishment of improved dynamic stability, but that the performed additional strength training for healthy elderly individuals shows no further effect on the ability to recover balance after unexpected perturbations during gait. ### **ANTICIPATIVE POSTURAL ADJUSTMENT STRATEGIES DURING CUTTING MANEUVER**

Mornieux, G., Gehring, D., Fürst, P., Gollhofer, A.

University of Freiburg

Introduction During complex whole body movements like cutting maneuvers, the time available to prepare the movement is of importance (Houck et al., 2006). With more time available, the anticipative postural adjustments (Patla et al., 1999; Jindrich et al., 2009) taking place at the foot, hip, trunk and head levels can be optimized in order to accelerate the center of mass in the new direction. For that purpose subjects typically regulate their foot placement already prior to the change of direction and adjust their trunk orientation (Patla et al., 1999). We hypothesized that less anticipation time would not allow regulating the foot placement, which in consequences would be compensated by a greater trunk orientation strategy. Methods 13 males (179±3 cm; 74±7 kg) performed cutting maneuvers with different cutting angles at a 5m/s approach velocity. All trials were randomized and subjects got the information in which direction they had to cut by means of a light system at different anticipation times, i.e. 850ms, 600ms or 500ms before the change of direction. Kinematics (Vicon) of the trunk and hip joints as well as the step width were measured at the time of foot off (FO) one step prior to the change of direction and then at the initial contact (IC) while changing direction. A variance analysis was used to determine the influence of the anticipation time on the different dependent variables during the 45° cutting maneuver. A significance level of  $p < 0.05$  was selected. Results With less anticipation time, the trunk was significantly less rotated towards the cutting direction at FO and IC ( $p = 0.03$ ). The step width was significantly reduced with less anticipation time at FO ( $p = 0.03$ ) and remained unchanged at IC. Finally, at IC, less anticipation time significantly increased the trunk abduction (from 15° to 19°;  $p = 0.01$ ) and tended to increase the hip abduction ( $p = 0.05$ ). Discussion The reduced trunk rotation reflected the difficulties for subjects to initiate the orientation of the whole body in the cutting direction when the anticipation time was limited. As the acceleration of the center of mass in the new direction could not be initiated through an appropriate foot placement, subjects used an increased trunk abduction strategy to realize the cutting maneuver with less anticipation time. However, increased trunk abduction could be associated with increased knee joint loading (Hewett and Myer, 2011). Therefore reducing the anticipation time to perform cutting maneuvers might be associated with higher knee injury risk. References Hewett TE, Myer GD (2011). *Exerc Sport Sci Rev*, 39(4), 161-166. ### **MUSCLE WEAKNESS IN PARKINSON DISEASE AS CONSEQUENCE OF IMPAIRED NEUROMUSCULAR CONTROL**

Moreno Catalá, M., Woitalla, D., Arampatzis, A.

Humboldt Universität zu Berlin

MUSCLE WEAKNESS IN PARKINSON DISEASE AS CONSEQUENCE OF IMPAIRED NEUROMUSCULAR CONTROL 1María Moreno Catalá, 2Dirk Woitalla, 1Adamantios Arampatzis 1Department of Training and Movement Sciences, Humboldt-University Berlin, Germany 2St. Joseph

Hospital of the Ruhr-University Bochum, Germany Introduction Muscle weakness has been observed in patients with the Parkinson Disease (PD) and correlated with clinical severity and several movement impairments like falls, reduced walking speed or dynamic postural instability (Stevens et al., 2011; Durmus et al., 2010; Nocera JR. et al., 2010). However the specific cause of this weakness is not well known. The aim of this study was to examine the muscle strength of the plantar flexors (PF) and knee extensors (KE) in faller and non-faller PD patients as well as in healthy control participants in order to determine whether muscle weakness originated from central or peripheral factors. Methods 23 young PD patients (13 fallers and 13 non-fallers, stage I-III H&Y scale) and 15 matched healthy controls performed several isometric maximal voluntary knee extension and plantar flexion contractions (MVC) of the most affected leg on a dynamometer. The antagonistic moment of hamstrings (HA) and tibialis anterior (TA) during contractions was estimated by establishing a relationship between EMG amplitude and exerted moment for HA and TA whilst working as agonist (Mademli et al. 2004). In order to assess the activation deficit of the plantar flexor (PF) and knee extensor (KE) muscles the twitch interpolation technique was used. Results The control participants showed higher moment values ( $p < 0.05$ ) in both PF ( $161 \pm 45$  vs  $115 \pm 29$  Nm) and KE ( $203 \pm 69$  vs  $159 \pm 45$  Nm) compared to the Parkinson fallers. No significant differences ( $p > 0.05$ ) were found for the resultant moment between the control group and the non-faller Parkinson group. During the MVCs the antagonist moment of the TA and the HA were significant higher ( $p < 0.05$ ) in the Parkinson fallers compared to the control group. Furthermore the Parkinson fallers showed a significant higher ( $p < 0.05$ ) activation deficit compared to the control group of the PF (14 vs. 9%) and KE (22 vs. 10%). Discussion Our results showed that the reason of muscle weakness in the Parkinson fallers derived mainly from central impairments. The reduced ability to activate the whole muscle and an impaired neuromuscular control between agonists and antagonists affected significantly the torque production. These impairments may contribute to the increased fall risk in these patients with PD. REFERENCES. 1. Stevens J. et al. (2011). *Neurorehabil Neural Repair*, Dec 2. 2. Durmus B. et al. ### **DYNAMIC KNEE JOINT VALGUS – THE RESULT OF A SPECIFIC NEUROMUSCULAR PATTERN DURING SIDECUTTING MANOEUVRES IN YOUNG FEMALE ELITE ATHLETES?**

Zebis, M.K.1,2, Bencke, J.2, Petersen, M.B.2, Curtis, D.2, Bloch-Lauridsen, H.2, Hölmich, P.2, Andersen, L.L.3, Myklebust, G.4, Aagaard, P.1

1: University of Southern Denmark (Odense, Denmark), 2: Copenhagen University Hospital (Denmark), 3: NRCWE (Copenhagen, Denmark), 4: OSTRC (Oslo, Norway)

Introduction Identifying risk factors for future ACL-injury is a promising way towards effective injury prevention. Dynamic lower extremity valgus has been identified to predict ACL-injury risk in female athletes (Hewett et al., 2005). Similar, the neuromuscular activity of agonist-antagonist knee joint muscles has been identified as a potential risk factor (Zebis et al., 2009). In the present study we investigated the association between knee valgus positioning and the underlying neural pre-activation pattern in medial (m. semitendinosus) vs. lateral (vastus lateralis) thigh muscles, in a movement associated with non-contact ACL-injury. The present investigation involved a population of young female elite athletes, known to be at high risk of sustaining non-contact ACL-injury (Lind et al., 2009). Methods Forty young female elite handball and soccer players (age  $15.9 \pm 1.4$  years) agreed, with their parent's consent, to participate. Five repetitions of each player's individual sidecut manoeuvre were investigated using an 8 camera Vicon 612 system and an AMTI force platform. Knee abduction (valgus) angle at initial contact (IC) was measured. Vastus lateralis (VL) and semitendinosus (ST) muscle activity (EMG) was measured in the 50 ms time interval prior to foot strike. EMG activity was normalized to peak EMG amplitude recorded during MVC, and VL minus ST pre-activity was calculated. Results The players were divided into a valgus or a varus group based on frontal plane knee joint angle at IC. Sixteen players landed in a knee valgus position ( $-1.7 \pm 0.8^\circ$ ) and 24 players in a varus position ( $3.7 \pm 2.4^\circ$ ) ( $P < 0.0001$ ). Valgus players showed larger VL minus ST EMG values compared with varus players ( $20 \pm 18\%$  vs.  $1 \pm 23\%$ ) ( $P = 0.004$ ). Discussion During rapid sidecutting, substantial neural pre-activation of the medial hamstring muscle (ST) is important to medially compress the knee joint and thereby limit the risk of excessive knee valgus positioning. The present data suggest that the occurrence of knee joint valgus during sidecutting is the result of reduced pre-activity in ST accompanied by high lateral quadriceps activity in the initial landing phase, altogether resulting in a movement profile with high risk of ACL-injury. ### **LEG LENGTH DIFFERENCE IN CYCLISTS: KINETIC IMBALANCES AND CORRECTIONAL OPTIONS**

Mann, M.

*Universal College of Learning (UCOL)*

Introduction: The purpose of this study was to investigate the relationship of leg length differences and kinetic imbalances in addition to the effect of existing correctional procedures on such imbalances in cycling. Methodology: On a preliminary visit, total, upper and lower leg lengths were measured from the greater trochanter of the femur (GT) to heel (H), the GT to lateral condyle (LC), and LC to H, respectively. Two interventions: crank length (CL) and cleat wedge (CW) and a control (normal bike set-up (N)) were performed in a randomised order with a 2-5 d period between trials. Participants ( $n=10$ ) performed a maximal isokinetic test (to allow for normalisation of EMG data) followed by three 15min work sessions (CL: CW: N) at ventilatory threshold (VT). Heart rate, cadence, power output and expired air were averaged over each 15min interval. Net torque, EMG taken from left and right vastus lateralis (VL), were taken and averaged during 40-50s of the 5th, 10th and 15th min. Video footage synchronised with torque measurements was digitised and used to analyse 2D mechanical angles (thigh to horizontal, knee joint and ankle joint). Results: There were no significant differences ( $p > 0.05$ ) between conditions indicating reliability for power output (W), cadence (rpm),  $VO_2$  ( $L \cdot min^{-1}$ ) and HR (bpm), averaged over each 15min period. In the cleat wedge condition, there was a reduction in between-leg variance ( $P < 0.05$ ) and a small effect size ( $ES = 0.18$ ) between left and right leg torque. EMG variability reduced under the same condition giving a medium effect size ( $ES = 0.51$ ). Discussion: results suggest that, given a longer intervention using the CW condition, imbalances could be reduced leading to improved performance and minimising friction, pressure and overuse injuries conditions common to endurance cyclists. Further research is required, using more subjects and an intervention period, as to how cyclists optimise force production while reducing variability between left and right legs.

### OP-PM48 Health and Fitness 3

#### **PHYSICAL ACTIVITY COUNSELLING AND EXERCISE REFERRAL INCREASES TOTAL PHYSICAL ACTIVITY IN LONG TERM UNEMPLOYED INDIVIDUALS: A CONTROLLED ACCELEROMETER TRIAL**

Gabrys, L., Michallik, L., Thiel, C., Vogt, L., Banzer, W.

*Goethe-University Frankfurt*

**Introduction** Physical activity is seen as an integral component of a healthy lifestyle and has the potential to produce significant health benefits amongst individuals (Pedersen & Saltin 2006). It therefore plays a major role in the field of public health and primary prevention. Compared to the general population, unemployed persons show higher levels of physical inactivity and less physical activity (Pockrandt et al. 2007). For this and other reasons like e.g. unhealthy eating, smoking or substance abuse unemployment is associated with a greater health risk that additionally rises with increased duration of unemployment (Hollederer 2011). Therefore, a sports medical service of physical activity counselling and exercise referral was established at regional job centres to refer older unemployed persons to existing local exercise for health programs. The aim of this accelerometer study is to assess the change in physical activity following standardised physical activity counselling and exercise referral. A secondary focus lies on the changes in subjective health outcomes such as health- and fitness status in elderly long-term unemployed persons over 50 years of age. **Methods** A sample of 51 long-term unemployed persons over 50 years received physical activity counselling and exercise referral to attend local exercise for health programs at no charge for the next months. Further 21 unemployed persons and 17 employed persons, defined as control groups with no counselling nor exercise referral, were included. Physical activity levels of all 89 participants were measured over 7 consecutive days prior to and 12 weeks after counselling by biaxial accelerometer (ActiGraph GT1M). **Results** Overall 58 persons completed pre/post measurements. Participants who started exercising increased their amount of moderate to vigorous physical activity (MVPA) from  $26 \pm 14$  to  $35 \pm 25$  minutes/day as well as total physical activity from  $207 \pm 86$  to  $288 \pm 126$  counts/minute significantly. At baseline, employed persons were more active than unemployed persons. Subjective health status decreased significantly in the unemployed control group after 12 weeks. **Discussion** Unemployed persons are less active and less healthy compared to employed study sample. Unemployed persons who are willing and motivated to change physical activity behaviour benefit from physical activity counselling and exercise referral and increase MVPA to a health promoting level according to the guidelines. Physical activity inequalities could be reduced. **References** Hollederer, A (2011). #### **WALKING AND TALKING FOR FITNESS AND WELL-BEING: EFFECTS OF A STRUCTURED WALKING INTERVENTION IN A COMMUNITY-BASED SOCIAL ORGANIZATION FOR OLDER ADULTS**

Pelssers, J., Delecluse, C., Opendacker, J., Kennis, E., Van Roie, E., Boen, F.

*KU Leuven*

**Introduction** This study evaluated a ten-week structured walking intervention with systematic training progression in a community-based social organization for older adults on promoting physical activity, fitness and well-being among older adults (>55). The intervention prescribed pedometer-based walks in weekly walking schedules. These were competence-tailored based on a walking assessment (6' walking test) and structured in walking load according to the principles of training progression. The intervention was implemented as a social activity in community-based meeting points of a social organization for older adults, including group walks. **Methods** The intervention condition consisted of 29 meeting points (n = 432) while 10 meeting points (n = 148) formed a waiting-list control condition. Measurements were at intervention start (pre-test) and end (post-test). The Godin LTEQ (Godin et al., 1985) was used to assess physical activity. The 6' walking test (6MWT; Butland et al., 1982) was used to assess fitness. Well-being included measures of anxiety (STAI; Spielberger et al., 1983), well-being (Marcoen et al., 2002), and subjective health. **Results** Intention-to-treat linear mixed models revealed intervention effects on moderate intensity (F = 7.276, p < .01) and total physical activity (F = 6.185, p < .05), fitness (F = 9.486, p < .01), anxiety (F = 5.261, p < .05) and subjective health (F = 3.960, p < .05), and suggested an effect on low intensity physical activity (F = 3.291, p = .07). The effects consisted of increased low intensity (t = -6.482, p < .001) and total physical activity (t = -3.589, p < .001), fitness (t = -7.017, p < .001) and subjective health (t = -4.723, p < .001), and of reduced anxiety (t = 4.957, p < .001) over time. Moderate intensity physical activity remained unchanged in the intervention condition (t = -1.707, p = n.s.), but was reduced in the control condition (t = 2.131, p < .05), indicating the counteraction of a season effect. **Conclusions** The intervention was effective in promoting physical activity, fitness and aspects of well-being. The results underline the value of (A) training progression in structured walking interventions and of (B) community-based social organizations for older adults as intervention setting. **References** Butland RJA, Pang J, Gross ER, Woodcock AA, Geddes DM. #### **HIGH INTENSITY INTERVAL TRAINING: A TIME SAVING ALTERNATIVE TO TRADITIONAL EXERCISE PRESCRIPTION FOR OVERWEIGHT, PHYSICALLY INACTIVE ADULTS**

Draper, N., Lunt, H., Marshall, H., Logan, F., Hamlin, M., Cotter, J., Shearman, J., Kimber, N., Blackwell, G., Frampton, C.

*University of Canterbury*

**Introduction** The incidence of obesity continues to rise in many developed countries and have been closely linked rises in physical inactivity (Blair, 2009). 'Lack of time' has been commonly cited as a major reason the decline in physical activity in these countries (Godin et al., 1994; Blair, 2009). Previous laboratory based research with clinical population and young active males suggest that high intensity interval training (HIIT) may provide a time saving alternative to traditional exercise prescription (Gibala et al., 2006). The application of these

findings to pre-clinical populations in a real-world setting has yet to be reported. The aim of this study was to investigate whether the time saving benefits of HIIT could translate to a community setting with participants who were overweight and physically inactive. Methods Forty-nine participants (36 female, 13 male; mean  $\pm$  SD) age 48.2  $\pm$  6.0 years, BMI 32.4  $\pm$  4.2 kg/m<sup>2</sup> were randomly assigned to low intensity endurance training (LIET – active control), HIIT and maximal volitional interval training (MVIT). All groups completed a 10 min warm-up and 5 min cool-down, followed by a group specific exercise protocol - LIET 33 min continuous exercise at 65 – 75 % HRmax; HIIT 4  $\times$  4 min exercise bouts with 3 min recoveries at 85 – 95 % HRmax; MVIT 4  $\times$  30 s maximal efforts with 4 min recoveries. The exercise sessions (3  $\times$  pw) took place at a local park, HIIT and LIET groups walking on the flat, MVIT group using a slope. Pre and post the 12 week intervention testing included, resting blood pressure (BP), VO<sub>2</sub>max, and waist circumference. Results Results indicated there were no significant differences between the groups, however, resting BP, waist circumferences, HR and VO<sub>2</sub> during the VO<sub>2</sub>max test were significantly lower post exercise intervention. Discussion Our findings suggest that both HIIT and MVIT present time saving alternatives to traditional LIET with similar health benefits post exercise intervention for overweight and previously physically inactive adults. Participants in the MVIT group reported a higher incidence of musculoskeletal injuries than either the LIET or HIIT groups. This finding suggests that for maximal effort exercise such as that completed by the MVIT group should be completed on non-weight-bearing exercise modes such as cycling or deep-water running. In a real world setting with overweight and previously inactive participants HIIT provides a time saving alternative to LIET with no apparent increased risk of injury. References Blair SN. ### STRENGTH COMBINED WITH WALKING BUT NOT WALKING TRAINING ALONE MAINTAINS FUNCTION IN OLD ADULTS

Hortobágyi, T.

*University of Groningen Medical Center*

STRENGTH COMBINED WITH WALKING BUT NOT WALKING TRAINING ALONE MAINTAINS FUNCTION IN OLD ADULTS Hortobágyi, T. Center for Human Movement Sciences, University of Groningen Medical Center (The Netherlands) Introduction Old adults use walking in an effort to maintain levels of physical activity and function. The purpose of the study was to clarify if walking alone is sufficient to circumvent losses in function and mobility in old adults or it would have to be combined with strength training. Methods Healthy old adults were randomly assigned to a walking (W, n=12) or a walking+strength training (W+S, n=12) exercise group in a retirement center and tested at baseline then bimonthly for 12 months for measures of function. Both groups followed ACSM exercise training guidelines. Results Relative to baseline, at 12 months W+S lifted 9.0 (SD  $\pm$ 3.8) kg more in two-legged 3-RM knee extension, improved 4.2 ( $\pm$ 2.3) kg in handgrip strength, performed 11 more knee extension repetitions at 75% of the initial 1RM load, had 5.0 ( $\pm$ 2.0) fewer falls, improved gait velocity by 0.51 ( $\pm$ 0.99) measured over 400-m path, and walked spontaneously 14.8 minute more per day (all  $p < 0.05$ ). Relative to baseline, at 12 months W lifted 8.0 (SD  $\pm$ 4.5) kg less in two-legged 3-RM knee extension ( $p < 0.05$ ), produced 4.2 ( $\pm$ 2.3) kg less in handgrip strength ( $p < 0.05$ ), performed 1.4 fewer knee extension repetitions at 75% of the initial 1RM load (n.s.), had no change in the number of falls, walked 0.10 ( $\pm$ 0.50) m/s slower measured over 400 m, and walked spontaneously 0.31 ( $\pm$ 0.2) minute more per day (n.s.). Changes in gait velocity and 3-RM leg strength correlated  $r = -0.79$  in W+S only. Neither program produced any changes in resting blood pressure and heart rate. Discussion Maintaining mobility and independence are key goals in old adults. Walking is often recommended as an exercise modality to maintain function. Within the limitations of the present study it, however, seems that a long-term walking program is actually accompanied by a loss of muscle strength and a dampened function-maintaining effect as compared with W+S. The data suggest that inclusion of 1-2x/week strength training sessions in healthy old adults' exercise program can slow loss of function and perhaps improve spontaneous gait speed. Walking alone does not seem to provide such a protective effect.

### A COMPARISON OF INTERVENTIONS TO SUPPORT WEIGHT LOSS AND IMPROVED BODY COMPOSITION

Stopforth, M., Baker, M.

*Southampton Solent University*

A COMPARISON OF INTERVENTIONS TO SUPPORT WEIGHT LOSS AND IMPROVED BODY COMPOSITION Stopforth, M.L & Baker, M. SOLENT UNIVERSITY, ENGLAND Introduction Obesity is a rapidly spreading epidemic, with treatment costing the UK billions of pounds a year (DOH, 2009). Annessi and Whitaker (2010) stated that behavioural support alongside nutritional education had a positive impact on weight loss. Commercial weight loss groups have been found to be effective (Jebb et. al., 2010), but as 30.1 million adults in the UK accessed the daily in 2010 (Office for National Statistics, 2010), support via the internet may also be viable way of providing support. Previous research has shown computer assisted dieting to be better than no support (Shroder, 2009), but the current pilot study aimed to compare computer aided support with a weekly support group and education alone. Methodology 26 participants whose high level of body fat posed a significant risk to their health were randomly allocated to one of three intervention groups: Social Support (SS; n=9); Online Support (OS; n=9); or Education Only (EO; n=8). All 26 participants attended an educational session which followed the NICE (2006) guidelines on obesity prevention and management. The OS group were then given a tutorial on how to use an online weight loss support tool, and the SS group attended weekly support sessions. Participants' body fat (%) and body mass (kg) were measured pre and post intervention (12 weeks). 24 participants completed post testing. Results Results showed a significant decrease in body fat ( $F(1,21) = 18.40$ ,  $p < 0.005$ , partial  $\eta^2 = 0.47$ ) and body mass ( $F(1,21) = 22.46$ ,  $p < 0.005$ , partial  $\eta^2 = 0.52$ ) in all three groups. However, there was no significant difference between the groups ( $F(2,21) = 2.20$ ,  $p = 0.32$ ). Discussion These findings suggest that low-cost (to the client) interventions such as online support or the provision of a one off educational session are as effective methods as methods requiring greater professional input, such as weekly support meetings. **Purpose** The rate of increase in oxygen uptake during submaximal exercise (VO<sub>2</sub> onset kinetics) has been shown to be a good marker of prognosis and functional capacity in patients with chronic heart failure (CHF) (Kemps, 2007). The purpose of the present study was to investigate the pathophysiological background of delayed VO<sub>2</sub> onset kinetics in CHF patients. Methods Twelve stable CHF patients (NYHA II-III) and 8 healthy subjects, matched for age and body mass index (BMI), were included. All subjects performed a submaximal constant load exercise test at 80% of the ventilatory threshold. VO<sub>2</sub> onset kinetics were expressed as the time constant of the mono-exponential VO<sub>2</sub>-increase ( $\tau$ -VO<sub>2</sub>). In order to assess changes in the ratio between oxygen delivery and oxygen utilization at the skeletal muscle level (Tissue Oxygenation Index, TOI), Near Infrared Spectroscopy (NIRS) was applied simultaneously at the vastus lateralis muscle. The rate of decrease in TOI was assessed by the mean response time, including a time delay and the time constant of the initial mono-exponential TOI-decrease. Results As expected peak oxygen uptake was significantly lower in CHF patients ( $20 \pm 5$  versus  $37 \pm 14$  ml/min/kg,  $p=0.005$ ). Also, VO<sub>2</sub> onset kinetics were delayed in CHF patients ( $\tau$ -VO<sub>2</sub>:  $64 \pm 25$  versus  $41 \pm 23$  sec,  $p=0.02$ ). This delay was associated with slower TOI onset kinetics in CHF patients (MRT-TOI:  $27 \pm 11$  versus  $19 \pm 3$  sec,  $p=0.02$ ). These results indicate a slower decrease in oxygen delivery relative to oxygen utilization in CHF patients, thereby suggesting, at least at a group level, a limiting role of oxygen utilization in exercising muscles. However, there was a considerable between-patient variation as shown by the lack of correlation between  $\tau$ -VO<sub>2</sub> and MRT-TOI in CHF patients ( $\rho$ :  $-0.25$ ,  $p=0.43$ ). Conclusion The results of the present study suggest that impaired skeletal muscle metabolism is an important contributor to delayed VO<sub>2</sub> onset kinetics in moderately impaired CHF patients. However, given the considerable between-patient variation, further research is needed to identify subgroups with different physiological profiles (Bowen, 2011). #### RELATIONSHIP BETWEEN V'O<sub>2</sub> KINETICS AND MAXIMAL OXYGEN UPTAKE IN THE ELDERLY.

Koschate, J., Drescher, U., Brixius, K., Montiel, G., Predel, H.G., Hoffmann, U.

German Sport University Cologne

**Introduction:** Maximal oxygen uptake (V'O<sub>2</sub>max) as well as V'O<sub>2</sub> kinetics depend on central factors, such as cardiac output and peripheral determinants like oxidative capacity of the muscles. Babcock et al. (1994) already showed results concerning the relation between V'O<sub>2</sub>max and V'O<sub>2</sub> kinetics within a group manifesting a wide age range; 30-60 years. This relation remains to be demonstrated in a homogeneous age group and would prove a considerable influence of V'O<sub>2</sub>-kinetics on aerobic capacity. Using a submaximal, non-invasive exercise test combined with an especially developed instrument, the Backward-Calculation-Method (BCM), muscular oxygen uptake kinetics will be calculated and correlated to V'O<sub>2</sub>max in elderly subjects. Method: 22 male elderly subjects were analyzed (72.91 ( $\pm 2.8$ ) years, 84.1 ( $\pm 9.1$ ) kg, 174.9 ( $\pm 4.2$ ) cm, 1.87 ( $\pm 0.41$ ) L\*min<sup>-1</sup>). All subjects completed an 'allout' test to measure V'O<sub>2</sub>max and a moderate test using pseudo random binary sequences (PRBS) to evaluate cardiorespiratory kinetics on a cycle ergometer. During the moderate test heart rate (H) and respiratory V'O<sub>2</sub> (R) were measured and muscular V'O<sub>2</sub> (M) was calculated. For this calculation the BCM-Method was used to compute the cardiorespiratory kinetics applying auto (ACF) and cross correlations (CCF). By the use of ACF and CCF a 'peak' (peak cross correlation time between work and parameter; velocity of the kinetics) was derived for each parameter. Data were analyzed via parametric correlations and linear regression, using IBM SPSS Statistics 20. Results: Mpeak and V'O<sub>2</sub>max correlate significantly ( $r=0.428$ ;  $p=0.023$ , one-tail) as well as Rpeak and V'O<sub>2</sub>max ( $r=0.425$ ;  $p=0.024$ , one-tail). There was no significant correlation concerning Hpeak and V'O<sub>2</sub>max. Performing a stepwise linear regression, including Hpeak, Mpeak and Rpeak as independent and V'O<sub>2</sub>max as the dependent variable, Mpeak shows the most important influence on V'O<sub>2</sub>max ( $p=0.047$ ). Discussion: There is good evidence regarding a relationship between V'O<sub>2</sub>max and V'O<sub>2</sub> kinetics in a homogeneous age group. Therefore, calculation of V'O<sub>2</sub> kinetics via PRBS might be used as an indicator for changes in V'O<sub>2</sub>max. The independency of this submaximal test concerning high motivation, which is usually needed to measure V'O<sub>2</sub>max, can be seen as a benefit for the elderly population or patients where V'O<sub>2</sub>max cannot be measured. Additionally these results demonstrate the importance of the calculated muscular V'O<sub>2</sub> with a potentially superior influence on V'O<sub>2</sub>max over V'O<sub>2</sub> measured at the mouth. #### DOES METABOLIC STRESS AFFECT THE DECREASE IN OXYGEN UPTAKE AT THE END OF ALL-OUT EXERCISE ?

Thomas, C.

INSEP

DOES METABOLIC STRESS AFFECT THE DECREASE IN OXYGEN UPTAKE AT THE END OF ALL-OUT EXERCISE ? Thomas, C.1,2, Delfour-Peyrethon R. 1, Perrey, S. 4, Dorel, S. 1,5, Lepretre, P.M., 6, Bishop, D. 3, Hanon, C. 1. 1 : INSEP (Paris, France), 2 : UEVE (Evry, France), 3 : ISEAL (Melbourne, Australia), 4 : M2H, Euromov (Montpellier, France), 5 : MIP EA 4334 (Nantes, France), 6 : UPJV (Amiens, France) Introduction The present study investigated the effects of altering extracellular buffer capacity during acute all-out exercise on VO<sub>2</sub> decrease. Although some previous studies have investigated the effects of prealkalosis on VO<sub>2</sub> kinetics during submaximal and supramaximal exhaustive exercises with controversial effects, we hypothesised that the VO<sub>2</sub> decrease at the end of supramaximal exercise performed until exhaustion could be affected by acidosis, and we further posited that preexercise-induced alkalosis could prevent the VO<sub>2</sub> decrease. Methods We investigated the oxygen uptake response and performance during 70-s all-out exercise performed in two conditions,

preexercise alkalosis (BIC : 0,3 g.kg<sup>-1</sup> NaHCO<sub>3</sub>) and placebo (PLA : 0.2 g.kg<sup>-1</sup> CaCO<sub>3</sub>) in highly-trained subjects. Exercise tests were conducted using an electronically braked cycle ergometer (Excalibur Sport, Lode, Groningen, The Netherlands). Blood samples were collected at rest, before the test and at 0, 5 and 8 min of 70-s exercise recovery (i-STAT, Abbott, Les Ulis, France). Results Significant differences between PLA and BIC are observed for power output during the last 50s (P < 0.05) and total power output (P < 0.01). Oxygen uptake response increase to a steady state corresponding to 95.2 ± 3.2 and 99.7 ± 2.8 % of VO<sub>2</sub>max for PLA and BIC respectively, before to significantly decrease of 9.2 ± 3.2 for PLA and 7.8 ± 1.9 % for BIC with no significant difference among groups. Discussion The results suggests that the decrease in VO<sub>2</sub> at the end of supramaximal exercise of 70 s can not be explained by middle acidosis (pH=7.13±0.01 in PLA vs 7.22±0.01 in BIC) since VO<sub>2</sub> decrease was also observed in alkalosis condition. As VO<sub>2</sub> decrease was related to a decrease in Ventilation in Pla group (r=0.71, P<0.01), muscle respiratory fatigue could be involved in this phenomenon. Indeed, subjects who presented higher VO<sub>2</sub> decrease are those with higher ventilation decrease in both conditions, but they did not present a decrease in arterial oxygen saturation compared to other subjects. If ventilatory muscle fatigue could be an important factor contributing to VO<sub>2</sub> decrease, others additional factors could be involved to explain this phenomenon, but not metabolic stress. ### IMPLICATION OF CEREBRAL DEOXYGENATION IN EXERCISE LIMITATION DURING INCREMENTAL EXERCISE

Oussaidene, K.

*université Lille2*

IMPLICATION OF CEREBRAL DEOXYGENATION IN EXERCISE LIMITATION DURING INCREMENTAL EXERCISE Oussaidene, K.1, Prieur, F.2, Bougault, V.1, Borel, B.1, Mucci, P.1 1: UDSL, EA 4488 (Ronchin, France), 2: CIAMS, EA 4532 (Paris-Sud - Orléans, France). Introduction During incremental exercise, cerebral oxygenation decreases at heavy intensities (Rupp & Perrey, 2008). This may induce an alteration of the central nervous control of motor output (Amann et al., 2006) and limit performance. Our objective was to investigate the involvement of O<sub>2</sub> availability in the brain as a limiting factor of incremental exercise by the use of hyperoxia. Methods Eight men, untrained in endurance physical activities (mean ± SD: age 27 ± 6 years, body mass 77 ± 6 kg, height 180 ± 5 cm, physical activities ≤ 3h/week, maximal oxygen consumption (VO<sub>2</sub>max = 3.49 ± 0.48 L.min<sup>-1</sup>), performed two incremental ramp exhaustive exercise (1W/3s) until volitional fatigue, on cycle ergometer, in a random order in normoxia (FIO<sub>2</sub> = 0.21) and hyperoxia (FIO<sub>2</sub> = 0.30). Cerebral oxygenation (COx) was assessed by near-infrared spectroscopy (OxyMon MKIII, Artinis) and pulmonary gas exchange and arterial hemoglobin O<sub>2</sub> saturation (SpO<sub>2</sub>) were measured. The respiratory compensation point (RCP) and the COx threshold decline (ThCOx) were determined during exercise in each subject in each condition. Results Hyperoxia improved significantly the maximal power output (Wmax: 302 ± 20 vs. 319 ± 28 W) and SpO<sub>2</sub> (95.75 ± 0.88 vs. 97.00 ± 0.53 %) compared to normoxia (P<0.05). In both conditions, COx decreases from heavy intensities (i.e > RCP) until achieving a minimal exercise level at Wmax (COxWmax). COxWmax was similar between normoxia and hyperoxia (4.73 ± 6.30 vs. 5.56 ± 4.73 μM, respectively). ThCOx decline was delayed with hyperoxia and appears for higher exercise intensities (259 ± 23 vs. 288 ± 30 W, P<0.05). This shift was significantly related to the improvement in Wmax (r = 0.71, P<0.05). Discussion In both conditions, COx decreased above RCP which is in agreement with the involvement of exercise hyperventilation in cerebral deoxygenation during exercise (Rooks et al., 2010). The significant relationship between the delay in the ThCOx decline and the Wmax improvement with hyperoxia supports a significant role of cerebral oxygenation in Wmax limitation in healthy untrained subjects. The lack of difference in COx Wmax in the two conditions suggests that a critical level of cerebral oxygenation was achieved at the end of exercise. ### IMPACT OF EXERCISE DURATION, INTENSITY AND EQUICALORIC ENERGY EXPENDITURE ON EXCESS POST-EXERCISE OXYGEN CONSUMPTION IN ADOLESCENT BOYS.

Serresse, O., Herbert, M.

*Université Laurentienne*

Introduction Whether exercises can modify the magnitude of EPOC remains a controversial subject. The purpose of this study is to describe the effects of exercise duration, intensity and energy expenditure on oxygen consumption, energy expenditure (EE) and fat oxidation (FO) during a 90min post exercise recovery period (PERP). Methods Ten adolescent boys were tested on four different occasions. On day 1, resting metabolic rate, anthropometric data and maximal oxygen consumption (VO<sub>2</sub>max) were measured. EE, metabolic response and FO from three different ergocycle exercise conditions (Cond) were investigated [(Cond1; 50% of VO<sub>2</sub>max for 30 min), (Cond2; 50% of VO<sub>2</sub>max for 60 min) and (Cond3; high intensity equicaloric as Cond2)]. Cond1 and 2 were randomly assigned. After all three conditions, EPOC, EE and FO were analysed during 90 minutes. Results No differences were observed between Cond1 and 3 for duration and Cond2 and 3 for EE during exercise. Energy expenditure during PERP were similar between the conditions (Cond1; 680kJ, Cond2; 687kJ, Cond3; 777kJ). Despite no differences in oxygen consumption and EE, energy from FO was significantly higher in Cond3 compared to Cond1 and 2. The total amounts of EE, during Cond2 and Cond3 and the PERP were significantly greater than Cond1 (Cond1; 1780KJ, Cond2; 2892KJ and Cond3; 3050KJ), but only the energy from FO during Cond2 was significantly higher than Cond1 and Cond3 (Cond1; 648KJ, Cond2; 996KJ and Cond3; 688KJ). Discussion Low intensity (LI) and High intensity (HI) equicaloric exercise did not significantly affect EE during 90min PERP and these results are in agreement with previous studies on 60min (Lazzer, et al., 2010) and on 24-h (Melanson, et al., 2002, Saris, et al., 2004) post-exercise EE. Longer duration and same intensity did not affect the EE post-exercise as reported by others (Lyons, et al., 2006, Warren, et al., 2009). The effects of intensity and duration on substrate oxidation are particularly relevant and important for obesity treatment. Contrary to Melanson et al. (2002) and Lazzer et al. (2010), FO post-exercise was found to be higher in HI when matching for exercise EE. When matching for intensity, the duration seems to have no effect on FO post-exercise. Total FO (exercise plus PERP) seems to be better during LI and long duration exercise. Consequently, it is wise to encourage LI and long duration exercises which enhance FO rates. ## IS-PM14 The Athletes Paradox Revisited: Athletic Lessons for Diabetic People (\*)

**EXERCISE INTERVENTIONS TO ENHANCE INTRAMUSCULAR LIPID METABOLISM AND INSULIN SENSITIVITY**

Shaw, C.S.

*Victoria University*

Intramuscular lipids (IMCL) are stored in discrete lipid droplets within the cytosol of skeletal muscle fibres. Imaging techniques have demonstrated that IMCL concentrations are 2-3-fold greater in type I muscle fibres and that lipid droplet morphology, localization and interaction with related proteins and organelles can change depending upon physical activity. Elevated IMCL concentrations in sedentary individuals are associated with impairments in insulin signal transduction and impaired glucose homeostasis. On the other hand, in endurance-trained individuals who are highly insulin sensitive, IMCL concentrations are also elevated and contribute significantly to fatty acid oxidation during exercise. At present, the exact mechanistic link between lipid accumulation and insulin resistance is unclear, although it is likely related to elevated concentrations of specific lipid metabolites rather than total IMCL concentrations. The improvements in oxidative capacity following endurance training permit improvements in IMCL oxidation during exercise and the regular depletion of the IMCL pool results in enhanced rates of intramuscular triglyceride synthesis. Recent evidence suggests that an improvement in this turnover of the IMCL pool is likely to reduce the concentrations of certain lipid metabolites and mediate the improvement in insulin action in skeletal muscle with regular exercise. In support of this hypothesis, endurance-type exercise training in insulin sensitive individuals and obese type 2 diabetes patients, results in increased IMCL storage alongside enhanced oxidative capacity and improvements in glycemic control. These adaptations are associated with increased IMCL oxidation during exercise specifically in type I muscle fibres. Furthermore, an increase in the expression of the lipid droplet-related proteins, perilipin 2 and perilipin 5, may be important in the observed improvements in IMCL metabolism. Such adaptations are not restricted to endurance-type activities. Recent data from our lab demonstrate that high intensity interval training induces comparable improvements in oxidative capacity and insulin sensitivity to endurance exercise, in addition to increases in IMCL content, perilipin protein expression and IMCL oxidation. These findings add to the growing evidence in support of high intensity interval training as an effective means to improve muscle insulin sensitivity. Furthermore, recent data from our lab provide evidence that the well described insulin sensitizing effect of resistance training may also be mediated in part by improvements in IMCL metabolism. Ongoing investigations will further our understanding of lipid droplet metabolism in skeletal muscle and its role in determining skeletal muscle insulin sensitivity.

