**Introduction** Barbell resistance exercises are used to develop maximum strength levels. Recruitment of a high proportion of motor units is important for adaptation to strength training (Behm, 1995). For example, greater recruitment has been associated with enhanced cross sectional area and force adaptations (Takarada et al., 2000). No studies have directly compared neuromuscular (NM) responses between commonly used barbell exercises, although research shows loading task influences NM recruitment (Mottram et al., 2005). Therefore, the study aimed to assess if NM response to a maximum strength session differed when performed with either squat or deadlift. **Methods** Nine elite trained subjects performed squat or deadlift sessions consisting of five sets of five repetitions, with matched loads, on separate days. The NM response to each exercise session was assessed with continual recordings of surface electromyography and barbell displacement, from which repetition electromyographic amplitude (RMS), muscle fibre conduction velocity (MFCV) and mean

power (MP) were derived. Pre- and post- session knee extension MVC force and central activation ratio (CAR) from superimposed stimulation during MVC were also assessed. Repeated measures ANOVA was used to assess changes in repetition RMS, MFCV and MP, and changes in pre versus post session MVC and CAR assessments. Results Repetition RMS significantly increased ( $p < 0.001$ ) within sets of squat (125.3%) and deadlift (114%), relative to repetition one. A significant interaction between session and set ( $p < 0.001$ ) demonstrated RMS increased more during squat. Repetition MFCV significantly reduced to 91.7% relative to repetition one within squat sets ( $p = 0.034$ ), but not deadlift. Repetition MP was unchanged during both sessions. There were no differences in MVC and CAR pre versus post either session. Discussion The findings suggest increased motor unit activation occurred to maintain MP during sets of squat and deadlift maximum strength exercise. However, acute peripheral fatigue was more likely to have occurred during squats, indicated by reduced MFCV. Increased RMS response may result from the demands of the lifting task, with or without fatigue. However, reduced MFCV was associated with greater RMS response, possibly indicating greater stimulus for adaption. No change in MVC and CAR suggested force capacity and central drive were not reduced following five sets of barbell exercise in well-trained subjects. References Behm D. ### PHYSIOLOGICAL AND NEUROMUSCULAR EFFECTS OF AN ELECTRONICALLY ACCENTUATED ECCENTRIC KNEE EXTENSION TRAINING

Kasperek, P., Thilo, E.J., Babiak, S., Ferrauti, A.

*Ruhr-University Bochum*

Introduction Studies have shown, that an accentuated eccentric strength straining comes along with an increased muscle damage and consequently with stronger concentric adaptations of strength (Brandenburg et. al., 2002). The aim of the present study was to define the most effective relation between concentric and eccentric loads concerning neuromuscular activity and physiological demands during an accentuated training with an electronically controlled knee extension machine. Methods 20 athletes (n=10 males and 10 females, age  $24.3 \pm 3.1$  yrs) completed three different training protocols during three experimental days, each at least three days apart. The training was conducted on an electronically leg extension machine (Milon Industries®, Germany), with separately adjusted concentric and eccentric resistance. Protocol A was defined as a traditional strength endurance training (TST) with equal loads (20 % 1 RM) in the concentric and eccentric movements. Protocol B (ECC+) and protocol C (ECC++) consisted of reduced concentric (B 16, C 12 % 1RM) and an increased eccentric load (B 24, C 28 % 1RM). During each protocol eight sets of eight repetitions (7.5 s each and 1 min duration per set) followed by 30 s recovery were completed. Results No differences were found for the mean heart rate (A  $106 \pm 13$ , B  $107 \pm 14$ , C  $103 \pm 12$  min<sup>-1</sup>) and perceived exertion (A  $14 \pm 1$ , B  $14 \pm 2$ , C  $14 \pm 1$ ). Mean oxygen consumption was significantly lower in Protocol C (A  $8.4 \pm 2.4$ , B  $8.4 \pm 1.6$ , C  $7.5 \pm 1.8$  ml·min<sup>-1</sup>·kg<sup>-1</sup>). M. vastus medialis activity tended to be higher during concentric contraction in A (A  $0.19 \pm 0.11$ , B  $0.14 \pm 0.06$ , C  $0.13 \pm 0.04$  mV) while no differences were found for the eccentric movements (A  $0.15 \pm 0.07$ , B  $0.14 \pm 0.04$ , C  $0.14 \pm 0.04$  mV). Neuromuscular activity decreased significantly during the second half of the eccentric movements in all protocols. Discussion Results showed that an accentuated eccentric strength training comes along with an overall lower energy demand despite of a similar power output and does not increase neuromuscular activity as expected under the conditions of our study. These results may be attributed to a faster movement in case of eccentric overload. References Brandenburg, J.P. & Docherty, D. (2002). The effects of accentuated eccentric loading on strength, muscle hypertrophy, and neural adaptations in trained individuals. *J. Strength Cond. Res.* 16 (1), 25-32.

#### CORRECT, FAKE AND ABSENT PRE-INFORMATION ABOUT THE THEORETICAL BASIS OF THE BILATERAL FORCE DEFICIT ACHIEVED PRIOR TO STRENGTH TESTING DOES NOT AFFECT ITS OCCURRENCE AND MAGNITUDE

Donath, L.1,3, Siebert, T.2, Faude, O.1, Puta, C.3

*University of Basel*

1 University of Basel, Institute of Exercise and Health Sciences, Basel, Switzerland 2 University of Jena, Institute of Sport Science, Motion Sciences, Jena, Germany 3 University of Jena, Institute of Sport Science, Sports Medicine and Health Promotion, Jena, Germany Introduction The Bilateral Force Deficit (BFD) is characterized by lower bilaterally (BL) generated maximal muscle strength compared to the sum of the unilaterally (ULright + ULleft) produced maximal strength. Beside spinal and supra-spinal inhibitory mechanisms during bilateral tasks, also volitional influences on these inhibitory pathways have been hypothesized (Jakobi & Chiibeck 2001, Secher et al. 1988). Thus, the present randomized cross-over study intended to differentiate whether no, fake or correct pre-information achieved prior to strength testing differently affect the occurrence and magnitude of the BFD. Methods 20 heterogeneously trained male adults (age:  $24.5 \pm 1.7$  years; weight:  $77.5 \pm 7.1$  kg; height:  $1.81 \pm 0.05$  m) were examined on three days within seven days employing a negatively inclined leg press slide with separate force plates for the left and right leg. Each participant semi-randomly completed three separated maximal isometric strength test sessions with no (first day), fake (bilateral force > sum of unilateral forces; second day) and correct (third day) pre-information during bilateral, unilateral-left and unilateral-right leg-press. The sum of left- and right-sided force values were calculated for bilateral ( $FBL = FBL_{left} + FBL_{right}$ ) and unilateral ( $FUL = FUL_{left} + FUL_{right}$ ) analyses. Results Comparative descriptive analysis for no pre-information (No) condition force (N) values revealed: Mean (SD):  $FUL_{No} = 3023$  N (435) vs.  $FBL_{No} = 2812$  (453), fake pre-information (Fa) showed  $FUL_{Fa} = 3013$  N (459) vs.  $FBL_{Fa} = 2843$  (446) and the correct (Co) pre-information revealed  $FUL_{Co} = 3035$  (425) vs.  $FBL_{Co} = 2844$  (385). The three (no, fake, correct) \* 2 (FUL, FBL) repeated measures analyses of variance revealed a high significant main effect of force ( $F = 61.82$ ,  $p < 0.001$ ). Neither the main effect for information ( $F = 0.11$ ,  $p = 0.90$ ) nor the interaction for information\*force ( $F = 1.07$ ,  $p = 0.35$ ) was significant. Discussion The occurrence and magnitude of the BFD both seem not affected by pre-information conditions. Our results indicate that volitional influences on the BFD on supra-spinal level might not be likely. However, bilateral maximal strength exercises in alternating multi-joint movements in closed chains, such as e.g. cycling, running and jumping should be supplemented by a proper

amount of alternating-unilateral strength exercises. References Jakobi JM & Chilibeck PD. (2001). *Can J Appl Physiol* 26, 12-33. Secher NH, Rube N & Elers J (1988). *Acta Physiol Scand.* 134, 333-339

### MAXIMUM NUMBER OF REPETITIONS AND LOSS OF VELOCITY WITH CLUSTER SET CONFIGURATION

Carballeira, E.1, Iglesias-Soler, E.1, Sánchez-Otero, T.1, Castro-Gacio, X.1, Mayo, X.1