**MYOCELLULAR LIPID DROPLET COAT PROTEINS IN TRAINED AND UNTRAINED SUBJECTS IN RELATION TO FAT OXIDATIVE CAPACITY AND INSULIN SENSITIVITY**

Hesselink, M.

*Maastricht University*

Storage of fat in myocellular lipid droplets has long been considered an inert resultant of spill-over of fatty acids from adipose tissue, originating from limited expandability of the adipose tissue or derangements in adipose tissue lipolysis. Nowadays, lipid droplets are considered active organelles involved in maintenance of cellular function. Fatty-acids released from myocellular lipid droplets serve at least 3 distinct processes, most of which are related to fat metabolism and maintenance of oxidative capacity: phospholipid synthesis, fuelling oxidative energy metabolism and signalling to PPAR responsive genes. Thus, aberrations in lipid droplet synthesis and degradation (jointly referred to as lipid droplet dynamics) are likely to affect myocellular function. Multiple proteins coating the lipid droplet, like proteins from the PAT family, lipases and (co)activators of these lipases are determinants of lipid droplet dynamics, which in turn is an important determinant of cellular mitochondrial function. Lack of lipolytic activity in ectopic tissues profoundly impedes (myo)cellular and mitochondrial function. In mice lacking the major triglyceride lipase ATGL, the negative effects of ATGL ablation can be circumvented by administration of a PPAR agonist. Testing this concept in 2 patients with mutations in the ATGL gene revealed important information on the role of lipid droplet lipolysis in muscle oxidative capacity. In a series of cell, animal and human experiments we have monitored basal levels of these proteins in healthy young subjects, trained athletes, obese normoglycemic subjects and obese type 2 diabetic subjects. In the latter 2 populations we have examined the effect of endurance training on these proteins. Of particular interest in this respect is the role of the lipid droplet coat protein OXPAT/PLIN5. We unmasked PLIN5 as a protein also present at interaction sites of lipid droplets and mitochondria. This observation was recently linked to the mitochondrial fusion protein OPA1. Thus, we studied if modulation of PLIN5 content affected OPA1 and interaction of mitochondria with LD. We observed that overexpression of PLIN5 in rats resulted in a near significant increase in OPA1 and a higher tolerance of mitochondria for fatty acids before lipotoxicity evolves. We are currently investigating if similar mechanisms also operate in human skeletal muscle upon training. Jointly, these studies indicate that a tight interplay of proteins involved in lipid droplet dynamics contributes to maintenance of muscle mitochondrial function and may partly explain the phenomenon referred to as the athlete's paradox.

**THE EFFECTS OF CHRONIC EXERCISE TRAINING REVEAL MECHANISTIC INSIGHTS INTO THE PATHOPHYSIOLOGY OF OBESITY AND TYPE 2 DIABETES**

Amati, F.

*University of Lausanne*

Skeletal muscle insulin resistance (IR) is associated with obesity and physical activity, and is crucial for the development of type 2 diabetes. The causes of insulin resistance within muscle are not known. One of the hypotheses being explored to explain the mechanisms by which obesity leads to IR is lipotoxicity. Also known as the lipid metabolite theory, lipotoxicity happens when fatty acid spillover in excess of the oxidative needs into harmful pathways of nonoxidative metabolism. Concerted efforts have been made of the past several years to understand the potential role of intramyocellular lipids (IMCL) accumulation in the development of IR. Multiple human studies confirmed the inverse association between IMCL and insulin sensitivity. However, this inverse association between IMCL and IR is not observed in

chronic exercise training and/or conditions for efficient fatty acid utilization. Chronic exercise has been shown to increase IMCL in parallel with improved IR, thus leading to a paradigm, known as the 'athlete paradox' where IMCL accumulation per se does not directly affect insulin action but where this negative effect appears to be linked with non utilization of the fatty acid reservoir and with the accumulation of metabolically active lipid intermediates. Among others, diacylglycerol (DAG) have been largely implicated in cellular and animal studies. In cross-sectional and intervention studies, we measured comprehensive profiles of distinct molecular species of DAG in skeletal muscle of obese, normal weight and athletic human subjects. Total DAG content was higher in athletes and was positively associated with insulin sensitivity. Furthermore, dissaturated DAG were significantly lower in highly insulin sensitive athletes compared to their insulin resistant counterpart. Our results, in accord with other recent studies, point to the fact that some DAG moieties are particularly abundant in human skeletal muscle: C16:0/C18:0, C16:0/C18:1 and Di-C18:0. Summed together, these three DAG species account approximately for 80% of total DAG. These results suggests that it is not the overall content of DAG that may be deleterious but that particular DAG moieties, even in smaller amounts, may carry the lipotoxic effect. Thus, DAG content in chronically exercised insulin sensitive muscle may represents another athlete paradox.

### OP-SH11 Physical Education and pedagogics 2

#### QUALITATIVE ANALYSIS OF THE INTERACTIVE DECISIONS OF THREE COACHES INVOLVED IN A "START TO RUN" SESSION

Cloes, M., Dethioux, S.

*University of Liege*

**Introduction** A growing number of programs are implemented to enable a smooth resumption of physical activity. "Start to run" is a running program promoted by the athletics federation that has gained a great notoriety in Belgium. It proposes sessions of 10 weeks during which participants are trained to run 5 km without stop (10 km for those who are not beginners). No data seems to be available about the coaching process in this specific context of active leisure. The purpose of this study was to enlarge knowledge on this topic. **Methods** Based on the principles of the qualitative research, we analyzed three sites: three groups involved in a Start to run session in different communities of the Liege's area (Wallonia, Belgium). In all sites, data were collected before, during, at the end and 12 weeks after the session. They provided information on the context as well as on the process (coaches and participants behaviors and perceptions), and participants' achievement and maintenance. In this paper, we will focus our analysis on the interactive decisions of the coaches. It will be based on the observation of three lessons in each site (2d, 5th and 8th weeks): one of the authors attended to the training session as participant observer. Moreover, we will also use data collected through interviews (description of the organization and content of the program) and questionnaires (feelings about the lessons). Participants were also requested to provide their perceptions about the lessons. As evidenced above, the validity of the analysis is guaranteed by the triangulation of the data. **Results** The three coaches described a similar teaching model but only subject #2 pointed out technical drills. Only subject #3 respected the "official" program developed by the athletics federation. The two other adapted it according to their experience and purposes of their groups. All of them considered that they were providing enough feedback and were active. On the other hand, they thought themselves as needing to encourage more and to be more effective in group management. Globally, participants confirmed the opinions of their respective coaches but they seemed more critical in group #3, showing a lower satisfaction about the motivational behaviors and feedback. The observation pointed out some problems in the clarity of the explanations (subject #1) and some divergences were reported with the actors. **Discussion** The triangulation of the data allows us to consider that the three coaches are doing a very good job and adapt themselves to the expectations and needs of the participants. The identification of the positive and negative aspects in each subject provides a basis to propose some recommendations. Moreover, we pointed out that encouraged to speak about their own teaching process, all coaches modified spontaneously their interactive decisions during the study. This underlines the interest of this systematic analysis in leisure physical activity as well as in other educational contexts.

#### DOES PERCEIVED SPORT COMPETENCE INFLUENCE PHYSICAL ACTIVITY ENJOYMENT?

Nart, A.I, Scarpa, S.2, Biancalana, V.1

*1: UNIURB (Urbino, Italy), 2: UNIPD (Padua, Italy)*

**Introduction** In the sport and physical activity (PA) field, enjoyment is a positive affective response to the sport experience (Scanlan & Simons, 1992) and it can also be considered an important factor in promoting active lifestyles and regular PA among school-aged children (Carraro et al., 2008). The aim of the present study was to investigate the effects of perceived sport competence on PA enjoyment. **Methods** Participants were 394 pupils (173 boys and 221 girls) aged between 12 and 13 years ( $M=12.2$ ). The Physical Self-Description Questionnaire-Short (PSDQ-S; Marsh et al., 1994) and the Physical Activity Enjoyment Scale (PACES; Carraro et al., 2008) were completed. Pearson's correlation test was used to measure the association between variables. Multiple linear regression analysis was conducted to investigate the correlation between PSDQ-S scores (independent variables) and PACES total score (dependent variable). **Results** Pearson's correlation test revealed the following positive associations between PSDQ-S variables and PACES total score: endurance ( $r = .527, p < .001$ ); flexibility ( $r = .206, p < .001$ ); strength ( $r = .365, p < .001$ ); coordination ( $r = .427, p < .001$ ); sport skill ( $r = .546, p < .001$ ). Multiple linear regression analysis showed the following score indices:  $SE = 7.76$ ;  $t = 20.79$ ;  $R^2 = .363$ ;  $F(5, 388) = 44.13$ ;  $p < .001$ . **Discussion** Our results highlighted positive associations between physical self-concept scales and PA enjoyment, and our hypothesis that perceived sport competence can be considered a good predictor of PA enjoyment was confirmed. The results could contribute to our understanding of the processes involved in the promotion of active lifestyles and regular PA among young people. **References** Carraro A, Young M, Robazza C (2008). ## MOTIVATIONAL CLIMATE, ACHIEVEMENT GOALS AND STUDENTS' ATTITUDE TOWARDS PHYSICAL EDUCATION

Martins, J.1, Marques, A.1, Sarmiento, H.2, Carreiro da Costa, F.1,3

1: CIPER, Faculty of Human Kinetics, Technical University of Lisbon; 2: University of Trás-os-Montes and Alto Douro; 3: Lusophone University of Humanities and Technologies

**Introduction:** In Physical Education (PE) settings there is a lack of research on associating motivational climate and goal orientation with individuals' attitude towards PE. Therefore, this study examined the relationship of students' attitude towards PE with their perceptions of PE classes' motivation climate and their goal orientations. **Methods:** Participants were 685 PE pupils (313 male, 372 female; aged 16.9±1.1 years) of 6 public schools. Motivational climate and achievement goals (focusing on mastery, performance-approach, and performance-avoidance goals; adapted from Papaioannou et al., 2007), attitude towards PE and physical activity (PA) participation were assessed using a self-report questionnaire. A hierarchical regression analysis was performed with attitude toward PE as dependent variable and motivational climates and goals as independent variables. Significance level was  $p < 0.05$ . **Results:** In the first step the three variables of motivational climate were entered. The perception of a mastery ( $\beta = 0.201; p < 0.001$ ), performance-approach ( $\beta = 0.084; p < 0.05$ ) and performance-avoidance ( $\beta = -0.258; p < 0.001$ ) environment had a significant contribution into the equation explaining 13.9% of the total variance of students' attitude towards PE. The entry of the three variables of achievement goals in step 2 increased significantly the explained variance by 29.4%. At this step however, the contribution of mastery ( $\beta = 0.119; p < 0.001$ ) and performance-avoidance ( $\beta = -0.075; p < 0.05$ ) climate slightly decreased, and performance-approach climate was not significant anymore ( $\beta = 0.02; p > 0.05$ ), suggesting that goal orientations mediates the relationship between students' perceptions of the learning environment and their attitude toward PE. The most significant predictors for explaining the total variance of students' attitude toward PE were the three achievement goals, respectively, mastery ( $\beta = 0.427; p < 0.001$ ), performance-avoidance ( $\beta = -0.205; p < 0.001$ ) and performance-approach orientation ( $\beta = 0.142; p < 0.001$ ), followed by the perception of a mastery-oriented motivation climate. **Discussion:** These findings highlight that a strong mastery-oriented climate and a strong mastery orientation, as well as a low performance-avoidance orientation, may have positive effects on students' attitudes towards PE. Furthermore, they underline the necessity of research on causal relationship between motivational climate, achievement goals, attitude toward PE and PA participation. **References:** Papaioannou et al. ## PSYCHOSOCIAL PROCESSES IN SPORTS AS DRIVER FOR SOCIO-EMOTIONAL DEVELOPMENT

Hilhorst, J.E.C.1,2,3, Steenbergen, B.2, Theeboom, M.1

1: Vrije Universiteit Brussel (Brussels, Belgium), 2: Radboud University Nijmegen (Nijmegen, the Netherlands), 3: Kennispraktijk (Nijmegen, the Netherlands)

**Introduction** Participation in sports can result in positive or negative behavioural outcomes for youth. Researchers increasingly stress the psychosocial processes and contextual factors in sports that may mediate socio-emotional development (Bailey, 2005; Coalter, 2007). In the present study we reviewed the literature on sports and socio-emotional development and determine the state of the art with respect to this topic. Guidelines and implications for future are subsequently provided. **Methods** First, a systematic literature search of studies on sports and social-emotional development was performed. Second, we used the PPCT model (Bronfenbrenner, 1995) in which a distinction is made between processes, personal characteristics, contextual factors and time factors, to categorize relevant mediators for the relation sports and socio-emotional development. **Results** Eighteen studies were selected and analyzed. Mediators of sports and socio-emotional development were identified and categorized to determine what kind of mediators it are and to give an overall picture of the categories. In thirteen studies were processes identified, in sixteen studies personal characteristics, in all studies contextual factors and in five studies time factors. **Discussion** The analysis showed that three clusters with psychosocial processes seem crucial for socio-emotional development in sports: player-player interaction, player-adult interaction and self-regulatory mechanisms. However, to date hardly any study has scrutinized how these processes affect the potential effects on social-emotional development of youth. Furthermore, a majority of the studies focused on the interaction between the adult sport coach and the young athlete in the context of competitive sports. Finally, none of the studies described the mutual relations between processes, personal characteristics, contextual factors and time factors. **Future research** should focus on how the three clusters with psychosocial processes in sports affect socio-emotional development, within the whole ecological approach, to make practical recommendations for enhancing sport settings that promote socio-emotional development. **References** Bailey, R. ## THE CONTENT OF PHYSICAL EDUCATION IN SWEDEN AND SOUTH AFRICA

Kougioumtzis, K., Patriksson, G., Toriola, A., Amusa, L.

*University of Gothenburg*

**THE CONTENT OF PHYSICAL EDUCATION IN SWEDEN AND SOUTH AFRICA** Kougioumtzis, K.1, Patriksson, G.1, Toriola, A.2, Amusa, L.3 1: GU (Gothenburg, Sweden), 2: TUT (Pretoria, South Africa), 3: VU (Thohoyandou, South Africa) **Introduction** The aim of this study is to highlight physical education (PE) content in Swedish and South African schools utilizing nation-wide stratified random samples of pupils in each country. **Methods** A questionnaire has been developed measuring health promotion, social development, personal development, as well as physical development and movement. The questionnaire was administered to pupils in primary and lower secondary school. The final sample consisted of 2.495 Swedish and 3.748 South African individuals. The answers of Swedish (SWE) and South African (SAF) pupils have been analyzed using ANOVA. **Results** In relation to health promotion, pupils' awareness of health related benefits of physical activity was higher in South Africa than in Sweden,  $MSAF = 4.28(77)$ ,  $MSWE = 3.93(98)$ ,  $F(1,6136) = 253.9$ ,  $p < .05$ . Regarding social development, South African pupils reported socialization effects connected to PE to a higher degree than Swedish pupils did,  $MSAF = 4.18(.98)$ ,  $MSWE = 3.74(.92)$ ,  $F(1,6092) = 307.0$ ,  $p < .05$ . In terms of personal development, Swedish pupils reported a more positive climate during PE classes than South African pupils did,  $MSWE = 3.73(.94)$ ,  $MSAF = 3.67(1.15)$ ,  $F(1,6093) = 4.7$ ,  $p < .05$ . As far as physical development and movement are concerned, Swedish pupils reported that they enjoy a spectrum of physical activities that was broader than that reported by South African pupils,  $MSWE = 3.44(1.00)$ ,  $MSAF = 3.22(.92)$ ,  $F(1,6138) = 79.9$ ,  $p < .05$ . **Discussion** Health promotion and social development are characterizing PE content in South Africa to a higher degree than in Sweden. This is in line with the fact that South African PE is part of the Life Orientation learning area (Van Deventer, 2009). On the contrary, personal development as well as physical development and movement are more evident in Swedish than in South African schools. This is in line with the strong connections between PE and physical

activity in Sweden as well as the distinct efforts to empower pupils on the basis of their own capabilities and aspirations. References Toriola A, Patriksson G, Amusa L, Kougioumzis K (2010). *AJPERD*, 16, 327-345. Van Deventer K, (2009). *SAJE*, 29, 127-145.

### EFFECTIVENESS OF DUTCH SPECIAL SECONDARY SPORTS SCHOOLS

Hakkers, S.

*Mulier Institute*

**EFFECTIVENESS OF DUTCH SPECIAL SECONDARY SPORTS SCHOOLS** Authors: Stephan Hakkers, Niels Reijgersberg, Agnes Elling & Fleur van Rens (Mulier Institute, Utrecht) Contact: s.hakkers@mulierinstituut.nl Introduction Combining school and sport is difficult for many aspiring elite athletes, especially since elite sporting demands have increased over the past decades due to international developments. In most sports talented athletes are expected to train many hours a week from an early age. However, only a few sports talents will become actual elite athletes, of whom most also need to find a job after their sports careers ended. Therefore, it is important that talented athletes are given the opportunity to attain a level of secondary education which reflects their cognitive abilities. In order to maximize performance development of aspiring athletes both in sports and education, the first Topsport Talentschools (TTS) were founded in the Netherlands in 1991, similar to the international development of Elite Schools of Sport (Radtke & Coalter, 2007). Only those schools in the Netherlands have ministerial consent to grant exemptions to sport talented students. Given that the majority of talented athletes does not attend TTS but mainstream schools (Reijgersberg et al., 2010) – that also might offer support in optimizing the school-sport balance –, it is interesting to gain insight in the effectiveness of TTS. The purpose of this article is therefore to investigate whether attending a TTS indeed leads to the intended positive effects of optimizing achievements in sports (flow of sports talent to high-level athlete) and education (highest feasible degree in education)? Methods We conducted a retrospective study amongst young people who were identified as talents during the years 2004-2008 by seven selected national sports federations with a substantial number of talents attending TTS and having sufficient contact informations of former talents. The (former) talents received an invitation letter from their federation to participate in an online survey, for which they received a login code. The questionnaire contained questions about socio-demographic characteristics, school career, sports career, motivation, school facilities and satisfaction. Apart from former talents, current sports talents were also invited to participate in this study. They received a similar online questionnaire with more focus on the current forms of support they received from schools and their degree of satisfaction to combine sports and education. A total of 407 retrospective and 478 sport talents have completed the digital questionnaire. Results The preliminary results show that there are hardly differences in the sports and educational careers of former talents attending either a TTS or mainstream secondary school, when controlled for other possible influencing variables, like hours of training, age when identified as talents and sports/school motivation. TTS talents however, were regarded as necessary for those talents with high training demands at an early age and they also appear to be more satisfied with balancing school and sport during adolescence. #### **PRESSURE PAIN MAPPING FOR THE INVESTIGATION OF MECHANICAL SENSITIVITY AMONG ELITE MALE FOOTBALL PLAYERS. EFFECTS OF TURF TYPE**

Domínguez-Marfín, M.A.1, López-Ruiz, F.1, Reyes-López, M.V.1, Valenza, G.1, Fernández-de-las-Penas, C.2,3, Madeleine, P.3

1: Universidad de Granada (Granada, Spain), 2: Universidad Rey Juan Carlos (Madrid, Spain) 3: Aalborg University (Aalborg, Denmark)

**Introduction** Differences in muscle restitution between artificial turf and natural grass could induce muscle fatigue and, hence increase the risk of injury among football players (Ekstrand et al., 2010). The mechanical sensitivity of muscle is changed in response to strenuous physical activity or training (Kawczynski et al. 2012). Thus, studies investigating deep structures sensitivity can be helpful to delineate differences among pitch surfaces. In this study, we investigated if artificial grass compared with natural grass would affect the pressure pain maps of the lower extremity in elite football players. **Methods** A total of 16 football players (mean age +/- SD: 22 +/- 2 years) for artificial turf and 13 football players (age: 22 +/- 3 years) for natural grass participated. Pressure pain thresholds (PPT) were measured bilaterally over 23 locations of the lower extremity, including the rectus femoris, tensor fasciae latae, vastus lateralis/medialis; external and internal hamstrings; tibialis anterior; peroneous; external and internal gastrocnemius, and soleus muscles, in a blinded design. **Results** The ANOVA detected significant differences in PPT between groups and measurement points ( $P < 0.001$ ), but not between sides ( $P = 0.804$ ). Football players playing on natural grass exhibited lower PPT as compared to those players playing on artificial turf ( $P < 0.05$ ). In addition, PPT over vastus medialis muscle was the lowest one (most sensitive) and significantly lower than PPT levels over the rectus femoris, external and internal hamstrings, tibialis anterior; peroneous, external and internal gastrocnemius, and soleus muscles ( $P < 0.01$ ); whereas PPT over the rectus femoris was the highest one (least sensitive) and significantly higher than PPT levels vastus lateralis and medialis, tibialis anterior, peroneous; external/internal gastrocnemius, and soleus muscles ( $P < 0.01$ ). **Discussion** We showed the ability of topographical mapping of pressure sensitivity to reveal heterogeneous distribution of mechanical sensitivity among football players in relation to turf type. The higher PPT levels found among elite male football players on artificial turf compared with natural grass underlining decreased mechanical pain sensitivity could be considered as a positive trend in agreement with (Ekstrand et al., 2010). However, such differences may also have adverse effects, i.e. less efficient protective mechanism and prospective studies are needed to confirm our findings. ## THE RELATIONSHIP BETWEEN LUMBOPELVIC MOTOR CONTROL AND TWO-DIMENSIONAL VIDEO ANALYSIS OF THE VERTICAL JUMP IN ELITE FEMALE ATHLETES

Dingenen, B., Malfait, B., Verschueren, S., Staes, F.

*KU Leuven*

**Introduction** Screening athletes to assess lower extremity injury risk has become a hot topic in research and clinical practice. Functional tests, such as the drop vertical jump (DVJ) test, are recommended to evaluate lower extremity movement quality as poor dynamic alignment is believed to be associated with an increased injury risk. Two-dimensional (2D) video analysis is a valid and reliable method to assess this movement quality (Munro et al., 2011). The inability to properly perform functional tasks can be related to multiple factors within the kinetic chain. An impaired lumbopelvic motor control (LPMC) is suggested to lead to compensatory movements of the lower extremity, resulting in injuries. However, the relation between clinical LPMC tests and quality of movement, analyzed with a 2D video analysis method, has not yet been established. **Methods** A total of 63 elite female athletes (35 soccer, 16 handball and 12 volleyball) who were injury- and pain free were tested. Hip flexion (HF), knee valgus (KV), knee flexion (KF) and ankle dorsiflexion (ADF) angles were measured during the deepest landing phase of the DVJ test. LPMC was evaluated by a set of 6 tests, described by Luomajoki et al. (Luomajoki et al., 2007). Correlations between the 2D angles and the LPMC tests were calculated with the Spearman rank test. Results In the soccer players, KV of the dominant leg ( $r=-0.243$ ) and non-dominant leg ( $r=-0.012$ ), HF ( $r=-0.142$ ) and KF ( $r=0.006$ ) were not significantly correlated, but ADF ( $r=0.369$ ;  $p=0.029$ ) was significantly correlated with the LPMC tests. In the handball players, KV of the dominant leg ( $r=-0.250$ ) and non-dominant leg ( $r=-0.025$ ), HF ( $r=0.031$ ), KF ( $r=0.033$ ) and ADF ( $r=-0.042$ ) were not significantly correlated with the LPMC tests. In the volleyball players, KV of the dominant leg ( $r=-0.379$ ) and non-dominant leg ( $r=-0.350$ ), KF ( $r=0.412$ ) and ADF ( $r=0.206$ ) were not significantly correlated, but HF ( $r=0.589$ ;  $p=0.044$ ) was significantly correlated with the LPMC tests. **Discussion** The findings of the present study show that less ADF in soccer players and less HF in volleyball players are significantly associated with decreased LPMC. Furthermore, there is a non-significant trend that more KV and less KF in volleyball players are associated with decreased LPMC. The high number of non-significant correlations suggests that the quality of movement during the DVJ test is also related to other factors than low load LPMC. Furthermore, a differentiation between sports is warranted. **References** Luomajoki H, Kool J, de Bruin ED, Airaksinen O. (2007). *BMC Musculoskeletal Disord*, 8, 90. ## NEUROMECHANICAL PROFILES OF THE TRICEPS SURAE MUSCLE-TENDON UNIT IN ATHLETES WITH AN ACHILLES REPAIR

Wang, H.K., Chiang, H., Lin, K.H., Chen, W.S., Shih, T.F., Huang, Y.C., Jiang, C.C.

*School and Graduate Institute of Physical Therapy, College of Medicine, National Taiwan University*

**Introduction** We compared the neuromechanical and functional characteristics of the legs of athletes with unilateral Achilles tendon repair at different postsurgery intervals and to determine any correlation between the characteristics. **Methods** There were 10, 8, and 8 athletes recruited into 3 groups:  $\geq 3$  and  $< 6$ ,  $\geq 6$  and  $< 9$ ,  $\geq 9$  and  $< 12$  months postsurgery, respectively [mean ( $\pm$ SD) age: 33.7 (4.5) years]. Bilateral measurements of activation strategy involving the triceps surae and tibialis anterior muscles and mechanical properties of the Achilles tendon and lower-extremity function were conducted. **Results** Compared to athletes in the other groups, results of those with repaired legs  $\geq 3$  and  $< 6$  months postsurgery showed lower activation (EMG and activation level) and altered antagonist coactivation (EMG ratio), less tendon stiffness, shorter hopping distance, and lower balance score ( $p < 0.015$ ). Compared to the controls, the repaired leg showed lower activation and antagonist co-activation in fast contractions, less tendon stiffness, greater tendon hysteresis, lower rate of force development, plantarflexion torques, active dorsiflexion range, shorter hopping distance, and lower balance score ( $p < 0.015$ ). Correlations between the neuromechanical profiles and performances were found ( $p < 0.05$ ). **Discussion** This study, performed on athletes after an Achilles repair, concluded bilateral and various neuromechanical deficits in the triceps surae muscle-tendon unit, including activation strategies and tendon mechanical properties, as well as performance reduction in the repaired and control legs within 1 year of surgery (Aagaard et al., 2002; Maffiuletti et al., 2002). Correlations between neuromechanical profiles and functional performance in these athletes indicate a requirement of 6 months of rehabilitation in athletes after Achilles repairs. **References:** Aagaard P, Simonsen EB, Andersen JL, Magnusson P, Dyhre-Poulsen P. (2002). *J Appl Physiol*, 93, 1318-1326. Maffiuletti NA, Pensini M, Martin A. (2002). *J Appl Physiol*, 2002, 92, 1383-1392.

## REDUCED POSTOPERATIVE PHYSICAL ACTIVITY OF CHILDREN WITH CONGENITAL HEART DISEASES

Reiner, N.1, Hess, J.2, Oberhoffer, R.1,2

*Technische Universität München (1), Klinik für Kinderkardiologie und angeborene Herzfehler - Deutsches Herzzentrum München (2)*

**BACKGROUND:** Children with congenital heart disease (CHD) have a reduced exercise capacity. Studies suggest that prolonged hospitalization might contribute to deconditioning in exercise capacity. This study examined the postoperative physical activity among children with CHD after a hospital stay. **PATIENTS and METHODS:** 34 children and adolescents with CHD (21 girls, 8.0 years [IQ: 6.0-11.0 years]) after open heart surgery or catheter intervention were included into the study. Directly after being discharged from hospital their physical activity was assessed with a GT3X accelerometer over the next consecutive 7 days. **RESULTS:** Physical activity was reduced to 58.5 minutes (IQ: 35-123 minutes) of at least moderate activity per day. Only the half of the examined children meet the actual guidelines of one hour of moderate to vigorous activity a day. There were no gender specific differences ( $p=.362$ ). There are differences between the various degrees of severity of congenital heart defects, but not significant ( $p=.784$ ) **CONCLUSION:** Children with CHD have a reduced physical activity after hospital discharge. Outpatient rehabilitation programs to increase physical activity should be aspired after hospital stay to prevent further deconditioning.

## GENERALIZED PREDICTION EQUATIONS FOR REGIONAL LEAN MASS IN PHYSICALLY ACTIVE ADULTS

Scafoglieri, A., Tresignie, J., Probyn, S., Marfell-Jones, M., Reilly, T., Bautmans, I., Clarys, J.P.

*Vrije Universiteit Brussel*

**Introduction** The ability to accurately estimate regional lean tissue masses in vivo is very important for applied and clinical applications such as muscle distribution and energy metabolism (Gallagher and Heymsfield, 1998; Müller et al., 2001). In literature, there is a limited number of anthropometry-based prediction equations for the estimation of regional lean tissue masses in adults (Arthurs and Andrews, 2009; Ritchie and Davidson, 2007; Holmes et al., 2005). Since it remains unknown whether anthropometry can be used to accurately

estimate lean tissue mass in all body regions, the aim of the present study was to develop and cross-validate anthropometrical prediction equations for regional lean tissue mass. Methods One hundred and seventeen physically active Caucasians (67 men and 50 women; mean age: 31.9±10.0y; BMI: 24.3±3.2kg/m<sup>2</sup>; sporting activities: 5.4±4.6hours/week) participated in the present study. Body mass (BM), stretch stature (SS), 14 circumferences (CC), 13 skinfolds (SF) and 4 bone breadths (BB) were used as anthropometric measurements. Regional lean tissue mass of both arms, trunk and both legs were measured by dual energy X-ray absorptiometry (DXA) as the criterion method. Results Three generalized prediction equations for regional lean mass were developed as follows: arms = 40.394(BM) + 169.836(CC arm-tensed) + 399.162(CC wrist) - 85.414(SF triceps) - 39.790(SF biceps) - 7289.190, where Adj.R<sup>2</sup>=0.97, p<0.001, and SEE=355g; trunk = 181.530(BM) + 155.037(SS) + 534.818(CC neck) + 175.638(CC chest) - 88.359(SF chest) - 147.232(SF supraspinale) - 46522.165, where Adj.R<sup>2</sup>=0.97, p<0.001, and SEE=1077g; and legs = 55.838(BM) + 88.356(SS) + 235.579(CC mid-thigh) + 278.595(CC calf) + 288.984(CC ankle) - 84.954(SF front-thigh) - 53.009(SF medial calf) - 28522.241, where Adj.R<sup>2</sup>=0.96, p<0.001, and SEE=724g. Cross-validation statistics showed no significant differences (p<0.05) between observed and predicted regional lean tissue mass. Root mean squared errors were smallest for arms (362g), followed by legs (820g) and trunk (1477g). Discussion The proposed anthropometric prediction equations can be used to safely and easily estimate regional lean tissue mass of the extremities and the trunk in groups of physically active adults, but estimation errors of 8 to 14% can occur in certain individuals. It needs to be reminded that DXA cannot distinguish between skeletal muscle and non-skeletal lean components such as skin, connective tissue and organs. Therefore conversion from lean mass to muscle mass is susceptible to significant error because we are dealing with two different models (Clarys et al., 2010). ### THE EFFECT OF HORMONAL FLUCTUATION ON GROSS AND FINE MOTOR COMPETENCE

Ghani Zadeh Hesar, N.1,2, Witvrouw, E.1, Peersman, W.1, Roosen, P.1, Van Ginckel, A.1,3, Braems, G.4, Lenoir, M.1

1: *UGent (Belgium)*, 2: *Urmia University (Iran)*, 3: *FWO (Belgium)*, 4: *UZ Gent (Belgium)*

Introduction The hormonal variation during the menstrual cycle (MC) influences neurological function, motor skill and joint laxity (Hampson and Kimura, 1988; Park et al., 2009). These seem to support the notion that hormonal changes affect motor coordination by means of a central and peripheral mechanism. But, the exact mechanisms behind changes of neuromuscular function during the MC are not yet known. Methods Twenty healthy adult females with no use of any forms of hormonal contraceptive participated. Gross and fine motor competence, body balance, and joint position sense (JPS), were evaluated by the Körperkoordinationstest für Kinder (KTK), the Bruininks-Oseretsky test (BOTMP), Neurocom balance master (NBM) and Biodex 2 isokinetic dynamometer respectively. Blood samples were analyzed for estradiol and progesterone levels in three phases of the MC: menstrual phase (MP), follicular phase (FP), and luteal phase (LP). Results The jumping sideways (JS) test of KTK showed significantly better performance in the LP compared to the FP (P=0.014). Forward lunge (FL) scores of NBM were significantly better in the LP as compared to the FP. A tendency toward shorter contact time, greater impact index and better force impulse was detected during the LP. The results showed no significant differences for the BOTMP and JPS tests between the three phases of the MC. Discussion In the JS test, the subjects performed significantly better performance in the LP compared to the FP. In accordance, Friden et al. (2006) showed better performance in fast jumping tasks when estradiol level was high. In both leg, the force impulse was smaller for the LP than the FP indicating that in the LP subjects performed less work overall. In this study, functional ability of the lower extremities during the LP and greater stability of the knee joint at the LP on the JS test was corroborated by a decreased knee laxity in the luteal compared with the other phases in study of Park et al. (2009). In accordance with Abt et al. (2007) the results showed no differences between the three phases of the MC for fine motor coordination. The findings suggest that ovarian hormones play some role in gross motor competence via central and peripheral mechanism but not on fine motor competence. ### OP-PM51 Training, testing and health

#### HIGH AND LOW LEVEL OF FLEXIBILITY IS NOT A PREDICTOR FOR SPEED AND EXPLOSIVENESS PERFORMANCE IN PROFESSIONAL SOCCER PLAYERS

Hadjicharalambous, M.1, Christou, M.1,2

1: *University of Nicosia (Nicosia, Cyprus)*, 2: *University of Cyprus (Nicosia, Cyprus)*

Introduction Flexibility has been considered to be an essential element of daily training programs in several sports (Magnusson and Restroom, 2006). It was suggested that increasing flexibility may contribute in improving exercise performance and preventing from injuries (Smith, 1994). However, no studies so far evaluated whether poor or good flexibility may influence fitness parameters in elite soccer-players. The purpose of the present study was to examine the effect of lower back and hamstrings' flexibility on several fitness parameters in elite soccer players. Methods Ninety four professional soccer players were initially evaluated, but, only seventy one (mean±SD) met the cut-off criteria and were included into the statistical analysis. These 71 players were separated into two groups based on their sit-and-reach flexibility score. The players whose reach score was less than 22cm developed the low-flexibility (low-Flex) group (n=28); and those whose reach score was above 28cm were included into the high-flexibility (high-Flex) group (n=43). A comparison between the two groups was performed following a series of anthropometric and fitness parameters evaluations. Results Sit-and-reach flexibility was significantly higher (p=0.0001) in high-Flex (31.4±3) compared with the low-Flex (17.4±6) group. No significant differences were observed on age, height, weight, body fat%, on several countermovement jumps and on 10 and 30 meters maximum speeds (p>0.05). Peak oxygen consumption (VO<sub>2peak</sub>) was significantly higher (p=0.004) in the high-Flex (56.03±3.2

ml/kg/min) compared with the low-Flex ( $VO_{2peak}$ : 53.87 $\pm$ 3.1 ml/kg/min) group. No statistical significant correlations were observed between flexibility score and any other depended variable measured in both groups. Discussion In conclusion, high level of sit-and-reach flexibility may contribute in enhancing aerobic capacity and/or low levels of sit-and-reach flexibility may diminish running economy in professional soccer players; but the exact mechanism responsible for this result still needs to be determined. However, neither high nor low levels of sit-and-reach flexibility should be considered as a limiting factor in speed and explosiveness performance but poor lower back and hamstrings' flexibility might be a limiting factor in achieving high endurance performance in soccer. ## **INLUENCE OF HEALTH STATUS, PHYSICAL ACTIVITY AND FITNESS IN AUTONOMY OF COMMUNITY-DWELLING OLD ADULTS OVER A FIVE YEAR PERIOD**

Pereira, C., Rebocho, L., Baptista, F.

*University of Évora*

INLUENCE OF HEALTH STATUS, PHYSICAL ACTIVITY AND FITNESS IN AUTONOMY OF COMMUNITY-DWELLING OLD ADULTS OVER A FIVE YEAR PERIOD Catarina L. Pereira<sup>1</sup>, Lurdes Rebocho<sup>2</sup>, Fátima Baptista<sup>2</sup>, <sup>1</sup>Department of Sports and Health, University of Évora, Portugal. <sup>2</sup>Exercise and Health Laboratory, Faculty of Human Movement, Technical University of Lisbon, Portugal Introduction As long as life expectancy increases, a significant number of people are likely to live longer while subject to infirmities and disabilities, and thus loss of autonomy. Studies focusing on disability and autonomy have been mainly cross-sectional and few studies have analyzed longitudinally predictors of health and physical functioning variables. Thus, the purpose of this study was to analyze the influence of health status, physical activity and fitness on the autonomy of community-dwelling old adults over a five year period. Methods Participants were 106 community-dwelling persons aged 60 years and older at baseline (67.4 $\pm$ 5.4 years). They were evaluated at baseline and after the 5-year follow-up period. Measures comprised autonomy/physical functioning, co-morbidities, physical activity, physical fitness including body composition, evaluated by the Composite Physical Function scale, International Physical Activity Questionnaire, Fullerton batteries and bioimpedance, respectively. Results Linear regression revealed that the main predictors of change in autonomy over a 5-year period were initial autonomy ( $\beta=0.032$ ,  $R^2=9.8\%$ ); health status (initial number of co-morbidities:  $\beta=-0.191$ ,  $R^2=6.3\%$ ; change in the number of co-morbidities:  $\beta=-0.244$ ,  $R^2=10.8\%$ ); and changes in agility ( $\beta=-0.288$ ,  $R^2=6.7\%$ ), aerobic endurance ( $\beta =0.007$ ,  $R^2=3.2\%$ ), and walking related energy expenditure ( $\beta =0.001$ ,  $R^2=5.1\%$ ), ( $P<0.05$ ). Conclusion Initial autonomy level and health status appear to influence autonomy change in community-dwelling old adults over a 5-year period, however physical activity (walking) and fitness (agility and aerobic endurance) also accounted for autonomy variability, justifying the promotion of intervention programs for the maintenance or improvement of these factors. Key words: Autonomy; Physical activity; Physical fitness; Elderly; Health Status

## **DOES HYDRATION STATUS AFTER TRAIL RUNNING INFLUENCE MUSCLE DAMAGE AND DOMS?**

Brooks, N.E., Esterhuizen, A., Myburgh, K.H.

*Stirling University,*

Introduction: The purpose of this study was to determine whether competitive trail running affects indices used to assess hydration status and muscle damage. We hypothesized that: i) body mass (BM) alone would not provide adequate assessment of hydration status after 23.4 km competitive trail running, ii) muscle damage would be accompanied by both pain and inflammation, even in well-trained competitive athletes and iii) an inability to maintain hydration status during the race may be associated with increased muscle damage and/or pain. Methods: Twelve endurance-trained male athletes (37 $\pm$ 2 yrs; BMI: 25.2 $\pm$ 0.8 kg/m<sup>2</sup>,  $VO_{2max}$ : 59.9 $\pm$ 1.9 ml/kg/min) completed a 23.4 km trail running race, the AfricanX Trail (South Africa). Urine samples, RPE, thirst and pain ratings were obtained pre- and post-race and 1 d post-race (d1post). Urine samples were analysed for urea, protein and creatinine [concentrations] and osmolality. Baseline and d1post blood samples were analysed for creatine kinase (CK) and lactate dehydrogenase (LDH) activities, myoglobin, C-reactive protein (CRP), [Na<sup>+</sup>], [K<sup>+</sup>], osmolality, creatinine content and [urea]. Results: Time to complete the race was 162 $\pm$ 9 min (average speed 8.93 $\pm$ 0.47 km/hr). RPE and thirst increased post-race ( $p<0.001$ ). Participants lost 2.7 $\pm$ 0.5% body mass during the race, but were fully rehydrated by d1post. [U-creatinine] increased post-race and remained elevated at d1post, whereas [U-protein] returned to baseline by d1post ( $p<0.05$ ). Serum osmolality and [creatinine] were similar between baseline and d1post. Blood [urea] and [K<sup>+</sup>] increased ( $p<0.001$ ) whereas [Na<sup>+</sup>] decreased d1 post. CK, LDH, [myoglobin] and [CRP] all increased d1post ( $p<0.05$ ). Standing pain increased post-race, but returned to baseline d1post while individual muscle group pain did not return to baseline ( $p<0.01$ ). Participants were separated into euhydrated (<3% BM loss during race; n=7) or dehydrated (>3% BM loss during race; n=4) groups. Dehydrated individuals reported higher RPE values ( $p=0.034$ ) and higher perception of pain after the race and d1post ( $p<0.05$ ). Discussion: As hypothesized, body mass alone provided a crude assessment of hydration status, whereas serum and urine measures of hydration status provided a more informative indication of the physiological response. Markers of muscle damage and perceived pain were elevated even in this cohort of well-trained athletes. Dehydration was causal for increasing post-race perception of effort and a higher perception of muscle pain post-race. Muscle soreness remained higher d1post and this effect does not appear to be mediated by greater muscle damage or inflammation since CK and CRP levels were similar in both euhydrated and dehydrated individuals.

## **EFFECTS OF THE FIFA 11+ INJURY PREVENTION PROGRAM ON NEUROMUSCULAR CONTROL, STRENGTH AND PERFORMANCE IN AMATEUR SOCCER PLAYERS: A RANDOMIZED CONTROLLED TRIAL**

Impellizzeri, F.M.1,2, Junge, A.1, Dvorak, J.1, Pellegrini, B.2, Schena, F.2, Bizzini, M.1

*1: Schulthess Clinic (Zurich, Switzerland); 2, CeRiSM, University of Verona (Rovereto, Italy).*

Introduction To develop an injury prevention program that can be easily implemented in the everyday training routine (especially at amateur level), the FIFA Medical Assessment and Research Centre (F-MARC) has developed an advanced version of a previous prevention program: "The 11+". A cluster randomized controlled trial has recently shown that "The 11+" is effective in reducing injuries (Soligard et al. 2008). "The 11+" is a warm-up routine designed for training some physical components: core stability, neuromuscular control and balance, eccentric training of the hamstrings, plyometric and agility. The aim of this study was to examine whether "The 11+" can improve neuromuscular control, strength and performance in amateur soccer players. Methods Eighty-four male amateur players from 6 teams participated to this parallel, two groups, pre-post, randomized controlled trial. They were allocated to "The 11+" (n=42) and control (n=39)

group using a restricted blocked randomization where each block corresponded to a team. The players had to complete the warm-up routines 3 times a week for 9 weeks. Outcome measures were: eccentric and concentric strength of flexors and extensors, star excursion balance test, time-to-stabilization, core-stability of the trunk, vertical jump, sprint, agility. Analysis was performed using mixed models and magnitude of inferences. Results No differences between groups were found in training load and training components (0.146 < p < 0.680). Both groups completed an average of 2.1 sessions a week. After controlling for confounders and baseline values, possible worthwhile differences (47 to 72%) in favor of the 11+ group were found for flexors concentric strength at 60°/s (3.2%, 95% CI 0.6 to 5.9%; ANCOVA p level=0.046) and 180°/s (4.6%, 95%CI 1.0 to 8.3%;p=0.038), flexors eccentric strength (3.8%, 95%CI 1.4 to 6.2%;p=0.010), sprint (-0.9%, 95%CI -1.9 to 0.1%;p=0.123), agility (-1.1%, 95%CI -2.6 to 0.1%;p=0.265). Likely worthwhile differences (93-95%) in favor of "the 11+" group were found for Time-to-stabilization (-2.8%, 95%CI -4.4 to -1.2%;p=0.005) and core-stability (-8.9%, 95%CI -15 to -3%;p=0.012). Discussion The results of this study showed that nine weeks implementing "The 11+" as a routine warm-up can induce substantial improvement in neuromuscular control and possible worthwhile changes in flexors strength. Therefore, the 11+ not only can prevent injuries but can also induce positive effects on important physical components in amateur players. ## INFLUENCE OF OBESITY ON EXCESS POST-EXERCISE OXYGEN CONSUMPTION AFTER DIFFERENT MODERATE AEROBIC EXERCISES

Galvani, C.1, Bruseghini, P.2, Casolo, F.2, Faina, C.1,3

*Applied Exercise Physiology Laboratory, Catholic University of the Sacred Heart*

ILaboratorio di fisiologia sperimentale, Scienze Motorie, Università Cattolica del Sacro Cuore, Milano, Italia 2Scienze Motorie, Università Cattolica del Sacro Cuore, Milano, Italia 3Istituto di medicina e scienza dello sport, CONI, Roma, Italia Introduction Excess post-exercise oxygen consumption (EPOC) increases caloric burn during the recovery period, to be considered in relation to energy balance and weight loss. The aim of this study was to evaluate the acute effects of various modes of aerobic exercise of moderate intensity on EPOC in a lean (NW) and obese (OB) female population. Methods A population of moderately active lean and obese female (NW: age, 24,3±0,6 yr; BMI, 23,1±2,1 kg/m<sup>2</sup>; OB: age, 36,3±4,5 yr; BMI, 31±5,4 kg/m<sup>2</sup>) participated in the study over a 3-week period. Subjects filled a Baecke questionnaire of habitual physical activity and undergone 3 incremental tests to exhaustion (V'O<sub>2</sub>peak at treadmill, cycle ergometer and arm ergometer). Thereafter they completed five bouts of 30 min of exercise separated by at least 48 hours of rest: treadmill walking\_TE, cycling\_CE, arm crank exercise\_AE, cross-training exercise combining walking, cycling and arm crank for 10 min each\_CTE (60% of V'O<sub>2</sub>peak) and daily living activities\_DLA (3-6 METs). Before (30 min pre) and after (2 hours post) each exercise bout a resting metabolic rate measurement was carried out in a sitting position (K4b2, Cosmed, Italy). A repeated measures ANOVA was used to analyse data. Results EPOC magnitude was not significantly different for the two groups, except for CTE (NW, 9±4,2 l; OB, 2,4±2,4 l; p<0,05), and accounted between 5% and 15% of total energy expenditure (TEE150min). V'O<sub>2</sub> during exercise (V'O<sub>2</sub>ex) and TEE150min were similar for both groups (NW: V'O<sub>2</sub>ex, 1,3±0,3 l/min; TEE150min, 320,4±57,1 kcal; OB: V'O<sub>2</sub>ex, 1,2±0,3 l/min; TEE150min, 306,6±45,9 kcal; p=ns). Respiratory exchange ratio was significantly lower for NW when compared with OB during exercise, allowing a greater fat utilization (NW: QR, 0,8±0,1; FAT, 95,1±43,3 kcal; OB: QR, 0,9±0,1; FAT, 59,1±32,5 kcal; p<0,05 and p<0,001, respectively). Discussion This study indicates that analysed aerobic exercises, included DLA, elicit similar EPOC responses. These findings confirm (i) the magnitude of EPOC (LaForgia, 2006), (ii) that women who are lean or obese respond similarly to aerobic exercise at similar relative intensities (Crommett, 2004; LeCheminant, 2008) and (iii) that exercise-induced fat oxidation is diminished in obese women, as it was already demonstrated for men (Wong, 2006). ## THE ANTHROPOMETRIC AND PHYSIOLOGICAL CHARACTERISTICS OF FEMALE UNIVERSITY LEVEL NETBALL PLAYERS IN RELATIONSHIP TO PLAYING POSITION.

Orme, D., Duckworth, K., Relph, N.

*University of Cumbria*

Introduction: Netball is a non-contact, intermittent, invasion team game where seven players per team occupy a 30.5 x 15.25 metre court divided into three equal sections, each playing position has a specific area of the court to occupy. Physiological profiling is used within team sports to assess both the demands of the sport and provide evidence of position specific requirements (Geithner et al., 2006). Differences in positional demands have been found between playing positions within netball, the centre positions being the most active (McManus and Stevenson, 2007). To date there is limited data on the anthropometric or physiological characteristics of netball players. The aim of this study was to analyse the anthropometric and physical performance characteristics of university level netball players in three positional groups; attack (A), defence (D), and centre (C) players. Method: Twenty one university level netball players (mean (±SD) age 20.2 ± 1.6yr, height 1.68 ± 0.10m and body mass 63.61±8.62 kg). A battery of tests were used on each player, anthropometric tests; height, weight, sum of 7 skinfolds and physical performance tests; multistage fitness test, 20m sprint, 505 test, flexibility and counter-movement jump (CMJ). Differences between positional groups were determined using one-way ANOVAs and significance accepted at p<0.05. Results: There were no significant differences between positional groups for any variable. However, considering mean data alone, group D were tallest, 1.73 ± 0.06m, had greatest body mass, 66.13 ± 10.85kg, CMJ 3111.7 ± 879.6W, flexibility 22.2 ± 12.2cm and estimated maximum oxygen uptake, 39.1 ± 8.6ml.kg<sup>-1</sup>.min<sup>-1</sup>. Group C, had the greatest sum of skinfolds 122.61 ± 28.6mm, were fastest across split times at 5, 10m and overall 20m sprint time (1.16 ± 0.11, 2.00 ± 0.18, 3.53 ± 0.33s) and the 505 agility test (2.64 ± 0.12 and 2.75 ± 0.25s for left and right legs respectively). Conclusion: No significant differences were found between A, C or D playing positions. This study would suggest that there is no need for position specific training programs at this level in netball. #### CHANGES IN RATE OF HEART RATE INCREASE AT ONSET OF CYCLING AT 100 WATTS PREDICTS CHANGES IN SUBSEQUENT EXERCISE PERFORMANCE

Buckley, J.D., Nelson, M.J., Thomson, R.L. Howe, P.R.C.

*University of South Australia*

**Introduction** Intense training leads to fatigue, which is associated with reduced parasympathetic autonomic tone. The rapid increase in heart rate (HR) at the onset of exercise is primarily mediated by parasympathetic withdrawal. We hypothesised that a reduction in exercise performance due to fatigue, and thus partial parasympathetic withdrawal, would be associated with a reduction in the rate of increase in HR at the onset of exercise. **Methods** In a randomised, counterbalanced, cross-over design, 18 competitive cyclists completed two weeks of heavy cycling training and two weeks of light cycling training. At the end of each training period, the maximum rate of increase in HR (Heart Rate Increase, HRI) during five minutes of cycling at a constant power output of 100 Watts (W) was determined, after which performance (work done) was assessed during a five minute maximal cycle time-trial. **Results** Compared with light training, heavy training reduced both time-trial performance ( $5.2 \pm 0.9\%$ ) and HRI ( $15.2 \pm 5.5\%$ ) ( $P < 0.02$ ). The percentage change in HRI was positively associated with the percentage change in time-trial performance ( $r^2 = 0.53$ ,  $P < 0.001$ ). **Discussion** Changes in HRI during standardized submaximal exercise are associated with changes in exercise performance and may be mediated by changes in vagal tone. HRI could be used by coaches and athletes to monitor the effects of training and competition programs to avoid excessive fatigue. **References** Iellamo F, Legramante J, Pigozzi F, Spataro A, Norbiato G, Lucini D, Pagani M. #### THE EFFECT OF ACUTE EXERCISE INDUCED FATIGUE ON THE RATE OF INCREASE IN HEART RATE AT THE ONSET OF SUBMAXIMAL CYCLING

Thomson, R.L., Rogers, D.K., Howe, P.R.C., Buckley, J.D.

*University of South Australia*

**Introduction** Previous studies have been unable to identify a reliable and convenient method for assessing fatigue status. Heart rate (HR) reflects the autonomic regulation of the heart which is influenced by fatigue. Fatigue is associated with reduced parasympathetic autonomic tone (Iellamo et al., 2002) and the rapid increase in HR at the onset of exercise is primarily mediated by parasympathetic withdrawal (Robinson et al., 1966). We hypothesised that a reduction in exercise performance due to acute exercise induced fatigue, and thus partial parasympathetic withdrawal, would be associated with a reduction in the maximal rate of increase in HR at the onset of exercise (HRI). **Methods** Fourteen healthy male triathletes completed a 2 hr run at 75-85% of maximum HR to induce acute fatigue. A 5 min standardised submaximal cycle test at 100 watts and a 5 min maximal cycling test were completed before and 1 hr after the run. HRI is the maximum rate of increase in HR and was calculated by fitting a sigmoidal curve to the HR during the submaximal cycle test. Performance was classified as the total work done (kJ) during the maximal cycling test. Pre-exercise HR (mean HR in the 30 seconds prior to starting the submaximal cycle test), HR recovery (change in HR in 2 min following end of performance test) and HR max (maximum HR value during the performance test) were also measured. **Results** Time trial performance was significantly reduced following the 2hr run ( $-6.7 \pm 2.8\%$ ,  $P < 0.001$ ). This was accompanied by a significant reduction in HRI ( $-47.0 \pm 25.6\%$ ,  $P < 0.001$ ). Pre-exercise HR was significantly higher before the submaximal cycle test following fatigue ( $73.0 \pm 8.4$  bpm v  $90.5 \pm 11.4$  bpm,  $P < 0.001$ ). When controlling for these change in pre-exercise HR following fatigue, there was a significant relationship between change in HRI and change in performance ( $r = 0.578$ ,  $P = 0.038$ ). No other HR indices measured were related to changes in performance ( $P < 0.6$ ). **Discussion** HRI at the onset of submaximal cycling slows in response to acute exercise-induced fatigue. The change in HRI (when controlling for differences in pre-exercise HR) was the only HR assessment measured that was associated with changes in cycling performance. HRI is able to predict changes in performance due to acute fatigue and could be used to predict an athlete's state of recovery and physiological readiness to perform. HRI is a potential tool for coaches and athletes to monitor the acute effects of training and competition to avoid overtraining. **References** Iellamo F, Legramante J, Pigozzi F, Spataro A, Norbiato G, Lucini D, Pagani M. (2002). *Circulation*, 105, 2719-24. Robinson B, Epstein S, Beiser G, Braunwald E. (1966). *Circ Res*, 19, 400-11.

#### RECOVERY HEART RATE IN DYNAMIC AND STATICS SPORTS

Beltran Contreras, S., Peinado, A.B.1, Butragueno, J.1, Rojo-Tirado, M.A.1, Benito, P.J.1, Calderón, F.J.1

*Facultad de Ciencias de la Actividad Física y del Deporte (INEF), Universidad Po*

**Introduction** The fall in heart rate (HR) immediately after dynamic exercise has been studied by some authors [1, 2]. This decrease is considered to be a function of the reactivation of the parasympathetic nervous system [1]. The aim of this study was to compare the rate of recovery of the HR in several sports classified as statics (S) and dynamics (D). **Methods** 294 Spanish athletes of international level, from statics ( $n=89$ ) and dynamics ( $n=205$ ) sports, were evaluated. Each subject performed an incremental test until exhaustion in treadmill or cicloergometer. The expired air was analyzed with a gas analyzer. The response of heart rate (HR) during the first 4 minutes of a passive recovery after maximum effort was analyzed. Recovery rate index (IR) was calculated using the equation proposed by Calderon (IR1) [3]. A Student's unpaired t test was used to compare the HR recovery and IR between S and D sports. The significance level was set at 0.05. **Results** The maximum HR was not different between groups ( $p > 0.05$ ) (D:  $195.6 \pm 9.9$  beats $\cdot$ min $^{-1}$  vs. E:  $194.7 \pm 10.4$  beats $\cdot$ min $^{-1}$ ). However, the basal HR in S group was higher than D sports ( $p < 0.05$ ) ( $60.5 \pm 11.6$  beats $\cdot$ min $^{-1}$  vs.  $57.2 \pm 9.4$  beats $\cdot$ min $^{-1}$ , respectively). The HR recovery in minute 4 during the passive recovery was not significantly higher in S ( $120 \pm 14.2$  beats $\cdot$ min $^{-1}$ ) than in D ( $117 \pm 14.6$  beats $\cdot$ min $^{-1}$ ). IR1 was not significantly higher in D (IR1 min4:  $56.8 \pm 8.6\%$ ) than in S sports (min4:  $55.4 \pm 7.4\%$ ). **Discussion** The recovery of HR in S and D sports was similar, showing that the type of training does not influence the rate of recovery of the HR [3]. The cardiac parasympathetic reactivation is the principal determinant of the immediate fall in HR when exercise ceases [1], and this mechanism seems to function

independently of the type of training. Indeed, we believe that use the IR proposed is more useful to study the HR recovery, since takes into account the HR reserve. References 1. ### CHARACTERISING THE PHYSIOLOGICAL RESPONSES TO VERTICAL TREADMILL EXERCISE

Jordan, A., Claxton, D., Fysh, M., Purvis, A.

*Sheffield Hallam University*

**Introduction** A vertical treadmill (VerT) is being developed for the physical conditioning or rehabilitation of athletes. It requires a running action in a recumbent position on a vertically hung, non-motorised treadmill whilst the limbs are supported with overhanging resistance cables. To compare VerT exercise with horizontal treadmill running, a Rate of Perceived Exertion (RPE) of 15 was chosen as it approximates Maximum Lactate Steady State (MLSS) which is the highest steady state intensity without a continual blood lactate accumulation (Dekerle et al., 2003). The aim of this study was to determine the acute physiological responses to VT exercise at an RPE of 15. **Methods** With institutional ethics approval, five males aged 26 (2) years, height 181.2 (6.1) m, body mass 76.3 (6.8) kg were recruited. The participants' maximum oxygen consumption (51.7 (2.7) mL/kg/min) and Respiratory Compensation Point (RCP) were determined on a horizontal treadmill. MLSS was predicted from RCP minus 10% when expressed as percentage of maximum oxygen uptake (Dekerle et al., 2003). VerT exercise was performed for three minutes at an RPE of 15 during which treadmill belt speed and pulmonary gas exchange were continuously measured. Blood lactate was measured at rest and immediately after VerT exercise. **Results** Predicted MLSS during horizontal treadmill running elicited an oxygen uptake equivalent to 73.9 (2.9)% of the maximum oxygen uptake and a corresponding heart rate of 93.3 (8.4)% of the maximum. At an RPE of 15 on the VerT (equivalent to MLSS intensity), oxygen uptake was 58.7 (8.6)% of the horizontal maximum oxygen uptake, heart rate was 74.5 (5.7)% of the maximum, blood lactate rose from 1.41 (0.41) mmol/L rested to 3.67 (1.6) mmol/L and VerT belt speed was 1.60 (0.25) m/s. **Discussion** VerT exercise elicits lower cardiovascular stress (HR and oxygen uptake) than horizontal running at the same perceived intensity. This might be explained by the participants in the current study being accustomed to, but not conditioned for VerT exercise as well as the effects of load bearing. During VerT exercise muscular force is required to draw the leg downwards against the resistance cables which adds to the postural effort. This might result in a contribution of type II fibres during VerT as evidenced by the 2.26 (1.53) mmol/L increase in blood lactate. Further research should make direct comparisons with RPE-matched horizontal running as a framework for characterising VerT. **References** Dekerle J, Baron B, Dupont L Vanvelcenaher J, Pelayo P. (2003). Maximal lactate steady state, respiratory compensation threshold and critical power. *Eur J Appl Physiol*. 89, 281-288.

### FLOW-MEDIATED VASODILATION DURING EXERCISE

Miura, H., Sugino, M., Maki, Y.

*University of Tokushima*

**Introduction** Arterial stiffness or compliance is widely used to evaluate arterial function in humans. Previous researches reported the improved arterial function after acute endurance exercise (Kingwell et al. 1997, Nickel et al. 2011). However, an individual's physical fitness level or recovery response usually influences the arterial function responses. In order to establish an optimal exercise prescription for improving arterial function, evaluating arterial function during exercise must be needed. Therefore, this study examined flow-mediated vasodilation (FMD) during acute endurance exercise. **Methods** Eight healthy recreationally active adult men participated in this study. They performed the 30 min-recumbent cycling at 25W. Upper arm cuff inflation to 50 mmHg over their systolic blood pressure (SBP) for 5 min and subsequent deflation was induced at rest, during exercise, and immediately after exercise while in the recumbent position. The measurements of the right brachial artery diameter were taken using high-resolution ultrasound device. FMD was then estimated as the percent change in the arterial diameter over the baseline value at maximal dilation during each reactive hyperemia. **Results** The 25W-cycling trial showed that FMD increased from 8.9±1.0% at rest to 10.2±1.8% during exercise, and returned to 9.1±1.4% immediately after exercise. There was a significant difference between rest and exercise ( $p<0.05$ ), and between exercise and recovery ( $p<0.05$ ). However, oxygen uptake, heart rate, and systolic/diastolic blood pressure remained stable through the trial. **Discussion** This study is the precious of its kind to evaluate the FMD response during exercise. Though it remained stable immediately after exercise, FMD increased during acute relative low intensity endurance exercise. Elevation of FMD during exercise is accounted for the increased shear stress by increment of cardiac output, and vasoactive substances including of catecholamine, atrial natriuretic peptide, adrenomedullin (Celermajer 1997, Krzemiński et al. 2006). These results suggested that FMD should be evaluated during exercise for identifying the arterial function and exercise intensity. Future measurements of FMD at various exercise intensities may therefore allow for the establishment of exercise guidelines for achieving an improved endothelial function. **References** Celermajer DS (1997). *J Am Coll Cardiol*, 30, 325-333. ### SIMULATION OF THE EFFECTS OF DEHYDRATION AND HYPERHYDRATION ON RUNNING ECONOMY

Ler, H., Thompson, M.W., Ruell, P.

*Univeristy of Malaya*

**SIMULATION OF THE EFFECTS OF DEHYDRATION AND HYPERHYDRATION ON RUNNING ECONOMY** Ler, H.Y. 1, 2, 3 Thompson, M.W.1 Ruell, P.1 1: The University of Sydney (Australia); 2: University of Malaya (Malaysia); 3: Tunku Abdul Rahman College (Malaysia) **Introduction:** Elite athletes appear to drink a relatively small volume of fluid during prolonged severe exercise, culminating in a bodyweight deficit of 1-4% due to dehydration. While HR is known to be elevated when exercising in a dehydrated state, we know of no research linking dehydration with running economy (RE). Theoretically, the oxygen cost of running is related to bodyweight, and if bodyweight is reduced then ultimately RE should improve. Conversely, added weight (weight jacket with small sand bags) around the torso should increase the oxygen cost of running and HR. This study investigated the simulation of dehydration and hyperhydration on RE and the HR response to these conditions. **Methods:** Sixteen well trained male distance runners performed a control trial in a euhydrated state and undertook either 2 added weight (AW) trials (n=8; age: 44.3±4.2 yr; 71.1±6.0 kg; 174.3±6.9 cm; VO<sub>2</sub>max: 58.6±6.3mL/kg/min) or 2 dehydration (D) trials (n=8; 45.3±2.9 yr; 74.8±8.4 kg; 175.3±7.2 cm; VO<sub>2</sub>max: 58.2±6.6mL/kg/min). Each trial consisted of four different submaximal running speeds (65, 70, 75, 80% of VO<sub>2</sub>max; 4 min stages for each speed) on the treadmill in thermoneutral conditions (20°C; 40%rh).

Hyperhydration was simulated with added weight to the torso which was equivalent to 3% (AW3) and 4% (AW4) BW while 3% (D3) and 4% (D4) BW deficit was induced via an exercise-heat exposure protocol. Expired respiratory gas samples were collected over the final 60s at each speed using the Douglas bag technique. Heart rate (HR) values were recorded within the final 15s of each speed of running. Results: Subjects were well hydrated prior to all AW and D trials with urine specific gravity <1.010. RE at each speed was expressed as both oxygen uptake (VO<sub>2</sub>, mL/kg/min) and caloric unit cost (CR, kcal/kg/km). VO<sub>2</sub> significantly increased with speed ( $r=0.999$ ;  $p<0.001$ ); together with average CR ( $p=0.263$ ) in all trials. No significant difference was found between D and AW trials in both VO<sub>2</sub> (mL/kg/min) and CR (kcal/kg/km). HR increased linearly with each increment in speed for all trials and was significantly higher at 75 and 80% of VO<sub>2</sub>max in D3 and 65 to 80% of VO<sub>2</sub>max in D4 compared with AW3 and AW4 trials, respectively [(D3 vs. AW3: 147±5 vs. 140±5; 159±6 vs. 152±5); (D4 vs. AW4: 128±10 vs. 119±7; 140±8 vs. 129±6; 150±6 vs. 141±6, 161±5 vs. 152±5 bpm)] ( $p<0.05$ ). Discussion: RE at speeds ranging from 65 to 80% of VO<sub>2</sub>max was not affected by 3-4% of bodyweight deficit or added weight. One possible explanation for these results is that when added weight is evenly distributed around the torso the additional oxygen cost is minimised and offset by an added contribution from the series and parallel elastic component of muscles and tendons at no metabolic cost.

### IS-SH11 European Sports Tradition: Towards Unified Concepts and Policies

---

#### MOVEMENT CULTURES IN EUROPE: SIMILARITIES AND CONTROVERSIES

Pfister, G.

*University of Copenhagen*

Introduction: In the last decades, intensive debates about the "European Sport Model" emerged not only in sport sciences but also in the context of EU sport policies. Despite the controversies about its meanings and benefits, most participants in these discussions agreed that this sport system has its roots in the European civil societies and differs decisively from sport models in other regions of the world. Aims and content: In this paper, I will retrace the origins and developments of various "movement cultures" on the European continent and reconstruct in particular the development of German Gymnastics/Turnen, Swedish gymnastics and English sport. I will explain the emergence of these different concepts against the backdrop of the socio-cultural and political situation in their respective countries. Theory and method: In the second part of the paper, the role of modern sport and its impact on German and Swedish gymnastics will be the focus. Using the theoretical concept of "sportification", the conflicts between sport and gymnastics as well as the "sportification" of the different gymnastics systems will be analyzed and described. The sources for this analysis are in particular gymnastics and sports magazines as well as the books of the proponents of the different sports/gymnastics movements. With regard to the sportification process I refer to Guttman's paradigm "From ritual to record" as well as the articles and books discussing this work. Results: Current studies about the sport habits and tastes in various countries indicate that some of the sport and gymnastics traditions still have an influence on the European sports cultures. Guttman, A. (1978). *From ritual to record: The nature of modern sports*. New York: Columbia University Press

#### SPORT, ORGANIZATIONS AND CHANGE IN EUROPE

Porro, N.

*Facoltà di Scienze motorie all'Università di Cassino*

By a sociological point of view one must preliminarily distinguish between Voluntarism at large and Voluntary Action. Voluntarism is a social sub-system which can be described according to institutional and organizational theories. Voluntary action means a collective practice inspired to a philosophy of solidarity and to a value oriented ethics. In Europe the sports organizations, including the most of performance competitive activities, since the late 19th century historically grounded in both the sub-system of voluntarism and the culture of voluntary action. By an organizational perspective they represented the social backbone of the sports system at large. At present the most of European sports clubs are rooted in the non profit private domain, in the Third Sector organizational area and in the so called Social Economy. At the same time the culture and the practice of voluntary sport have been influenced by social changes and by the uprising of new lifestyles, attitudes, preferences and tastes. The so called European sports system is still strongly differentiated and reflects various and highly heterogeneous dynamics of formation and development which on turn refer to the profile of the Nation building, to specific forms of modernization, to the social stratification etc. In each country role, structure and regulation of the sport system depend on (i) different legal statuses assigned to sport; (ii) various typologies of acknowledgement of the non profit system at large; (iii) organizational histories, to be linked with specific experiences (regarding sports disciplines, network frames, influence of exogenous and endogenous factors), and on (iv) an emerging role exerted by over-national bodies like EU. To a closer analysis of its social, cultural and organizational landscape sport for all itself means as an umbrella formula in which are represented many fields of action, sometimes conflicting each other. One can describe it as a typical political arena according to the classic Benson's definition (1988), implying different actors, several stakeholders and specific priorities and motivations. According to our approach we can locate three main organizational identities: (i) grassroots movements, (ii) sport for citizenship associations and (iii) sport for everybody offer system. On turn, changes and trends in sports organizations will be analysed adopting on one hand a socio-historical approach and, on the other, an emerging sociological analysis of organizations. The presentation emphasizes the relationship between these conceptual and methodological contributions and the specific role of sport in producing social capital.

#### FOOTBALL RESEARCH IN AN ENLARGED EUROPE: A ROAD MAP FOR INNOVATIVE IDENTITY RESEARCH

Sonntag, A.

*ESSCA School of Management*

Introduction Researchers from the social sciences who work on football-related topics often face two major handicaps: not only do they often work in a rather isolated manner within the borders of their academic discipline, but they hardly ever have sufficient budgetary

means to test their hypotheses in large-scale surveys. This is particularly true for researchers dealing with issues like mutual perception patterns between different communities or the impact of international football on ongoing contemporary identity dynamics in the age of globalisation. Methods The paper presents a methodological road map for a large-scale collaborative research project on European football, which is carried out within the 7th European Framework Programme under the topic line "The Anthropology of European Integration". The project, which is entitled "FREE – Football Research in an Enlarged Europe" and scheduled to run from April 2012 to March 2015, is an attempt to overcome both the disciplinary and budgetary handicaps mentioned above and to realise a truly interdisciplinary synergy of research approaches with the help of a complex methodological architecture. Its perspective is distinctly European, working on transnational tendencies and commonalities rather than national prisms and case studies. Results/Discussion At the moment of the ECSS Congress, it will be too early to present first tangible results. It will, however, be possible to put to discussion the assumptions and hypotheses which underpin the project and open up a controversial debate. At the same time the paper will be an opportunity to invite interested scholars to contribute actively to this ongoing project. Issues discussed will include the social impact of European football competitions, football as a producer of collective memory, football and gender construction, identity formation from the local to the transnational, the European football community as a public sphere, as well as transnational movements of stakeholder empowerment in football governance. ### IS-BN09 Neuromechanics of Stretch Shortening Cycle: Application to Sports

#### ANYTHING SPECIFIC ABOUT THE FASCICLE- TENDON INTERACTION AMONG THE WORLD TOP LEVEL MARATHON RUNNERS?

Ishikawa, M.1, Sano, K.1, Nobue, A.1, Danno, Y.1, Akiyama, M.1, Oda, T.2, Ito, A.1, Nicol, C.3, Locatelli, E.4, Komi, P.5  
*Osaka University of Health and Sport Science (Osaka, Japan)*

1: Osaka University of Health and Sport Science (Osaka, Japan), 2: Hyogo University of Teacher Education (Hyogo, Japan), 3: University of the Mediterranean (Marseilles, France) 4: International Association of Athletics Federations (Monaco), 5) University of Jyväskylä (Jyväskylä, Finland) Recent years have demonstrated great success of African runners in general and that of the Kenyan runners in particular. The success of the Kenyan runners has been so dramatic that scientists and practitioners alike wondered, whether this success is not only as a result of superior training system and athletic selection but also due to the genetic make-up, specifically providing the runners with exceptional preconditions for high level performance. Contrasting the expectations, the reliable studies conducted on the Kenyan runners have not shown that they would be markedly different in many basic physiological parameters from their e.g. European counterparts. Nevertheless, they seem to have high maximal aerobic capacity associated with exceptionally good running economy (Saltin et al. 1995 a,b). This finding of high running economy could not be explained by any of the histochemical and/or biochemical parameters measured from the muscle biopsy samples. Consequently, it was a clear conclusion of these reports of Saltin et al (1995 a,b) that one of the possible reasons for the high mechanical efficiency (or running economy) could be the special biomechanical make up of these runners. The question can therefore be asked whether the Kenyan runners possess a particular type of triceps surae muscle-tendon complex, which could favor efficient storage and use of elastic energy in Achilles tendon during natural forms of locomotion. The present study was therefore focused on examining the anthropometric characteristics and the muscle-tendon interaction of the Kenyan runners belonging to the elite category of performance as measured by their success in international achievement as medal winners or running records. The present report will emphasize how the muscles of these athletes function efficiently during stretch-shortening cycle exercises References Saltin B et al. (1995a) *Scand J Med Sci Sports*. 5: 209-221. Saltin B et al. (1995b) *Scand J Med Sci Sports*. 5: 222-230.

#### IDENTIFICATION OF FASCICLE-TENDON INTERACTION DURING SSC IN SKIING TECHNIQUES

Lindinger, S.1, Ishikawa, M.2, Komi, P.V.3,4, Holmberg, H.C.5, Rapp, W.3,4, Müller, E.1, Linnamo, V.3,4  
*University of Salzburg*

Identification of fascicle-tendon interaction during SSC IN SKIING TECHNIQUES Stefan J. Lindinger<sup>1</sup>, Masaki Ishikawa<sup>2</sup>, Paavo V. Komi<sup>3</sup>, Hans-Christer Holmberg<sup>4</sup>, Walter Rapp<sup>3</sup>, Erich Müller<sup>1</sup>, Teemu Lemmettylä<sup>3</sup>, Stefan Gressenbauer<sup>1</sup> and Vesa Linnamo<sup>3</sup> <sup>1</sup>University of Salzburg, Austria, <sup>2</sup>Osaka University, Japan, <sup>3</sup>University of Jyväskylä, Finland, <sup>4</sup>Mid Sweden University, Östersund KEY WORDS: skiing, MTU, ultra sound Identification of stretch-shortening cycles (SSC) in cross-country skiing (XC) can be obtained using kinematics in combination with EMG of the respective muscles (indirect methods). Consequently a clear hypothesis was developed (Norman & Komi/Komi & Norman 1987) that XC benefits from a sequence of flexion-extension movements that contain SSC actions, shown in later studies (Vähäsöyrinki et al. 2008; Lindinger et al. 2009). Encouraged by these findings we wanted to identify the possible fascicle-tendon interaction also in different other XC techniques. While making progress in these series of studies it was decided to add also alpine skiing in the measurement protocol. Testing followed the basic models used in previous measurements obtained for XC skiing, but concentrated more on the double poling (DP) used on a treadmill. In free technique V2 skating was taken as a major object, and in Alpine skiing (AS) recordings were made for Slalom while in both on snow studies the unique nature of these measurements included the use of ultrasonography (Prosound C3cv, Aloka Japan) to observe the fascicle-tendon interaction during these performances. Goniometers/video was used for joint kinematics. So the fascicle-tendon interaction of selected muscles during the important functional phases of the performances, such as the ski and pole contact during skating and the preparation and action during slalom turns could be examined. The recorded muscles included shoulder and arm extensors for DP and leg extensors for skating and slalom. When applicable the sEMG was also recorded from all these muscles simultaneously with other systems also including pole and leg forces. Results of these series of studies confirm the occurrence of speed and subject dependent SSC in elbow and shoulder joints during DP. In skating as well as Slalom skiing (in particular the inside leg during turns) most of the measured muscle fascicles were stretched in the MTU stretching phase followed by shortening in the MTU shortening phase while the relative stretching and shortening amplitudes in both techniques were specific for each muscle. Although part of the analysis is still ongoing, the major conclusion can be reached to support the hypothesis that both XC and AS techniques contain important elements of SSC, which can be used to apply respective training techniques for further

improvement of performance. REFERENCES Lindinger et al. (2009), Changes in upper body muscle activity with increasing double poling velocities in elite cross-country skiing. *Eur J of Appl Physio.* 106(3):353-363.