1. UDC (A Coruña, Spain)

**Introduction** The purposes of this study were: monitoring the maximum number of repetitions (MNR) achieved before failure through a cluster set configuration (insertion of pause between every repetition), and studying the loss of velocity, of a high intensity parallel squat exercise (Sq). **Methods** Nine male subjects (body mass=84.1±17.2 kg; height=175.6±8.41 cm; age=23.8±4.09 years) volunteered for participation in this study. All of them had at least 18 months of experience in weight training, with a minimum frequency of two training sessions per week. In a first session four repetition maximum load (4RM) for Sq was obtained. During a second session, called failure session (FS), subjects were instructed to perform MNR within each of the 3 sets of Sq with 4RM load. Three minutes rest were fixed between sets. Finally in a third session, called cluster session (CS), MNR was obtained with the same load than in FS, but individual resting time between each repetition was set as the ratio between the total pause in FS (360 seconds) and the sum of the total number of completed repetitions in FS minus 1. **Results** The number of repetitions completed during FS was of 9.7±2.1. The obtained MNR in CS was of 45.3±32.2. The ratio MNR in CS respect the total number of completed repetitions in FS was 4.9±3.5. In addition, mean velocity of propulsive phase (Sanchez-Medina et al., 2010) resulted higher in CS than in FS (p=0.054, T-test for paired samples). Furthermore, repeated measures ANOVA showed that the loss of velocity in CS (% of first repetition velocity) was significant from 60 % of MNR. No significant correlation was found between MNR in CS and the total number of completed repetitions in FS. **Discussion** The use of pauses between every repetition allows to improve mechanical performance of a training session (Haff et al., 2003; Iglesias-Soler et al., 2012). Since the development of sets to failure entails reduction in intensity of training (de Salles et al., 2009), the results of the present study suggest that CS is an interesting approach to improve mechanical stimuli of high intensity and high volume lower body workouts. These results are coincident with others obtained previously for upper-body exercises (Iglesias et al., 2010). **References** de Salles BF, Simao R, Miranda F, Novaes JS, Lemos A, Willardson JM. ### PERFORMING EACH REPETITION AT MAXIMUM VELOCITY PRODUCES GREATER GAIN IN STRENGTH COMPARED TO PERFORMING EACH REPETITION AT 50% OF THE MAXIMUM VOLUNTARY VELOCITY

Pareja-Blanco, F.1, Rodríguez-Rosell, D.1, Otero-Esquina, C.1, Mora-Custodio, R.1, González-Badillo, J.J.1

University Pablo de Olavide

**Introduction** When designing resistance programs to optimize athletic performance a key variable used is training velocity. To be specific, the intention to move a load explosively has been regarded as well suited for developing strength at high contraction velocities (1). This study compares the effects of performing each repetition at maximum voluntary velocity, by measuring the exact velocity of each repetition. **Methods** Twenty-one young and healthy men to take part in this study (mean (SD): age 22.3(3.2) yr, body weight 72.6(9.2) kg, height 1.77(0.07) m), were randomly assigned to one of two groups: maximum voluntary velocity (V100; n=10) or 50% of maximum velocity (V50; n=11) with each load. Subjects trained during 6 wk for a total of 18 sessions following a periodized resistance training program using the full squat. The two groups trained at the same relative intensity in each session (increasing from 60% to 80%RM) but differed in the velocity reached in each repetition (100% vs. 50% of maximum possible velocity). Velocity was monitored in each session (T-Force System, Ergotech, Spain). A covariance test was used to compare the changes between the groups. A t-test for paired samples was used to compare pre-test and post-test measurements in each group. **Results** Both groups obtained significant increases in 1RM strength (18.6% vs. 10.3%), mean velocity with absolute loads common to both test (MV) (15.9% vs. 7.5%) and CMJ (8.7% vs. 2.5%) in V100 (p<0.01) and V50 (p<0.05), respectively. Furthermore, on comparison, V100 had significantly higher gains (p<0.01) for CMJ than V50. **Discussion** These results indicate that short-term velocity-based resistance training produces greater neuromuscular performance improvement when performing each repetition at maximum velocity. Several studies show that training to maximal voluntary velocity produces greater improvements in rate of force development and power, and similar gains in strength (2-3). In addition, the present study shows greater improvements in physical performance measured by CMJ. **References** Behm, DG, and Sale, DG. ### A COMPARISON BETWEEN A VERSA-PULLEY™ FLYWHEEL AND THE FREE WEIGHT RESISTANCE DURING A 6X6 REPEATED POWER ABILITY TEST.

Nunez, F.1,2, Suárez-Arrones, L.1,2, Cater, P.3

(1) Universidad Pablo de Olavide (Seville, Spain). (2) VF Sport (Seville, Spain) (3) www.Athlete-International.com (EE.UU).

**Introduction** The majority of research concerning flywheel resistance has been performed with Tesch's Yo-Yo technology. To date, there are few known peer reviewed journal articles investigating the VersaPulley device. The current research comparing Versapulley high-pull (VPHP) and Olympic barbell high-pull (OBHP) with standard velocity and relative load between both forms. The investigation hypothesizes that eccentric loading characteristic of the VersaPulley will increase metabolic demand and therefore be a more efficient and safer method of power endurance training. **Methods** 15 sub-élite rugby players performed totally 6x6 maximal sets, with 20 seg. of rest, on the Versapulley and in Olympic barbell high-pull. Peak force, mean force, time force, were measured in concentric and eccentric phase. Mean propulsive velocity, peak propulsive velocity, peak acceleration, mean propulsive acceleration and propulsive phase (%), was measured or calculated in concentric phase. Heart rate between sets and accumulated blood lactate immediately following the series of 6 sets, 3 and 5 minutes post-test, were measured **Results** The maximal concentric force was significant higher in the 6th set with barbell. The VP average eccentrics were significant higher in all sets. During the first 3 sets, versapulley force time is higher in concentric phase, and lower in eccentric phase, than with barbell. Peak velocity and mean propulsive acceleration were significant higher with versapulley

than with barbell. The heart rate were significant higher with versapulley in all sets. The lactate concentration was higher in all measures too. Discussion The results of the study show that using versapulley we can produce the same concentric power and force than using free weight exercise, but higher values for the eccentric phase. VersaPulley will have greater accumulated blood lactate, heart rate and total work in the same magnitude of exercise when compared to free weights. Concentric displacement and eccentric loading characteristic of the VersaPulley will increase metabolic demand and therefore be a more efficient and safer method of power endurance training. ### **LOW INTENSITY ECCENTRIC EXERCISE WITH BLOOD FLOW RESTRICTION IMPROVES ECCENTRIC STRENGTH WITHOUT MUSCLE SORENESS.**

Kubota, A.

*School of Health and Sports Science, Juntendo University*

KUBOTA, A.1, SAKURABA, K.1, 2, FUJIMINE, S.1, FUJITA, S.2, OGURA, Y.3, KOH, S.4, NAKADAKE, M.1, SHIKAKURA, J.1 1: School of Health and Sports Science, Juntendo University, Japan, 2: Graduate School of Health and Sports Science, Juntendo University, Japan, 3: St. Marianna University School of Medicine, Japan and 4: Koh Orthopaedic Clinic, Japan Introduction Strenuous eccentric exercise improves eccentric strength, while it results in muscle damage with muscle soreness. Low intensity training with blood flow restriction is known to increase muscle strength equivalent to high intensity training. The aim of this study is to clarify whether low intensity eccentric exercise with blood flow restriction improves eccentric strength without muscle soreness. Methods Twelve-college students (4 males and 8 females, Age: 20.7yr) volunteered for this study. They were divided into two groups: low intensity exercise (~30% of peak torque) without blood flow restriction (control group: CON) and that with blood flow restriction (compressive force = 120 mmHg, blood flow restriction group: BFR). The dominant arm of all subjects was assigned to eccentric exercise and the opposite arm was assigned to concentric exercise in the both groups. The exercise, consisted of 3 or 4 sets of 15 elbow flexion using the Biodex unit, performed 3 times a week for 8 wk. Before and after the experimental period, elbow flexor muscle torque was evaluated in following settings: concentric contraction at angular speeds of 60 and 120 deg•s<sup>-1</sup> (CC60 and 120), eccentric contraction at angular speeds of 60 and 120 deg•s<sup>-1</sup> (EC60 and 120), and isometric contraction. Elbow flexor muscle cross sectional area (CSA) was also analyzed with MRI before and after the experimental period. Muscle soreness of the upper arm was evaluated by a visual analog scale during the experimental period. Results In the CON, all the elbow flexor torque was not significantly increased after 8 wk. In the BFR, the concentric exercise significantly increased the torque of CC60 (pre: 28.8 ± 12.2 N•m, post: 32.6 ± 12.1 N•m), whereas the eccentric exercise significantly increased that of EC60 (pre: 54.0 ± 17.4 N•m, post: 59.6 ± 20.1 N•m) after 8 wk (p < 0.05). However, the concentric exercise did not increase eccentric strengths, and vice versa. CSAs in elbow flexor muscles significantly increased after the experimental period in the both exercises respectively (p < 0.05), the difference between both exercises in the BFR were not significant for the percent changes of CSAs. Muscle soreness was never developed in the both groups during the experimental period. Conclusion Low intensity eccentric exercise combined with blood flow restriction improves an eccentric strength without muscle soreness. Our results also indicate that the effect of low intensity training with blood flow restriction is contraction mode-specific.