## RELEVANCE OF SSC FUNCTION ON SPORT PERFORMANCE

Komi, P.V.1, Ishikawa, M.2, Linnamo, V.1

*Neuromuscular Research Center*

1: University of Jyväskylä (Jyväskylä, Finland), 2: Osaka University of Health and Sport Science (Osaka, Japan) In 1885 the French physiologists Marey and Demeny noted that when two vertical jumps are performed successively, the second one is higher than the first one. This potentiation effect was later called "wind-up" movement (Asmussen & Sorensen 1971) and currently called as stretch-shortening cycle (SSC) (Norman & Komi (1979)). SSC is the natural way the skeletal muscles function during locomotion, and can be easily identified in running, jumping and throwing. In the contact phase of running, for example, SSC refers to lengthening of the active muscle followed by its immediate shortening. The basis for the use of SSC instead of pure concentric muscle actions is simple: the neuromuscular system tries to perform movement as efficiently as possible. The fundamental characteristics of SSC have been examined quite extensively with isolated muscle models (e.g. Cavagna et al, 1965 and 1968) and also with human muscles (e.g. Bosco et al 1981; Komi, 1983). In SSC the active stretching (eccentric phase) allows storage of elastic energy which can be utilized partly in the subsequent shortening (concentric phase). The centrally controlled preactivation combined with the active eccentric phase prepare the muscle to receive the "impact" and store this elastic energy. The passive (non-active) muscle can only store a minimum amount of elastic energy. One important point in the discussion of SSC potentiation is the interaction between fascicles and tendon structures. The definition of SSC as given above, relates to the entire muscle-tendon unit (MTU) and can be considered too simple. The fascicles may not necessarily, and in some instances not at all, follow the stretch-shortening pattern of MTU. Depending on the imposed impact load the fascicles may show lengthening, which can be very short-lived and the possible reflex induced force potentiation may not be visible if ultrasound scanning frequency is low (Ishikawa & Komi, 2008). The present report will emphasize how this fascicle-tendon interaction will be influenced by the type of muscles, intensity of effort, aging process, fatigue and training. It is believed that considerable amount of information is already available to demonstrate how this interaction applies to various sport activities as well. ### IS-PM15 Exercise in cancer patients (\*)

#### PHYSICAL EXERCISE IN CANCER PATIENTS

Velthuis, M.

*Comprehensive Cancer Centre the Netherlands*

As in many countries, the number of cancer survivors increases every year in the Netherlands: from 366.000 in the year 2000, to expected 692.000 in 2015. Physical exercise has been associated with benefits during and after cancer treatment, including reduction of treatment related side effects and improvements in physical and psychosocial outcomes. The presentation will focus on effects of physical exercise in cancer patients during and after rehabilitation with a curative intent and will be based on the Dutch evidence based guideline Cancer rehabilitation 1 and recently published studies 2, 3. The guideline Cancer rehabilitation 1 as well as Velthuis et al. 2 state that physical exercise during cancer treatment seems to be feasible, causes no additional health risk and seems to have promising effects, at least in breast cancer patients. Further studies are needed in other cancer diagnoses. The effects in patients diagnosed with colon cancer will be studied in de Physical Activity during Cancer Treatment (PACT) – study 4. The guideline Cancer rehabilitation recommends rehabilitation after cancer treatment has been finished that consists of aerobic and progressive resistance exercises. The rehabilitation programme should be determined per patient. Velthuis et al. 3 recommends to screen on fear of movement prior to the start of rehabilitation. The expectation is that cancer survivors with increased fear of movement might benefit from rehabilitation programmes focused on reducing fear of movement. While cancer survivors without fear of movement might benefit less from these programmes and can be offered regular physical exercise programmes. References 1Guideline Cancer rehabilitation. #### EXERCISE AND CANCER— HOW TO PLAN AN EFFECTIVE INTERVENTION?

Nikander, R.

*Helsinki Metropolia University of Applied Sciences*

Over 20 million cancer patients worldwide are alive because of effective but demanding cancer treatments, and the number of survivors is increasing. More than half of survivors are over 65 years of age and they need to cope with cancer per se, in addition to the cancer treatment related lymphedema, weight gain or loss, premature menopause (women), fatigue, depression, and poor quality of life. Exercise as a planned and structured form of physical activity has been successfully used to improve the survivors' physiological and psycho-

social health, and it can even prevent relapses of the disease. Indeed, there is some evidence that exercise has small or moderate effect on survivors' cardiorespiratory fitness, physical functioning and quality of life in many cancer types, and it can help to cope with weight gain and fatigue in breast and prostate cancer survivors. There is little evidence of exercise on cancer patients' survival. Adverse effects of exercise such as lymphedema, shoulder tendonitis or joint pain have been quite rarely reported. Despite the beneficial evidence, the amount of exercise training is often low in cancer patients. Both supervised institutionalized and self-directed home exercise interventions lasting six to 26 weeks have been utilized in exercise interventions. These interventions have mostly consisted of aerobic exercise such as walking and cycling or resistance training. Exercise intensity has varied greatly due to various exercise modes. The frequency and duration have varied between 10 to 75 minutes per session and two to seven times a week. Adherence to exercise training has mostly been over 60%. Exercise training has several small positive effects for cancer survivors health.

### EXERCISING DURING CHEMOTHERAPY - POTENTIALS AND CONTRAINDICATIONS

Baumann, F.T.

*German Sport University Cologne*

Introduction: Cancer patients suffer not only because of illness and medical therapies but also due to lack of mobility during the phase of chemotherapy [Baumann 2009]. Immobility, which may result in muscle atrophy or pneumonia, can become life threatening [Bartsch 2000]. Between 70 and 100% of all cancer patients are suffering from fatigue during chemotherapy [Mock 2001, Jacobsson 1998, Irvine 1994]. In addition, the psychological burden is enormous. All of these factors have a detrimental effect on their quality of life, as several studies have shown. Results: In our studies we show a positive effect of endurance training on physical constitution and quality of life on leukemia and lymphoma patients during high dose chemotherapy. With breast cancer patients we made resistance training during chemotherapy. The level of resistance of the patients was maintained and even increased. The affected arm showed a significant increase in the maximum resistance. Regarding the outward rotation of the shoulder significant improvements were found for effort and performance. Regarding the assessment of quality of life, as significant improvement could be achieved in Fatigue. Discussion and Conclusion: Physical exercise programs still play only a minor role during the treatment of cancer inpatients. Only limited experience exists regarding resistance training with cancer patients [Courneya 2007]. No signs of complication were registered in our studies. Different therapeutic exercise interventions for the individual cancer entities are necessary due to varying medical treatments and side effects. Existing views that early exercise parallel to and immediately after medical therapy would pose a health risk to the patient and should only be introduced after a complete remission are incorrect. However, further studies have to be conducted, in order to better understand the exact effects of exercise and the different training intensities. Literature: Baumann et al. ### OP-PM53 Training and Testing: Fatigue

#### INFLUENCE OF FATIGUE ON UPPER LIMB MUSCLE ACTIVITY AND PERFORMANCE IN TENNIS

Rota, S., Morel, B., Rogowski, I., Hautier, C.

*University of Lyon 1*

INFLUENCE OF FATIGUE ON UPPER LIMB MUSCLE ACTIVITY AND PERFORMANCE IN TENNIS Rota, S.1, Morel, B.1, Rogowski, I.1, Hautier, C.1 1: CRIS (Lyon, France) Introduction Fatigue in tennis is multifactorial and influences the outcome of a match (Hornery et al., 2007). Indeed, fatigue can engender performance impairment, including mistimed strokes (velocity and precision), altered on-court movements (velocity, footwork and positioning to the ball) and incorrect tactical choices (Davey et al., 2002). The aim of this present study was to investigate the effect of a fatiguing tennis intermittent exercise on the upper-limb muscle electromyographic (EMG) activation level, ball velocity, stroke accuracy and consistency. Methods Height elite tennis players performed a fatiguing tennis exercise composed of 4 sets of 8 minutes maximal tennis hitting (serve and forehand). Before and after fatigue protocol, subjects performed isometric maximal voluntary contractions (IMVC) as well as forehand and serve skill tests. Heart rate, blood lactate concentration and rating of perceived exertion were monitored during the fatigue protocol. Force and EMG were recorded during IMVC for internal arm rotators, wrist flexors and wrist extensors. Ball velocity, stroke accuracy, error percentage of strokes and EMG of height upper-limb muscles were assessed during the skill tests. Results Mean heart rate, blood lactate and perceived exertion values attained respectively 176±9 beats/min, 5.7±2.5 mmol/L and 17.5±0.5 after fatigue. Significant decreases in serve velocity (3.2%) and forehand accuracy (21.1%) were observed after the fatiguing intermittent exercise. Error percentage of both strokes tended also to decline (p=0.056). EMG activation level for pectoralis major (PM) and flexor carpi radialis (FCR) significantly decreased during serve and forehand drives. EMG level of extensor carpi radialis activity decreased only during forehand drives. Force (-14%) and PM EMG amplitude declined during IMVC after fatigue. EMG activity for FCR was significantly lower in post-IMVC than in pre-IMVC while force stayed unchanged. Discussion This study demonstrates that a fatigue protocol can simulate physiological strain induces by intense rallies and that generates significant performance decrease during serve and forehand drives. Velocity and accuracy losses were accompanied by a significant EMG decrease observed during tennis strokes and IMVC for PM and FCR principally. As discussed by Welsh (2002), fatigue seems to be associated with a decrement in central control. Thus players have to decrease velocity in order to maintain a high degree of accuracy in serve whereas during forehand the preservation of velocity appeared to be detrimental on stroke accuracy. ## ANALYSIS OF MECHANICAL PARAMETERS RELATED TO FATIGUE IN HIGH LEVEL SPRINTERS DURING SPRINT WORKOUTS

GARNACHO-CASTANO, M.V.1, CUADRADO-PENAFIEL, V.2, ORTEGA-BECERRA, M.A.3, MATÉ-MUNOZ, J.L.1, CONCEICAO, F.4, JIMÉNEZ-REYES, P.1,5

1: *Universidad Alfonso X El Sabio, UAX (MADRID, ESPAÑA)*, 2: *UCLM (CASTILLA LA MANCHA, ESPAÑA)*, 3: *UPO (SEVILLA, ESPAÑA)*, 4: *FADEUP (PORTO, PORTUGAL)*, 5: *UCAM (MURCIA, ESPAÑA)*

**Introduction** The ability to sprint is a key parameter in many sports and the focus of many training programs. Biomechanically sprint is composed of acceleration, maximum velocity and deceleration phases (Volkov & Lapin, 1979). Contact time, top speed and the moment in which this top speed is achieved in a sprint race are parameters influencing the performance in sprint running (Gajer et al, 1999). To our knowledge, no data exists that analyse the relationship between these parameters and phases of a sprint race. Thus, the aims of this study were: 1) to measure mechanical parameters during maximal sprint running in different distances, 2) to investigate relationships between those mechanical parameters and different phases for a sprint race, and 3) to quantify changes in these data due to fatigue induced by sprints repetition. **Methods** Nine high level sprinters (age  $23.1 \pm 4.4$ yr, body mass  $73.7 \pm 4.6$ kg, height  $177.6 \pm 5.9$ cm; body fat  $9.6 \pm 2.9\%$ ) participated in the study. They did sprints of 40, 60 and 80m at maximum speed possible up to lose 3% of the speed. Instantaneous running velocity ( $v$  in  $m \cdot s^{-1}$ ) over time and distance was recorded with a radar Stalker ATS System™ (Radar Sales, Mineapolis, MN, US). Contact time was analyzed by photogrametry with Kwon3D biomechanical analysis software (Vison, Cheolsan-dong, Korea). **Results** In this study, fatigue was induced by repeated maximal efforts, leading to a decrease in performance over the different distances respectively. Top speed and the moment which is achieved in the race significantly decreased ( $p < 0.001$ ); likewise contact time in the different phases significantly increased ( $p < 0.001$ ): values increased 2% for acceleration phase to 15% in deceleration phase. **Discussion** This study highlights the importance of Rate of Force Development (RFD) like one of the most important factors influencing performance in sprint. This is by the fact that the values of strength and power as the fatigue is necessary to be greater when the available time to apply force is lower (Hakkinen, 1989), and this is what happens during the maximum speed phase, in which the available time to apply force is lower than in the acceleration phase. Thus, the marked alterations observed in this study during repeated running sprints, which in turn is affected by fatigue and this on key parameters in sprint performance (i.e. contact time and top speed). Such data would provide new information on the mechanical manifestation of fatigue during repeated sprinting, which would then be used to design optimal training routines to improve athlete's sprint training session. **References** Gajer, Thépaut-Mathieu & Lehenaff. ## EFFECTS OF INDUCED MENTAL FATIGUE ON PHYSICAL PERFORMANCE DURING PROLONGED INTERMITTENT SPRINTING

Coutts, A.J.1, Smith, M.1, Marcora, S.2

1: *UTS (Sydney, Australia)*, 2: *University of Kent (Medway, United Kingdom)*

**Introduction** Mental fatigue has been shown to impair performance during constant-power exercise, however its effects on performance during freely paced exercise are yet to be examined. The purpose of this study was to examine the influence of induced mental fatigue on performance during prolonged, intermittent sprinting. Furthermore, the study aimed to investigate the physiological and psychological factors that underpin any potential changes. **Methods** In this single blind, randomized, crossover study, eight team sport athletes (age:  $21 \pm 2$  y, stature:  $182 \pm 4$  cm, body mass:  $76 \pm 6$  kg,  $VO_{2max}$   $47 \pm 4$  ml/kg/min) completed a 45-min intermittent running protocol that simulated typical team activity demands on a non-motorised treadmill on two separate occasions, following either 90-min of demanding mental activity (mental fatigue) or 90-min of emotionally neutral documentaries (control). The 45-min protocol consisted of one 3-min block repeated 15 times to allow for data comparison. Velocity and distance were measured at a frequency of 10 Hz throughout the protocol and analysed in 3-min blocks. Heart rate (HR) and oxygen consumption were recorded as 5-s averages while blood glucose and lactate concentrations were measured every 9 min. All physiological variables were analysed in 9-min blocks. Rating of perceived exertion (RPE) was measured every 5-min using a CR-100 scale. The effects of condition on all variables were tested using two-way repeated-measures ANOVA. **Results** The demanding cognitive task increased mental fatigue ( $P < 0.05$ ), which caused a reduction in velocity of lower intensity activities (LIA) ( $P < 0.001$ ) while higher intensity activities and peak sprint velocity were not different between conditions. A condition  $\times$  time interaction effect was also observed for LIA velocity ( $P = 0.003$ ). Mean oxygen consumption and HR were lower in the mental fatigue condition (oxygen consumption:  $34 \pm 4.9$  ml/kg/min; HR:  $158 \pm 15.8$  bpm) when compared with the control condition (oxygen consumption:  $36 \pm 4.0$  ml/kg/min; HR:  $160 \pm 11.9$  bpm;  $P < 0.001$ ), while blood glucose and lactate concentrations were not affected by mental fatigue. When normalised to velocity, RPE was higher in the mental fatigue condition ( $P = 0.027$ ). **Discussion** Mental fatigue impairs performance during prolonged intermittent running. This is primarily observed as a reduction in LIA velocity. It appears that this reduction in performance is not mediated through physiological mechanisms but rather the athletes perceived exertion. Future studies should explore this relationship between mental fatigue and physical performance further.

## PASSIVE VERSUS ACTIVE COLD WATER IMMERSION POST-EXERCISE: CORE TEMPERATURE 'AFTER' AND SUBSEQUENT EXERCISE PERFORMANCE.

Crampton, D.

*Trinity College Dublin*

**PASSIVE VERSUS ACTIVE COLD WATER IMMERSION POST-EXERCISE: CORE TEMPERATURE 'AFTERDROP' AND SUBSEQUENT EXERCISE PERFORMANCE.** Crampton, D. 1, Donne, B. 1, Warmington, S.2, Egana, M.1 1: Physiology Department, Trinity College Dublin, Ireland, 2: Exercise and Nutrition Sciences, Deakin University, Melbourne, Australia. **Introduction** Cold water immersion (CWI) is a popular recovery intervention following high-intensity training and competition across a variety of sports. 'Afterdrop' is the decrease in core temperature ( $T_c$ ) occurring after prolonged CWI. This study investigated the magnitude of the afterdrop induced and sprint capacity following active and passive CWI. **Methods** Male triathletes ( $n=8$ ) completed sets of 3 by 30-s Wingate tests (4 min rest interval) on a Lode electromagnetic cycle ergometer pre- and post- randomised 30-min recovery periods. Passive hip-level CWI at  $15^\circ\text{C}$  (CW15) was compared with active CWI at  $15^\circ\text{C}$  (CW15-EX), active thermoneutral immersion at  $34^\circ\text{C}$  (TWI-EX) and active non-immersed control (CON-EX). The active component consisted of seated arm-cranking at 40%  $P_{max}$  on an adapted Monark cycle ergometer during the immersion phase. At 3 hour pre-

test volunteers ingested a gastrointestinal sensor (CorTemp); core temperature (T<sub>c</sub>) and blood lactate (BLa) data were assessed at regular intervals during exercise and recovery. Data were analysed using two-way repeated measures ANOVA, detected differences quantified using post-hoc Tukey tests ( $P < 0.05$ ) and presented as mean  $\pm$  SEM. Results Recovery delta T<sub>c</sub> (pre- to post-recovery) was significantly greater following CW15 (-0.8  $\pm$  0.2) compared with CW15-EX, TWI-EX and CON-EX (-0.2  $\pm$  0.1; -0.1  $\pm$  0.1; -0.2  $\pm$  0.1 °C, respectively;  $P < 0.05$ ). The initial post-immersion afterdrop (delta T<sub>c</sub>: end-recovery to start-exercise) was significantly greater following CW15-EX and CW15 (-0.4  $\pm$  0.1; -0.4  $\pm$  0.1) vs. TWI-EX and CON-EX (-0.1  $\pm$  0.1; 0.0  $\pm$  0.0 °C, respectively;  $P < 0.001$ ). Relative BLa post-recovery expressed as % remaining was greater following CW15 (58  $\pm$  2%) vs. CW15-EX, TWI-EX and CON-EX (39  $\pm$  2; 45  $\pm$  3; 39  $\pm$  2%, respectively;  $P < 0.001$ ) inferring reduced lactate clearance. Average mean power normalised to body mass was significantly lower following CW15 (7.3  $\pm$  0.1) vs. CW15-EX, TWI-EX and CON-EX (7.7  $\pm$  0.2; 8.0  $\pm$  0.2; 7.9  $\pm$  0.2 W.kg<sup>-1</sup>, respectively;  $P < 0.001$ ). In addition, average mean power normalised to body mass was significantly lower following CW15 and CW15-EX (7.3  $\pm$  0.1; 7.7  $\pm$  0.2) compared with pre-recovery data (7.9  $\pm$  0.2; 8.1  $\pm$  0.2 W.kg<sup>-1</sup>,  $P < 0.05$ ), however, following TWI-EX and CON-EX data were unchanged. Discussion Arm-cranking exercise (40% P<sub>max</sub>) limited the decrease in T<sub>c</sub> during CWI; however, both passive and active CWI resulted in a significant core temperature afterdrop effect post-immersion. Overall BLa clearance during CWI was significantly improved with the addition of low intensity arm exercise. Both passive and active CWI had a negative effect on subsequent sprint performance however this effect was greatest following passive CWI.

## THE EFFECT OF ICE SLURRY INGESTION ON PERCEIVED THERMAL STRESS AND FLUID INTAKE DURING A SIMULATED TRIATHLON

Dascombe, B.J., Stevens, C., Callister, R., Sculley, D.V., Boyko, A.

*University of Newcastle (Newcastle, Australia)*

**Introduction** The effect of internal pre-cooling strategies prior to exercise has been of research interest in recent times (Siegel and Laursen, 2012), however the efficacy of internal cooling strategies is largely unknown. Perceptions of thermal stress (PTS) and thirst (as measured through voluntary fluid intake (VFI)) assist in the regulation of endurance performance in the heat (Schlader et al. 2011). Therefore, this study investigated the effect of ice slurry ingestion on measures of PTS and VFI during the run leg of a simulated triathlon. **Methods** Nine well-trained male triathletes (29.1  $\pm$  3.6 yrs, 61.7  $\pm$  4.7 mL.kg<sup>-1</sup>.min<sup>-1</sup>, best ODT time: 02:10:37  $\pm$  00:08:32 hr) performed two randomised trials of a simulated triathlon in controlled hot conditions (32-34°C). The triathlon consisted of a paced 1.5 km swim (pool) and 1 hr cycle (ergometer), prior to a self-paced 10 km (treadmill) run. In the middle half of the cycle leg, participants consumed either 10 g.kg<sup>-1</sup> BM of ice slurry (ICE) or room temperature (CON) sports drink. Water intake was also allowed ad libitum throughout the cycle leg and at 2 km intervals in the run leg. Physiological and perceptual measures (100mm visual analogue scales) were taken during the cycle and run legs. Paired sample t-tests and two-way repeated-measures analysis of variance with Scheffe post hoc tests were used to determine the effects of ice slurry ingestion. **Results** Overall, self-paced 10 km run time significantly improved in the ICE condition (43.4  $\pm$  3.7 vs. 44.6  $\pm$  4 min;  $P = 0.03$ ). Voluntary fluid intake was significantly ( $P = 0.03$ ) lower in the ICE (1258  $\pm$  401 mL) compared to the CON (1393  $\pm$  356 mL). PTS was significantly lower at 5 km of the run leg in ICE (73  $\pm$  9 vs. 80  $\pm$  7 mm;  $P = 0.04$ ) and remained lower throughout the rest of the run leg. Importantly, the 5-10 km split was significantly different between conditions (21.3  $\pm$  1.9 vs. 22.1  $\pm$  2.4 min;  $P = 0.02$ ). Heart rate, sweat rate, and rating of perceived exertion were similar between conditions. **Discussion** These results demonstrate that ice slurry ingestion has a significant effect on triathlon performance, which may be a result of a reduction in the PTS during exercise. Alterations in PTS have been related to the self-selection of exercise intensity, with an increase in PTS having been shown to be related to a decrease in self-selected exercise intensity in the absence of an increased rectal temperature (Schlader et al. 2011). The reduction in VFI in the ICE condition may reflect an anticipatory response to an increase in body heat content (Sawka and Noakes, 2007). As such, the ingestion of ice slurry during endurance exercise appears to be effective in providing both physiological and perceptual thermoregulatory relief. **References** Siegel, R. and Laursen, P.B. *ASPIRE*

1. ASPIRE, QATAR 2. Aspetar, QATAR 3. Carlton Football Club, AUSTRALIA 4. UTS, AUSTRALIA **Introduction** The purpose of the present study was to examine performance and physiological responses to a 14-day pre-season training camp combining heat exposure and hypoxia during sleeping (hypoxia) and training (hypoxia and heat) in 17 professional Australian Rules Football (ARF) players (22  $\pm$  2 yr). **Methods** Players participated in 10 outdoor ARF-specific skills (32  $\pm$  1°C, 39  $\pm$  5% RH, total=11.5 h) and 8 indoor strength (23  $\pm$  1°C, 57  $\pm$  2%) sessions. In addition, they slept (12 nights) and cycled indoors (22  $\pm$  1°C, 58  $\pm$  2%, 7 'interval cycling' sessions, total 4.3 h) in either normal air (NORM, n=8) or normobaric hypoxia (14  $\pm$  1 h/day, 2500-3000m, HYP, n=9). The camp was followed by a week of unloaded training (4 skills [ $\approx$ 29°C,  $\approx$ 55%] and 7 strength [indoor] sessions, 10.5 h) and 10 d of unsupervised training. Training load was monitored using session-RPE x duration. Players performed the Yo-Yo Intermittent Recovery level 2 (Yo-YoIR2) in temperate conditions (23  $\pm$  1°C, 57  $\pm$  2%, normal air) at pre, post and 3 weeks post camp. Hemoglobin mass (Hbmass) and blood volume (BV) were measured at similar time points. **Results** There was no clear difference in total training load between both groups during the camp (9786  $\pm$  286 vs. 9904  $\pm$  200 A.U. for HYP vs. NORM, respectively, -1% 90%CL (-3;1)) and the following weeks. Both groups showed very large improvements in Yo-YoIR2 post camp (+44% (38;50), ES = +2.3), with no between-group differences in the changes (-1%(-9;9) for HYP vs. NORM). Three weeks post camp, there was a possibly better Yo-YoIR2 performance maintenance in HYP (+6%(-2;15) for HYP vs. NORM). In HYP, Hbmass was likely (+3%(1;5), ES = 0.3) and very likely (+6%(2;10), ES = 0.7) increased post camp and 3 weeks after, respectively. Conversely, Hbmass did not change in NORM (0%(0;0) post camp). Post camp, both groups showed a likely (HYP, +4%(0;7), ES = 0.5) and very likely (NORM, +5%(2;9), ES = 0.8) increase in BV. Three weeks after, BV was very likely further increased in HYP (+7%(3;11) compared with pre-camp, ES = 1.3), while it tended to return to baseline in NORM (+2%(-5;9), difference rated as unclear). **Discussion** Large increases in BV and high-intensity, intermittent running performance were observed after only 2 weeks using the present training model, with no additional benefit of hypoxic exposure at this time. However, only players that were exposed to hypoxia maintained their physical performance 3 weeks post camp, which was associated with an increased Hbmass and BV. While heat exposure is likely to account for rapid and important (but transient) changes, hypoxic exposure may enable more consistent (but delayed) effects. **In conclusion**, in addition to the well-known heat and/or altitude acclimation effects, the combination of heat and hypoxic exposure during sleeping/training times might offer a promising 'conditioning cocktail' in team sports.

**ALLOMETRIC SCALING TO PREDICT TIME TRIAL PERFORMANCE AND MAXIMAL OXYGEN CONSUMPTION. DIFFERENCES BETWEEN MALE AND FEMALE CYCLISTS.**

Davidowitz, K.J.1, Lambert, M.I.1, Noakes, T.D.1, Lamberts, R.P.1

*1: UCT/MRC Research Unit for Exercise Science and Sports Medicine, Department of Human Biology, University of Cape Town, South Africa.*

Introduction A recent publication by Lambert et al (2012) showed allometric scaling of peak power output (PPO) was the most accurate method to predict 40km time trial (40km TT). This finding confirmed that the proposed allometric scaling method by Swain (1994) can, in addition to professional cyclists (Mujika et al, 1998), also be used in trained in well-trained male cyclist. However, as females have different body compositions than males, relatively higher body fat and lower muscle mass percentages, it is questionable if the same allometric scaling methods can also be used in female cyclists. Therefore the aim of this study was to determine if the same allometric scaling method used in male cyclists can also be used in female cyclists to predict 40km TT performance. Methods Twenty trained to well-trained female cyclists ( $287 \pm 25$  W;  $50.5 \pm 3.4$  ml/min/kg), between the ages of 18 and 45 years, completed a peak power output (PPO) test (including respiratory gas analysis (VO<sub>2</sub>max)) and a 40km flat time trial (TT). All tests were performed between days 7 to 21 of the participant's menstrual cycle to ensure that this had no effect on the measured performance parameters. After the tests, relationships between VO<sub>2</sub>max and 40km TT performance and absolute (W), relative (W/kg) and peak power output normalized for body mass to the exponent of 0.32 (W/kg<sup>0.32</sup>) were determined. Relationships found in the female cyclists were compared to a data set of 45 trained to well-trained male cyclists (Lamberts et al. 2012). Results In the female cyclists, strong relationships were found between PPO and VO<sub>2</sub>max. A similar relationship between male and female cyclists was found when PPO and VO<sub>2</sub>max were expressed absolutely (W and l/min, respectively). However when PPO and VO<sub>2</sub>max were expressed relatively (W/kg and ml/min/kg, respectively) a similar slope but different y-axis intercept was found ( $p < 0.0001$ ). In the female cyclists, 40km TT performance (s) also showed to have the strongest relationship with allometrically scaled PPO ( $r = -0.87$ , 95% CI - 0.95 to - 0.70,  $p < 0.0001$ ). When this relationship was compared to male cyclists, a different slope was found allometrically scaled PPO (W/kg<sup>0.32</sup>) and 40km TT performance (s) ( $p = 0.0005681$ ). Discussion As in males, the strongest relationship with 40km TT time in female cyclists was found with allometrically scaled PPO (W/kg<sup>0.32</sup>). However when comparing the relationship found in female cyclists to male cyclists significant slope differences were found, suggesting that additional weight in female cyclists is less of an advantage when performing a flat TT performance than in male cyclists. This can possibly be explained by difference in body composition between male and females, as additional weight in females consists of relatively more body fat and less muscle mass than in males. **THE EFFECT OF WHOLE-BODY PRE-COOLING ON 30KM SELF-PACED CYCLING IN THERMONEUTRAL AND WARM ENVIRONMENT CONDITIONS**

Oliveira, G.G.A.1,2, Maia-Lima, A.1, Ramos, G.P.1, Pacheco, D.A.S.1, Goulart, K.N.O.1, Nunes-Leite, M.M.S.1, Amorim, F.T.4, Silami-Garcia, E.1, Gomes, E.C.1,3

*1 Exercise Physiology Laboratory, Federal University of Minas Gerais (UFMG), 2 Catholic University of Minas Gerais, Brazil; 3 Biochemistry and Immunology Department, UFMG, Brazil; 4 Exercise P*

Endurance exercise induces hyperthermia and increases physiological strain. When a warm environment is added these variables are further affected and so is performance. Nevertheless, the effects of pre-exercise cooling in these responses remain unclear, be it in a warm or thermoneutral environment. Therefore, the aim of this study was to investigate the effects of a pre-exercise whole-body cooling method on physiological strain and performance during a 30km time trial cycling in two environments. Methods: 8 male cyclists (mean $\pm$ SD: 28.8 $\pm$ 2.7 years; 72.7 $\pm$ 8.4 kg; 9.7 $\pm$ 2.4 % body fat; 58.2 $\pm$ 11.0mlO<sub>2</sub>/kg/min) performed, in a randomized balanced order, four 30km time trials in an environmental chamber set at: warm (35°C; 68%RH) and thermoneutral (24°C, 68%RH). In two trials, the exercise was preceded by a whole-body water immersion (24°C) until rectal temperature (Tre) decreased 0.4°C compared to rest value. The exercise was then performed either in the warm (PREC35) or the thermoneutral (PREC24) environment. The other two trials were the control conditions, and exercise was performed without the cooling procedure (CON24 and CON35). Throughout the exercise protocols the subjects' Tre, heart rate (HR) and thermal comfort were measured every 2km and they were allowed water ad libitum. Data was analyzed using a 3-way ANOVA with repeated measures and Tukey's post-hoc test (STATISTICAL 7.0 Program). Values are reported as mean $\pm$ SD. Results: Subjects' performance was significantly impaired in the heat ( $p < 0.05$ ), and was not affected by pre-cooling ( $p = 0.063$ ) (PREC24= 54.7 $\pm$ 4.4min; CON24= 56.0 $\pm$ 4.0min; PREC35= 59.6 $\pm$ 3.4min; CON35= 61.0 $\pm$ 3.4min). Tre was affected both by the environmental conditions and by the pre-cooling (PREC24= 36.4 $\pm$ 0.3°C at 0km; 38.7 $\pm$ 0.3°C at 30km; CON24 = 37.0 $\pm$ 0.2°C at 0km; 38.7 $\pm$ 0.4°C at 30km; PREC35=36.3 $\pm$ 0.5°C at 0km; 39.0 $\pm$ 0.4°C at 30km; CON35= 37.2 $\pm$ 0.2°C at 0km; 39.7 $\pm$ 0.5°C at 30km). HR was significantly lower pre-exercise in the pre-cooling conditions but was not affected by the environmental conditions. In the thermoneutral environment subjects' reported a better thermal comfort but this variable was not affected by the pre-cooling procedure. Conclusion: The pre-cooling method was not sufficient to improve performance on a 30km time trial cycling in a thermoneutral or warm environment conditions, despite the reduced Tre observed in the pre-exercise cooling conditions.

**WIND COOLING DURING A SELF-PACED CYCLING TIME TRIAL**

Teunissen, L., de Haan, A., de Koning, J., Daanen, H.

*VU University Amsterdam*

WIND COOLING DURING A SELF-PACED CYCLING TIME TRIAL Teunissen, L.1,2, de Haan, A.1,3, de Koning, J.1, Daanen, H.1,2 1: MOVE, VU University (Amsterdam, The Netherlands), 2: TNO (Soesterberg, The Netherlands), 3: MMU (Manchester, UK) Introduction Wind has been

shown to be an effective cooling method during fixed-paced exercise in the heat, decreasing thermal strain and increasing time to fatigue. However, it has been scarcely investigated in what way these observations translate to self-paced performance. So the aim of this experiment was to study how wind cooling affects thermal strain, thermal perception, pacing and performance during a 15 km cycling time trial in strenuous climatic conditions. Methods Ten male subjects performed two 15 km cycling time trials in a climatic chamber set at 28°C and 80% relative humidity. In one of the time trials, a wind tunnel unexpectedly provided head wind (~4 m/s) during the middle part of the race (3-12 km). Conditions (control: CO and wind: WI) were offered in balanced order with at least two days in between. Measurements included rectal temperature (Tre), average skin temperature (Tsk), heart rate (HR), fluid loss, rate of perceived exertion (RPE, each km), thermal sensation (TS, each 5 km), thermal comfort (TC, each 5 km), power output (PO) and finish time. Results WBGT was similar at the start of both trials (26.5±0.08°C) and dropped when wind was applied to 26.0±0.04°C. Overall, subjects had a higher PO in the WI-trial than the CO-trial (246±11 vs. 235±9 W), leading to a 75±24 s faster finish time. Per kilometer, PO differences between conditions were detected from km 4 to 14. These differences were largest in km 4 and km 11-14 (14-19 W). Tre was similar for CO and WI during each kilometer of the trial. However, wind application induced a clear difference in Tsk from km 4 to 15, being maximally 1.98±0.16°C lower for WI than for CO (km 12). This was reflected in lower RPE values during km 5-13 and improved TS and TC values at the 5 and 10 km mark of the WI-trial. HR was lower during km 10-15 of WI (about 4-6 bpm). No differences in fluid loss and fluid ingestion were observed. Discussion Despite a nearly similar WBGT value, wind application during self-paced exercise in a warm humid environment substantially reduced thermal strain and improved performance. Wind instantly induced a decrease in Tsk, attenuation of RPE and increase in power output. The higher PO was maintained throughout the wind interval at similar or lower Tre and HR values than during the CO-trial, with subjects feeling less exerted, cooler and more comfortable. This may have led to the slightly increased power profile in the last 5 km of the WI-trial (even though wind stopped blowing at 12 km), while PO in the CO-trial was not increased until the final kilometer. In conclusion, wind is an effective tool to provide immediate and constant benefits in thermal perception and performance during self-paced exercise in the heat.

### THE INFLUENCE OF HIGH ALTITUDE TRAINING ON CERTAIN IMMUNOLOGICAL AND HAEMATOLOGICAL COMPONENTS AS WELL AS ON THE PERFORMANCE OF MIDDLE AND LONG DISTANCE RUNNERS

Coetzee, B.

*North-West University*

Coetzee, B. 1: NWU (Potchefstroom, South Africa) Introduction A fair amount of controversy exist with regard to the benefits of altitude training for improved sea-level performance (Friedmann-Bette, 2008). Therefore, the purpose of this study was to determine what influence a three week long altitude training program at 3200m above sea-level have on certain haematological and immunological components as well as the distance and sprint running performance of middle and long distance athletes. Methods Nine middle and long distance runners of the university's athletics team were recruited to participate in the study. On the first pre-test day athletes completed a questionnaire after which their body weight and stature were taken. After a warm-up period, blood samples were taken (pre 1), followed by the execution of either a 2- or 5-min distance-in-time-test. Blood samples were again taken after completion of the test (pre 2). A rest period of 5 minutes followed after which a 300m-sprint test was completed and more blood samples taken (pre 3). The athletes then participated in a training camp for three weeks at an altitude of 3200m above sea level. Following the three weeks, each of the athletes were again subjected to the last mentioned tests (post 1, post 2 and post 3). The blood samples were analysed for the following haematological and immunological components: blood lactate, whole blood cell count (WBC), red blood cell count (RBC), haemoglobin blood content (HGB), hematocrit blood count (HCT), mean cell volume (MCV), mean cell haemoglobin volume (MCH), mean cell haemoglobin concentration volume (MCHC), red cell distribution width (RDW), platelet count (PLT), neutrophil (NE), lymphocyte (LY), eosinophil (EO), basophil (BA) and monocyte (MO) blood cell count. Results Only blood lactate (pre 3 to post 3), RBC (pre 1, 2, 3 to post 1, 2, 3), HGB (pre 1, 2, 3 to post 1, 2, 3), HCT (pre 1, 2, 3 to post 1, 2, 3), MCHC (pre 1, 2 to post 1, 2), PLT (pre 1 to post 1) and MPV (pre 3 to post 3) revealed large practical significant differences between the measurements for the pre- and post-altitude training periods when the effect sizes were determined. None of the other haematological and immunological components or performance related variables obtained large practical significant values in terms of the pre- and post-altitude training differences. Discussion In conclusion, these results show that a three week long altitude training program at 3200m above sea-level was sufficient in enhancing haematological components which are related to the oxygen carrying capacity of the blood, but insufficient in changing the immunological components and to improve the distance and sprint running performances of middle and long distance athletes. Sport scientists, therefore, need to investigate the efficacy of altitude training programs, especially in view of the financial implications of these programs. References Friedmann-Bette, B. (2008). Classical altitude training. *Scandinavian Journal of Medicine and Science in Sports*, 18(1), 11-20.

### THE EFFECTS OF NORMOBARIC HYPOXIA ON MITOCHONDRIAL RESPIRATION IN HUMANS.

Bishop, D.J., Ferri, A., Granata, C., Oliveira, R.S.F., Hedges, C., Miserocchi, G., Lima-Silva, A.E.

*Victoria University*

Introduction In response to stays at high altitude, contrasting mitochondrial changes have been reported. An early study reported increases in cytochrome c oxidase, while more recent research has observed decreases in oxidative capacity [1]. Consistent with this latter study, researchers have also observed decreases in mitochondrial volume, which were accompanied by increases in lipofuscin [1]. However, none of these studies directly measured mitochondrial respiration. We have recently observed an increase in maximal ADP-stimulated mitochondrial respiration in rats after 30 days of normobaric hypoxia (10% O<sub>2</sub>). The purpose of this study was to investigate the effects of 19 days of normobaric hypoxia on mitochondrial respiration in humans. Methods Five untrained men lived at altitude (3500 m), 24 h/day, for 19 consecutive days. Muscle biopsies were taken from the vastus lateralis muscle before and immediately following the stay at altitude. Maximal (5 mM ADP) ADP-stimulated mitochondrial respiration was determined on permeabilised muscle fibers. Both daily physical activity and caloric intake were monitored before entering the altitude hotel, and were subsequently maintained at these levels for the duration of the stay. Results There was a 10% increase in maximal ADP-stimulated respiration for both complex I and the combination of complex I and II following 19 days of living at 3500 m. There was no change in non-coupled respiration, but a 20% increase in complex IV reserve respiration. Interestingly, ADP sensitivity (0.1 mM ADP) showed no significant change. Discussion We have shown for the first time that there is an increase in mitochondrial respiration in humans after exposure to 19 days of hypoxia. This increase is similar to that found in a previous study in rats (16%, ns) [2], and also to our unpublished data with rats. Our results indicate that mitochondrial adaptations are complex, and that prolonged exposure to high altitude (3500 m) promotes increases in mitochondrial respiration despite previous reports of decreases in mitochondrial volume. tations to hypoxia. *J. Exp. Biol.*, 2001. 204: p. 3133-3139. 2. Novel-Chaté, V., et al., Chronic Exposure of Rats to Hypoxic Environment Alters the Mechanism of Energy Transfer in Myocardium. *Journal of Molecular and Cellular Cardiology*, 1998. 30(7): p. 1295-1303.

### PROLONGED EXERCISE IN HYPOXIA INDUCES TISSUE-SPECIFIC OXYGENATION PROFILES

RUPP, T.1, JUBEAU, M.1,2,3, WUYAM, B.1, MILLET, G.Y.1,3, PERREY, S.4, VERGES, S.1

Introduction: Tissue oxygenation, assessed by near-infrared spectroscopy, is altered during hypoxia at rest and during exercise (1). However, it remains still debated, depending on hypoxia severity and exercise characteristics, whether the tissue oxygenation perturbations are similar between sites especially within cerebral areas implicated in motor output (2). Also, it is unknown how far systemic arterial desaturation impacts muscle and cerebral oxygenation during exercise in hypoxia. The purpose of our study was to compare arterial and tissue oxygenation on multiple sites during prolonged submaximal cycling in hypoxia. Methods: Twelve healthy males completed three experimental conditions. After a 4-h wash-in period, either in normoxia (NE,  $FiO_2=21\%$ ) or hypoxia (HE,  $FiO_2=11\%$ ), subjects performed a 80-min cycling exercise at 45% of their maximal aerobic power. A 3rd control condition, in hypoxia, consisted on a 80-min resting period in which the arterial saturation ( $SpO_2$ ) reached during HE was matched by adjusting  $FiO_2$  (HR,  $FiO_2=9\%$ ). Quadriceps, prefrontal (PFC) and motor cortices oxy[HbO<sub>2</sub>]- deoxy[Hb] and total[THb]-haemoglobin concentration changes were continuously investigated using near-infrared sensors to assess tissue oxygenation status. Results: HR and HE resulted in similar  $SpO_2$  reduction ( $\approx -20\%$ ). For the quadriceps, exercise-induced [Hb] rises were associated with increased and unchanged [THb] in NE and HE, respectively, while [THb] dropped significantly in HR. PFC showed a large [THb] increase at exercise with a four-fold [HbO<sub>2</sub>] increase compared to [HHb] in NE versus a four-fold [Hb] increase compared to [HbO<sub>2</sub>] in HE. Motor cortex showed similar [HbO<sub>2</sub>] decrease and [HHb] increase than PFC in HR but not at exercise. Indeed, motor cortex [THb] was stable in HE and NE while [HbO<sub>2</sub>] decreased and [HHb] increased in NE, these latter changes being significantly accentuated in HE. Discussion: This study quantifies for the first time the respective effects of prolonged cycling exercise and systemic arterial desaturation in muscle and cerebral oxygenation responses in hypoxia. These results demonstrate that specific responses to prolonged exercise and/or hypoxia are found between tissues and between cortical sites implicated in physical exercise, as shown by concomitant CPF hyperoxygenation and motor cortex deoxygenation in NE. #### PHYSICAL ACTIVITY, FITNESS, AND HEALTH

Ainsworth, B.

*Arizona State University*

In 1985, Professor Claude Bouchard provided a model showing the relationships between heredity, health-related fitness, physical activity, health, and multi-level factors. Health-related fitness includes morphological, muscular, motor, cardiorespiratory, and metabolic conditions. Health outcomes include wellness, morbidity, and mortality. Physical activity domains include leisure, occupation, transport, and home activities. Multi-level factors include lifestyle behaviors, personal attributes, physical environment, and the social environment. This presentation provides an overview of the model and highlights key research to support and extend the reach of Bouchard's model as a research paradigm for understanding the importance of physical activity on health and longevity.

#### HEMORHEOLOGICAL ALTERATIONS IN YOUNG SUBJECTS DUE TO ACUTE EXERCISE.

Alis, R.1, Romagnoli, M.1, Ibanez, S.1, Vaya, A.2

*Universidad Catolica de Valencia*

Hemorheological alterations in young subjects due to acute exercise. Alis, R.1; Romagnoli M.1; Ibañez, S.1, Vaya, A.2 1 Catholic University Valencia (Valencia, Spain). 2 La Fe University Hospital (Valencia, Spain) Introduction: Acute exercise causes changes in red blood cells (RBC) and blood flow characteristics [1]. In this study we explore the alterations in RBC rheology and blood flow during exhaustive exercise in young subjects. Methods: 10 young subjects ( $13,90 \pm 1,60$  years, 1 male 9 female) performed an incremental maximal treadmill test in fasting conditions. Blood samples were collected before and just after cessation of exercise from antecubital vein. Samples were analyzed in the first hour after extraction. RBC deformability at 12, 30 and 60 Pa (Rheodyn SSD, Myrenne, Germany), plasma fibrinogen (ACL-TOP autoanalyzer), native blood viscosity (NBV) and corrected at 45% hematocrit at 230 s<sup>-1</sup> (Brookfield DV III; Brookfield Engineering Laboratories, Inc., Stoughton, MA, USA), plasma viscosity at 37°C (PV) (Fresenius GmbH, Germany) and basic hematological parameters were analyzed. RBC aggregation measures were performed using an erythrocyte aggregometer (Myrenne GmbH Germany) at stasis and at low shear rate, and using a SEFAM erythro-aggregometer which determines the aggregation time, the aggregation index at 10 s

and the disaggregation threshold. Differences between pre and post measures were assessed using multiple analyses of variance (MANOVA). When data weren't normally distributed non parametric tests were used. p values <0.05 were considered as statistically significant. All values as mean±sd. Results: All deformability indexes decreased significantly (p<0.001). Hematocrit augmented significantly (pre: 40,40±2,84 %, post: 41,84±2,85 %, p<0,05). PV increased with exercise (pre: 1,22±0,04 mPa•s, post: 1,27±0,05 mPa•s, p<0,05). All aggregation parameters present a not significantly decrease with exercise. NBV augmented but not significantly (pre: 4,02±0,66 mPa•s, post: 4,20±0,47 mPa•s, p=0,378). Discussion As observed in other studies [1] acute exercise has effects on RBC rheology parameters in young subjects. Native blood viscosity increased but not significantly although RBC deformability and plasma viscosity were augmented. Blood viscosity is a function of plasma viscosity, RBC aggregation, RBC concentration and RBC deformability [2]. At high shear rates aggregation doesn't occurs and blood viscosity is inversely related to RBC deformability [2]. Our data points that the observed increase in hematocrit and plasma viscosity and the decrease in RBC deformability although significantly, are not enough to cause a significant increase in blood viscosity due to acute exercise in young subjects. ### GREATER COMPLIANCE IN SUPERFICIAL THAN DEEP VEIN DURING RESTING AND SYMPATHOEXCITATION

Ooue, A., Sato, K., Hirasawa, A., Sadamoto, T.

*Japan Women's College of Physical Education*

Introduction Venous compliance of the extremities is a major determinant of venous pooling that contributes to return blood to central region during physiological stress. Extremities have deep and superficial veins, which return blood from muscle and skin, respectively. But superficial venous compliance has not been measured. The superficial vein has a rich innervation of sympathetic nerves compared to the deep vein and plays an important role in the thermoregulation by pooling blood and facilitating heat loss. Thus, it is hypothesized that 1) the superficial vein has a greater compliance than deep vein and 2) sympathoexcitation has a greater effect on the superficial vein than deep vein. To clarify hypotheses we compared superficial and deep venous compliance during resting and sympathoexcitation. Methods Fifteen young subjects participated in this study. Cuff on upper arm was inflated to 60 mmHg for 8 min, and the cuff pressure reduced at 1 mmHg/s from 60 to 0 mmHg (Control condition: CON). Static exercise (EXE) and cold pressor test (CPT) were used as sympathoexcitatory maneuvers. Cross sectional area (CSA) of basilic (superficial) and brachial (deep) vein of the upper arm was measured by ultrasound technique. The compliance was calculated from the equation; compliance =  $\beta_1 + 2\beta_2 \times (\text{cuff pressure})$ , in which  $\beta_1$  and  $\beta_2$  were given by the pressure-CSA curve described by Halliwill et al (1999). In addition, compliance at an arbitrary pressure of 20mmHg (C20mmHg) was determined as  $C_{20\text{mmHg}} = \beta_1 + 2\beta_2 \times 0$ . Results C20mmHg in superficial vein was greater than deep vein (CON: 0.13±0.02 vs. 0.06±0.01 mm<sup>2</sup>/mmHg, P < 0.05; EXE: 0.12±0.02 vs. 0.09±0.01 mm<sup>2</sup>/mmHg, P < 0.05; CPT: 0.14±0.02 vs. 0.08±0.01 mm<sup>2</sup>/mmHg, P < 0.05). The sympathoexcitation of EXE and CPT did not change compliance in superficial vein, but produced a higher compliance in deep vein compared to CON (P < 0.05). Discussion The higher compliance in the superficial vein than that in the deep vein was probably due to a lower external pressure to the superficial vessel. In contrast to the hypothesis, the sympathoexcitation of EXE and CPT only increased the compliance in deep vein but had no effects on the superficial vein. Since the EXE and CPT selectively reduces the arterial blood flow in the skeletal muscle, the reduction in the blood volume contained within the deep vein occurred and thereby increase in the compliance in deep vein during EXE and CPT. On the contrary, the EXE and CPT did not alter the arterial blood flow in skin area and the containing blood volume in the superficial vein and thereby producing the unchanged compliance. ### METABOREFLEX CONTRIBUTION TO THE BLOOD PRESSURE CONTROL DURING ISOMETRIC EXERCISE IN BOYS AND MEN

Papadopoulos, S.I, Dipla, K.I, Zafeiridis, A.I, Kyparos, A.I, Nikolaidis, G.M.I, Vrabas, S.I.I

*Aristotle University of Thessaloniki*

METABOREFLEX CONTRIBUTION TO THE BLOOD PRESSURE CONTROL DURING ISOMETRIC EXERCISE IN BOYS AND MEN Papadopoulos, S.I, Dipla, K.I, Zafeiridis, A.I, Kyparos, A.I, Nikolaidis, G.M.,I Vrabas, S.I. 1. DPSS-AUTH(Serres, Greece) Introduction During exercise, the 'central command', the 'exercise pressor reflex' (mechanoreflex and metaboreflex), and baroreceptors integrate total peripheral resistance and cardiac output, resulting in an effective elevation of blood pressure (Kaufman et al. 1983; O'Leary, 1996; Ogoh et al. 2007). Whether the metaboreflex contribution to the arterial pressure control during isometric exercise is different in children and in adults has not been investigated. Therefore, the aim of this study was to assess in boys and men the hemodynamic parameters that control arterial pressure during the activation of the muscle metaboreflex. Methods Twelve pre-adolescent boys and twelve men performed a testing protocol involving a 3-min baseline, 3-min isometric handgrip exercise (at 30% of maximal voluntary contraction), 3-min post-exercise circulatory occlusion, and 3-min recovery. The same protocol was repeated without occlusion. Beat to beat AP was measured by finger photoplethysmography (Finometer). Results During baseline, boys had lower arterial pressure, higher heart rate, and lower low/high frequency ratio of heart rate variability (p<0.05). During exercise, heart rate was the key contributor to the arterial pressure response in adults, whereas in boys, the lower percent increase in heart rate was counterbalanced by an increase in stroke volume, resulting in similar percent increase in mean arterial pressure to adults. Post-exercise occlusion resulted in a similar elevation in blood pressure in both age groups (by ~15mmHg); however, during this period, boys exhibited a lower (p<0.05) increase in peripheral resistance and a greater bradycardic response than adults. Discussion During the isolated metaboreflex, the magnitude of the blood pressure response was similar in boys and in men. However, the interplay of the mechanisms controlling the rise in mean arterial pressure was not similar between the two groups. ## HAEMOGLOBIN MASS MEASUREMENTS IN PROFESSIONAL CYCLISTS DURING A LONG STAGE RACE: THE GIRO D'ITALIA

Artuso, P., Bosio, A., Guardascione, C., Pecci, C., Riggio, M., Rampinini, E.

*Mapei Sport Research Centre*

HAEMOGLOBIN MASS MEASUREMENTS IN PROFESSIONAL CYCLISTS DURING A LONG STAGE RACE: THE GIRO D'ITALIA Artuso P.1, Bosio A.1, Guardascione C.2, Pecci C.1, Riggio M.1, Rampinini E.1,3 1: HPL, MAPEI Sport (Castellanza, Italy) 2: Team Lampre ISD (Heiden, Switzerland) 3: Faculty of Exercise and Sports Sciences, Università degli Studi di Milano (Milan, Italy) Introduction The total amount of haemoglobin in the blood (Hbmass) is an important determinant for VO<sub>2</sub>max (Heinicke et al., 2001). Schmdit and Prommer (2005) proposed an optimised CO re-breathing method for Hbmass determination. In two studies it was demonstrated that Hbmass is stable during short stage races (4 and 6 days long) in Under 23 male and top level female cyclists (Schumacher et al., 2008; Garvican et al., 2010). No study investigated Hbmass changes during a long stage race in top level professional cyclists. The aim of the present study was verify the influence of three weeks of race on Hbmass values of professional athletes. Methods Nine professional cyclists (age 31±5.5 yrs, heights 178.7±5.1 cm and body mass 67.7±5.9 kg) of the same team were involved in the study. Using a simplify CO re-breathing method (Schmdit and Prommer, 2005), Hbmass of each individual was determined before (PRE, 2 days before the start), during (MID, at day 14) and after (POST, 1 day after the race) the Giro d'Italia 2011. Three athletes did not finish the race. Data of the 6 cyclists who completed the race was used for statistical analysis. The differences in Hbmass were determined using a one way ANOVA repeated measure. Results Hbmass of the six athletes remained stable (p=0.308) during the three-week stage race (PRE, 1080±86 g; MID, 1098±66 g; POST 1100±80 g). Discussion The main finding is that the strain induced by a long stage race like the Giro d'Italia, does not seem able to determine a decrease in Hbmass of the athletes. The results of the present study confirm other information collected during shorter stage races in different population of cyclists (Schumacher et al., 2008; Garvican et al., 2010). Since the Hbmass seems to be very stable even during the stage races, the CO re-breathing may be a useful tool to detect the use of blood doping made during the competition. The results seems to confirm also that hematocrit and haemoglobin blood concentration decreases previously reported during a long stage race are probably due to plasma volume expansion in the blood (Morkeberg et al., 2009). ## SEASONAL VARIATION OF HAEMOGLOBIN MASS IN PROFESSIONAL AND UNDER 23 CYCLISTS

Tornaghi, M., Bosio, A., Guardascione, C., Pecci, C., Connolly, D., Rampinini, E.

*Sport Service Mapei S.r.l.*

SEASONAL VARIATION OF HAEMOGLOBIN MASS IN PROFESSIONAL AND UNDER 23 CYCLISTS Tornaghi M.1, Bosio A.1, Guardascione C.2, Pecci C.1, Connolly D.1, Rampinini E.1,3 1 HPL, MAPEI Sport (Castellanza, Italy) 2 Team Lampre ISD (Milan, Italy) 3 Faculty of Exercise and Sports Sciences, Università degli Studi di Milano (Milan, Italy) Introduction Maximum oxygen uptake (VO<sub>2</sub>max) is a good indicator of the aerobic systems efficiency and it has been found to be related to Haemoglobin mass (Hbmass) (Heinicke et al., 2001). VO<sub>2</sub>max may increase after a period of intense training while Hbmass appears to remain stable during a season in endurance athletes (Prommer et al., 2008). No study has verified seasonal changes in both VO<sub>2</sub>max and Hbmass in competitive cyclists. The aim of this study was to verify seasonal changes of VO<sub>2</sub>max and Hbmass in professional (PRO) and Under 23 (U23) cyclists. Methods Ten male PRO cyclists (age 28±4 yrs, heights 176±5 cm and body mass 66.0±5.0 kg) performed an incremental test to establish VO<sub>2</sub>max and peak power output (PPO), and Hbmass was measured using an optimised CO re-breathing method (Schmdit and Prommer, 2005). Each test was performed three times during the season (November-December, pre-preseason period START; January-February, before the competitive season, PRE and March-August, during the competitive season, MID). In addition, 12 male U23 cyclists (age 20±1, heights 180±7 and body mass 73.2±10.1 kg) underwent the same evaluations twice a year (January, PRE1 and PRE2 and May, MID1 and MID2) for 2 consecutive seasons. Results In PRO cyclists absolute and relative VO<sub>2</sub>max and PPO significantly increased (all p<0.023) during the season (VO<sub>2</sub>max: 70.0±4.5, 73.7±3.4 and 73.1±4.1 ml/kg/min at START, PRE and MID, respectively and PPO: 433±52, 456±28 and 460±24 W at START, PRE and MID, respectively). Hbmass remained stable (1034±133, 1026±95 and 1025±99 g at START, PRE and MID, respectively, p=0.805). U23 cyclists absolute and relative VO<sub>2</sub>max and PPO significantly increased (all p<0.022) during the two years (VO<sub>2</sub>max: 65.7±4.7, 67.3±4.9, 69.4±4.5 and 71.1±5.1 ml/kg/min at PRE1, MID1, PRE2 and MID2, respectively and PPO: 436±37, 456±39, 453±39 and 463±33 W at PRE1, MID1, PRE2 and MID2, respectively). Hbmass remained stable (1007±169, 996±146, 1019±163 and 1003±159 g for PRE1, MID1, PRE2 and MID2, respectively, p=0.225). Discussion This study confirmed that a preparation period increases aerobic efficiency, while demonstrating that Hbmass is stable in both PRO and U23 cyclists. Other physiological factors like cardiac output or plasma volume expansion must account for the VO<sub>2</sub>max increases observed. Given that Hbmass appears to be stable across competitive seasons, the CO re-breathing method may be a useful tool to detect the use of blood doping. ## VASCULAR FUNCTION, ATHEROSCLEROSIS AND INFLAMMATION OF NEPHRECTOMISED APOLIPOPROTEIN E KNOCK-OUT MICE IN RESPONSE TO VOLUNTARY EXERCISE OR TOCOPHEROL SUPPLEMENTATION

Coombes, J.S.1, Fasset, R.G.2, Peake, J.I, Shing, C.M.3

1: University of Queensland (Brisbane, Australia) 2: Royal Brisbane and Women's Hospital Brisbane (Brisbane, Australia), 3: University of Tasmania (Launceston, Australia)

Introduction: Elevated levels of oxidative stress, inflammation and endothelial dysfunction are believed to contribute to the development of cardiovascular disease, which begins in the initial stages of CKD. Antioxidant therapy and exercise have the potential to reduce oxidative stress, inflammation and endothelial dysfunction. The aim of this study was to investigate the effects of 12 weeks of voluntary exercise or tocopherol supplementation on vascular function, aortic plaque and inflammation using the apoE<sup>-/-</sup> mouse with 5/6 nephrectomy (NX). Methods: Following NX or sham surgery apoE<sup>-/-</sup> mice were allocated to one of six groups: 1) sham (n=8); 2) NX (n=8); 3) sham undertaking voluntary exercise (sham Ex) (n=8); 4) NX undertaking voluntary exercise (NX Ex) (n=8); 5) NX and α-tocopherol supplemented diet (n=10); 6) NX and mixed tocopherol supplemented diet (n=10). In vitro aortic smooth muscle contraction was assessed by the dose response to noradrenaline (NA) (10<sup>-9</sup> to 10<sup>-5</sup>M). Acetylcholine (ACh) and sodium nitroprusside (SNP) induced relaxation assessed endotheli-

al-dependent and endothelial-independent relaxation, respectively. Plasma cytokine and creatinine concentrations and aortic plaque area were determined at sacrifice. Results: Average running distance was not significantly different between NX Ex and sham Ex groups ( $p > 0.05$ ). NX was associated with significantly higher plasma creatinine concentration when compared to the sham operated group ( $p < 0.05$ ). NA induced aortic vasoconstriction and SNP induced relaxation were not significantly different between NX, sham and exercise groups ( $p > 0.05$ ). Relaxation in response to Ach was significantly impaired in NX group when compared to the sham group ( $p < 0.05$ ). NX significantly impaired relaxation in response to SNP when compared to both NX tocopherol supplemented groups ( $p < 0.05$ ). Mixed tocopherol supplementation following NX significantly enhanced vasoconstriction in response to NA when compared to sham, NX and  $\alpha$ -tocopherol supplemented mice ( $p < 0.05$ ). Plasma concentrations of IL-6, TNF- $\alpha$  and MCP-1 were significantly elevated in the NX group when compared to the sham group ( $P < 0.05$ ), while voluntary exercise with NX was associated with significantly lower plasma IL-6 concentration when compared to the NX group ( $p < 0.01$ ). There were no significant differences in cytokine concentrations between the NX and NX tocopherol supplemented groups. Voluntary exercise ( $p < 0.05$ ) and  $\alpha$ -tocopherol supplementation ( $p < 0.01$ ) significantly reduced aortic plaque area of NX mice. Discussion: Vascular relaxation in apoE<sup>-/-</sup> mice is impaired following NX while mixed tocopherol supplementation enhances aortic vasoconstriction. Voluntary exercise reduces the NX induced increase in plasma IL-6 concentrations, while voluntary exercise and  $\alpha$ -tocopherol supplementation are effective in reducing aortic plaque area following NX.

### EFFECTS OF BLOOD FLOW RESTRICTION DURING LOW-INTENSITY RESISTANCE EXERCISE ON HIGH-ENERGY PHOSPHATE METABOLISM AND TISSUE OXYGENATION IN SKELETAL MUSCLES

Yanagisawa, O., SANOMURA, M., FUKUBAYASHI, T.

*Waseda university*

[Introduction] Previous studies have reported that low-intensity resistance training with blood flow restriction (BFR) dramatically leads to muscle hypertrophy and strength gain [1, 2]. These adaptations may be attributed to the greater metabolic stress during low-intensity resistance exercise with BFR, but the exact mechanism has not yet been clarified. The purpose of this study was to evaluate the effects of low-intensity resistance exercise with BFR on high-energy phosphate metabolism and oxygenation in human skeletal muscles. [Methods] Seven men performed dynamic ankle plantar flexion exercise (30% one repetition maximum) using a non-magnetic, custom-made device for 4 min (30 repetitions/min) with and without BFR (130% of systolic blood pressure) inside the bore of a 1.5T magnetic resonance device. Inorganic phosphate-to-phosphocreatine (Pi/PCr) ratio and intracellular pH in the medial gastrocnemius before, during, and after the exercise were determined using <sup>31</sup>P-magnetic resonance spectroscopy. Concentration changes in oxygenated, deoxygenated, and total hemoglobin/myoglobin (Hb/Mb) in the medial gastrocnemius were determined using near-infrared spectroscopy. Moreover, rating of perceived exertion (RPE; Borg 6-20 scale) was obtained in each exercise condition. [Results] Pi/PCr ratio significantly increased at 1-4 min in both the exercise conditions, with the BFR-condition values being greater than the control-condition values. Intracellular pH significantly decreased during exercise in the BFR condition but remained unchanged in the control condition. In addition, the BFR condition showed markedly decreased oxygenated and increased deoxygenated Hb/Mb concentration during the exercise compared with the control condition. Moreover, this condition resulted in increased oxygenated and total Hb/Mb in exercised muscle after exercise. The BFR condition ( $17.1 \pm 1.3$ ) exhibited significantly greater RPE value than the control condition ( $12.6 \pm 1.0$ ). [Conclusion] Low-intensity resistance exercise with BFR places greater stress on high-energy phosphate metabolism and oxygenation in muscles than exercise with normal blood flow. In addition, this exercise causes an increase in blood volume in exercised muscle after exercise. [References] 1. Takarada Y, Takazawa H, Sato Y, et al. ### THE EFFECT OF 3-WEEK UPPER LIMB IMMOBILIZATION ON BRACHIAL ARTERY STRUCTURE AND FUNCTION

Nakamura, F., Hamaoka, T., Nirengi, S., Esaki, K.

*Community Health Promotion Center*

Introduction Vascular dysfunction associated with physical inactivity is a risk factor for cardiovascular diseases (Thijssen et al, 2010). Therefore, it is important to find an intervention method for preserving structural and functional vascular deterioration due to the muscle disuse. However, the knowledge of vascular adaptations that occur as result of inactivity in humans is less clear. Therefore, the purpose of this study was to examine the effect of disuse using 3-week upper limb immobilization on the structure and function of the conduit artery at rest and after cuff occlusion. Methods Eight male volunteers (19.5 years on average) participated in the experiment after having been approved by the institutional ethical committee and obtained a written informed consent. Non-dominant arm was immobilized with a cast for 3 weeks. At first, resting brachial artery diameter and blood velocity were measured in a prone position. After resting period of 5 min, the cuff around the upper arm was inflated for 5 min, followed by measurements of hyperemic blood flow (BF) and diameter. The blood velocity and vessel diameter (D) of the brachial artery were measured using ultrasound Doppler and B-mode methods at rest and after cuff occlusion. BF was calculated from the blood velocity and D. Change in hyperemic diameter was calculated using the equation: (hyperemic diameter-resting diameter)/ resting diameter \* 100. Muscle oxygenation was also measured using near-infrared spectroscopy. Results A significant ( $p < 0.05$ ) decrease was found in the vessel diameter at rest pre- and post- immobilization (-3.5%). Brachial artery blood velocity and BF at rest showed no significant interaction pre- and post- immobilization. A significant ( $p < 0.05$ ) decrease was found in the peak vessel diameter after cuff occlusion before and after immobilization (-7.2%). Brachial artery blood velocity and BF after cuff occlusion showed no significant interaction before and after immobilization. The change in the peak hyperemic diameter was significant decreased ( $p < 0.05$ ) before and after immobilization (-40 %). Conclusion The vessel diameter of the conduit artery at rest and after cuff occlusion was decreased, indicating the arterial remodeling and endothelial dysfunction by the 3-week upper limb immobilization. ### THE EFFECT OF ERGOMETER-SPECIFIC EXERCISE MODALITIES ON BLOOD COAGULATION IN NON-ELITE FOOTBALL PLAYERS

Omar, A.S., El-Sayed, M.S., Hadida, E.M.

*Faculty of physical education and sport sciences*

THE EFFECT OF ERGOMETER-SPECIFIC EXERCISE MODALITIES ON BLOOD COAGULATION IN NON-ELITE FOOTBALL PLAYERS Omar. AS, El-Sayed. MS and Hadida EM. Tripoli University, Faculty of Physical Education and Sport Sciences, Tripoli-Libya Introduction: Previous re-

search indicated that cardiovascular, respiratory, and metabolic responses are significantly different between cycling and running when performed at the same overall metabolic rate. Although blood coagulation and fibrinolysis have been extensively studied and reviewed, the effect of ergometer-specific exercise modalities on blood coagulation is not known (El-Sayed et al. 2011). Therefore the present study was designed to assess the effect of exercise modes (cycling versus running) at 60% VO<sub>2</sub>max for 45-min on blood coagulation in non-elite football players. Aim of the study: 1) To ascertain the influence of ergometer-specific on blood coagulation indices in non-elite football players. Methods: Venous blood samples were removed from ten non-elite football players before and immediately after two separate ergometer-specific cycling and running test trials performed at 60% VO<sub>2</sub>max for 45-min. Blood were assayed for lactate, haematocrit (Hct) and haemoglobin (Hb); while citrated plasma was analyzed for prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT), factor VIII activity (VIIIa), fibrinogen (Fb), and thrombin antithrombin complexes (TAT). Results and Discussion: Cycling and running exercise induced similar activation of blood coagulation as reflected by a significant (P<0.05) shortening in APTT, and nearly 2.5 fold rise (P<0.05) in VIIIa. Although plasma fibrinogen increased significantly (P<0.05) following exercise trials, no significant interaction was found between exercise modality and plasma fibrinogen responses. In accordance with fibrin formation and activation of blood coagulation, we observed an increase (P<0.05) of TAT which was found in all subjects after the cycling and running test trials. Exercise was not associated with any demonstrable change (P>0.05) in TT or PT. The increase in TAT complexes may suggest that the generated thrombin was inactivated by antithrombin III and therefore did not lead to the formation of fibrin. Conclusions: This investigation demonstrates that ergometer-specific exercise trials performed at 60% VO<sub>2</sub>max for 45-min are associated with similar activation of blood coagulation system and the increase in TAT complexes highlights the importance of antithrombin III in the control of fibrin formation in vivo. #### EFFECTS OF COMPRESSION CLOTHING IN ELITE FEMALE ICE SPEED SKATERS

Born, D.P.1, Herlitz, B.1, Zinner, C.2, Richter, K.1, Lefter, M.1, Sperlich, B.1

1: University of Wuppertal, Department of Sport Science (Germany), 2: German Sport University Cologne, Institute of Training Science and Sport Informatics (Germany)

Introduction Compression clothing has become increasingly popular in particular in endurance sports due to the evidence of improved performance in running and cycling (Bernhardt et al. 2005, Chatard et al. 2004). While compression is a possible mean to increase venous return (Ibegbuna et al. 2003) there are conflicting results regarding the use of compression on blood lactate concentration and oxygen uptake (Ali et al. 2010, Berry et al. 1987, Bringard et al. 2006, Rimaud et al. 2010). Since elite speed skaters produce a high muscle force during the long gliding phases with restricted intramuscular blood flow (Foster et al. 1999) elite speed skaters could benefit of compression due to 1) improved blood flow, 2) increased muscle oxygenation, 3) less blood lactate accumulation and 4) increased performance. Therefore, the aim of the study was to evaluate the effect of lower body compression clothing on performance and cardio-respiratory as well as metabolic parameters in female elite ice speed skaters. Methods 6 female elite German ice speed skaters volunteered for this study (60.5±7.3kg, 168±6cm, 19.8±3.3%, VO<sub>2</sub>max 57.8±5.9 ml/min/kg). All participants performed two on-ice 3000m trails with and without lower-body compression clothing in a random order and an incremental test to determine VO<sub>2</sub>max. During the trails VE, VO<sub>2</sub>, VCO<sub>2</sub> and HR were measured continuously with a portable spirometer (Cortex Metamax & Polar). Tissue saturation index (TSI) and blood volume (tHb) were determined by the concentrations of oxy-, deoxy- and total haemoglobin measured with near-infrared spectroscopy (NIRS, Portamon). Capillary blood samples were collected before, immediately after, 10 and 30 minutes after the exercise and analysed using amperometric-enzymatic determination of lactate (Eppendorf). Additionally, the subjects rated their perceived exertion (BORG's scale) before and after both trails. Results The application of lower-body compression clothing did not show any benefits on performance determined by the time to complete 3000m. Furthermore, no differences were observed in respiratory measurements (VE, VO<sub>2</sub>, RER), HR, La, NIRS data (TSI, tHb) or RPE (p > 0.05). Discussion & Conclusion The results show no detectable effects of compression on performance or any physiological measurements in female elite ice speed skaters. These results go in line with earlier studies showing no benefits of compression in well-trained endurance athletes (Ali et al. 2010, Sperlich et al. 2011).

#### THE RELATIONSHIP BETWEEN ENERGY COST OF TURN MOVEMENTS AND RUNNING SPEEDS

Hatamoto, Y., Yamada, Y., Sagayama, H., Ueno, S., Ichikawa, M., Higaki, Y., Kiyonaga, A., Tanaka, H.

Fukuoka University

Introduction When evaluating the energetic demands of a ball game, both the distance covered as well as the energy cost of other movements (e.g. jumping, dribbling and tackling) should be considered. Bloomfield et al. (2007) reported an average of 700 changes of direction ("turn movement") per match in English Premier League soccer, and Bradley et al. (2009) found that soccer players performed high intensity running (>14 km/h) more than 250 times in a match. Extra energy is expended during a turn movement because of the extra muscle activity involved. However, there is limited research on the physiological demands of turn movements. We developed the "Different Frequency Accumulation Method (DFAM)" for evaluating the instantaneous physiological demands of turn movements during running. The purpose of the present study was to measure the physiological demands of turn movements at different running speeds using the DFAM. Methods Eight healthy young men (aged 18-22 years) participated in the study. Five trials were performed where the subjects were required to run at different speeds (3, 4, 5, 6, and 7 km/h). Each trial included four incremental stages of turn frequency (13, 18, 24 and 30 per minute), with each stage lasting 3 minutes. Each trial required the subject to run along a line and perform 180° turn movements at the required speed and turn frequency. The oxygen consumption during the trial was determined using respiratory gas analysis. The oxygen consumption of a turn at each speed was calculated from the slope of the regression for oxygen consumption against the turn frequencies using the DFAM. Heart rate (HR), post-trial blood lactate, and ratings of perceived exertion (RPE) were also measured. Results The oxygen consumption values, for a turn movement at 3, 4, 5, 6 and 7 km/h, were 0.26 ± 0.04, 0.35 ± 0.05, 0.46 ± 0.11, 0.68 ± 0.09, and 0.89 ± 0.13 ml/kg/min, respectively. ANOVA revealed that the oxygen consumption of a turn movement increased

as the running speed increased ( $P < 0.001$ ). HR, blood lactate and RPE increased with each running speed and increase in turn frequency. Conclusion We suggested the equation describing the relationship between running speeds and the oxygen consumption of a turn movement would be in accordance with the well-known formula for kinetic energy,  $E = 1/2 mv^2$ , where  $m$  is the body mass and  $v$  is the speed, with the oxygen consumption of a turn movement possibly proportional to  $v^2$ . This information could possibly be used for estimating the energy cost of a ball game. References Bloomfield, J. et al. (2007). ## REPEATABILITY OF PERFORMANCE GAINS IN A 1000 KJ CYCLING TIME TRIAL FOLLOWING SODIUM PHOSPHATE SUPPLEMENTATION

Brewer, C.P., Dawson, B., Wallman, K.E., Guelfi, K.J.