### **THE EFFECT OF A RESISTANCE TRAINING PROGRAM ON DETECTING MUSCLE IMBALANCE BETWEEN HAMSTRINGS AND QUADRICEPS OF NONDOMINANT AND DOMINANT LEGS**

Elnemr, A.1, Elkhateb, N.2, Elnemr, O.3

*Faculty of physical education / Helwan University 1: HFPE (Giza, Egypt), 2: GFPE (Giza, Egypt), 3: HU (Cairo, Egypt)*

Introduction Exercises selected for soccer should maintain a balance of muscular strength across joints and between opposing muscle groups to prevent the the risk of injury due to a disparity between the strength of the agonist, (the muscle or muscle groups actively causing the movement (e.g., the quadriceps in the leg extension exercise), and the antagonist, (the muscle or muscle group located on the opposite side of the limb (e.g., the hamstrings in the leg extension exercise). Methods 12 soccer players ages 17-18 years participated in the study. Tests for determination right and left hamstrings and quadriceps 10 RM strength were undertaken before and after 10 weeks of training. The pretest results showed that the right and left hamstrings were extremely weak compared with the right and left quadriceps and the hamstrings and quadriceps of the non dominant leg (the lift leg) were extremely weak compared with the dominant leg (the right leg). The researchers designed a training program to restore strength balance to achieve a ratio not less than 90:100 between the left and right hamstrings to the left and right quadriceps, the left hamstrings to the right hamstrings and the left quadriceps to the right quadriceps. The training program of the right quadriceps, left quadriceps, right hamstrings and left hamstrings started with (one 10 RM set, 3d / wk), (two 10 RM sets, 3d / wk), (three 10 RM sets, 3d / wk) and (four 10 RM sets, 3d / wk) respectively. Results Strength variables increased according to the training program. The ratio between the left and right hamstrings to the left and right quadriceps was improved, the ratio between the left hamstrings to the right hamstrings was improved and the ratio between the left quadriceps to the right quadriceps was improved. Discussion The results of the present study seem to correspond to the fact that if certain patterns or muscular actions are performed repeatedly, muscles develop more in either the front of the body or the back of the body. Players in soccer benefit from a well- rounded muscular training program focusing on the hamstrings and quadriceps, dominant and nondominant to prevent injuries and enhance performance.(Foran, 2001, Baechle & Earle, 2000, and Spring et al., 1991) References Baechle, T., ed.(2000). *Essentials of Strength Training and Conditioning* (2nd ed). ## POWERLIFTERS IMPROVED STRENGTH AND MUSCULAR ADAPTATIONS TO A GREATER EXTENT WHEN EQUAL TOTAL TRAINING VOLUME WAS DIVIDED INTO 6 COMPARED TO 3 TRAINING SESSIONS PER WEEK

Raastad, T., Kirketeig, A., Wolf, D., Paulsen, G.

*Norwegian School of Sport Sciences*

**Introduction** Traditionally, powerlifters have divided total training volume into 3-4 weekly training sessions, where each of the three competition lifts (squat, deadlift and bench-press) typically is trained twice a week in addition to other exercises. Interestingly, in weightlifters and female athletes favourable training adaptations have been indicated when training volume was divided into more frequent and smaller training sessions (1, 2). Therefore, the aim of this study was to compare the effect performing three large vs. six small training sessions per week in a group of competitive powerlifters. **Methods** A total of 16 powerlifters with the mean age of  $21.1 \pm 3.6$  years volunteered for the study (13 men, and 3 women). All subjects had competed in national powerlifting competitions within the last 6 months, and all had trained continuously for competitive powerlifting for at least 1 year before entering the study. Effect of training was assessed as changes in 1 RM in squat, bench-press and deadlift (all tests were performed without powerlifting suits), and as changes in cross sectional area (CSA) of m. quadriceps. Testing was conducted before and after a 15 week intervention period, in which the weekly training volume was distributed as either 3 or 6 weekly training sessions. Total training, volume, training intensity and exercises was identical in the two training groups, and briefly the lifters in the 3/week group performed twice as many sets as the 6/week group in each session. **Results** At the start of the study performance without suits in squat, bench press and deadlift were similar in the two groups ( $167 \pm 45$ ,  $123 \pm 40$  and  $201 \pm 46$  kg respectively). After the 15 week intervention period 1 RM in squat and bench-press increased more in the 6/week than in 3/week group ( $11 \pm 6$  vs.  $5 \pm 3\%$  and  $11 \pm 4$  vs.  $6 \pm 3\%$ , respectively,  $p < 0.05$ ), whereas no significant difference between groups was observed for the deadlift ( $9 \pm 6$  v.  $4 \pm 6\%$ ). CSA of m. quadriceps increased more in the 6/week group than in the 3/week group ( $4.2 \pm 4.3$  vs.  $-0.6 \pm 1.6\%$ , respectively). **Discussion** Dividing total training volume into 6 smaller sessions was more effective than the traditional 3 sessions per week regime both for the increase in 1 RM in squat and bench-press, as well as for the increase in thigh muscle CSA. The mechanisms behind the superior effects of more frequent and smaller sessions cannot be directly addressed in this study, but more frequent stimuli for hypertrophy and less fatiguing sessions might be possible explanations. 1 Häkkinen & Kallinen (1994) *Electromyogr. Clin. Neurophysiol.* 2 Hartman et al. (2007) *Int. J. Sports Physiol. Perform.*

## SESSION-RPE AT DIFFERENT TIME POINTS AFTER A CIRCUIT WEIGHT TRAINING WORKOUT

Silva, L.H.1, Fontes, E.B.2, Drigo, A.J.3, Ribeiro, L.F.P.1,3

*1: UESC (Ilhéus, Brasil), 2: UNICAMP (Campinas, Brasil), 3: UNESP (Rio Claro, Brasil).*

**Introduction** Session RPE (SRPE) taken after the exercise bout is considered to provide a quantitative evaluation of the entire exercise session (Foster et al., 2001). Yet, controversial results exist regarding its correspondence to averaged acute RPE in resistance exercise (Egan et al., 2006; Singh et al., 2007). In addition, the influence of the interval length between exercise cessation and rating moment on SRPE (Singh et al., 2007) and the usefulness of differentiating it in central and peripheral components are underexplored. Thus, we investigated the effects of time lag between exercise termination and rating moment on overall and differentiated SRPE and their usefulness against RPE in a circuit weight training (CWT) workout. **Methods** Ten healthy volunteers ( $22.3 \pm 2.8$  yrs) completed a CWT workout involving 3 circuits of single sets in 5 exercises (lying row, squat, shoulder press, dead lift and bench press). 20 repetitions at 30% 1RM were performed in each exercise, with 3 min and 30 sec rests between exercises and circuits. HR was continuously monitored during the workout and blood lactate ( $[\text{La}]_{\text{cb}}$ ) was determined after each circuit. Overall, chest and active muscle RPE were assessed at the end of each circuit by means of the Borg's 6-20 scale. Using the modified CR-10 scale by Foster et al. (2001), overall, chest, and active muscle SRPE were taken at minutes 10, 20 and 30 after CWT cessation. Averaged RPE values were transformed for comparisons to SRPE. **Results** Mean HR and  $[\text{La}]_{\text{cb}}$  during the session were  $66.8 \pm 4.4\%$  HRmax and  $6.4 \pm 1.0$  mM. Overall, chest and active muscle RPE increased significantly ( $P < 0.05$ ) throughout the workout. Stable values were observed for overall ( $3.7 \pm 0.6$ ,  $3.8 \pm 0.7$  and  $3.7 \pm 0.6$ ), chest ( $3.7 \pm 0.6$ ,  $3.8 \pm 0.8$  and  $3.8 \pm 0.8$ ) and active muscle ( $3.9 \pm 0.8$ ,  $3.6 \pm 0.7$  and  $3.7 \pm 0.7$ ) SRPE assessed 10, 20 and 30 min after the CWT, with no significant main effects or time x SRPE type interaction ( $P > 0.05$ ). No significant differences ( $P > 0.05$ ) were observed between averaged SRPE and RPE (overall:  $3.7 \pm 0.6$  vs  $3.5 \pm 0.9$ ; chest:  $3.8 \pm 0.7$  vs  $3.6 \pm 0.8$ ; active muscle:  $3.7 \pm 0.7$  vs  $3.5 \pm 0.7$ ). **Discussion** Stability of SRPE at different time points after exercise argues against the statement that it should be taken 30 min after the bout in order to avoid the influence of particular easy or hard effort towards the end of the session (Foster et al., 2001). In line with Egan et al. (2006) but in contrast to Singh et al. (2007), averaged RPE and SRPE provide similar ratings for overall and differentiated perceptions. These results suggest that SRPE, irrespective of the moment at which it is taken, is an useful tool for assessing whole session strain in a CWT workout in healthy men. **References** Foster C, Florhaug JA, Franklin J, Gottschall L, Hrovatin LA, Parker S, Doleshal P, Dodge C. ## PREDICTING THE 1RM FROM THE LOAD-VELOCITY RELATIONSHIP

Jidovtseff, B.1, Harris, N.2, Cronin, J.2, Crielaard, J.M.1

*University of Liege*

**PREDICTING THE 1RM FROM THE LOAD-VELOCITY RELATIONSHIP** Jidovtseff B1, Harris N2, Cronin J2, Crielaard JM1 1:ULG (Liege, Belgium), 2:AUT (Auckland, NewZealand) **Introduction** Determination of the 1RM is often considered to be problematic for populations such as the young as well as aged. As a result different methods have been developed to allow the estimation of 1RM from performing sub-maximal repetitions to failure (1). The accuracy of this method depends on several parameters such as the number of repetitions, type of exercise, training background and the population used (1). Very recently, authors have suggested to use the load-velocity relationship in order to determine the 1RM (2,3). The aim of the present study was to investigate the ability of such method to predict the 1RM in different strength exercises and with different technological devices. **Methods** Data from five studies including in their protocol the 1RM determination and the load-velocity relationship profiling were gathered for the present analysis. Bench press, half-squat, horizontal press, leg curl and lat pulldown exercises were selected. A laboratory very accurate inertial dynamometer (4) was used for half-squat and bench press exercise. The Myotest (Myotest, Switzerland) accelerometer was used for bench press, leg curl, horizontal press and lat pulldown exercises. Each study contain two sessions. The first was used for position standardisation, exercise familiarisation and 1RM determination. In the second session, velocity was measured at three or four increasing loads ranging from 30 to 95% of the 1RM. For each subject and each exercise, the best fit load velocity relationship and equation was determined. Associated parameters such as slope and intercept point

on the Y axis were calculated and used for 1RM estimations. Results Our study demonstrated contrasted results for the 1RM prediction using load-velocity relationship. Average velocity appears to be more relevant than peak velocity to estimate 1RM. The Myotest, that only allow peak velocity measurement, showed slightly lower prediction ability. With laboratory device, bench press 1RM prediction was practically perfect ( $r=0.98$ ) providing evidence that the load-velocity relationship may be used to estimate 1RM with a standard error of estimate (SEE) of 7%. Acceptable correlations were observed with half-squat ( $r=0.76$ ,  $SEE=11\%$ ), horizontal press ( $r=0.75$ ,  $SEE=10\%$ ) and lat pulldown ( $r=0.62$ ,  $SEE=8\%$ ) exercises. For equipment reason it was impossible to estimate the 1RM for the leg curl exercise. Discussion Bench press results confirm the use of the load-velocity relationship in the 1RM prediction. Unfortunately, prediction appears to be dependant from selected parameter, device, exercise and equipment. References : 1. Horvat, et al. J Strength Cond Res 17: 324–328, 2003. 2. Jidovtseff et al. #### VARIABILITY OF HEART RHYTHM OF ELITE ATHLETES AT ACTIVE ORTHOSTATIC TEST

Sukhov, S.

*National Research and Practical Centre of Physical Culture*

**Introduction** Vegetative nervous system (VNS) plays important role in regulation of adaptation to intensive physical load. One of the most informative methods of study of VNS is spectral analysis of variability of heart rhythm at active orthostatic test (VHR at AOT). Goal of the study was to compare VHR at AOT of elite athletes and young male non-athletes. **Methods** Twenty-five elite judoists (experimental group) and fifteen healthy young male non-athletes (control group) have been examined. VHR at AOT according to the International Standard (1996) was conducted with use of hard- and software complex VNS-Spectrum. Study protocol included a 350-second registration of ECG in supine position and after standing up with determination of spectral power in each frequency range (High Frequency – HF, Low Frequency – LF and Very Low Frequency – VLF) and total power (TP) of the range, recording of systolic pressure in the supine position and 3 minutes after standing up. K30:15 coefficient (ratio of R-R30 to R-R15) was registered. **Results** In the experimental group the heart rate at AOT was  $78.2 \pm 2.5$  bpm, and in the control group –  $98.1 \pm 3.3$  bpm ( $p < 0.05$ ). Athletes showed growth of TP at AOT as compared with  $5189 \pm 806$  ms<sup>2</sup>/Hz at rest to  $9682 \pm 903$  ms<sup>2</sup>/Hz, relative input of LF-component in the structure of spectral power practically was the same (28.2 % at rest and 29.7% after standing), HF-component declined from  $43.5 \pm 2.9\%$  to  $35.8 \pm 4.0\%$ , growth of the ratio of LF/HF was less as compared with the control group (from  $0.65 \pm 0.10$  at rest up to  $0.83 \pm 0.29$  at standing up), share of VLF-component has increased from  $28.3 \pm 3.6\%$  to  $34.5 \pm 4.2\%$ . The ratio of LF/HF in the athletes group evidences to parasympathotonia. At conducting AOT in the control group, the TP also grew in comparison with the resting position, from  $2450 \pm 643$  ms<sup>2</sup>/Hz to  $5512 \pm 1640$  ms<sup>2</sup>/Hz, the absolute capacity of LF-component increased and the relative input of the LF-component in the structure of spectral power has grown (from 28,7% at rest to 42,1% at standing up), HF-component did not change, and the ratio of LF/HF increased from  $0.78 \pm 0.16$  to  $1.18 \pm 0.41$ , while the share of VLF-component dropped from  $34.7 \pm 6.4$  to  $22.2 \pm 4.9\%$ . K30:15 in experimental group was  $1.50 \pm 0.06$ , while in the control group –  $1.27 \pm 0.04$  ( $p < 0.05$ ), with the normal values above 1.35 and borderline values of 1.35–1.2. Drop of systolic pressure after standing up in AOT was less than 10 mmHg in both groups, which was in normal ranges. **Conclusion** Indicators of VHR at AOT in athletes and non-athletes differ substantially. This test allows collecting objective information on the state of VNS, and has diagnostic and prognostic value.

#### CHARACTERISTICS OF HEART RATE VARIABILITY DURING NIGHT SLEEP IN ELDERLY LONG-DISTANCE MALE RUNNERS

SHIMAMOTO, H.1, TANIDA, K.2, SHIBATA, M.2

*1: Osaka University (Osaka, Japan), 2: University of Hyogo (Akashi, Japan)*

**Introduction** Light-to-moderate exercise habituation induces a shift to a predominance of parasympathetic nervous system (PNS) activities and/or the extension of slow-wave sleep (SWS) time during night sleep. However, the influence of exercise itself on heart rate variability (HRV) during the night is not known in the case of elderly men habituated to high-intensity and highly frequent exercise. Therefore, to evaluate the influence of exercise habituation on HRV during the night, we compared the HRV on the exercise (E) day and rest (R) day in elderly men habituated to long-distance running. **Methods** This study involved 6 elderly male long-distance runners (mean  $\pm$  SD: age,  $67.8 \pm 9.1$  years) who were habituated to high-intensity and highly frequent exercise for over 20 years or more. On the R day and E day, a Holter electrocardiography monitor (FUKUDA FM-160, Japan) was used for recording R-R Interval (RRI) data, with 1 kHz sampling frequency. The RRI data were analyzed for each 10-min segment by using a time series-power spectral analysis software, MemCalc/Win ver.2 (GMS, Japan). The frequency band power was divided into 2 parts: low-frequency (LF, 0.04-0.15 Hz) and high-frequency (HF, 0.15-0.4 Hz) components. The relative PNS and sympathetic nervous system (SNS) activities were evaluated using the HF/(LF+HF) and LF/HF values. These HRV indices were compared for the first 1 h, first 3 h, and throughout the sleep period during the night on the E and R days. Repeated one-way ANOVA was used to evaluate the significance of the difference between the 2 settings. **Results** During the first 1 hour of sleep, PNS was higher on E day ( $p < 0.05$ ) and SNS was higher on R day ( $p < 0.05$ ). However, these differences were not seen during the first 3 h of sleep and for the entire nighttime sleep period. **Discussion** Previous studies reported that SNS activities were lower during slow-wave sleep than other sleep stages during non-rapid eye movement (N-REM). PNS activities were higher during rapid eye movement (REM) than N-REM sleep (Busek et al., 2005). Overnight PNS activity is reported to be positively correlated with SWS duration (Brandenberger et al., 2003). The results of our study were in accordance with those of these previous studies in that the quality of sleep was higher on the E day than on the R day during the first 1 h of sleep. In conclusion, elderly people who have long-term habituation to high-intensity and high-frequency running exercise have higher quality night sleep during the first 1 h on days when they exercise than when they rest. ## IMPACT OF BODY SCALES AND THE TYPE OF SPORTS ON THE LEFT VENTRICULAR DIMENSIONS IN JUNIOR COMPETITIVE ATHLETES

Kinoshita, N.1, Ishida, H.2, Katsukawa, F.2

1. Hosei University, 2. Keio University

**Introduction** Left ventricular (LV) dilatation/hypertrophy is commonly observed in competitive athletes (athlete's heart). Both body scales (body surface area [BSA] or fat free mass [FFM], etc.) and types of physical training were predictors for LV geometry of athlete's heart (1). However, the most evidences for the impact of those determinants were of adult athletic population. The aim of the study was to compare LV geometry of junior athletes with 2 extreme types of body scales; male professional sumo wrestlers (SUMO) and female long distance runners (LDR) and to evaluate the role of body scales in LV dimensions in junior athletes. **Methods** The subjects were Japanese 26 female LDR (160.5 cm, 46.5 kg) in a highly competitive team with the national level of achievements and 24 male SUMO (179.3 cm, 111.9 kg). All were 17-18 y/o and had had 2-3 years of competitive training career for each discipline. Echocardiography and underwater weighing (LDR) or air plethysmography (SUMO) were performed. LV mass (LVM) was calculated according to Devereux RB, et al (2) and LVM and LV end diastolic dimension (LVDd) were indexed to  $\text{height}^{2.7}$ , BSA, and FFM. The differences in variables were tested by unpaired t-test ( $p < 0.05$  was considered significant) and all values were expressed by the mean. Results LVDd and LVM of SUMO were significantly larger than those of LDR (58.0 vs 49.8 mm and 179.3 vs 160.5 g, respectively). LVDd of almost all LDR did not exceed the normal limits ( $< 54$ mm). After adjusted to body scales, however, LDR had significantly larger LV dimensions than SUMO: LVDd/BSA; 33.7 vs 25.4  $\text{mm}/\text{m}^2$ , LVDd/FFM; 1.24 vs 0.73  $\text{mm}/\text{kg}$ , LVDd/ $\text{height}^{2.7}$ ; 13.9 vs 12.0  $\text{mm}/\text{m}^{2.7}$ , LVM/FFM; 3.69 vs 2.93  $\text{g}/\text{kg}$ , respectively). LVM/BSA was not different from each other (101.3 vs 100.6  $\text{g}/\text{m}^2$ ) and SUMO had larger LVM/ $\text{height}^{2.7}$  than LDR (47.8 vs 41.3  $\text{g}/\text{m}^{2.7}$ , respectively). **Discussion** Female junior LDR had large adjusted LVDd corresponding to the level of elite male adult endurance athletes (3). Although LVDd of SUMO exceeded the normal limits, adjusted LVDd were smaller than those of LDR. The same was the case as for LVM except for LVM/BSA. These indicated that as in adult athletes, endurance training had powerful impact on the development of LV dilatation and adjustment to body scales was necessary when LVDd was evaluated in junior athletes. Adjustment by BSA or  $\text{height}^{2.7}$  might be appropriate to compare LVM in junior athletes with extremely different body scales. **References** 1. ## AUTONOMIC CONTROL OF HEART RATE IN CHILDREN. EFFECT OF BODY POSITION ON HEART RATE VARIABILITY

Gobbo, M., Capogrosso, M., Gheza, A., Perini, R.