*University of Western Australia*

**Introduction** Sodium phosphate supplementation has been shown to improve endurance exercise performance (Czuba et al., 2009; Kreider et al., 1992) and maximal oxygen uptake in well-trained athletes when 3-4 g per day is ingested for 3-6 days (Cade et al., 1984; Czuba et al., 2009; Kreider et al., 1992). The purpose of this study was to determine whether sodium phosphate ingestion had a repeatable effect on exercise performance if supplementation was repeated. **Methods** Nine well-trained male cyclists ( $\dot{V}O_{2peak}$   $65.2 \pm 4.8$  ml•kg<sup>-1</sup>•min<sup>-1</sup>; mean  $\pm$  SD) participated in a randomised, repeated-measures, double-blind crossover study. First, each participant completed a baseline 1000 kJ cycling time trial, followed 48 hours later by an incremental exercise test to exhaustion to determine maximal oxygen consumption. Upon completion of these baseline trials, participants completed three 6 day loading phases of supplementation with either 50 mg•kg<sup>-1</sup>•FFM<sup>-1</sup>•day<sup>-1</sup> of tribasic sodium phosphate or a combined glucose and NaCl placebo (two phases involved supplementation with sodium phosphate and one phase with placebo in a randomised order). On the 7th day, participants again performed the 1000 kJ cycling time trial followed 48 hours later by the incremental exercise test to exhaustion. Time to completion, cycling power output, heart rate and lactate were assessed during the time trial, while oxygen consumption and lactate were determined for each stage of the incremental test. Participants had a 14 day washout period between finishing one loading phase and starting the next. **Results** There was no significant difference in time to completion of the 1000 kJ cycling time trial between sodium phosphate and placebo supplementation phases ( $p = 0.573$ ), however, there was a tendency for faster completion time (mean 1.9-2.7 % or 58-69 s) and mean power output (2.1-3.3 % or 4.9-6.8 W) with sodium phosphate supplementation when compared to baseline or placebo conditions. There was a significant increase ( $p < 0.01$ ) in maximal oxygen consumption after the first phase of phosphate loading compared with baseline and placebo conditions ( $p < 0.01$ , 3.5- 4.3 %), with further increases displayed in the second phase of phosphate loading compared with the first phosphate supplementation phase ( $p < 0.05$ , 7.5- 7.9 %). No differences in heart rate or lactate values were found between conditions. **Discussion** In summary, sodium phosphate supplementation resulted in increased maximal oxygen consumption, with further improvements found when sodium phosphate supplementation was repeated. Cycling time trial performance tended to be better after sodium phosphate supplementation, but was not significantly so. **References** Cade R, Conte M, Zauner C, Mars D, Peterson J, Lunne D, et al. ## ESTIMATION OF VELOCITY AT VO2MAX IN WELL-TRAINED SWIMMERS

Almeida, T., Espada, M., Reis, J., Bernardo, R., Vleck, V., Alves, F.

*Faculty of Human Kinetics, Technical University of Lisbon*

**Introduction** Maximal oxygen uptake ( $\dot{V}O_{2max}$ ) has long been recognized as a poor performance determinant in high level competitive swimming. For specific training prescription,  $\dot{V}O_{2max}$  needs to be associated with performance parameters, particularly maximal aerobic velocity ( $v\dot{V}O_{2max}$ ), which serves as a basis for individualizing the relative intensity of training. The use of mean velocity during a 400 m freestyle event (S400), or more accurately, the central 300 m mean velocity (MAV), has been identified as a predictor of  $v\dot{V}O_{2max}$  (Lavoie & Montpetit, 1986), and used extensively in training and research. However, race pacing strategies and other contextual factors may hinder its usefulness. The aim of the present study was to ascertain the prediction power of S400 or MAV for the estimation of  $v\dot{V}O_{2max}$ , determined by a standard incremental protocol. **Methods** Fourteen competitive male swimmers completed an incremental test composed by 5x250 and 1x200 m front crawl for  $\dot{V}O_{2max}$  and  $v\dot{V}O_{2max}$  determination. Breath-by-breath gas exchange was measured throughout each test with a telemetric system (Cosmed K4b2, Rome, Italy), using the aquatrainer swimming snorkel® for expired gas collection.  $\dot{V}O_2$  data were averaged every 15 s. Before each test, the oxygen analyzer system was calibrated according to the manufacturer's instructions while the turbine flowmeter was calibrated using a 3-L syringe (Quinton Instruments, Wis., USA). The criteria used to define  $\dot{V}O_{2max}$  were a plateau in  $\dot{V}O_2$  despite an increase in swimming velocity (SV) and a heart rate in excess of 90% of the predicted maximal heart rate. In this protocol of incremental exercise,  $v\dot{V}O_{2max}$  was defined as the lowest SV at which  $\dot{V}O_{2max}$  occurred, according to Billat & Koralsztein (1996). 800 and 400 m performances in a swimming competitive event were recorded, the latter for determination of S400 and MAV. **Results** As expected,  $\dot{V}O_{2max}$  showed no association with performance, both in the 400 and the 800 m freestyle events. On the contrary,  $v\dot{V}O_{2max}$  could explain an important variation of performance at both distances ( $r = 0.66$ ,  $p < 0.01$  and  $r = 0.74$ ,  $p < 0.01$ , respectively).  $v\dot{V}O_{2max}$  ( $1.44 \pm 0.04$  m.s<sup>-1</sup>) was significantly different from S400 ( $1.48 \pm 0.04$  m.s<sup>-1</sup>), but not from MAV ( $1.45 \pm 0.04$  m.s<sup>-1</sup>). However, adjusted  $r^2$  was only 0.6, with a SEE of 0.025, in spite of standardized residuals remaining within the 95% confidence interval limits, indicating a fairly good estimation model. **Discussion**  $v\dot{V}O_{2max}$  can be estimated from MAV, but not from S400. The degree of accuracy of the model is acceptable for many training design and evaluation purposes. However, individual estimations should be done carefully. **References** Lavoie, J.M. & Montpetit, R.R. (1986). *Sports Med*; 3: 165-189. Billat, L.V. & Koralsztein, J.P. ## ENERGY EXPENDITURE DURING CONSTANT AND VARIABLE INTENSITY CYCLING: VALIDITY OF POWER BASED ESTIMATES

Haakonssen, E.1, Martin, D.1, Burke, L.1, Jenkins, D.2

1: AIS (Canberra, Australia), 2: UQ (Queensland, Australia)

**Introduction** Accurate estimates of exercise energy expenditure (EE) influence energy intake recommendations for elite athletes. Commercially available power meters (i.e., SRM Julich, Germany) are used to quantify training load and estimate cycling EE. The aim of this study was to measure gross efficiency (GE) during constant and variable intensity cycling to evaluate the accuracy of estimating EE with power meters. **Methods** Nine national team female cyclists (mean±stdev; 24.2±3.1 yrs, 57.7±5.1 kg, 64.2±4.0 ml·kg<sup>-1</sup>·min<sup>-1</sup> VO<sub>2</sub>pk, 287±23 W Maximum Aerobic Power (MAP)) were recruited. Cyclists completed a gross efficiency test (GE<sub>test</sub> = 4 min at ~45%, ~55%, ~65% and ~75% MAP) followed by 10.5 min of either constant or variable intensity cycling averaging ~55% MAP and then completed a second GE<sub>test</sub>. The variable power trial involved 1 min @ 45% MAP and 30sec @ 75% MAP repeated 7 times. Testing was performed on a high kinetic energy, wind-braked cycle ergometer instrumented with a SRM PowerMeter (Science Version, 8sg). Cadence was self selected. Expired gases were analysed by open circuit, indirect calorimetry using a custom built automated Douglas Bag system. During GE<sub>tests</sub>, Economy (W.L-1), VO<sub>2</sub> at 150 W (VO<sub>2</sub>@150W) and average Gross Efficiency (GE) were calculated. EE (kJ) for 1hr of constant and variable cycling was estimated using indirect calorimetry and compared to predicted EE based on power (SRM) and GE estimated for the group and for the individual. **Results** Typical error (Mean±90% CI) calculated from pre-GE<sub>tests</sub> log-transformed data reflect reliable measurements of Economy - 7.0±6.0%; VO<sub>2</sub>@150W - 2.4±2.1%; and GE - 2.1±1.8%. Individual GE ranged from 16.0–21.2%. Following constant and variable intensity cycling, there were small but consistent changes in Economy (~3–8%), GE (~2%) and VO<sub>2</sub>@150w (~3%). GE during constant (18.4±1.6%) and variable intensity cycling (18.6±1.1%) was similar. SRM based estimates of EE for 1hr of cycling using the average GE (18.5%) were within ~30 kJ (<1%) of EE estimated from indirect calorimetry. However, individual errors ranged from -15% to 14%. Using each individual's GE produced estimates of EE within ~10 kJ (<0.4%, range: -1% to 4%). **Discussion** The gross efficiency (GE) of cycling for national team female cyclists was ~19%. GE was similar for ~10 min of constant and variable intensity cycling. Findings support the use of calibrated SRM power meters for estimating cycling EE. For trained, competitive female road cyclists, total mechanical work (kJ) multiplied by 5.3 provides a valid estimation of total EE during constant and variable cycling <75% VO<sub>2</sub>pk. Combining SRM power meter data with each cyclist's individually assessed GE greatly improves the accuracy of estimates for EE (<4% error in all cases).

## PRELIMINARY ANALYSIS OF PACING STRATEGIES IN A PROFESSIONAL BASKETBALL

Kavaliuskas, M.

University of Worcester

**Introduction** Pacing is the distribution of muscular work rate during exercise (Foster et al., 2004). Although pacing has been studied extensively in individual endurance sports, little research has investigated the distribution of work rates within team sports. The aim of this preliminary investigation was to analyse workload distribution of an individual player over the course of a basketball game. **Methods** A professional male basketball player (small forward; age (years) – 24; height (cm) – 196; body mass (kg) – 85.2) from a British Basketball League team participated in this study. 1 digital video camera (Sony DRV900E) was used to film a home game which was replayed on SportsCode software for coding of activity patterns. Activities were coded based on five arbitrary locomotor categories in a horizontal direction (Dogramaci et al., 2011). Categories 0,1,2,3 and 4 corresponded to non-participation (i.e. substituted), stationary, walking, jogging, and sprinting respectively. Frequency of actions within each category were calculated for each quarter (Q1,2,3,4) of the match and the Coefficient of Variation (CV) was used to indicate the degree of variability in actions performed. **Results** The player was active during Q1, Q2, and Q3 but did not participate in Q4. The frequency of category 1, 2, and 3 actions was greatest in Q1, while the greatest frequency of category 4 activity (sprinting) occurred in Q2. Analysis of CV indicates that the degree of variability in total activity values decreased from 68.5%, to 46.5% and 45% through Q3, Q2 and Q3 respectively. **Discussion** Pacing changes were observed throughout the game with less heterogeneous patterns occurring in the second and third quarters, largely due to the high frequency of periods when the player was engaged in lower intensity (category 1 and 2) activities in Q1. However, no 'end-spurt' phenomenon could be identified since the player was substituted and did not play during Q4. Currently, there is little known about the exact mechanisms underpinning work rate distribution with a range of physiological, psychological and tactical factors potentially contributing to the selection and maintenance of different pacing strategies (St Clair Gibson et al., 2006). Match dynamics and positive emotional state may have affected the player's pacing strategy with no reduction in work-rate as the match progressed because the team was winning. Therefore, further research examining pacing strategies during basketball is warranted. **References** Dogramaci SN, Watsford ML, Murphy JA (2011). J Strength and Cond Res, 25 (3), 852-859. ## EFFECT OF DISPARITIES OF FEEDBACK ON PACING IN CYCLE TIME TRIALS

Nyberg, K., Jaime, S., Rodriguez-Marroyo, J., Condello, G., Casolino, E., Dodge, C., Mikat, R., Wright, G., Foster, C.

University of Wisconsin-La Crosse

**Introduction** The purpose of this study is to understand the effect of hypoxia during warm-up and competition on performance during cycle time trials. If the pre-exercise warm-up is manipulated by the use of hypoxia, when does the hypoxic challenge influence pacing during the time trial, performed under either normoxic or hypoxic conditions? **Methods** Seven well-trained subjects performed a VO<sub>2</sub> max test, two habituation trials, and four randomly ordered, single-blind 5 km time trials. Subjects performed HH (hypoxic WU/hypoxic TT), HN (hypoxic WU/normoxic TT), NH (normoxic WU/hypoxic TT), or NN (normoxic WU/hypoxic TT) with hypoxia (FIO<sub>2</sub> =0.15) and normoxia (FIO<sub>2</sub>=0.21). **Results** The hypoxic warm-up elicited a significant (p < .05) decrease in arterial saturation (hypoxic SaO<sub>2</sub>=86%, normoxic SaO<sub>2</sub>=97%) and increases in perceived exertion (RPE) and blood lactate (HLA). During the time trial significant differences in PO between hypoxic and normoxic time trials began at 1.0 km, continuing for the duration of the time trial (NN PO @ 1,2,3,4,5 km=271, 271, 260, 256, 304W. NH PO=251, 239, 219, 212, 247W. HN PO=259, 258, 257, 250, 294. HH PO=238, 215, 212, 205, 245). There was no significant difference in initial PO. **Discussion** Despite manipulating the pre-exercise template, PO is not reduced until physiological feedback occurs within the time trial. In this study physiological feedback modifications were evident after ~1.0 km with significant adjustments in PO based on the FIO<sub>2</sub>. It is essential for the athlete to prepare an effective pacing strategy and constantly be interpreting and responding to environmental and internal cues (Mauger et al., 2011; Tucker et al., 2009). Apparently, with changes in FIO<sub>2</sub> subjects cannot distinguish this change, even if a low FIO<sub>2</sub> is presented during warm-up, until physiological feedback mechanisms have time to act during the time

trial. Since initial PO was not significantly different, changes in pacing strategy occurred only after afferent feedback was received. References Mauger AR, Jones AM, Williams CA. (2011). *Br J Sports Med* 45:225-229. Tucker R, Noakes TD. (2009). *Br J Sports Med* 43(6):392-400.

### ASSOCIATION BETWEEN MUSCLE FORCE PRODUCTION DURING STEADY-SPEED RUNNING AND RUNNING ECONOMY IN COMPETITIVE ATHLETES

Di Michele, R.

*University of Bologna*

**ASSOCIATION BETWEEN MUSCLE FORCE PRODUCTION DURING STEADY-SPEED RUNNING AND RUNNING ECONOMY IN COMPETITIVE ATHLETES** Di Michele, R.1, Merni, F.1 1: Department of Histology, Embryology and Applied Biology, Faculty of Exercise and Sport Sciences, University of Bologna (Bologna, Italy) Introduction Running economy (RE) is a key determinant of performance in distance running, and it is of interest to understand how RE is associated to biomechanical characteristics of running gait. Previous studies showed that RE is proportional to the rate of muscle force production during running (Kram & Taylor, 1990; Pontzer 2007). In steady-speed running, the highest portion of muscle force is applied to support one's own body weight (Kram & Taylor, 1990; Chang & Kram, 1999), but a significant amount of force is used to accelerate the center of mass (Chang, 1999) and to swing the oscillating limb (Modica & Kram, 2005). Therefore, the purpose of this study was to analyze the association between RE and the overall rate of force production, as estimated using a mathematical model. Methods RE was measured in ten high-level athletes while running on a track at the steady speed of 14 km/h. Furthermore, ground reaction force (GRF) data were collected with a force plate while running at the same speed. A mathematical model, adapted from Pontzer (2007), was used to estimate the rate of force production during running as a combination of i) the rate of the vertical component of GRF, ii) the rate of the horizontal component of GRF, and iii) the average force required to swing the limb in a stride, determined using a specific equation. A linear regression was conducted to assess the proportion of variance in RE explained by the modeled force values. Results The mean rate of the vertical component of GRF, when considered alone, explained a large portion of variability in RE ( $R^2 = 0.71$ ). The explained variance increased when the horizontal component of GRF and the force required to swing the limb were included in the model ( $R^2 = 0.79$  and  $0.88$ , respectively). Discussion The present results confirm the previous conclusions that the force needed for supporting the runner's body weight is a major determinant of RE (Kram & Taylor, 1990). Furthermore, including the horizontal component of GRF and the force needed for swinging the limb allows to obtain an index of overall force production that is highly associated with RE in trained distance runners. This finding provides further support to the observation that RE is proportional to the rate of force produced during running. From an applied perspective, the model used here can provide a reasonably simple evaluation tool when analyzing an athlete's running mechanics with the goal to improve the economy of his/her running style. ### EFFECT OF ECCENTRIC CONTRACTIONS WITH A PRE-EXERCISE GLYCOGEN DEPLETION PROTOCOL ON METABOLIC RESPONSES DURING SUBMAXIMAL CYCLING

Gavin, J.P., Myers, S.D., Clements, R.E., Willems, M.E.T.

*University of Chichester*

**Introduction** Glycogen depletion following prolonged exercise is often associated with susceptibility to, and recovery from, exercise-induced muscle damage (EIMD). In a state of EIMD, cardiorespiratory responses may become compromised during subsequent moderate- and high-intensity cycling. Yet, the effects on metabolic and cardiorespiratory responses during low-intensity cycling are unclear. **Methods** Ten men ( $22 \pm 3$  yr,  $180 \pm 7$  cm,  $81 \pm 16$  kg) exercised at 60 rpm for 10-min on a cycle ergometer at 50% maximal oxygen uptake prior to, and 12-hr after completing 100 unilateral maximal voluntary eccentric contractions with knee extensors of each leg. The evening before the eccentric bout, a unilateral glycogen depleting protocol (Pilegaard et al., 2002) was performed to lower muscle glycogen in the right leg. Eccentric contractions were performed on an isokinetic dynamometer (Humac Norm, USA) from full knee extension to flexion ( $1.57 \text{ rad} \cdot \text{s}^{-1}$ ). Cardiorespiratory responses were recorded using a portable metabolic cart (Cosmed K4b2, Italy) during cycling, with fat and carbohydrate oxidation calculated using stoichiometry equations (Jeukendrup & Wallis, 2005). Changes in maximal isometric voluntary force (MVIF) were used to assess EIMD. Paired samples t-tests were used to detect difference in pre- and post-values for MVIF, and metabolic and cardiorespiratory measures during the last minute of exercise. Results Twelve hours post, EIMD was evidenced by MVIF reductions of: 7% (left leg;  $P=0.06$ ) and 8.3% (right leg;  $P=0.008$ ). Respiratory exchange ratio reduced from  $0.97 \pm 0.05$  to  $0.92 \pm 0.05$  ( $P=0.02$ ), while oxygen uptake ( $1.5 \pm 0.2$  to  $1.6 \pm 0.2 \text{ L} \cdot \text{min}^{-1}$ ,  $P=0.39$ ), carbon dioxide output ( $1.4 \pm 0.3$  to  $1.4 \pm 0.2 \text{ L} \cdot \text{min}^{-1}$ ,  $P=0.54$ ), minute ventilation ( $36.9 \pm 0.7$  to  $38.1 \pm 0.6 \text{ L} \cdot \text{min}^{-1}$ ,  $P=0.69$ ) and heart rate ( $110 \pm 2$  to  $111 \pm 2 \text{ beats} \cdot \text{min}^{-1}$ ,  $P=0.85$ ) were similar. Fat oxidation increased post from  $0.16 \pm 0.1$  to  $0.26 \pm 0.1 \text{ g} \cdot \text{min}^{-1}$  ( $P=0.05$ ), but carbohydrate oxidation was unchanged ( $1.6 \pm 0.3$  to  $1.4 \pm 0.4 \text{ g} \cdot \text{min}^{-1}$ ,  $P=0.36$ ). **Discussion** Eccentric exercise preceded by a unilateral glycogen depleting protocol altered metabolic responses during low-intensity cycling exercise. Increased fat oxidation may be due to impaired insulin action with EIMD; but this was not supported by cardiorespiratory responses. Such may be attributable to limited damage induced by the eccentric bout, the intensity of the cycling exercise or a combination of both. Regardless, the design may have utility in examining mechanisms underpinning the physiological responses to exercise in an EIMD state. References Jeukendrup AE, & Wallis GA. (2005). *Int J Sports Med*, 26, S28-S37. Pilegaard H, Keller C, Steensberg A, Helge JW, Pedersen BK, Saltin B, Neufer D. (2002). *J Physiol*, 541(1), 261-271.

### EXERCISE AS AN EXTERNAL CUE FOR MAINTAINING CIRCADIAN RHYTHM – RECTAL TEMPERATURE RECORDINGS VS A NEW NON-INVASIVE HEATFLUX TECHNOLOGY

Stahn, A.1, Mendt, S.1, Steinach, M.1, Opatz, O.1, Werner, A.1, Kunz, D.1, Belavy, D.2, Felsenberg, D.2, Sattler, F.3, Koch, J.3, Gunga, H.C.1

**Introduction** Travelling across different time zones requires athletes to quickly adapt to altered day and night cycles. Athletes are therefore prone to suffer from jet lag due to desynchronization of their internal body clock. Exercise has recently been outlined as a potential countermeasure to promote the entrainment of the circadian timing system (CTS). Previous studies, however, have been limited in isolating the effects that can be purely attributed to exercise. In addition, an easy and non-invasive technology for assessing the CTS is lacking. The

aims of this study were therefore: (1) To investigate the effect of 60 days of bed-rest and different exercise protocols on circadian rhythm and (2) to assess whether rectal temperature recordings and a new heatflux sensor (Double Sensor) can be considered as interchangeable methods for determining circadian rhythm. Methods 24 healthy men were exposed to 60 days of 6-degree head-down tilt bed-rest as part of the Berlin Bed-rest Study 2 (BBR2-2). Subjects were randomly allocated to a resistance (RE), a combined resistance and vibration exercise (RVE), or a control (CTR) group. Core body temperature profiles for 36 h were determined every week weeks bed-rest using both rectal recordings and a recently developed Double Sensor positioned at the forehead. Cosinor analysis was employed to quantify circadian rhythm by mesor, acrophase, and amplitude. Results No significant differences could be observed between rectal recordings and the new non-invasive heat-flux technology for mesor, acrophase, and amplitude ( $P = 0.12$  to  $0.98$ ). The strong associations between the two methods was also confirmed by high correlations ( $r = 0.92$  to  $0.97$ ) between rectal and Double Sensor recordings. While RE and VRE showed no significant difference in circadian rhythm throughout the study, CTR exhibited a significant increase in acrophase from week 1 to week 7 ( $P = 0.016$ ). In addition, CTR was characterized higher variability in acrophase and mesor compared to RE and VRE. Discussion The present study confirms our previous findings indicating that circadian rhythm of core body temperature can be reliably and continuously determined using a new heatflux sensor (Double Sensor) located at the head. In addition, there was a tendency for exercise to offset some of the detrimental effects of bed-rest on the CTS, substantiating the use of exercise as a potential countermeasure against alterations of the CTS during transmeridian travel. It is concluded that the present Double Sensor technology might be useful in better understanding the impact of jet lag as well as improving respective adaptation strategies for optimizing individual performance of athletes. Finally, it is suggested that the Double Sensor technology might be a useful approach in better understanding the interaction between the CTS and thermoregulation during exercise.

### PHYSICAL CHARACTERISTICS AND PHYSIOLOGICAL ATTRIBUTES OF FEMALE VOLLEYBALL PLAYERS – THE NEED FOR INDIVIDUAL DATA

Nikolaidis, P.T.1, Ziv, G.2, Veniamakis, E.E.3, Arnon, M.2, Lidor, R.2

1: *Laboratory of Human Performance and Rehabilitation, Hellenic Army Academy (Athens, Greece)*, 2: *Wingate Institute (Netanya, Israel)* 3: *Department of Nutrition and Dietetics, Technological Education*

**Introduction** The purpose of this study was twofold: (a) to profile physical characteristics and physiological attributes of adolescent and adult Greek female volleyball players ( $n=61$ ) who were members of the A (the best league for female volleyball players) and B (the second- best league for female volleyball players) Series clubs in Greece, and (b) to examine the intra-individual variability among these players in all physical and physiological measurements that were undertaken in the study. **Methods** The participants were divided into three age groups - under 14, 14-18, and over 18 years. They underwent a series of physical (e.g., height, body mass, and percentage of body fat) and physiological (e.g., aerobic profile, flexibility, and vertical jumping ability) tests. **Results** Three main findings emerged from the data analysis: (a) differences in physical characteristics and physiological attributes existed between the three age groups. For example, fat free mass was lower in players under the age of 14 ( $41.6 \pm 6.1$  kg) compared to players between the ages of 14-18 ( $50.2 \pm 7.0$  kg) and players over the age of 18 ( $52.0 \pm 3.4$  kg). In addition, the relative peak power as measured in the WAnT was the highest in the over-18 group ( $9.72 \pm 0.65$  W.kg<sup>-1</sup>), lower in the 14-18 group ( $8.95 \pm 0.77$ ), and the lowest in the under-14 group ( $8.32 \pm 0.78$  W.kg<sup>-1</sup>), (b) large intra-individual variability existed in most physical characteristics and physiological attributes measured in the study, and (c) the intra-individual variability was observed in all three groups. **Conclusions** These findings emphasize the need for coaches to examine the intra-individual variability within the players on their teams, and to use this information when designing training programs and strength and conditioning programs.

### EFFECT OF VARYING WARM-UP INTENSITIES ON INTERMITTENT SPRINT PERFORMANCE

Wallman, K.

*The University of Western Australia*

**EFFECT OF VARYING WARM-UP INTENSITIES ON INTERMITTENT SPRINT PERFORMANCE** Anderson, P.1, Wallman, K.1, Landers, G.1 1: *The University of Western Australia* **Introduction:** Warm-up (WUP) is a well-accepted practice considered by many athletes to be an essential precursor to exercise. Physiologically, an active WUP is proposed to improve subsequent exercise performance as a result of numerous temperature and non-temperature related benefits (see reviews by Bishop, 2003a, Bishop 2003b). While a number of studies have investigated the effect of WUP on subsequent continuous exercise or single-sprint performance, few studies have assessed the effects of WUP, compared to no-WUP, on intermittent sprint performance, with results being equivocal (Bishop & Claudius, 2004; Mohr et al., 2004). Further, there has been minimal research that has assessed the effects of WUP on exercise where WUP intensities were based on individual lactate thresholds. Therefore the aim of this study was to investigate the effect of different WUP intensities, based on lactate accumulation, on 10-min of subsequent intermittent sprint performance, and to determine whether core temperature ( $T_c$ ) correlated with performance. **Methods:** Eleven male, team-sport athletes performed four experimental trials in a randomised, Latin-square, cross-over design, each separated by one week, consisting of an intermittent sprint protocol (15 x 20 m sprints, separated by 30 or 60-s) that followed either no-WUP or one of three 10-min WUP trials. WUP intensities were performed at either (1) half the difference between anaerobic threshold (AT) and lactate threshold (LT)  $[(AT-LT)/2]$  below the LT level = WUP 1; (2) mid-way between LT and AT level = WUP 2; (3) half the difference between LT and AT,  $[(AT-LT)/2]$  above AT level = WUP 3. **Results:** Individual sprint times showed a significant main effect for sprints ( $p = 0.001$ ) but not for trials ( $p = 0.434$ ), with sprint 4 being faster than sprint 3 and sprints 4, 5, 7 and 10 being faster than sprint 12 ( $p < 0.05$ ). Warm-up 3 resulted in faster individual sprint times for sprints 1, 2, 3, 5, 6, 8, 9, and 14 (Cohen's  $d = 0.51 - 1.13$ ), compared to WUP 1 and no-WUP, as well as faster accumulated sprint times for the entire 15-sprint protocol, with moderate to large effect sizes found for accumulated sprints 1 - 10 ( $d = 0.50 - 1.05$ ). There were no significant correlations between  $T_c$  assessed immediately after each WUP and any performance variable. **Conclusion:** A WUP performed half the difference between LT and AT above AT (i.e., WUP 3) resulted in faster intermittent sprint performance compared to lower intensity WUPs and no-WUP. Significant increases in  $T_c$  were not correlated with exercise performance. **References:** Bishop D. Warm Up 1 (2003a). *Sports Med*, ;33(6):439-54. Bishop D. Physiological and anthropometrical variables of Iranian elite kayakers Introduction: Anthropometric profiles of World-class athletes offer useful data for coaches when initially selecting talented individuals for development programs (Ackland et al., 2003). Sprint kayaking is characterized by exceptional demands on upper body performance (Michael et al., 2008). Olympic kayak paddlers not only need a high aerobic power, but the anaerobic contribution is also very important for successful performance (Bishop 2000). The aim of this study was investigated of physiological and anthropometrical profile of Iranian elite kayakers. Methods Eight Iranian male kayak athletes with mean age: 19.7±1.98 (year) were examined. Anthropometric measurements: A total of anthropometric variables were directly and indirectly measured according to the methods of standard International Society for the Advancement of Kinanthropometry (ISAK). Aspect of upper-body peak power and anaerobic capacity using the 30-second exhaustive Wingate Anaerobic Test (WAnT). An incremental test was used to determine . Breath-by-breath gas analysis was conducted throughout using an automated Jaeger Oxycon Pro system (cosmed, Finland). All physiological testing was conducted on a calibrated, wind-braked kayak ergometer (K1 Ergo, Garran, Australia). Descriptive statistics were performed on the group data using standard statistical procedures. (Mean±SD). Result: Anthropometrical and body composition measurements indicated that: age: 19.7±1.98(year), straight height: 184.21±5.27(cm), sitting height: 98.43±1.62(cm), arm span:189.21± 5.95(cm), body mass: 79.04± 4.66(kg), lean body mass:71.81±3.59(kg), body fat: 10.84±6.18(percent), BMI: 21.69± 4.7(kg/m<sup>2</sup>). Aerobic and anaerobic tests showed: Vo<sub>2</sub>max: 4.07±0.24 (L/min), Vo<sub>2</sub>max: 50.69±3.34 (ml/kg/min), Heart rate to Vo<sub>2</sub>max: 183.1± 7.4(lb/min), Mean power:395.45±23.46(W), Mean power: 4.5± 0.24(W/kg), Peak power: 882.54±120.36, Peak power: 11.00± 1.27. Discussion: Our result indicated that these kayakers have straight and sitting height near the average of world elite kayakers (Ackland et al 2003). Their relative VO<sub>2</sub> max was 50.69±3.34 (ml/kg/min) and its accordance with Ackland et al (2003) results. Anaerobic peak power and mean power it's near to elite kayakers. In conclusion these kayaker have a good state in anthropometrical and physiological variables. References: Bishop, D. **PASSIVE RECOVERY IS SUPERIOR TO ACTIVE RECOVERY DURING A HIGH INTENSITY SHOCK MICROCYCLE.**

Wahl, P.1,2,3, Zinner, C.1, Bloch, W.2,3, Mester, J.1,3

*German Sport University*

1: Institute of Training Science and Sport Informatics, German Sport University Cologne (Germany) 2: Department of Molecular and Cellular Sport Medicine, Institute of Cardiovascular Research and Sport Medicine, German Sport University Cologne (Germany) 3: The German Research Centre of Elite Sport, German Sport University Cologne (Germany) Introduction: In the last years there was a great scientific discussion about high intensity (interval) training (HIT). However few is known about the arrangement of interval training and its integration into the training cycle. In most cases active recovery is performed during high intensity interval training, in order to normalize lactate and pH-values and performance faster compared to passive recovery. However, recent investigations showed that lactate and pH act as signaling molecules inducing adaptations. Their time of exposure is decreased if active recovery is performed, may be leading to a decreased (metabolic) stimulus. The aim of the present study was to examine the effects of a two week high intensity shock microcycle on maximal oxygen consumption and parameters of exercise performance in junior triathletes on the one hand, and to compare the long term effects of active (A) vs. passive (P) recovery on the other hand. Methods: 16 healthy competitive junior triathletes from a local team (12 male, 4 female) participated in this study. For the assignment to the A- or P-group subjects were matched according to age and performance. Within two weeks, a total of 15 high-intensity interval sessions were performed within three 3-day training blocks. Before and one week after the last training session, athletes performed a ramp test to determine VO<sub>2</sub>max, a time trial (TT) and a Wingate-test. Furthermore total Hb-mass was determined. The results of the whole group, independent of the arrangement of recovery were analyzed at first; second the A- and P-groups were analyzed separately. Results: Peak power output (PPO) during ramp test and TT performance significantly increased in the whole group. The comparison of the two groups revealed increases for the mentioned parameters and for VO<sub>2</sub> and power output at VT<sub>2</sub> only for the P-group. VO<sub>2</sub>max did not change. Wingate performance increased in the A-group only. Total hemoglobin mass slightly decreased in the whole group. Discussion: The main finding of the present study was that a 14-day HIT shock microcycle is able to improve TT performance and PPO in junior triathletes in a short period of time. Furthermore, not only the intensity, but also the arrangement of interval training seems to be important as well, since only the P-group showed improvements in endurance performance, despite a slightly lower training volume. These findings might be relevant for future arrangements of high intensity interval training.

**DOES PRIOR HEAT EXPOSURE REDUCE CONSEQUENCES OF ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE?**

Easthope, C.S.1,2, Mavros, Y.1, Fatarone Singh, M.A.1, Brisswalter, J.2, Caillaud, C.1

*1: USYD (Sydney, Australia), 2: UNSA (Nice, France)*

Introduction Eccentric exercise-induced muscle damage (EIMD) is a well-described phenomenon, but the precise mechanisms leading to the attenuation through repeated bouts are still poorly understood. Stress proteins such as heat shock protein (HSP)-72 and -27 may protect against the development of EIMD (1). This study investigated if HSP-inducing passive heating would attenuate EIMD-related changes in voluntary muscle activation (VA), force production and pain over repeated exposure to EIMD. Methods EIMD was assessed by increases in self-reported pain, reduction in force and changes in VA of muscles following a downhill running model of eccentric exer-

cise. Healthy young subjects (n=35) are being recruited to run downhill (-15°) for 30 minutes at a speed corresponding to 70%VO<sub>2</sub>max on two occasions 3-5 weeks apart as a model of EIMD. Half of the subjects were randomly selected for passive heating (lower limb immersion, 75 min, 43°C) 48 hr before their first running session, controls had no prior treatment. Before, and then 1 hr, 24 hrs and 48 hrs after downhill running, all subjects completed isometric (70° knee flexion) and eccentric (100°/s) force tests with electrical twitch stimulation (ITT, 400V, 50us) and EMG (quadriceps fem. and biceps fem.). They then reported contra-lateral thigh muscle pain on an analog scale. Results Preliminary data indicate that during heating all subjects reached a core body temp of >39°C. Mean isometric force reduction 24hrs after downhill running was attenuated in heated subjects (-8±5%) after the first downhill running session when compared to control (-17±4%, p=0.04) but not after the second (p=0.29). Perceived muscle pain increased significantly at 24 hrs post downhill running (p>0.02) in both groups (p=0.42). Following downhill running, VA was depressed (p=0.04) and antagonistic co-activation was increased (p=0.03) with no group differences (p=0.5). Discussion Heating the muscle 48 hrs before eccentric exercise attenuates the force reduction related to EIMD, but does not alter the subsequent increases in pain or decreases in muscle activation or persist over repeated exposure to EIMD. These findings partially support the conclusions from earlier investigations (2), but require further study to elucidate the mechanisms and persistence of this potentially protective adaptation to limit muscle damage. ### AVAILABILITY OF ORTHOSTATIC TEST FOR THE EVALIETION OF PHYSICAL CONDITION IN ACCLIMATIZIOM PROCESS OF HIGH ALTITUDE TRAINING

Hisashi, K., Hidetaka, T., Taro, S., Masaki, T.