University of Brescia

**Introduction** Cardiac autonomic activity has been evaluated extensively by analysis of Heart Rate Variability (HRV) in physiological and pathological conditions in subjects of different ages. HRV data are less consistent in very young individuals than in adults. Modifications in HRV autonomic indices, especially of vagal activity, have been observed during childhood and adolescence, likely as the result of the maturation of HR nervous control mechanisms. The influence of this process on the cardiac response to perturbations, such as orthostatic load, has not been clearly defined. We therefore evaluated the sympatho-vagal interaction in a group of pre-pubertal children by analyzing differences in HRV in different body positions. **Methods** 30 children (9 females) aged 9-10 years (gr A) and 24 children (9 females) aged 11-12 (gr B) participated in the study. All of them were healthy, pre-pubertal, normally active. In each subject R-R intervals were continuously recorded (Polar S810) in resting condition for 10 min in supine (Sup) and for additional 10 min in sitting (Sit) position. By time and frequency domain (AR method) analysis of HRV, the following parameters were calculated: standard deviation of the R-R intervals (SDNN); root mean square of successive differences of R-R intervals (rMSSD); power of the low frequency (LF, 0.04-0.15 Hz) and high frequency (HF, 0.15-0.4 Hz) bands in normalized units (nu), i.e. as percent of total power; the ratio between LF and HF. **Results** HR was similar in group A and B in Sup ( $79 \pm 2$  b/min) and significantly increased by about 8 b/min in Sit in both groups. Both SDNN and rMSSD were significantly higher in gr A (respectively  $90 \pm 32$  ms and  $100 \pm 50$  ms) than in gr B ( $62 \pm 25$  ms and  $62 \pm 30$  ms) and decreased by about 20-25 % in Sit ( $p < 0.05$ ). LF and HF powers were similar in the two groups, respectively  $45 \pm 18$  nu and  $53 \pm 22$  nu in Sup and  $63 \pm 18$  nu and  $31 \pm 16$  nu in Sit ( $p < 0.05$  between positions). LF/HF was  $1.3 \pm 0.9$  in Sup, independently of the group, and significantly higher in Sit ( $3.1 \pm 1.1$ ). **Discussion** The higher HR in Sit than in Sup was coupled with the reduction of all vagal markers, namely SDNN, rMSSD and HF, and with the increase of LF/HF, as expression of sympatho-vagal interaction. Thus, the modifications in HRV autonomic indices induced by the change in body position are comparable to those described for adults. The lack of differences between the two groups suggests no main effect of age on this autonomic functional response, at least in the range here evaluated. Nonetheless, the markedly different values of time domain parameters, i.e. SDNN and rMSSD, found in the two groups, could be the expression of the reducing vagal prevalence in autonomic interaction, possibly occurring with growth.

## PROLONGED STRENUOUS EXERCISE - IMPACT OF EXERCISE MODE UPON MYOCARDIAL TISSUE VELOCITIES

Williams, K., Whyte, G., George, K.

University of Surrey

**Introduction** A dose dependent relationship has been suggested previously whereby increasing aspects of exercise volume such as intensity, frequency and duration has a positive impact upon cardiovascular function up to an individually defined maximum. Exercise beyond this limit has been associated with a decline in myocardial tissue velocities and a subsequent decrease in cardiac function. Exercise induced cardiac fatigue has been reported in a number of sports, predominantly running and cycling however few studies have assessed whether mode has an impact upon the level decline in cardiac function. **Methods** Seven trained athletes completed a two hour bout of running and cycling exercise at 90% of their calculated anaerobic threshold on two separate occasions. Echocardiographic scans to measure myocardial tissue velocities at the septal wall, the left ventricular wall and right ventricular wall were performed pre, post, two hours post and 24 hours post each exercise bout. **Results** Changes in ventricular wall tissue velocities were minor and not cumulative across both cycling and running modes. Peak atrial diastolic tissue velocity in the left ventricular free wall increased ( $P < 0.05$ ) from 11 to 18  $\text{cm} \cdot \text{s}^{-1}$  during the running bout but this did not significantly impact the ratio of early to late diastolic wall motion. In the cycling group there were no pre-post exercise bout changes in cardiac function ( $P < 0.05$ ). **Discussion** The lack of apparent change in cardiac function during each exercise bout and the dislocation of the kinetics of septal, left and right ventricular wall velocities between modes of exercise suggest that cardiac dysfunction is not impacted by the mode of exercise. In summary, changes in cardiac function during a separate cycling and running exercise bout displayed limited evidence of accumulation between bouts which suggests that athletes coped well with the extreme cardiac work demanded by the different exercise protocol and no mode of exercise resulted in a greater decline.

**RELIABILITY OF A NEW PROTOCOL TO ASSESS HR RECOVERY AFTER SUBMAXIMAL EXERCISE.**

Romagnoli, M.1, Alis, R.1, Basterra, J.1, Villar, J.1, Perez, P.2, Arduini, A.3

*Catholic University of Valencia*

Reliability of a new protocol to assess HR recovery after submaximal exercise. Romagnoli M.1, Alis, R.1; Basterra, J.1, Villar, J.1, Perez P.2, Arduini, A.3 1 Catholic University Valencia (Valencia, Spain). 2 University of Valencia (Valencia, Spain) 3 Harvard University (Boston, MA, USA) Introduction: HR recovery after exercise is a measure used to assess adaptation to training and it has been proposed as independent predictor of all-cause mortality. The reliability of models for HR recovery assessment at submaximal intensities is poor and there a lack of standardization of the duration of recovery. It has been established that submaximal exercise is more reproducible than maximal and allows a better standardization of the test [1]. Our purpose is to determine the reliability of the indexes of HR recovery after a test on cycle ergometer at two submaximal exercise intensities (65% and 80% HRmax). Methods: HR recovery was assessed by 8 models, based on monoexponential kinetics or absolute recovery (recovered HR at fix time points) on 21 healthy subjects. Intraclass correlation coefficient (ICC) and standard error of measurement (SEM, %SEM) were used to address reliability of measurements. Results: Our results point to: assessment of HR recovery after 80% HRmax exercise is more reliable than after 65% HRmax (mean ICC: 0.827 vs. 0.747); at longer recovery time we found better absolute consistency of the measurement (%SEM: 26.7 at 60 s, 19.5 at 120 s and 16.3 at 180 s, irrespective of model or exercise intensity); to assess the fast component of HR recovery (HR kinetics calculated over  $\leq 60$  s) after exercise T30min is more reliable than T30 (ICC: 0.691 vs. 0.528; %SEM: 28.5 vs. 70.8). Discussion The protocol exhibits a good sensitivity of measurement - large ICC and small SEM - for analysis of HR recovery after submaximal exercise on cycle ergometer. Internal workloads of 80% HRmax has better reliability and the consistency of the results at this intensity increases with the duration of recovery. References 1. Cole, C.R., et al., Heart Rate Recovery after Submaximal Exercise Testing as a Predictor of Mortality in a Cardiovascularly Healthy Cohort. *Annals of Internal Medicine*, 2000. 132(7): p. 552-555.

**EFFECT OF AGING AND AEROBIC PHYSICAL TRAINING ON THE RAT ISOLATED HEART CONTRACTILITY.**

Souza, H., Tezini, G., Becari, C., Salgado, M.

*University of Sao Paulo*

EFFECT OF AGING AND AEROBIC PHYSICAL TRAINING ON THE RAT ISOLATED HEART CONTRACTILITY. Souza HC, Tezini GCSV, Becari C, Salgado MCO. School of Medicine of Ribeirão Preto, University of São Paulo, Brazil. Introduction Clinical and epidemiological studies show a low incidence of cardiovascular diseases (CVDs) in pre-menopause women compared to men at the same age group (Reckelhoff et al, 2001). On the other hand, such a difference decreases with age, especially after menopause when cardiovascular diseases become an important cause of death (Colditz et al, 1987). However, the mechanisms involved in the cardioprotective action of ovarian hormones have not yet been established. Therefore, we investigate in female rats the effects of aging on blood pressure, heart rate and heart contractility. Additionally, we investigated the effects of physical training on all parameters evaluated. Methods Female Wistar rats (10 and 70 weeks old, n=11) were divided into four groups: sedentary young rats, trained young rats, sedentary aged rats, and trained aged rats. Animals from the trained groups were submitted to a physical training protocol (swimming) for 10 weeks. After blood pressure and heart rate measurements, the rat heart was isolated and perfused by a Langendorf apparatus to measure the inotropic responses to the agonists dobutamine (0.5, 1, 10, 50 nmoles,  $\beta_1$ -adrenergic receptors) and salbutamol (0.5, 1, 10, 50, 100 nmoles,  $\beta_2$ -adrenergic receptors). Results Aging rats showed higher mean blood pressure and heart rate compared to young rats (109 $\pm$ 2 vs. 93 $\pm$ 2 mmHg, p<0.0001, and 403 $\pm$ 10 vs. 359 $\pm$ 6 bpm, p<0.001). Physical training did not change blood pressure (94 $\pm$ 2 mmHg,) but decreased heart rate (324 $\pm$ 5bpm, p<0.0001) of young rats. In the aged rats, physical training decreased both blood pressure (97 $\pm$ 2 mmHg, p<0.0001) and heart rate (339 $\pm$ 8 bpm, p<0.0001). The isolated heart contractility of sedentary aging rats in response to dobutamine was significantly depressed compared to the young group (Emax: 3.4 $\pm$ 0.2 vs. 6.2 $\pm$ 0.6 g, p<0.001). Physical training increased the responses to dobutamine in both young (9 $\pm$ 0.7 g, p<0.01) and aged rats (5.6 $\pm$ 0.9 g, p<0.05). In contrast, contractile effects induced by salbutamol were not affected either by aging or by physical training. Discussion Aging in female rats is associated with augmented blood pressure and heart rate and diminished inotropic response to  $\beta_1$ -adrenergic receptors activation. Additionally, physical training improves the hemodynamic parameters and cardiac contractility in aged rats. References Reckelhoff JF, Fortepiani LA. (2004). Hypertension. 2004; 43:918-923. **HEART RATE VARIABILITY IN ATHLETES AND SEDENTARY CONTROLS DURING ACTIVE ORTHOSTATIC TEST**

Somlev, P.

*National Sports Academy "Vassil Levski", Sofia*

Introduction Studies comparing heart rate variability (HRV) at rest between athletes and non-athletes suggest that endurance training is related to changes in cardiac autonomic regulation (Aubert et al., 2003). The active orthostatic task has been used to evaluate HRV in trained and untrained subjects, but the results are scarce and contradictory. Aim of this investigation was to assess the differences in HRV between endurance trained athletes and sedentary controls at rest and during active orthostatic test (AOT). Methods Sixteen endurance trained athletes (age=22.0 $\pm$ 2.42 years) and sixteen (age=21.5 $\pm$ 1.03 years) untrained controls participated in the study. In the supine position after 20 min of rest RR intervals of each subject were recorded for 5 min with Polar S810i heart rate monitor. After that subjects actively stood up (AOT) and data were collected for 5 min from 3th to 8th minutes in upright position. HRV parameters were obtained with Kubios HRV 2.0 software and included Mean RR, SDNN, RMSSD, pNN50%, LF power and HF power, (both in absolute and normalized units - ms<sup>2</sup> and nu), and LF/HF ratio. Aerobic fitness (VO<sub>2</sub>max) was determined indirectly with Astrand cycle ergometer test. Results VO<sub>2</sub>max in athletes was higher (p<0.05) than in sedentary subjects. During AOT in both groups there were significant increase (p<0.05) in Mean HR, LF nu and HF/LF ratio and significant decrease (p<0.05) in SDNN, RMSSD, pNN50%, HF ms<sup>2</sup> and HF nu. During supine rest Mean RR, RMSSD, pNN50%, HF ms<sup>2</sup> and HF nu were significantly greater (p<0.05) in athletes than in untrained subjects and LF nu and HF/LF ratio were significantly lower (p<0.05) in athletes than in untrained. Athletes also demonstrated lower heart rate at rest. During AOT there were no differences in all HRV indices between athletes and untrained controls. Discussion These results indicate that athletes have an increased vagal influence on heart rate and an attenuated sympathetic tone in supine position in comparison with sedentary controls. In both groups AOT induces identical changes in HRV indices, showing decrease of vagal activity and increase of sympathetic activity. Active standing eliminates the differences in HRV between athletes and untrained subjects. This effect requires further study. References Aubert AE, Seps B, Beckers F. (2003). *Sports Med* 33, 889-919

**ASSESSMENT OF SYMPATHOVAGAL BALANCE IN SOCCER PLAYERS**

Somlev, P., Uzunova, G., Pavlova, E.

*National Sports Academy "Vassil Levski", Sofia*

Introduction Heart rate variability (HRV) has been used as a method to assess the influence of training on sympathovagal balance mostly in endurance athletes. Studies with HRV, evaluating athletes from sports with aerobic and anaerobic training, are scarce. Soccer is a sport in which both endurance and anaerobic capabilities are important (Helgerud et al., 2001, Bangsbo et al., 2006). Aim of this investigation was to assess the sympathovagal balance in soccer players with HRV. Methods In the study participated 11 elite soccer players (age=21.5±3.8 years), 14 non-elite soccer players (age=21.6±1.4 years) and 14 soccer players, who have stopped their training (age=21.8±2.5 years). The elite players were studied during transition period. Non-elite players were studied during competitive season. RR intervals of each subject were recorded for 5 min with Polar S810i heart rate monitor in supine rest. HRV indices included SDNN, RMSSD, pNN50%, LF ms2, LF nu, HF ms2, HF nu. Sympathovagal balance was assessed with LF/HF ratio and newly proposed SD/RMSSD ratio (Balocchi et al., 2006). Cardiorespiratory fitness was determined indirectly with PWC170 cycle ergometer test. Results Physical working capacity was greatest in elite players. Heart rate was lower ( $p<0.05$ ) in elite and non-elite group than in the group of former players. SDNN in elite and non-elite players was higher ( $p<0.05$ ) than in former players. RMSSD and pNN50% were higher ( $p<0.05$ ) in the elite and non-elite players than in former players. LF ms2 was higher ( $p<0.05$ ) in the non-elite players than in former players. HF ms2 was higher ( $p<0.05$ ) in elite and non-elite players than in former players. LF nu was lower ( $p<0.05$ ) in elite players than in former players. HF nu was higher ( $p<0.05$ ) in elite players than in former players. LF/HF ratio was lower ( $p<0.05$ ) in elite players than in former players. There is no difference in SD/RMSSD ratio between the three groups. Discussion Bradycardia and vagal related HRV indices show a shifting in autonomic balance toward parasympathetic predominance in elite and non-elite soccer players in comparison with former soccer players. HRV of non-elite players may reflect the known sympathetic activation related to intensive training or competitive constraint (Bricout et al., 2010). The use of SD/RMSSD ratio as an alternative of LF/HF ratio for assessment of sympathovagal balance in athletes needs further study. **PHYSICAL TRAINING HAS FEW EFFECT ON THE AUTONOMIC CARDIOVASCULAR CONTROL IN OLD RATS SUBJECTED TO EARLY OVARIAN FAILURE.**

Souza, H., Tezini, G.

*University of Sao Paulo*

PHYSICAL TRAINING HAS FEW EFFECT ON THE AUTONOMIC CARDIOVASCULAR CONTROL IN OLD RATS SUBJECTED TO EARLY OVARIAN FAILURE. Souza HC and Tezini GCSV. School of Medicine of Ribeirão Preto, University of São Paulo, Brazil. Introduction Women with loss of ovarian function before 40 years old, a condition defined as premature menopause or early ovarian failure, are more susceptible to cardiovascular diseases (Coulam et al., 1986). Some authors showed that this condition, compared to physiological menopause or physiological ovarian failure, is associated with even more severe heart dysfunctions (Atsma et al., 2006). These dysfunctions are usually associated with impairment in the cardiac autonomic control. Therefore, we have investigated and compared the effects of physiological ovarian failure (POF) and early ovarian failure (EOF), including the effect of physical training on the cardiovascular autonomic control of elderly female rats by using different approaches. Methods Seventy-two female rats were assigned to 3 groups: control (22 weeks old), POF (82 weeks old) and EOF (82 weeks old). Half of the animals of each group underwent physical training. All groups were submitted to double autonomic blockade (DAB) with methylatropine and propranolol; baroreflex sensibility (BRS) and spectral analysis of heart rate variability (HRV). Results The sedentary groups (POF and EOF) had hypertension, tachycardia, and reduced intrinsic heart rate (HR). After physical training, only POF group had a reduction in the mean arterial pressure. In turn, all trained groups had a decrease in the basal HR despite the fact that only control and POF groups showed a reduction in intrinsic HR. The evaluation of cardiac autonomic tone showed that the vagal autonomic component was predominant in the control group, whereas the other groups had a sympathetic predominance. Analysis of the heart rate variability (HRV) showed no difference between the sedentary groups in normalized units. On the other hand, control and POF groups had a decrease in the low-frequency oscillations (LF, 0.25-0.75 Hz) and an increase in the high-frequency oscillations (HF, 0.75-2.5 Hz) following physical training. With regard to the systolic arterial pressure variability, our results showed that POF and EOF groups had increased LF oscillations, whereas only POF group had a reduction after physical training. Finally, analysis of the baroreflex sensitivity showed that POF and EOF groups had a reduced gain (ms2/mmHg), which was attenuated by the physical training. Discussion The ovarian failure, either physiological or premature, promotes negative effects on arterial pressure, HR, and cardiac autonomic control. On the other hand, physical training promoted few positive effects on animals undergoing EOF compared to those undergoing POF. References Coulam CB, Adamson SC, Annegers JF. Cardiac response to acute high-intensity interval and moderate-intensity continuous exercise in untrained females Lancaster, RE.1, Castle, P.1, George, K.2, Oxborough, D.3, Sculthorpe, N.1 1: Institute of Sport and Physical Activity Research, University of Bedfordshire 2: Research