*Doshisha University*

AVAILABILITY OF ORTHOSTATIC TEST FOR THE EVALIETION OF PHYSICAL CONDITION IN ACCLIMATIZIOM PROCESS OF HIGH ALTITUDE TRAINING Hisashi, K.I., Hidetaka, T.I., Taro, S.I., Masaki, T.I. 1: Doshisha University (Kyoto, Japan) Introduction It has been known that ascend to high altitude is associated with the down regulation in cardiac autonomic nervous activity as compared to sea level(Hainsworth et al. 2007; Iwasaki et al. 2006). These regulations seemed to be gradually approached to near sea level with high altitude acclimatization. The purpose of this study was to investigate the availability of orthostatic test reflecting cardiac autonomic nervous activity for the evaluation of physical condition in acclimatization process of high altitude training. Methods Cross-country skiing athletes (10 males, 6 females, 20.4±1.2) lived 1 day at sea level for collecting control data and lived and trained for 8 days at the ambient altitude approximately 1,600m above sea level. Heart rate (HR) during 10 minutes orthostatic test, HR, arterial blood oxygen saturation and blood lactate during 3 minutes step test, amylase in the saliva, urine specific gravity and subjective feeling of fatigue were measured at the every morning. Time trial of 1,500m running as an index of endurance performance was conducted at altitude in day 1, day 4 and day 8. To evaluate an influence of training loads on cardiovascular system, HR during training was recorded and calculated training impulse (TRIMP). Analysis of variance was used for the statistical evaluation. Results No significant changes were found in HR response during orthostatic test, HR response during 3 minutes step test, the other physiological parameters and 1,500 m running performance on a subject's mean level during 9 days. Because, there were individual differences in all variables, looking at subject's individual data, some of subjects revealed good response to acclimatization process of high altitude training. It showed gradually approached to near sea level with high altitude acclimatization. Discussion It is suggested that there is definite individual differences in the cardiac autonomic nervous activity response to high altitude acclimatization process. But some of subjects revealed good response to acclimatization process to high altitude training. Therefore, these responses imply that orthostatic test could be one of indexes reflecting physical condition during acclimatization process of high altitude training in endurance athletes. However, it is needed a further research to identify the individual differences of HR response. References Banister EW, Morton RH, Fitts-clarke J. (1992). *Ann. Physiol. ### EFFECTS OF MENSTRUAL CYCLE PHASE-BASED ENDURANCE TRAINING ON ENDURANCE PERFORMANCE IN FEMALES WITHOUT VERSUS FEMALES WITH ORAL CONTRACEPTION

Han, A.I, Sung, E.I, Hinrichs, T.I, Vorgerd, M.I, Platen, P.I

*Ruhr-University Bochum*

Purpose: The menstrual cycle is divided into 2 main phases, the follicular (FP) and the luteal phase (LP). Each phase is characterized by a certain profile of different hormones, including variations in anabolic hormones. Oral contraception (OC) alters the profile of these hormones. We could recently demonstrate that adaptation to strength training is slightly higher in females who mainly conduct their training in FP compared to LP. This study analyses the effects of menstrual cycle-based endurance training and compares the effects between non-OC users and OC users. Methods: 27 healthy females (n=13 non-OC users (25.1 ± 3.6 yrs, 164.8 ± 6.8 cm, 67.7 ± 17.7 kg) and 14 OC users (23.9 ± 3.1 yrs, 168.4 ± 6.9 cm, 61.9 ± 8.8 kg) completed an one-leg endurance training on a cycle ergometer for each leg for 3 months. Both groups trained one leg mainly in the 1st half of the menstrual cycle (follicular phase training (FT) and quasi-follicular phase training (qFT)) and the other leg mainly in the 2nd half of the cycle (luteal phase training (LT) and quasi-luteal phase training (qLT)). Concentrations of estradiol (E2), progesterone (P4), total testosterone (T) and free testosterone (free T) were analyzed in FP and LP. One-leg peak oxygen uptake (VO<sub>2</sub>peak), one-leg-maximal workload (Wmax), muscle fiber composition (F%area), fiber diameter (Fdm) and cell nuclei to fiber ratio (N/F) (biopsies of m. vastus lateralis, n=8) were analyzed prior to and after the training period for each leg separately. Results: Concentrations of E2, T and free T were significantly higher in non-OC users compared to OC users (p<0.05). Free T was higher in FP compared to LP and in qFP compared to qLP (p<0.05). P4 level was highest in LP compared to all other phases (p<0.05). Increase in Wmax was higher in FT (+34.8 W) compared to LT (+27.8 W) (p<0.05) and did not differ between qFT and qLT (+32.3 vs. +35.9 W), without any significant differences between non-OC and OC-users. VO<sub>2</sub>peak tended to increase after FT (+3.3 ml/min/kg) and LT (+2.8 ml/min/kg) and increased significantly after qFT (+5.7 ml/min/kg) and qLT (+5.3 ml/min/kg) without any differences between non-OC and OC-users. Muscle fiber parameters did not show any clear alterations after training. Conclusions: Despite clearly higher concentrations in anabolic hormones in non-OC users compared to OC-users, increase in aerobic performance and maximal workload did not differ between these groups. Within the respective groups, however, adaptation to aerobic training was slightly higher in FT and qFT compared to LT and qLT.

## THE EFFECT OF MODERATE ALTITUDE ON OBJECTIVE AND SUBJECTIVE SYSTEMS OF TRAINING LOAD QUANTIFICATION

Ferliche, B.1, Rodríguez, F.A.2, Iglesias, X.2, Calderón, C.3, Barrero, A.2, Pérez-Medina, I.2, Barrero, A.2, Vázquez, J.2, Ábalos, X.2, Rodríguez-Zamora, L.2, Truijens, M.4

1: FCAFD, University of Granada (Granada, Spain); 2: INEFC-Barcelona Sport Sciences Research Group, University of Barcelona (Barcelona, Spain); 3: CAR Sierra Nevada (Granada, Spain), 4: Royal Dutch Sw

**Introduction** Objective and subjective training load indicators, such as training impulses (TRIMPs) and ratings of perceived exertions (RPE) have been used to monitor elite swimmers under normoxic conditions (Wallace et al., 2009). However, their usefulness and validity under hypoxic conditions has not been studied to date. This study aims to analyse the effect of 3-weeks exposure to moderate altitude on the relationship between objective (TRIMPs) and subjective (s-RPE) systems of training load quantification in elite swimmers. **Methods** 40 elite swimmers were assigned to two groups: Lo, who lived and trained at sea level, and Hi, who lived and trained at moderate altitude (CAR Sierra Nevada, Spain, 2320 m above sea level). During three consecutive weeks all training sessions were monitored. Heart rate (HR) and time were recorded to compute TRIMPs (Banister & Hamilton, 1985). Session-RPE (s-RPE) based on the CR-10 scale (Foster et al. 2001) was self-administered within 30 min after each swimming (S1, S2) and dry-land (DI) training sessions. **Results** There were no differences in S1 and S2 training loads (TRIMPs) in any of both Hi and Lo groups. s-RPE showed differences between groups that were significantly smaller in the Hi group in S1 ( $p < 0.001$ ). In DI differences were noted between both groups in all training sessions ( $P < 0.05$ ). The association (Pearson's  $r$ ) between s-RPE and TRIMPs during swimming sessions was moderate both in S1 (Hi: 0.42; Lo: 0.76;  $p < 0.001$ ) and S2 (Hi: 0.69; Lo: 0.56;  $p < 0.001$ ). In DI sessions no association was found between methods (Hi: 0.02; Lo: 0.02;  $p > 0.05$ ). **Discussion** The relationship between TRIMPs and s-RPE training load indicators is low-moderate. Therefore, we consider they should not be used indiscriminately in altitude, at least during the acclimatization phase. s-RPE appears to be more sensitive to an increase in the intensity of the internal load than to a rise in training volume (Sweet et al., 2004). This is supported by our observation that there were differences in s-RPE between the Hi and the Lo groups in the first two weeks, but not in third week when training intensity tend to equalize. TRIMPs do not seem to constitute an appropriate quantification procedure for workload during dry-land sessions. **References.** Banister EW & Hamilton CL. (1985). *Eur J Appl Physiol*, 54, 16-23. Foster et al. (2001). *J Strength Cond Res*, 15, 109-115. Wallace et al. (2009). *J Strength Cond Res*, 23, 33-38. Sweet et al. (2004). *J Strength Cond Res*, 18, 796-802.

## RESEARCH OF EXTERNAL BREATH PARAMETERS OF GYMNASTS DURING PERFORMANCE OF THE MAIN GYMNASTIC EXERCISES

Shlyakhtov, V.

*Velikiye Luki State Academy of Physical Education and Sports*

**Introduction.** The modern artistic gymnastics is characterized by the intensity of competitive activity and training process, and also necessity of formation of stable and reliable technique skills. The key moment in the gymnasts' preparation is improvement of functional readiness. Unfortunately, till now, it was possible to measure the data of the gas exchange and external breath only in laboratory conditions during special testing of gymnasts. In this connection the value of research of breathing system functioning during performance of the gymnastic exercises in natural conditions raises substantially. The purpose of the present research was to consider the method of ergospirometry during performance of the main gymnastic exercises as giant circles (forward and back) on the horizontal bar, swings to the handstand on the parallel bars, and acrobatic forward handspring, and to use the received data at different stages of gymnasts' training. **Methods.** 6 gymnasts aged 12-14 took part in the research. To study the gymnast's external breath parameters during performance of the exercises the telemetric ergospirometry complex «Oxycon mobile» by VIASYS and specialized software package was used. The video shooting of performance of the exercises was simultaneously done and synchronized with parameters of external breath. **Results.** The average duration of performance of the exercises was: forward handspring 2.05 sec., forward giant circle 1.67 sec., back giant circle 1.26 sec., swings to the handstand 1.38 sec. The average parameters of the breath in (l/sec.) in this exercises were: forward handspring 2.25/1.3, forward giant circle 1.71/0.8, back giant circle 1.86/0.7, swings to the handstand 1.38/0.5. The average parameters of the breath out (l/sec.) were: forward handspring 2.18/0.7, forward giant circle 1.48/0.9, back giant circle 1.53/0.6, swings to the handstand 1.48/0.9. The short breath holding was also observed during performance of this exercises. **Discussion.** The received data testify that the gymnast use monotype respiratory system work that characterizes identity of its work during performance of the main gymnastic exercises as giant circles (forward and back) on the horizontal bar, swings to the handstand on the parallel bars when the breath out phase coincides with the main phase of the performance of this exercises. Performing forward handspring gymnasts use two different models of the breathing system functioning. The former – the main movements are made breathing out to strain the skeletal muscles, to reinforce the power of the performance. The latter – there is a short breath holding during the exercises to exclude extra involvement of the muscles, which leads to muscle work minimization.

## THERMAL IMAGING AS A TOOL OF DIFFERENT BREATHING EXERCISE CHARACTERIZATION: A CASE STUDY

Formenti, D., Ludwig, N., Gargano, M., Garaldi, M., Ongaro, L., Alberti, G.

*State University of Milan*

**INTRODUCTION** Specific respiratory muscle training improves athletes' performance particularly at high intensities (Esposito et al., 2010). The aim of this study was to evaluate two types of breathing, thoracic and diaphragmatic, used in respiratory training. **METHODS** An evaluation of different respiratory muscle training is possible by the use of IR thermography (AVIO, TVS-700), a non-invasive technique that visually represents the whole process during and after training (Merla et al., 2010). The subject performed the exercise with SpiroTiger® for 5 minutes, followed by a 5 minute recovery. The exercise was repeated 15 minutes after the end of recovery-time. Thoracic and diaphragmatic breathing exercises were performed using the same protocol in different days. Ten Regions of Interest (ROI) were selected following anatomical and functional correspondence with the muscles involved in breathing (Zaidi et al., 2007). The data were analyzed with specific thermal images software. **RESULTS** In order to check functional behaviour of respiratory muscles, we calculated the correlation coefficient (R) among thermal data of all the ROI and then grouped together ROI with strong correlation ( $R \geq 0.85$ ). In thoracic exercises, correlated ROI were grouped into 4 areas corresponding to: pectoral muscles, rectus abdominus, intercostal muscles, abdominal oblique. In diaphragmatic exercises we found a strong correlation ( $R \geq 0.96$ ) between thermal data of all the ROI. The temperature of the torso decreased by a few degrees during both trainings, but there was also an increase in pectoral muscles areas to be considered. **DISCUSSION** ROI of pectoral muscles in thoracic breathing are characterized by a linear heating during exercise and also a linear trend in

the cooling-down process during the recovery time. The heating-up is linked to the work of the superficial muscles located in the upper part of the trunk that characterized the thoracic breathing. In diaphragmatic breathing, which mainly uses internal musculature, temperature does not increase in pectoral muscles areas. There is in fact a lesser contribution of superficial muscles used in thoracic breathing. In diaphragmatic breathing, more muscles synergistically participate to carry out an action: this is the reason for the strong correlation between the thermal data of all the areas. ### PREDICTION OF RELATIVE BODY FATNESS IN „WORLD GYMNAESTRADA“ PARTICIPANTS

Taeymans, J.1,2, Clijsen, R.3, Deriemaeker, P.2, Aerenhoudts, D.2, Cabri, J.4,5, Clarys, P.2

1: BUAS (Berne, Switzerland), 2: VUB (Brussels, Belgium), 3: THIM (Landquart, Switzerland), 4: NSSS (Oslo, Norway), 5: FMH-UTL (Lisboa, Portugal)

**Introduction** A low degree of relative body fatness (%BF) may be an important factor of success in sports with a high esthetic component such as gymnastics or dance. The aim of this study was to establish a prediction equation for %BF based on data gathered by an easy-to-conduct (kin-anthropometric test battery in male and female gymnasts. **Methods** Data were collected during the „World Gymnaestrada“ (Dornbirn, Austria, July 2007). From the 25'000 participating gymnasts, over 1400 volunteered in this study. In total, 818 participants agreed to conduct also a Bioelectrical-Impedance-Analysis (BIA) test. %BF was the dependent variable in the established equations in this study and was assessed using the BIA method (Tanita TBF-611, Tanita Inc., Tokyo, Japan). Kinanthropometric variables (such as Handgrip (HGR) and sum of 4 skinfolds (sum4SF) were measured using the ISAK guidelines (ISAK, 2002). Lifestyle habits under investigation were: smoking status, fruit and vegetables intake, physical activity (IPAQ), physical inactivity (minutes sitting per day) and years of gymnastic training. A backwards regression analysis was used to establish the prediction models. Significance was set at 5%. **Results** Participants from 31 different countries volunteered in this study. The best represented countries were Switzerland (35%), Germany (20%), Holland (5%) and Denmark (5%). All but 12 participants in the sample were Caucasian. Age of the active gymnasts ranged from age 12 to 82 years while mean years of training was about 28 years in the total sample. The best equation was established as:  $\{\%BF = -0.927 + (0.069 \times \text{sum4SF}) + (0.090 \times \text{HGR}) + (0.912 \times \text{BMI}) - (10.906 \times \text{GENDER})\}$  ( $p < 0.001$ ;  $R^2 = 0.700$ ;  $\text{RMSE} = 4.25\%$ ). If gender was removed from the prediction equation, the model remained significant ( $p < 0.001$ ), but its predictability ( $R^2 = 0.568$ ) and its precision decreased ( $\text{RMSE} = 5.11\%$ ). Removal of BMI from the model showed similar confounding effects ( $R^2 = 0.631$ ;  $\text{SEE} = 4.69$ ;  $p < 0.001$ ). However, removing HGR or sum4SF did not change the predictability nor the precision of the model. **Conclusion** This study presents a simple equation model including 4 predictor variables based on easy-to-conduct measurements to predict %BF in a sample of active gymnasts. Gender and BMI are confounders in the model. **References** International Society for the Advancement of Kinanthropometry, ISAK, 2002.

### PP-PM61 Health & Fitness: BMI 1

#### GROUP FITNESS ACTIVITIES ON ELDERLY: WHO IS ELIGIBLE AND WHO IS NOT?

Bianco, A.1, Patti, A.1, Centineo, V.1, Cataldo, M.C.2, Tabacchi, G.1, Mamma, C.1, Palma, A.1

1: University of Palermo. 2: Public Health District (ASP 6).

**Introduction** While it is impossible to prevent every injury, literature suggests that injury rates could be reduced by 25% if people took appropriate preventative action. On the other side, one major problem of Group Fitness Instructors is to find the right intensity/level suitable for every attendee during classes (e.g. ballroom dancing). Therefore, the aim of this study was to examine the opportunity to adopt already validated function ability tests on group fitness activities with the aim to prevent injuries and maintain or increase quality of life. **Methods** The study was conducted with a quasi-experimental design. The Berg Balance Scale (BBS) and the Barthel index (BI) were administered to an experimental group (EG) and a control group (CG) of elderly persons living in an inner city area of Palermo, Italy. EG was enrolled in three classes of ballroom dancing. Participants were assessed by BI and then submitted the BBS. The exclusion criteria were: 1) persons aged less than 58; 2) persons with a diagnosis of a disabling disease; 3) ex-professional athletes; 4) for EG, no more than 2 months of previous ballroom dancing experience. Means and SD were used to report preliminary descriptive results. For the purposes of our study a score of 70% for both scales (BBS-70% and BI-70%) was identified as the threshold value between a good and a poor performance. The STATISTICA software was adopted to perform the K-S normality test. **Results** One hundred twenty people participated to the study. We recruited 66 people as a CG (77.2 ± 6.4 yrs; 26.4 ± 4.4 BMI) and 54 people as EG (69.3 ± 8.3 yrs; 26.6 ± 4.4 BMI). The BI and BBS of CG were 76.51 ± 32 and 31.3 ± 13.2 respectively, while the BI and BBS of EG were 97.5 ± 7.7 and 51.2 ± 5.9, respectively. The BI of CG showed 0.33 K-S values while the same analysis for SG gave 0.47. We found the same trend on BBS values of CG (0.06) compared to EG (0.22). In EG, BBS-70% included 92.6% of cases compared with 24.2% of CG. The Barthel Index indicated a very similar profile: for EG BI-70% accounted for 98.1 of cases while BI-70% of CG 69.7%. **Discussion** BBS and BI promise to be able to predict who is eligible to start with Group Fitness and who is not. Indeed, the majority of the elderly persons belonging to EG reported higher BBS and BI values than the 70% threshold. Larger numbers and an accurate statistical analysis are necessary to confirm these findings. Preliminary results are very encouraging. **References** 1. ## METABOLIC, INFLAMMATORY AND FUNCTIONAL INDICATORS IN OBESE WOMEN SUBJECTED TO PILATES METHOD OF EXERCISE PROTOCOL: A PROPOSAL FOR THE PROMOTION OF HEALTH

Guimaraes, B.R.1, Neiva, C.1,2,3, Pimenta, L.D.1, Pessoa-Filho, D.M.2, Furukawa, M.3, Zaia, J.E.1

1: UNIFRAN (Franca, Brasil), 2: UNESP (Bauru, Brasil), 3: UPM (Madrid, España)

Introduction Obesity is recognized as a chronic disease of complex etiology, indicated by several authors as a worldwide epidemic, and also as one of the most important factors for the appearance of the chronic-degenerative diseases, being the main cause of morbidity and incapacity in the world. Among the most frequent problems associated with the pathology are the appearance of a chronic inflammatory state, the reduction of the basal energy expenditure, and the progressive loss of functionality. Currently, the adipose tissue is one of the main focuses of researches on obesity due to the evidence of its endocrine role in metabolic and physiologic processes that influence the pathogenesis of chronic diseases. Thus, the aim of this research was to assess the effects of an exercise program of Pilates method in promoting the general health of obese women through of modulation on inflammatory, metabolic and functional parameters. Methods Sixteen females, from 29 to 57 years old (average of 43,5 years old) were selected. The Pilates Training was executed for 8 weeks, three times a week. The plasmatic concentrations of inflammatory cytokines, the daily resting metabolic rate (RMR), and the functional capacity of the studied subjects were analyzed pre- and post-application of training period. Results The results obtained showed that physical fitness presented statistical difference between the pre and pos training period. With regard to the inflammatory cytokines studied in blood, the protocol does not promoted significant changes in the concentrations of IL6 and CRP. However, circulating CRP concentrations of 6 subjects were above normal in pre intervention featuring a subclinical inflammation State, and of these, 4 subject presented standardization of these values, after applying the training protocol. In relation to the analysis of RMR, the results obtained by the respiratory gasimetry revealed the efficiency of the protocol employed at elevation of metabolic expense (P 0.0001). Discussion The RMR is probably one of the most important factors in controlling and reducing the weight, may be strongly associated with improvement in inflammatory and functional profiles of the indicators. We conclude with the study that a Pilates training protocol can contribute greatly to improving the general health of obese women.

## INVERTED BMI VERSUS BMI AS PROXY-INDICATORS FOR ADIPOSITY DURING ADOLESCENT GROWTH

Leitao, R.1,2, Rodrigues, L.3,4, Neves, L.1, Carvalho, G.2

1: College of Education at Polytechnic Institute of Viana do Castelo (Portugal), 2: Research Centre on Child Studies at University of Minho (Portugal),

Introduction Inverted Body Mass Index (iBMI cm<sup>2</sup>/kg) has been recently proposed as a better adiposity indicator than body mass index (BMI kg/m<sup>2</sup>) based on data from a sample of healthy subjects aged 16 years and over (Nevill et al., 2011). The unstable relation between BMI and percentage body fat (%BF) during growth and its marked sex-differences are additional limitations of using BMI as an indicator of %BF in children and adolescents. Therefore, we investigated whether the inversion of BMI would result in an improvement of such limitations from a longitudinal perspective. Methods Data for the present analysis were derived from a previous study in which we have examined the individual trajectories of adiposity based on %BF in a cohort of 288 Portuguese children followed from age 9 (baseline) to age 15 (follow-up) at school setting (Leitão et al., 2011). Anthropometric parameters (Stature, weight, triceps and subscapular skinfold thickness) were measured using the standard procedures suggested by Lohman et al. (1988). BMI, iBMI and %BF derived from skinfolds (Slaughter's equations) were calculated. The non-normally distributed variables (BMI and %BF) were log transformed at both assessment time points. Pearson correlation coefficients between BMI and %BF, and between iBMI and %BF, were determined separately by sex and compared. Results Similarly to the results of the work by Nevill et al. (2011), iBMI also showed to be better approximated by the normal distribution at both age 9 and age 15. Pearson's correlation between iBMI and %BF was high at both 9 and 15 years, in boys and in girls. At baseline, r values were -0.89 (P=0.00) and -0.91(P=0.00) for boys and girls, respectively. At follow-up, r values were -0.81 (P=0.00) and -0.80 (P=0.00) for boys and girls, respectively. There were no significant differences between these values and those observed for the correlation between BMI and %BF (z-tests, P>0.05). Conclusion Although iBMI seems to correlate with %BF similarly to BMI during growth, it showed advantages for statistical applications. Further research is needed for a better understanding of the biological significance and clinical relevance of this candidate indicator of adiposity. ## BODY COMPOSITION, MUSCLE STRENGTH AND REACTION TIME FOLLOWING THREE DAYS OF FOOD RESTRICTION IN MALES

Silalertdetkul, S.

*Srinakharinwirot University*

BODY COMPOSITION, MUSCLE STRENGTH AND REACTION TIME FOLLOWING THREE DAYS OF FOOD RESTRICTION IN MALES Silalertdetkul, S. Sport Science Department, Faculty of Physical Education, Srinakharinwirot University, Thailand. Introduction Body weight is regulated by the energy balance between energy intake and energy expenditure. A decreased energy intake might affect on body composition and physical performance. Therefore, the objective of this study was to investigate the effect of three days food restriction on body composition, muscle strength and reaction time in young males. Methods Eleven active males age between 19 and 22 years participated in this study, which had been approved by the local ethics committee (body mass index, 23 ± 1 kg/m<sup>2</sup>; percent body fat, 11 ± 2%; percent fat free mass, 89 ± 2%; resting heart rate, 64±7 beat/min; maximum oxygen consumption, 58 ± 3 ml/kg/min; mean ± SD). This experiment was cross-over design with two main trials separately by at least 14 days. Participants reduced their daily food intake approximately 50% for three days. Body composition (BioScan; Maltron, United Kingdom), muscle strength (TAKEI, Japan), reaction time (THAI PHAN, Thailand), subjective feeling of hunger as well as rating of perceived exertion were measured before and after in control and food restriction group. Fasting venous blood samples were taken at the same period of time. The data were analyzed using two way repeated measures ANOVA and paired t-test. Results Total body fat (before: 7.8±1.9 kg; after food restriction: 7.2±1.8 kg, P= 0.05), total body fat free mass (before: 59.6±4.0 kg; after food restriction: 58.8±3.8 kg, P= 0.05), protein (before: 14.4±1.0 kg; after food restriction: 14.1±1.1 kg, P= 0.03), glycogen (before: 542.2±77.6 g; after food restriction: 534.5±79.0 g, P= 0.04), body weight (after control: 67.2 ± 5.4; after food restriction: 66 ± 5.4 kg, P< 0.01), leg reaction time (before: 0.68±1.1; after food restriction: 0.56 ± 0.08 ms, P= 0.04) and fasting triglyceride concentrations (before: 70±22; after food restriction: 53 ± 20 mg/dL, P= 0.02) decreased significantly following 50% of food restriction. There was

no change in muscle strength, muscle mass, arm reaction time, subjective feeling of hunger and rating of perceived exertion. Discussion A decreased 50 percent of daily food intake for three days induced decreased in body composition but there was no affect on arm reaction time, muscle mass and muscle strength.

### THE ENERGY "GAP" AND RISK OF WEIGHT-LOSS RELAPSE: DIFFERENCES IN SELF-REPORTED VS MEASURED PHYSICAL ACTIVITY

Hume, D.J., Kroff, J., Carstens, M., Goedecke, J., Lambert, E.V.

*University of Cape Town*

**Introduction:** Relapse in the first 3-5 years following weight loss is a common problem in obesity management (Ross, 2009). The extent to which physiological (Jackman et al., 2008) vs behavioural adaptations contribute to weight loss relapse is not clearly understood. Moreover, there is some indication that an 'energy gap' or leading to positive energy balance and weight regain (Ross et al., 2000) may be related to lower levels of physical activity. The present study was designed to identify measurable differences in energy metabolism and substrate utilization (both at rest and during exercise, respiratory exchange and maximal rate of fat oxidation during exercise, Fatmax), as well as differences in self-reported energy and nutrient intake, reported and measured physical activity energy expenditure, in weight-stable (WS) and reduced-obese (RO) women, matched for body mass index and age. **Methods:** In a convenience sample of 44 women, body mass index, waist circumference, body composition (BIA), energy intake and nutrient intake, physical activity (Actigraph GT3X), and energy metabolism (resting respiratory exchange ratio and Fatmax) were measured. Questionnaires related to family history, demographics, physical activity (PA, Global Physical Activity Questionnaire), and eating and dieting behaviour were administered. **Results:** Mean age was 38 +/- 11 yrs and mean BMI was 24 +/- 2 kg/m<sup>2</sup>. No significant differences were found between the RW subjects and the WS group for weight, waist circumference, fat-free-mass (FFM) or body fat percentage. Group were different for highest adult weight (P = 0.00028), total weight lost and percent body weight lost (P < 0.00001). Groups were also similar with respect to dietary energy intake, resting energy expenditure and maximal rates of fat oxidation during exercise. Measured physical activity was not different between groups, however, self-reported moderate PA (270 vs 113 min/wk; P = 0.02) was higher in the RW group. **Discussion:** Eating behaviour, energy metabolism, and fat oxidation appear to remain unperturbed in women who experience reductions in body weight of 14+/- 5.4% or less. However, the RW women over-reported moderate PA by more than 100 min on average per week. This finding suggests that reduced weight women are at risk of weight regain due to errors in perception related to levels of physical activity, rather than weight loss-induced changes in physiology. **References:** Ross R. ### SEASONAL VARIATION OF BODY COMPOSITION OF EACH BODY SEGMENTS IN JAPANESE FEMALE UNIVERSITY STUDENTS.

Yumigeta, R., Tsunoda, N., Horikawa, H.

*Showa university*

**SEASONAL VARIATION OF BODY COMPOSITION OF EACH BODY SEGMENTS IN JAPANESE FEMALE UNIVERSITY STUDENTS.** Yumigeta, R.1, Tsunoda, N.2, Horikawa, H.1 1:Showa University (Yamanashi, Japan), 2:Kokushikan University (Tokyo, Japan) **Introduction** It is important for keeping health to recognize the change in the body composition. In previous study, it is well known that seasonal variation of body composition in human body. However, whether the body fat and the muscle in which segments of the body were changed when the variation is seen in the body composition is not clear. The purpose of this study was to clarify the seasonal variation of body composition of each body segments in Japanese female university students. **Methods** The subjects were 139 healthy female university students who live in the dormitory for nine months. And also, the subjects were the almost the same life style. Their mean (SD) values of age, height and BMI were 18.2(0.5) yrs, 159.2(5.1) cm, 21.0(2.2), respectively. Body weight(BW), percentage of body fat in whole body(FWB), left arm(FLA), right arm(FRA), left leg(FLL), right leg(FRL) and trunk(FTK) and muscle volume in whole body(MWB), left arm(MLA), right arm(MRA), left leg(MLL), right leg(MRL) and trunk(MTK) were measured by bioelectrical impedance analysis method(TANITA, Japan). Each item was measured in spring(April), summer(July), autumn(October) and winter(November). And also, each item was measured that subjects get up and after urination as soon as possible. **Results** Significant increase for BW was showed from summer to autumn and autumn to winter. Significant decrease for FWB was showed from spring to summer. On the other hands, significant increase for FWB was showed from summer to autumn. Significant increase for MWB was showed from spring to summer and autumn to winter. FRA and FLA were significant increased from summer to autumn and autumn to winter. FRL, FLL and FTK were significant decreased from spring to summer. On the other hands, FRL, FLL and FTK were significant increased from summer to autumn. **Discussion** From these results, significant increased for BW from summer to autumn was caused to FWB. On the other hands, significant increased for BW from autumn to winter was caused to MWB. Significant decreased for FWB from spring to summer was caused the decrease of FRL, FLL and FTK. On the other hands, It was considered that a significant increase for FWB from summer to autumn was depended on the increase of FRA, FLA and FTK and the increase of FRL and FLL according to significant decrease of the MRL and MLL. **Reference** Abe, T., Tanaka, F., Kawakami, Y., Yoshikawa, K., and Fukunaga, T.(1996)*Med.Sci.Sports Exerc.*, 28, 908-912.

### INFLUENCE OF GENDER, AGE AND BMI OF ADOLESCENTS IN THEIR PHYSICAL ACTIVITY PATTERNS

Botelho, G., Ferrao, A., Aguiar, M.

*Coimbra College of Agriculture, Polytechnic Institute of Coimbra*

**INFLUENCE OF GENDER, AGE AND BMI OF ADOLESCENTS IN THEIR PHYSICAL ACTIVITY PATTERNS** Goreti Botelho<sup>1,2</sup>, António Ferrão<sup>3</sup> and Marco Aguiar<sup>3</sup> 1: Department of Food Science and Technology, Coimbra College of Agriculture, Polytechnic Institute of Coimbra, (Coimbra, Portugal), 2: CERNAS Research Unit, Coimbra College of Agriculture, (Coimbra, Portugal), 3: University of Trás-os-Montes and Alto Douro (Vila Real, Portugal). **Introduction** During adolescence, regularly practicing physical exercise promotes the harmonious development of the body and improves physical appearance which is very important. However, physical activity patterns in youth have changed as a result of an increase in time spent watching television, the advent of video games and the internet, and a decrease in the opportunities for physical activity in schools and/or communities. This study aimed to investigate relationships among gender, age, body mass index (BMI), and physical activity (PA) patterns of 9-14 years Portuguese adolescents. **Methods** A new questionnaire entitled "Questionnaire to Assess Physical Activity and Sedentarism, QAPAS" based on two previous questionnaires, QAPACE (Barbosa et al., 2007) and

HBSC (2001-02) was developed and applied. Participants of this school-based cross-sectional study were a random sample of 1403 students, 9-14 years (mean age:  $10.64 \pm 0.76$ , 50.0% males and 49.9% females, with 0.1% of no answer) from 7 public schools of the municipality of Viseu city (representing 86.9% of the total students population of these schools). BMI was calculated and the adolescents were categorized as underweight, normal weight, overweight and obese, according to CDC guidelines. Data analysis was performed using SPSS software v. 20.0. Results From BMI results, 4.4% of adolescents are underweight (2.0% males, 2.4% females), 68.1% show normal weight (32.5% males, 35.6% females), 18.6% are overweight (10.3% males, 8.3% females), and 8.6% are obese (5.2% males, 3.4% females). Discussion Analysing PA duration by age, statistically significant differences between students with different ages were found, only for the last seven days (30 min. per day). In general, the PA increases with age, from 9 to 14 years. Taking into account the influence of gender, a statistical significant difference of PA patterns was found, with male students showing more time spent with physical activities in the past seven days and in a normal week of the year. ### **BODY COMPOSITION DETERMINED BY BIA METHOD IN CHILDREN AND USE FOR OVERWEIGHT AND OBESITY ASSESSMENT.**

Bunc, V., Hráský, P., Balas, J., Skalská, M.

*Faculty of P.E. and Sports Charles University*

BODY COMPOSITION DETERMINED BY BIA METHOD IN CHILDREN AND USE FOR OVERWEIGHT AND OBESITY ASSESSMENT. Bunc, V., Hráský, P., Baláš, J., Skalská, M. Faculty of Physical Education and Sports Charles University Prague, Czech Republic Introduction The prevalence of overweight and obesity varies according to age, gender, race and socioeconomic classes. Body mass (BM) is a function of energy and nutrient balance over an extended period of time. Energy balance is determined by macronutrient intake, energy expenditure, and energy nutrient partitioning. The obesity management is strongly dependent on the methods that may be used for detection of early overweight or obesity. Increases in childhood overweight and obesity have emphasized the importance of accurate and accessible body composition (BC) assessment, especially in monitoring prevention and treatment effort. Using body mass index (BMI) is slightly simpler than using the prediction equations and can be used in big population studies, but the standards are strongly dependent on the population and age of evaluated subjects. BMI has achieved international acceptance because of being calculated from the subject's BM and body height that are easy to be individually measured. Bioimpedance analysis (BIA) seems to be one of the simple, safe, and inexpensive method for assessment of BC in children. Therefore we focus on verification of BIA method in children and thus on development of the obesity identification tool that are dependent on the gender, age and level of fitness, but also on fat distribution. Methods and Results Four-thousand-forty five children aged 6-14 years (2486 – 57.9% boys, and 1809 – 42.1% girls) were evaluated BC by multi-frequency bioimpedance analyser by using of adapted prediction equation for Czech children. The verification of predicted equation was realized with help of DEXA method. The mean value of %BF in all boys was  $19.79 \pm 2.37\%$ , and the same in girls was  $22.18 \pm 4.51\%$ . In age of 6 years we found in group of boys the mean %BF  $22.4 \pm 4.1\%$ , the  $8.0 \pm 1.0\%$  of boys was obese and  $15.0 \pm 3.1\%$  boys was overweight, in girls of the same age we found  $24.5 \pm 4.0\%$ ,  $8.0 \pm 1.5\%$  and  $16.0 \pm 2.1\%$ , the same data in boys of age 14 years were  $18.0 \pm 2.8\%$ ,  $11.0 \pm 2.0\%$ ,  $19.0 \pm 3.0\%$ , and the same in girls  $21.4 \pm 3.0\%$ ,  $12.0 \pm 1.7\%$ ,  $19.5 \pm 2.0\%$ . Linear regression analysis showed a significant positive relationship between %BF measured and BMI  $\%BF(\%) = 0.921 * BMI(kg.m^{-2}) - 4.292$ ,  $r = 0.858$ ,  $r^2 = 0.736$ ,  $SEE = 1.22\%$  in boys, and in girls  $\%BF(\%) = 1.284 * BMI(kg.m^{-2}) - 6.906$ ,  $r = 0.903$ ,  $r^2 = 0.815$ ,  $SEE = 1.05\%$ ,  $p < 0.0001$  in both cases. Conclusions The BIA method is a useful method for detecting BC in children and may be declared like a precise tool for measuring of BC in epidemiological studies in children. The decisive role for this using of this method plays the population oriented prediction equation and subject's hydration state. The study was implemented with support from Research Grant of Czech Ministry of Education MSM 0021620864.

### **DIFFERENTIATED APPROACH TO DEVELOPMENT OF PHYSICAL ACTIVITY PROGRAMS FOR WOMEN BASED ON THE PPARG AND ACE GENES POLYMORPHISMS**

Drozdovska, S., Andrieieva, E., Borovik, O.

*NATIONAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORT OF UKRAINE*

Introduction The differentiated approach allows improving the therapeutic effects, achieving the agreement of the aim and training effect as well as avoiding unwanted effects and complications. The modern methods of molecular genetics of physical activity make possible individualization of the training based on the genetic markers – the polymorphisms of the genes coding the metabolic and muscular tissue features in human (Bouchard C., 2001; Ahmetov I., 2006). Manifestation of the health improving effects of fitness exercises include the changes in the body composition. The objective of the study is to investigate the relationship between body composition and polymorphic variants of PPARG and ACE genes in people involved into exercise training. Methods The body composition of 44 women involved into different types of physical exercises was evaluated. DNA was isolated from the buccal epithelium. I/D polymorphism of ACE gene and Pro/Ala polymorphism of PPARG gene were studied using the method of polymerase chain reaction (PCR). The body composition was determined on TANITA device. Results The correlation between BMI, physical fitness index, body composition and polymorphisms of ACE and PPARG genes were determined in women aged 21-35 years. The polymorphism of PPARG gene had a definite effect on Pignet index value ( $p=0.031$ ). Pignet index was 2.1 higher in the group with Pro/Pro genotype than in the group of Ala allele carriers. BMI was 18.7% higher in the women with D/D genotype than in the group with I/D genotype. Strength training resulted in significant changes in the body composition with insignificant reduction of the body weight and girth measurements in the women aged 21-35 years with Pro/Ala and Ala/Ala genotype. The women with Pro/Pro genotype had more evident reduction of the body weight and girth measurements, but the body composition changed less significantly. Aerobic training resulted in 4.3% reduction of the body weight and 3.98% reduction of the fat content in the women with Pro/Pro genotype; in women with Pro/Ala and Ala/Ala genotype these parameters were reduced by 6% and 6.97%, respectively. Discussion Different types of physical exercises cause monodirectional changes of the morphofunctional parameters in the women aged 21-35 years with the different genetic traits. However, dependence of the parameter increase values on the molecular genetic features was observed. Their determination makes possible to identify the exercises most favorable for physical fitness improvement, to develop the appropriate training program and to avoid the risk of the unwanted consequences. The strength training was less effective for the weight reduction in the women with Pro/Ala and Ala/Ala genotype. The most effective changes in the body weight after strength training were recorded in the groups of the women with Pro/Pro genotype.

changes in BMI confirm this tendency. References Bouchard C. (2001). *Med Sci Sport Exerc*, V. 33., P. 446-451. Ahmetov I. (2006). *The 5th International Conference on Strength Training*, Odense, Denmark, P. 7.

#### DO BODY MASS INDEX, SEX, TREATMENT AND AGE INFLUENCE THE BODY WEIGHT LOSS?

Rojo-Tirado, M.A.1, Benito, P.J.1, Peinado, A.B.1

*Facultad de Ciencias de la Actividad Física y del Deporte (INEF), Universidad Politécnica de Madrid (Madrid, España)*

**Introduction** Most studies have described how the weight loss is when different treatments are compared (1-3), while others have also compared the weight loss by sex (4), or have taken into account psychosocial (5) and lifestyle (6, 7) variables. The aim of this study was to compare the body weight (BW) loss slope between overweight (OW) and obese (OB) people, taking into account the sex, treatment and age influences. **Methods** One hundred eighty people (84 OW and 96 OB, with BMI: 25-29.9 and 30-34.9 kg•m<sup>-2</sup>, respectively), aged from 18 to 50 years, participated in the study (36 and 49 males, and 48 and 50 females, respectively) during 6 months. Four types of treatments were randomly assigned: strength training (S, n=19 and 24), endurance training (E, n=25 and 26), combined S and E training (SE, n=22 and 24), and diet and physical recommendations (C, n=18 and 22). All participants followed a 25% calorie restriction diet. Slopes of the dynamics of weight loss were obtained through a linear equation, when initial and final BW was plotted on a graphic. A MANOVA was used to determine differences between slopes. Probability level for statistical significance was set at  $\alpha=0.05$ . Results The slope of OB (-0.804±0.041) was higher than OW (-0.555±0.044) (F<sub>1,134</sub>=17.143; p<0.001). When the slope was compared between groups, only S and E had higher slope in OB (-0.781±0.076 and -0.897±0.077, respectively) than in OW (-0.426±0.094 and -0.566±0.08, respectively) (p<0.05). When the slope was compared between sexes, men and women from OB had higher values (-0.825±0.058 and -0.783±0.057, respectively) than OW (-0.627±0.069 and -0.482±0.057) (p<0.05). When the slope was compared between age ranges, only the ranges 18 to 30 and 41 to 50 years of OB (-0.829±0.09 and -0.865±0.051, respectively) had higher values than OW (-0.491±0.095 and -0.622±0.062, respectively) (p<0.05). **Discussion** The slope of BW loss is higher for OB than OW. By groups, S and E in OB have higher slope than in OW. By age, 18 to 30 and 41 to 50 of OB have higher values than OW. Both sexes have higher slope in OB than in OW. **References** 1. #### ASSOCIATIONS BETWEEN BODY MASS INDEX AND OSTEOARTICULAR SYMPTOMS IN DIFFERENT BODY REGIONS AMONG WORKERS

Silva, I., Santos, R., Mota, J.

*FADEUP*

**Introduction:** Obesity rates are high among employed adults and have shown consistent increase over the past few decades. Musculoskeletal disorders related to work are a major cause of disability in working age individuals. Several studies have linked obesity with musculoskeletal disorders, the repetitive work can contribute significantly to the increase of these disorders in obese workers. The aim of this study was to verify the Associations Between Body Mass Index (BMI) and osteoarticular symptoms in different body regions among workers. **Methods:** The sample derived from worksite intervention with 212 factory workers (124 women), aged 37.6±8.2 years. Weight and height were measured with standardized protocols and BMI was calculated and participants were classified as normal weighted (BMI≤24.9kg/m<sup>2</sup>) or overweight/obese (BMI≥25kg/m<sup>2</sup>). Musculoskeletal pain was assessed with the Nordic Questionnaire of Osteoarticular Symptoms. **Result:** Baseline results from this worksite intervention show that overweight or obese participants were more likely to have Osteoarticular Symptoms in the shoulders (OR=2.203, p=0.009) and in the hand (OR=1.780, p=0.04). **Discussion/Conclusion:** Our results emphasise the need of worksite intervention to promote healthy weight as a way to prevent Osteoarticular Symptoms.

#### THE VERTICAL CHANGE OF THE CENTER OF GRAVITY BROUGHT BY THE INCREASED STEP LENGTH

Miyamoto, R.1,2, Muranaga, S.1, Ishige, Y.3, Osawa, Y.1, Ino, Y.1, Higashi, T.1

*1:Kameda Institute of Sports Sciences and Medicine(Chiba,Japan),*

**Introduction** One of the biggest factors to hinder the expansion of healthy life expectancy is a decline of the walking ability. Studenski have reported that there is a relationship between walking speed and life span. Muranaga et al developed a simple test, which is called "2 steps test", to measure walking ability easily. In our facility, we conduct the "2 step test" as an enlightenment activity to prevent falls in elderly population. The purpose of this study is to compare of body center of gravity in vertical direction measured by the "2 steps test". For reference, 2 steps value 0.8 is considered as a fall danger and its 1.5 is a normal. **Method** Subjects were 10 healthy males and 10 healthy females. (age:24.0±2.7year • 4.8±4.6years, height173.8±5.9cm • 162.4±4.6cm,weight65.8±5.4kg • 58.4±5.7kg ) Each subjects performed 2 trials and the 2steps value must be from 0.8 to 1.5. 29 landmarks on the subject's body were captured and analyzed by the motion capture system (Eva-RT, Motion Analysis, USA) and the ground reaction force was also measured during all trials. Musculoskeletal model (nMotion muscular, NAC, JAPAN) was used to calculate the body center of gravity. We compiled statistics on the 2 steps value from 0.8 to 1.5. They were processed through the one way analysis of variance and multiple comparisons. **Results** The averaged center of gravity in vertical direction displacement was 7cm. This was corresponded the 2 steps value 0.8, which was in dangerous level for falling. At its value 1.2, it showed 11.4cm in unstable gait level and showed 18.6cm in normal gait level at its value of 1.5. There were statistically significant difference between 2 steps level 0.8 and 1.2, 1.3, 1.4, 1.5 (P<0.05). **Conclusion** The result of this study showed that the averaged center of gravity in vertical displacement was 18.6cm corresponding to 2 steps value 1.5, which is in normal gait level. Furthermore, this

difference in the center of gravity was about 10cm when 2 steps value 0.8 was compared with its 1.5. Therefore, we considered that the muscle strength in lower extremity needed to be able to tolerate the vertical displacement in the center of gravity. In addition, the resemble strength is indispensable to improve in walking ability to prevent fallings. It is proven that an extended step length brought the greater vertical displacement in center of gravity. This suggests that walking with larger strides would become one of the useful training to develop the muscle strength in lower extremity. We plan on introducing muscle activation value measures by EMG and joint torque as our next step. References Studenski S et al, (2011) The Journal of the American Medical Association, 305(1) 50-58

### **'AN EXAMINATION OF SEDENTARY AND EATING ATTITUDES OF A SPANISH UNIVERSITY POPULATION: THE INFLUENCE OF STUDYING NURSERY ON ITS STUDENTS OWN BEHAVIOUR.'**

Varela, V., Cancela, J.M., Ayán, C.

*Vigo University*

Introduction: Future education and health professionals will be responsible for encouraging physical activity and correct eating habits among the general population. However, it has been noted that the period of undergraduate study is often a phase of change in terms of practice of PA, often reduced<sup>1</sup>, and indeed dietary habits curb to less healthy options<sup>2</sup>, notably among females university students. The aim of this study was to discover the prevalence of physical activity and the existence of eating disorders among Nursing, Physiotherapy and Education students. Materials and Methods: A transversal descriptive study through a combination of the International Physical Activity Questionnaire and the Eating Attitude Test 40 was directed to students that take part in the aforementioned degrees in the Pontevedra Campus at Vigo University. The data collection took place during a single day in the class with the most registered students for the selected course and academic year through an individual, anonymous and voluntary questionnaire on an "ad hoc" basis. Results: The data showed that 64% of Nursing students and 72% of Teaching students were qualified as sedentary individuals, while 19.5% and 15.3% of them respectively were likely to suffer from eating disorders. A significant association between physical activity performance and disturbed eating behaviours was observed among Education students. Discussion: The practice of PA has been identified as a risk factor linked with the existence of DEA3 among university students<sup>4</sup>, which coheres with the results of this particular study. However, this behaviour was only found to be significant among teaching students, albeit the results that showed that Nursery and Teaching students presented similar health patterns. As a result, it has been recognised that sedentary behaviour and poor dietary habits are linked to students within the vocations of health and education. References: 1. ### **BODY COMPOSITION AND PHYSICAL FITNESS AMONG ITALIAN POLICE OFFICER.**

MASSIDDA, M.1, ARGIOLAS, C.2, DIANA, A.3, CARBONI, D.2, CALO, C.M.1

*University of Cagliari and Italian State Police*

Introduction Police officers need to be physically fit, due to the potential need for officers to be able to exert maximum efforts and to undertake the role operationally. A review of the literature suggests that officers achieve an acceptable measure of physical fitness during academy training and before the fitness test for become a policeman. However, without fitness maintenance programs, these gains achieved are shortly lost (Lee, 2007). Purpose The aim of this study was to determine the impact of body weight on fitness tests among the personnel of an Italian State Police Department. Methods Twenty nine police officers (37.3 +/- 4.9 years; body mass index 26.1 +/- 1.9; body mass 78.4 +/- 8.2 kg; height 173.1 +/- 4.1 cm; body fat percentage 17.0 +/- 3.0; predicted VO<sub>2</sub> max 46.0 +/- 6.5 mls/kg/min) participated in this study. In order to evaluate the fitness level of the policeman, we applied a testing procedure that included measurements of 4 fitness tests and 9 body anthropometric tests. The body composition was analyzed by bioelectrical impedance analyses (Handy 3000, DS Medical), while the neuromuscular capacity was measured by Squat Jump, Counter Movement Jump and Bench press tests (Myotest PRO) and the aerobic capacity by Cooper test. Results A negative correlation was found between body fat parameters and Cooper test (Arm Fat Area, r=-0.63; Calf Fat Area, r=-0.62; Biceps thickness, r=-0.57; Triceps thickness, r=-0.67; Calf thickness, r=-0.64; Fat%, r=-0.58). Also a negative correlation was found between body fat percentage and VO<sub>2</sub>max (r = -0.58), while a positive correlation was found between the power and strength of upper limb and Arm Muscle Area (Power, r=0.76; Strength, r=0.74). Finally, a positive correlation was found between VO<sub>2</sub> max and lactate (LA) concentration measured during the second minute after Cooper test (r=0.58). Discussion The positive correlation between VO<sub>2</sub> max and LA concentration after exercise suggested that the policemen lactate tolerance is a benefit that combines the capacity of fatigue tolerance with the good value of VO<sub>2</sub> max. These two factors are essential for exert effort during particular situation, as apprehending the suspect. Finally, our results showed a great heterogeneity among the sample as far as aerobic capacity and fat parameters. It would be useful a reduction of this variability through a weight-management program realized with a structured physical activity protocol. This requires long-term physical activity program inside the policeman's everyday tasks. References Lee, J. (2007). Handbook of Police Administration, 289-303. Jim Ruiz and Don Hummer Eds.

### **VALIDITY AND ACCURACY OF THE OMRON WALKING STYLE PRO PEDOMETER – COMPARISON OF DIFFERENT WEARING LOCATIONS**

Hinrichs, T., Platte, K., Moschny, A., Platen, P.

*University of Bochum*

Introduction: As pedometers are inexpensive tools to measure walking, they are frequently used as motivational tools in walking interventions. To increase compliance with pedometer use, handling should be as easy and convenient as possible. According to the manufacturer, the Omron Walking Style Pro pedometer can be worn at various locations on the body. The aim of this study was to evaluate validity and accuracy of this pedometer when worn at different locations. Methods: Forty subjects (20 males, 20 females) aged 37.5 ± 14.7 years (body mass index 24.4 ± 3.8 kg/m<sup>2</sup>) participated in the study. All participants wore the Omron Walking Style Pro (HJ-720IT-E2; Omron Healthcare) pedometer on the left side of the body at the following locations: shirt's chest-pocket, waist belt, sling bag, and pant's front-pocket. One single instrument was used for all measurements to exclude any influence of inter-instrumental differences on the results. Every participant walked (self-paced) four times on an oval 400 meter outdoor track. The wearing location of the pedometer was

changed (in randomized order) after every lap. To determine the actual steps (AS) taken, every lap was videotaped and analyzed for number of steps and time. For every location the intra class correlation (ICC) between AS and steps measured by pedometer (PS) and the absolute percentage error [APE=(PS-AS)/AS\*100%] was calculated. Results: AS, walking speed, and stride length did not differ between the four wearing locations. ICC (95% confidence interval) between AS and PS was 0.990 (0.980; 0.995) for the shirt pocket, 0.989 (0.980; 0.994) for the waist belt, 0.988 (0.976; 0.994) for the sling bag, and 0.968 (0.941; 0.983) for the pant pocket. APE was  $-0.35 \pm 0.92\%$  for the shirt pocket,  $0.03 \pm 1.03\%$  for the waist belt,  $-0.35 \pm 0.99\%$  for the sling bag, and  $-0.22 \pm 1.80\%$  for the pant pocket. Conclusion: This study revealed a high validity and accuracy of the tested pedometer during self-paced walking when worn at different locations on the body.

#### **BIOELECTRICAL IMPEDANCE VECTORIAL ANALYSIS AND THE EVALUATION OF A BODY WEIGHT REDUCTION PROGRAM IN OBESE WOMEN.**

Lima Ribeiro, S., de Melo, C.M., Louzada, E., Tirapegui, J.

*University of São Paulo*

This study aimed to introduce bioelectrical impedance vectorial analysis (BIVA) for the evaluation of a body weight reduction program in obese women. Twenty-four women, aged 30 to 50 years old and BMI of 30 - 45 kg/m<sup>2</sup> were studied. The women were submitted to a nutritional education and a physical exercise program for four months, and were evaluated for: body mass index; body fat mass and fat free mass (DEXA-dual energy X-ray absorptiometry); bioelectrical impedance vectorial analysis-BIVA; serum albumin (by colorimetric method) and total body water (by deuterium). As main results, total body water presented normal range values at the end of the program; however, fat free mass and serum albumin were reduced. The data for BIVA suggest that water imbalance may contribute to the reduction in fat-free mass in some of the participants. As conclusion, BIVA analysis was found to be a promising tool to investigate body composition changes in low-grade obese women, but it should not be adopted as an exclusive analysis. In addition, individual analysis of results seems to be more appropriate than statistical comparison between groups.

#### **AGREEMENT BETWEEN ESTIMATED FAT MASS BY ANTHROPOMETRY AND BIOIMPEDANCE IN GIRLS AGED 11-15 YEARS**

Simoes, F.1, Rego, I.1, Machado-Rodrigues, A.1, Valente-dos-Santos, J.1, Leite, N.2, Ronque, E.3, Cyrino, E.S.3, Rama, L.1, Courteix, D.4, Coelho-e-Silva, M.J.1

*Universidade de Coimbra*

AGREEMENT BETWEEN ESTIMATED FAT MASS BY ANTHROPOMETRY AND BIOIMPEDANCE IN GIRLS AGED 11-15 YEARS Simões F1, Rêgo I1, Machado-Rodrigues A1, Valente-dos-Santos J1, Leite N2, Ronque E3, Cyrino E3, Rama L1, Courteix D4 Coelho-e-Silva MJ1 1Faculty of Sports Sciences and Physical Education, University of Coimbra, Coimbra, Portugal; 2State University of Londrina, Parana, Brazil; 3Federal University of Parana, Curitiba, Brazil; 4Laboratory of Biology of Physical Activity (EA 3533), University of Clermont Ferrand, France Introduction Percent of body fat mass estimated by anthropometry (Slaughter et al. 1988) is often used. The equations emerged from a sample of 136 females (16 prepubescent, 29 pubescent, 59 postpubescent, 32 adult) using the triceps and subscapular skinfolds [%BF<sub>TS</sub>=1.33\*(T+S)-0.013\*(T+S)<sup>2</sup>+2.5; when T+S<35 mm]. In contrast to males, equations were not specific for pubertal groups. The present study examined the agreement between estimates of FM by anthropometry and bioimpedance assessment (BIA). Methods Eighty-nine adolescent females participated in this study (11.0-15.7 years; 46.5 (7.9) kg; 157.1 (8.5) cm). Skinfolds were measured as described by Lohman et al (1988). Fat mass (FM) was assessed with a standard tetrapolar BIA technique (BIA 101 Impedance Analyzer; Akern, Florence, Italy). The normality was verified by Kolmogorov-Smirnov test, with Lilliefors' corrections and by visual inspection. Linear regression was used to examine the coefficient of determination (R<sup>2</sup>), standard error of estimation (SEE), slope, intercept and agreement between methods (Bland-Altman plots). Results Anthropometry underestimated FM when compared with BIA (R<sup>2</sup> = 0.78, 95% CI 0.68-0.85; SEE= 1.7 kg, 95% CI 1.5-2.0). The slope of the calibration equation was 1.1 (95% CI 0.97-1.2) suggesting no proportional error between methods. The intercept of the calibration equation was 1.6 (95% CI 0.33-2.8) which was significantly different from zero (p<0.05). Mean difference between estimates was 2.4 kg (SD=1.7 kg) and limits of agreement ranged from -0.9 kg to +5.8 kg. Meantime, stepwise linear regression, based on log transformed values, obtain a model that significantly predicts FM by BIA from FM by anthropometry, body mass, suprailiac and abdominal skinfolds (R<sup>2</sup> = 0.85 95% CI 0.79-0.89; SEE= 1.4, 95% CI 1.24-1.67). Discussion/Conclusion Although BIA is not a criterion method, its agreement with equations proposed by Slaughter and colleagues (1988) seemed to be improved when body mass and skinfolds are considered. Since body mass is moderately related with pubertal status and maturation, future research is needed to propose specific equation for pre-pubertal, pubertal and post-pubertal girls. #### **COMPARING OF PEAK TORQUE ON LOWER LIMBS BETWEEN INDIVIDUALS WITH PARKINSON DISEASE AND HEALTHY INDIVIDUALS.**

Silva, M., Fonseca, R., Lima, R., Martins, W., Medeiros, F., Costa, J., Tolentino, G., Cruz, L., Oliveira, R.

*Universidade de Brasília - UnB*

Introduction Of the many motor symptoms associated with Parkinson's Disease (PD), the symptoms considered cardinal are: shaking palsy, bradykinesia or slowness of movement, rigidity and postural instability (Fahn, 2003). Muscle weakness also has been identified as one of the most important motor symptoms associated with PD, manifesting itself since the beginning of the disease, but there are not many studied about this (Cano-de-la-Cuerda et al, 2010; Corcos et al, 1996). Thus the present study aim is comparing the muscular

strength of lower limbs in individuals with PD and neurologically healthy individuals matched by age and gender. Methods Participated in this study 27 volunteers that were divided into Parkinson's group (PG - age: 63.5 SD 1.8 years, body weight: 74.7 SD 13 kg, height: 1.67 SD 0.08 m) and control group (CG - age: 61.5 SD 1.9 years, body weight: 76.2 SD 7.2 kg, height: 1.69 SD 0.06 m). Muscle strength was measured by the extent of knee isokinetic (Biodex System 3) at a speed of 90 ° per second and the highest value was determined as Peak of Torque (PT). T test was used to compare means between groups ( $p \leq 0.05$ ). Results The results showed no significant differences for the absolute peak torque of the lower limbs between PG (132.4 SD 41.8 N / min) and CG (140.2 SD 21.4 N / min). Discussion This study did not find significant differences between groups. These results may be consistent with the speed of movement in the motor disturbances resulting from Parkinson's Disease does not affect the execution of movements. Studies have shown a tendency to decrease in muscle strength with increasing speed of movement in individuals affected by PD (Pedersen et al, 1997; Nogaki et al 1999; Inkster et al., 2003, Paasuke et al., 2004). The motor symptoms associated with loss of strength in PD is known for Bradykinesia (Berardelli et al, 2001) and apparently moving speed protocol used in this study indicates the time that this motor symptom is not present. ## NEUROMUSCULAR FATIGUE DURING REPEATED MAXIMAL STATIC EXERTION IN INTERNATIONAL RUGBY UNION PLAYERS.

Lacome, M.1,2, Piscione, J.1, Bourdin, M.2

1. Research Department, F.F.R (Marcoussis, France) 2. University of Lyon, LBMC, (Lyon, France).

Introduction Rugby is an intermittent high intensity activity, which differs in nature with player position. Forwards are mainly involved in static exertion whereas backwards performed more sprints. Physiological and metabolic responses of repeated-sprint activities specific to field-based team sports had previously been well documented (e.g. (1)) but studies dealing with physiological consequences of repeated isometric activity were scarce. The aim of this study was to explore neuromuscular fatigue occurrence during repeated isometric maximal exercise simulating scrum effort. Methods The experiments were carried out on 9 French male international rugby union players (18.8 ± 0.4 years, 186 ± 5.5 cm, 100.8 ± 11.2 kg). Subjects were asked to perform, as hard as they can, twelve 5-s isometric static exertions against a scrum simulator (FFR-Thales Scrum Simulator) interspaced with 15-s rest. Strong verbal encouragement was provided to each subject during the entire testing procedure. During the test, all the forces expressed against the scrum simulator were recorded with 3 forces sensors MC5-10000 (AMTI inc, Waterdown, MA). EMG signal was treated using Root Mean Square (RMS) and Mean Power Frequency (MPF) methods for rectus femoris (RF), vastus medialis (VM) and vastus lateralis (VL). EMG RMS and MPF were normalized with respect to the value obtained for the first repetition. All data were synchronized using a Biopac MP150 (Biopac System inc, CA, USA). Results Preliminary results demonstrated that mean force decreased significantly ( $p < 0.05$ ) from the fourth repetition (1966.5 ± 336.4 N) to the last one (1819.2 ± 454.8 N). Normalized RMS of the VM was significantly lower from the fourth repetition ( $p < 0.05$ ). For RF and VL, normalized MPF decreased significantly from the fourth repetition (96.0 ± 4.2 and 95.7 ± 3.8 % respectively;  $p < 0.05$ ) but not for VM. Discussion In line with previous study about repeated sprint exercise (2), our preliminary results showed decline in performance during repeated maximal isometric exercise matched with neuromuscular fatigue. Decrease in RMS values for VM could be interpreted as change in coordination. Decrease in MPF values for VL and RF tended to demonstrate that peripheral fatigue occurs. It is interesting to note that decrease in force was less than these observed in repeated maximal running or cycling (2) for similar exhausting conditions. References 1. ## COMPARISON OF AN INTERMITTENT AND CONTINUOUS FOREARM MUSCLES FATIGUE PROTOCOL WITH MOTORCYCLE RIDERS AND CONTROL GROUP

Marina, M.1, Torrado, P.1, Angulo-Barroso, R.1, Busquets, A.1, Rios, J.G.2, Gasol, X.3, Turmo, T.3

1: INEFC (Barcelona, Spain); 2: Facultad Biología (UB); 3: CAR (San Cugat, Spain)

Introduction The motorcycle riders fatigue of the right forearm muscles is particularly relevant given their functional role in braking and accelerating. EMG frequency decrease and EMG amplitude increase during a sustained submaximal contraction until failure in a fatigue protocol are widely accepted. In contrast, EMG outcomes from an intermittent fatigue protocol are quite controversial (Clancy et al., 2008; Quaine et al., 2003). Methods Twenty road racing motorcycle riders participated as the experimental group whereas 39 subjects participated as a control group. Once obtained the maximal voluntary contractions (MVC) baseline value, 50% and 30% of MVC were calculated and normalised. All subjects performed an intermittent protocol (IP: composed by 25 rounds as maximum) and a continuous one (CP: 50% MVC until exhaustion). A forearm discomfort questionnaire was conducted with the riders. To measure the force exerted against the brake lever we used a unidirectional gauge. A ME6000 EMG system was used to register flexor digitorum superficialis (FS) and carpi radialis (CR) EMG signals (normalized RMS -NMRS- and median frequency-NMF-). Results In the CP, riders and control groups' average durations were not different ( $t=1.85$ ;  $p=0.07$ ). In the IP, the mean number of rounds per group was significantly different ( $p \leq 0.001$ ). The IP' NMVC was the same between the two groups but revealed a significant decrease across the relative rounds ( $p \leq 0.001$ ). Significant protocol and relative round main effects were observed (both  $p \leq 0.001$ ) for both EMG parameters (NMF and NRMS) and both muscle groups. No significant interactions or group main effects were found for NMF and NRMS of the FS. For the CR' NMRS, a significant 3-way interaction was found ( $p \leq 0.001$ ). A significant correlation was found between the forearm discomfort and the number of rounds accomplished in the IP ( $r = -0.92$ ;  $p \leq 0.001$ ). Discussion and conclusion The IP not only discriminate better the riders from the control group but has also a strong relationship with the level of forearm discomfort within the riders. Both protocols induce different EMG results, confirming a stronger fatigue round effect in the CP. The CR revealed more differences among groups and protocols than the FS. Because braking requires feeling and precision the riders possibly are more habituated to coactivate the CR. References Clancy, E. A., Bertolina, M. V., Merletti, R., & Farina, D. (2008). ### WHAT HAPPEN WITH THE CONTRACTION TIME AND THE HALF TIME TO RELAXATION OF THE FOREARM MUSCLES DURING AN INTERMITTENT FATIGUE PROTOCOL?

Marina, M.1, Torrado, P.1, Angulo-Barroso, R.1, Busquets, A.1, Rios, J.G.2, Gasol, X.3, Turmo, T.3

**Introduction** After revision of the literature (Celichowski et al, 2006; Hubal et al., 2006), we hypothesized that contraction (CT) and relaxation time (RT) should increase because of fatigue. Nevertheless the use of different contraction modes such as voluntary contraction, evoked force or single twitches may certainly affect the results. **Material and Methods** 20 subjects carried out an intermittent protocol composed by 25 rounds as maximum. Each round was composed by two sections: 1) composed by six 5 s-voluntary contractions of 30% MVC, with resting periods of 5 s, 2) To mainly assess the effect of fatigue, composed of 3 s MVC followed by 1-min-resting period and a 50% MVC maintained during 10 s. The force exerted against the brake lever, time to MVC (CT) and half time to relaxation (1/2RT) were measured by a unidirectional gauge connected to a MuscleLab system. A ME6000 EMG system was used to register flexor digitorum superficialis (FS) and carpi radialis (CR) EMG signal during MVCs was RMS. The number of rounds of each subjects was normalized (Mamaghani et al., 2002). Each relative round (n=4) corresponds to the 25% of the test for each subject. Repeated measures ANOVAs and regression analysis were used to study changes in the NMVC, RMS, Ct and 1/2RT. Results Significant decrement of the NMVC and RMS' MVC of the Carpi radialis (CR) and flexor superficialis (FS) were observed ( $p \leq 0.001$ ). No significant differences were found for the CT ( $F(4,16)=2.69$ ;  $p=0.069$ ). Nevertheless, for the 1/2RT significant differences were observed ( $F(4,16)=13.51$ ;  $p \leq 0.001$ ). Post-hoc analysis revealed differences only between the basal 1/2RT value and the four relative rounds ( $p \leq 0.001$ ) whereas no significant trend was observed throughout the fatigue protocol ( $F(3,17)=1.88$ ;  $p=0.171$ ). Regression analysis showed a significant decrement ( $p \leq 0.05$ ) in 35% of the subjects with CT and 15% with 1/2RT. **Discussion** The decrement of NMVC and RMS' MVC confirm the occurrence of fatigue. From the very beginning of the fatigue protocol 1/2RT is longer in comparison to the non fatigued state of the basal assessment. This result confirm only partially previous authors (Celichowski et al, 2006; Hubal et al., 2006; Orizio et al., 1999) possibly because they used electrically evoked single twitches instead of MVC as in our study. **References:** Celichowski, J., Pogrzebna, M., & Krutki, P. ### EFFECT OF AGE ON NEUROMUSCULAR COORDINATION STRATEGIES DURING STABLE AND UNSTABLE ENVIRONMENTAL INTERACTIONS

Holl, N., Wübbenhorst, K., Behrens, M., Zschorlich, V.

Rostock University

**Introduction** We have previously identified adjustments in movement orchestration and neural control mechanisms following changes in environmental dynamics. These changes in mechanical interaction with the environment create different stability demands and were studied during performance of a unilateral ballistic force production task (Wübbenhorst & Zschorlich 2011; Holl & Zschorlich 2011). Here, we ask whether coordination patterns of involved muscles change in healthy elderly in comparison to young healthy adults. We predict that the elderly show a reduced ability of maximal force output accompanied by specific changes in temporal coordination patterns according to muscle function and environmental dynamics. **Methods** Six young healthy participants (YPs) (mean age: 23.8 years) and six aged healthy participants (APs) (mean age: 73.5 years) were asked to produce maximal force in a time-reaction paradigm. The task comprised a ballistic knee extension movement in our movement-sled influenced by one of three environmental conditions that differ in the degree of instability: 0 degrees of freedom (DoF), 1 and 3 DoF. Forces were recorded by use of a three dimensional KISTLER force transducer. Temporal coordination patterns were assessed by use of the cross-correlation technique of EMG-signals of eight different muscles: M. vastus medialis (VM), M. tibialis anterior, M. peroneus longus, M. rectus femoris, M. semitendinosus, M. soleus, M. gastrocnemius medialis and M. biceps femoris. For each correlation the VM served as reference muscle. **Results** Our results showed that the AP-group produced less maximal forces as compared to YPs when increasing the DoFs. As basic mechanisms of this decrease we identified altered coordination patterns in comparison of YPs and APs showing a significant effect of age and muscle ( $p=0.0057$ ). These adjustments in temporal coordination of individual muscles were specific for DoF-condition and age. Taken together, the changes between groups (APs vs. YPs) while increasing the DoFs of the task became manifest by either congruent (maintaining the same coordination strategy but shifted in time) or incongruent (temporal shifts based on differing strategies) strategies. **Discussion** The results indicate that the individual age-groups compensate for the loss of effective force transmission by adjusting temporal coordination strategies. Consequently, each group uses unique motor control mechanisms taking the individual physical preconditions that occur with aging into consideration. However, the changes in temporal neuromuscular control may contribute to increased risks of injury in the elderly. **References** Wübbenhorst K, Zschorlich V (2011). ### MUSCLE ACTIVATION DURING EXPLOSIVE CONTRACTIONS EXCEEDS THAT AT MAXIMUM FORCE, AND HIGH INITIAL ACTIVATION APPEARS TO BE FOLLOWED BY AN INHIBITORY RESPONSE

Folland, J.P., Fry, A.

Loughborough University

**Introduction** There is considerable debate about the maximality of muscle activation during different types of contractions. The magnitude and pattern of muscle activation during explosive contractions has not been carefully documented and may exceed that achieved at maximum voluntary force (MVF) i.e. the rising vs plateau phase of isometric contraction. This study investigated the magnitude and pattern of muscle activation during explosive contractions compared to at MVF. **Methods** Healthy, untrained, young men (n=27) performed two identical trials of isometric contractions of the knee extensors at a knee joint angle of 120°, 7 days apart, with data averaged across both trials. A strain gauge perpendicular to the tibia measured force and double differential surface EMG was recorded from two sites over each of the three superficial agonist muscles (RF, VM, VL) to assess muscle activation. Participants performed: two series of four maximum voluntary contractions of 3-s duration in order to measure MVF and EMG amplitude (RMS of a 500-ms epoch around MVF, EMG@MVF); and 10 explosive contractions of ~1-s duration as 'fast and hard' as possible from rest. For the explosive contractions, force and EMG amplitude (moving 25-ms RMS window) were assessed from 50-ms before until 150-ms after force onset in order to describe their temporal pattern and determine peak EMG (EMGEXP-PK). **Results** Whole quadriceps EMGEXP-PK exceeded EMG@MVF ( $209 \pm 96$  vs  $178 \pm 84$   $\mu$ V;  $P < 0.001$ ), reaching  $122 \pm 18$  %EMG@MVF, and this was the case for all three agonist muscles (All,  $P < 0.01$ ; VM 130, VL 125 and RF 118 %EMG@MVF). Participants with a high (HIGH, n=8) vs low (LOW, n=8) capacity for activation (EMGEXP-PK) during explosive contrac-

tions showed a different EMG pattern and magnitude. For HIGH time aligned EMG peaked at  $138 \pm 12\%$  EMG@MVF (45-ms), followed a marked decline of  $>1/3$  to  $88 \pm 23\%$  EMG@MVF (99-ms) before returning to  $>96\%$  EMG@MVF (116-ms onwards). For LOW time aligned EMG peaked at  $92 \pm 11\%$  EMG@MVF (59ms;  $P < 0.01$  vs HIGH), and remained similar thereafter ( $83-91\%$  EMG@MVF). Furthermore in the whole group, EMGEXP-PK was strongly related to the subsequent decline in EMG for the whole quadriceps ( $R = 0.67$ ;  $P < 0.01$ ) and this effect was particularly strong for the vasti muscles (VM,  $R = 0.78$ ; VL,  $R = 0.75$ ; both  $P < 0.01$ ). Conclusion In these untrained individuals activation during explosive contractions substantially exceeded that at MVF, indicating that activation at MVF was not maximal. Individuals with high activation during explosive contractions showed even higher initial values, but this was followed by a rapid decline that was strongly related to the amplitude of the initial peak. This study provides novel evidence for an inhibitory response to these initial high levels of activation.

### COMPARISON BETWEEN TWO THRESHOLD METHODS RELATED-BASELINES FOR THE EMG ONSET DETECTION IN TRUNK MUSCLES DURING GOLF SWING

Silva, L.1, Vaz, J.1, Marta, S.1, Paula, A.1, Castro, M.A.2, Fernandes, O.3, Pezarat-Correia, P.1

1: FMH-UTL (Lisbon, POR), 2: ESTESC-IPC (Coimbra, POR) 3: ECT-UE (Évora, POR)

**Introduction** Several approaches have been proposed for EMG onset detection, but there is not a standardized method. Onset detection accuracy has been shown to be related with muscle baseline activity (Hodges & Bui, 1996; Allison, 2003). The aim of this study was to compare two threshold methods related-baselines for onset detection. **Methods** Eight golfers (handicap =  $15.7 \pm 3.2$ ; range 11-20) performed 10 shots with two different clubs (5 with pitch and 5 with 4-iron). 80 shots were used for analysis. Surface EMG on both sides of trunk was recorded from Rectus Abdominis (RA), External Oblique (EO) and Erector Spinae (ES). In method A threshold was calculated by the baseline activity recorded between two MVC. In Method B threshold was determined by the mean activity before the beginning of backswing [-1000: -500 ms]. The mean of 50 samples of a sliding window above threshold level was used for the onset detection. Visual inspection was also performed. **Results** ANOVA showed no significant interaction between clubs, muscles and methods. Significant differences were found between methods and muscles (left:  $F(1.432, 90.225) = 194.905, p \leq .01$  right:  $F(1.764, 119.985) = 124.137, p \leq .01$ ). Left and right RA showed a high correlation and agreement with the Bland-Altman mean of 0.7 ms [-10, 8.7] and 0.2 ms [-5.1, 4.5], respectively. The left and right EO had good correlation between the baselines, but less agreement than RA, showing a bias of 89 ms [-88, 265] and 38 ms [-162, 237], respectively. ES had a lower correlation between method A and B. **Discussion** During golf swing RA showed high correlation and agreement between methods which means that the chosen baseline method did not affect the onset parameter due to a high signal-to-noise ratio. The EO showed higher variability than the others muscles in peak timing, with high bias between methods for the left side. Due to its role on pre-swing posture maintenance the ES had high background activity that affects the agreement between methods. So, for this muscle it is not advisable to use the repetition baseline for threshold calculation. In that case, EMG activity could not be related to the motor skill (Vaisman et al., 2010). The choice of the parameters to be included in threshold methods seems to have influence on onset detection (Hodges and Bui, 1996). The appropriate threshold method to determine the EMG onset of trunk muscles during the golf swing depends on the studied muscle. **References** Allison GT (2003). J Electromyogr Kines 13: 209-216. ### APPLICATION OF INVERSE ANALYSIS AND FINITE ELEMENT METHOD FOR PROGRESSING OF SURFACE EMG ANALYSIS

SAITOU, K.1, INOUE, S.2, MIYAZAKI, M.3, ITOH, H.4

1 Nagoya Gakuin University (JAPAN), 2 Saga University (JAPAN), 3 Obirin University (JAPAN), 4 Nagoya Institute of Technology (JAPAN)

**Introduction** In order to extract the information about anatomy and physiology of motor units as the active source through the inverse analysis of surface EMG, valid surface EMG simulation that is considered about the inhomogeneous layer under skin is required. And, the model for the simulation must be as simple as possible. In this study, the potentials as surface EMG were calculated by finite element method (FEM) by using three-layer or four-layer model that were consisted of muscle tissue, subcutaneous tissue and skin. Furthermore, the effect of those potentials on the solutions through the inverse analysis was investigated. **Methods** Cylindrical model with 40 mm in radius and 300 mm in length was used in the calculation of FEM. These simulations with FEM were executed by varying the value of thickness and conductivity of each layer except for muscle region. The thickness of skin (dermis + epidermis) ranged from 0.75 to 3.0 mm and the conductivity of skin ranged from 0.2 to 1.2 S/m in the three layers model. The thickness of dermis ranged from 0.5 to 2.5 mm and the conductivity of dermis ranged from 0.3 to 1.2 S/m, and the thickness of epidermis ranged from 0.25 to 0.5 mm and the conductivity of epidermis ranged from 0.0001 to 0.0005 S/m. The thickness was 5.0 mm and the conductivity was 0.4 S/m of the subcutaneous tissue in both models. In the inverse analysis of surface EMG, the active sources were estimated with image method that was more simple method than the other methods. **Results and Discussion** As the results of the simulation with FEM, the effects of the conductivity of skin layer on the surface potential were larger than those of the thickness of skin layer in the three-layer model. In the four-layer model, the effects of the thickness and the conductivity of epidermis layer on the surface potential were small. And then, the error of peak value of surface potential between both layer models was about 20% in the case of 0.5 mm in thickness of epidermis, and about 11% in the case of 0.25 mm in thickness of epidermis. The differences of these results influenced into the estimation through the inverse analysis about anatomy and physiology of active motor units. **References** Stegeman DF, Blok JH, Hermens HJ and Roeleveld K: Surface EMG models: properties and applications, J.