Institute for Sport and Exercise Sciences, Liverpool John Moores University, Liverpool 3: School of Healthcare, University of Leeds, Leeds

Introduction Research on cardiac responses to acute exercise has focused on prolonged exercise and athletic populations. Untrained individuals and shorter bouts of exercise (<60 minutes) have received less attention. This study aimed to evaluate the acute response in untrained females to isocaloric high-intensity interval exercise (HIIE) and moderate-intensity continuous exercise (MICE). Methods 15 female participants ( $20.9 \pm 4.8$  yr) undertook assessments of body composition, blood pressure, echocardiography and  $\text{VO}_2\text{MAX}$ . Participants completed both a HIIE and a MICE session in a counterbalanced design with >7 days between tests. HIIE consisted of  $6 \times 3$  min high intensity efforts interspersed with  $6 \times 3$  min recovery. MICE consisted of 50 min steady state exercise. Protocols were matched for average intensity, distance, duration and calories expended (Bartlett et al. 2011). Echocardiography was performed pre, and 0.5 hr, 4 hr, and 24 hr post exercise. Measurements included; left ventricular (LV) dimensions and volumes using Simpsons biplane, left atrial diameters, peak early ( $E_m$ ) and peak atrial ( $A_m$ ) transmitral flow, tissue Doppler imaging (TDI) longitudinal peak systolic ( $S'$ ), early diastolic ( $E'$ ), and late diastolic velocities ( $A'$ ) and isovolumic relaxation time, as well as  $E_m/E'$ . Bioelectrical impedance and metabolic rate were measured at rest and 24 hours post exercise. Results LV end-diastolic volume was increased ( $p < .05$ ) 4 hours following HIIE from pre-exercise, however no differences were observed following MICE. No other trial or time effects were observed in any cardiac or non cardiac indices. Discussion There is little difference in the acute (< 24 hr) cardiac response to HIIE and MICE in untrained females. This suggests that the stimulus for the differing cardiac responses in high and moderate intensity training programmes (Wisloff et al., 2006) is related to the exercise stress and not any persistent alterations in cardiac function. ### PHYSIOLOGICAL RESPONSES IN SUPRAMAXIMAL HIGH-INTENSITY INTERMITTENT TRAINING IN YOUNG COMPETITIVE CYCLISTS

Nicolò, A., Bazzucchi, I., Lenti, M., Haxhi, J., Scotto di Palumbo, A., Conti, A., Sacchetti, M.  
*University of Rome "Foro Italico"*

Introduction High intensity intermittent training (HIT) is recognized to be the preferential type of exercise to elicit further adaptations in already highly-trained endurance athletes (Laursen and Jenkins, 2002). However, the acute physiological responses of HIT protocols remain to be fully explored. We investigated two types of supramaximal HIT protocols used by some cycling coaches to notably stress both the aerobic and anaerobic metabolism. Methods Thirteen competitive cyclists ( $19 \pm 2$  yr,  $\text{VO}_2\text{max}$  of  $63.1 \pm 4.2$   $\text{ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ ) performed a maximal incremental test and two randomized HIT protocols to exhaustion during the competitive season. HIT protocols differed in work and rest duration (40 s:20 s and 30 s:30 s) but had the same work (135% of peak power output) and rest (0 W) intensity. Gas exchange and ventilatory parameters, heart rate (HR), blood lactate [ $\text{La}^-$ ] and surface electromyographical (sEMG) parameters (root mean square and muscle fibre conduction velocity) from the vastus lateralis (VL) muscle were collected. Results Time to exhaustion was  $10 \pm 3$  min and  $38 \pm 13$  min, and average  $\text{VO}_2$  was  $89 \pm 4\%$  and  $75 \pm 4\%$  of  $\text{VO}_2\text{max}$  for 40 s:20 s and 30 s:30 s, respectively. Maximum values of  $\text{VO}_2$  and ventilation ( $V_e$ ) for 40 s:20 s were significantly higher ( $p < 0.01$ ) than those of the other two trials. Peak [ $\text{La}^-$ ] value was significantly higher ( $p < 0.01$ ) for 40 s:20 s than for 30 s:30 s ( $13 \pm 1.5$ ,  $10 \pm 2.9$ ) while mean values of [ $\text{La}^-$ ] for 30 s:30 s were at or above the 8 mmol/l value for about 20 min. The kinetics of  $V_e$  as a function of time was incremental while that of  $\text{VO}_2$  was quite stable throughout the test, except for a slight but significant ( $p < 0.05$ ) decrease in the last part of the trial. The HR kinetics showed a cardiac drift. All the kinetics described were similar between the two HIT tests. The EMG analysis indicated a substantial neuromuscular involvement of the VL but did not detect significant changes in the sEMG parameters kinetics during the two trials. Discussion In the two HIT tests, the metabolic and ventilatory parameters seemed to better explain athlete exhaustion than the neuromuscular ones. The aerobic and anaerobic metabolism appeared highly stimulated, although in different ways, due to the different mean total exercise duration. The 40-s:20-s test enabled physiological parameters to reach maximum values, while the 30-s:30-s one stimulated the lactate tolerance, allowing to maintain quite high [ $\text{La}^-$ ] levels for a long period of time. Moreover, both the HIT tests provide an important tool to reach high levels of  $V_e$ . These results can help coaches and exercise scientists choose and prescribe supramaximal HIT protocols. ### NOCTURNAL CARDIAC AUTONOMIC RECOVERY AFTER HIGH-INTENSITY INTERVAL AND LONG-SLOW DURATION TREADMILL RUNNING IN YOUNG MALE, ELITE ENDURANCE ATHLETES

Mikkilä, S., Welde, B.

*North Troenderlag University College*

NOCTURNAL CARDIAC AUTONOMIC RECOVERY AFTER HIGH-INTENSITY INTERVAL AND LONG-SLOW DURATION TREADMILL RUNNING IN YOUNG MALE, ELITE ENDURANCE ATHLETES Mikkilä, S. Welde, B. North-Troenderlag University College (Levanger, Norway) Introduction Extensive training in elite athletes requires adequate recovery in order to increase performance or performance potential, and to avoid overtraining or other health problems. Heart rate variability (HRV) has been said to reflect the state in the autonomic nervous system and to provide essential information of the parasympathetic regulation, which is significant for post-exercise recovery. HRV has been widely investigated during and after exercise in daytime and after exercise at night, with conflicting results. Therefore, the aim of this study was to investigate the nocturnal cardiac autonomic recovery after one high-intensity interval training session (HIIT) and one long-slow duration training session (LSD), with approximately equivalent training impulse (TRIMP). We hypothesized a greater impact on HRV after the HIIT session and more rapid recovery after the LSD session. Methods 4 well-trained endurance athletes' nocturnal HRV was monitored during a 7-day protocol: after two non-training days, and for two nights after HIIT and LSD training sessions. Recommendations of Brandenberger et al. (2005) were followed in order to isolate a 5-minute sequence during the first slow wave sleep for further HRV analysis. HRV data for frequency analyzes were processed by Kubios HRV software. TRIMP was calculated prior to exercise according to Foster et al. (2001). Also, TRIMP was calculated after the sessions according to the actual %HRmax during both training sessions. Athletes' life satisfaction was investigated using the Quality of Life Index questionnaire in order to consider the non-training stressors influencing the HRV. Results No significant effect in the nocturnal cardiac autonomic recovery was found between rest and training, or between the training sessions. Also, no significant change in the non-training stressors was found. Discussion HIIT or LSD sessions did not introduce significant effects on cardiac autonomic recovery when the non-training stressors remain unchanged. Therefore, the results do not support the hypothesis that a HIIT session would cause greater changes in HRV compared to a LSD session. Also, the hypothesis regarding

more rapid recovery after LSD session is not supported. These results are in partial conflict with previous studies, although these did not investigate a single session of exercise. ### **EFFECT OF HIGH-INTENSITY INTERVAL TRAINING ON CARDIO-METABOLIC RISK MARKERS IN ADOLESCENTS: 3-MONTH FOLLOW-UP OF PROJECT FFAB**

Taylor, K., Azevedo, L., Bock, S., Batterham, A.M.

*Teesside University*

Effect of high-intensity interval training on cardio-metabolic risk markers in adolescents: 3-month follow-up of Project FFAB (Fun Fast Activity Blasts) Taylor, K.1, Azevedo, L.1, Bock, S. 2, Batterham, A. M. 1. 1Teesside University (Middlesbrough, UK). 2Durham University, UK. Introduction Project FFAB is an exploratory controlled before and after study of the effects of a practical and engaging low-volume high-intensity training (HIT) intervention on cardio-metabolic risk markers. The extent to which adaptations to HIT can be maintained is unknown (Gibala & McGee, 2008). We aimed to evaluate the maintenance of any beneficial intervention effects at 3 months follow-up. Methods Participants were 102 adolescents (64 male; 14.3 ± 0.3 years; mean ± SD) from four schools; two schools were assigned to the Intervention (n = 41) and two to the Control, matching for socioeconomic status. The intervention comprised four sets of 45 s maximal effort exercise (at least 90% of maximum heart rate) involving boxing, dance, soccer and basketball drills, with 90 s rest between sets, up to three times weekly for 10 weeks. The number of sets was increased by one every two weeks. Outcomes were blood lipids and glucose, waist circumference, C-reactive protein, blood pressure, physical activity levels (7-day accelerometry), aerobic fitness (multistage fitness test), and carotid artery intima-media thickness. The difference in the change from baseline (intervention minus control) was estimated for each outcome, with sex, the baseline value, and maturity offset as covariates. Using magnitude-based inferences (MBI) with qualitative probabilistic descriptors (Hopkins et al., 2009), we calculated the probability (P, MBI) that the true population effect was greater than the minimum important difference (MID; 0.2 standard deviations). Results Compliance was indicated by 75% of the intervention group completing at least 70% of the sessions. At the post-intervention time point, we had previously observed clinically relevant improvements vs. control ('likely' or 'very likely' to be greater than the MID) in triglycerides (-24%), waist circumference (-2.7 cm), and mean daily moderate to vigorous physical activity (MVPA) (14.3 min). At 3-months follow-up the mean triglyceride level was 6% lower in Intervention vs. Control (90% confidence interval, -22 to 14%; P, MBI = 0.38), waist circumference was 2.2 cm smaller (-3.4 to -1.1 cm; P, MBI = 0.43), and mean daily MVPA was 12.8 minutes greater (-12.0 to 37.7 minutes; P, MBI = 0.69). All three effects were 'possibly' important. There was no substantial effect on any other outcome. Discussion Clinically relevant post-intervention effects were attenuated at 3-months follow up. There is some evidence of a possible residual benefit, but exercise interventions must be regular to maintain beneficial adaptations. ### **SHORT TERM INTERVAL TRAINING IMPROVES MITOCHONDRIAL RESPIRATION AND EXERCISE CAPACITY**

Gant, N., Vincent, G.E., Edge, J.A., Vincent, P.J., MacDonald, J., Hickley, A.J.R.

*The University of Auckland*

Purpose Low volume high-intensity interval training (HIT) is a potent exercise strategy that stimulates metabolic adaptation in humans. However, current training protocols consisting of repetitive 'all out' maximal sprinting efforts of ~30 s require a high level of participant motivation and specialized laboratory equipment. Recently, a more practical HIT model has been introduced involving tolerable intensity and extended duration bouts, which are interspersed with appropriate recovery periods. The influence of HIT on mitochondrial respiration has yet to be studied. Method Here we use groups of matched males and females to show the effects of HIT over a short period (2 weeks) on whole body and mitochondrial respirometry, skeletal muscle performance, and cellular adaptation. Eight men and eight women (age 22 ± 2 y, body mass 75 ± 14 kg) performed one-legged VO<sub>2</sub> peak tests with bilateral muscle biopsies (vastus lateralis) taken before and after two weeks of HIT. Training involved single-leg cycling using the non-exercising leg as the control. Exercise bouts were performed 4 days/week and comprised 12 x 1 min intervals at 120% of peak power output performed during VO<sub>2</sub> peak tests, separated by 90 s of rest. Mitochondrial respiration and the activity of enzymes citrate synthase and lactate dehydrogenase were quantified. Results Training increased peak power in the trained limbs of both males (22.9%) and females (45.9%) (P < 0.05). Maximal oxidative phosphorylation capacities improved in male participants (20.7%), as did cytochrome c-oxidase respiration (12.9%) and citrate synthase activity (79.6%) (P < 0.05 for all). Apparent enhancements in mitochondrial and enzymatic function failed to reach statistical significance in females. Baseline training status, antioxidant capacities and stress-induced responses may explain the gender differences. Conclusion HIT is a time-efficient training method that can improve exercise capacity and mitochondrial function over a 2-week period.

### **PHYSIOLOGICAL AND PSYCHOLOGICAL RESPONSES TO ROYAL AUSTRALIAN AIR FORCE ENVIRONMENTAL SURVIVAL TRAINING IN THE TROPICS**

Edwards, A., Chester, A.L., Crowe, M., Quirk, F.

*James Cook University*

Title: Physiological and Psychological Responses to Royal Australian Air Force Environmental Survival Training in the Tropics. Authors: Edwards AM1, Chester AL1, Crowe M1, Quirk F2 1 Institute of Sport and Exercise Science, James Cook University, Australia 2 School of Medicine and Dentistry, James Cook University, Australia Introduction: Military personnel experience extreme levels of physiological and psychological stress during sustained operations [1]. Stressful, realistic training is recognised as a key element of physical and psychological preparation for military operations, yet the extent to which existing training practices prepare military for combat and/or survival situations are rarely reported [2]. The aim of this study was to quantify the physiological and psychological responses to a 15 day programme of RAAF Environmental Survival Training (EST) in the tropical conditions of Far North Queensland. Methods: Fourteen RAAF volunteers were assigned to an experimental group (9 males, 5 females), while a further 10 matched for age and fitness (7 males, 3 females) were recruited to a control group. The experimental group completed a series of physical challenges throughout EST in different environmental conditions while the control group maintained typical day-to-day activities. The physiological and psychological impact of EST was measured through: 1) biochemical markers (IL-6 and creatine kinase), 2) physiological and anthropometric variables (vertical jump, body mass, flexibility and hydration) and 3) psychological questionnaires. Results: Creatine kinase concentration significantly increased (p<0.01)

in experimental at day 5 ( $p<0.05$ ) and remained elevated over the survival course ( $p<0.01$ ). Vertical jump height (-8.8%), peak power output (-6.2%), average power output (-15.5%) and body mass (7.0%) all declined in experimental ( $p<0.01$ ). Perception of pain increased ( $p<0.01$ ) over EST while no significant changes were found in IL-6, flexibility, blood lactate or hydration. The EST produced negative psychological responses such as mood ( $p<0.01$ ), depression ( $p<0.05$ ), anxiety ( $p<0.01$ ) and stress ( $p<0.01$ ). No significant changes were observed in the control condition. Conclusion: The RAAF EST imposed significant physiological and psychological stress evident from markers of muscle damage, deterioration in physical performance, substantial weight loss, negative mood and psychological distress. However, as IL-6 concentrations did not change in response to EST, this suggests the imposed training load was challenging, yet probably not so substantial as to compromise the immune system. ### TESTOSTERONE, CORTISOL, T:C RATIO AND EXERCISE RESPONSES DURING 135 MILES MOUNTAIN FOOT RACE

Belli, T.1,2, Araújo, G.G.2, dos Reis, I.G.M.2, Scariot, P.P.M.2, Ackermann, M.A.2, Gobatto, C.A.2

1: Sao Paulo State University (UNESP), Rio Claro/SP, BRAZIL. 2: State University of Campinas (UNICAMP), Limeira/SP, BRAZIL.

Introduction: It is widely documented that exercise produces an imbalance between anabolic and catabolic hormones, however, the relationship of these hormones with exercise performance during ultramarathon races has not been studied. Thus, the aim of this study was assess the relationship between testosterone, cortisol and T:C ratio responses and exercise performance during 135 miles race. Methods: It was studied 10 male athletes (43±3 years; 171.4±1.9 cm height; 72.0±3.1 kg body weight; 15±3 years of race training; 118±20km/week of training volume) that participated of the 'BAD 135 World Cup' mountain race called "Brazil 135 Ultramarathon". Race and pause time were obtained by official race reports. Blood samples were obtained at baseline, 52, 110 and 135 miles to testosterone (T) and cortisol (C) determinations (Siemens Coat-A-Count kits®). All data were expressed by mean ± SEM, repeated measures ANOVA was used to comparisons, Scheffé post hoc test was performed when appropriate and Pearson's correlation coefficient was used for analyzing relationships (statistical significance  $P<0.05$ ). Results: The subjects completed the race in 46.8±3.4h, speed average of 3.1±0.2 mph and total pause time of 3.9±0.9 h. C levels increases whereas T:C ratios decreases significantly ( $P<0.05$ ) from baseline to 52, 110 and 135 miles (195±40, 252±42, 176±45% and -64±11, -69±11, -59±21%, respectively). Furthermore, C levels at 135 miles were positively correlated ( $P<0.05$ ) with running velocity ( $r=0.82$ ) as well as inversely correlated ( $P<0.05$ ) with race time ( $r=-0.83$ ) and pause time ( $r=-0.78$ ) while T levels and T:C ratio at 135 miles were positively correlated ( $P<0.05$ ) with pause time ( $r=0.65$ ;  $0.77$ , respectively). Discussion: Present investigation showed increases in C concentrations, corroborating previous studies (Nieman et al. 2006, Nieman et al. 2007), and decreases in T:C ratios denoting a catabolic profile during the race. In addition, we observed that higher running intensity and lower race and pause time may be related to greater C levels whereas higher pause time may be related to greater T levels and T:C ratio after 135 miles mountain foot race. ### TOTAL IGF-I RESPONSES TO A 5-DAY MILITARY COURSE WITHOUT CALORIE RESTRICTION

Teo, Y., Nindl, B., Lee, J.

1: DSO National Laboratories, Republic of Singapore, 2: Yong Loo Lin School of Medicine, National University of Singapore, Republic of Singapore, 3: The U.S. Army War College, Carlisle, United States

INTRODUCTION Insulin-like growth factor I (IGF-I) is an important metabolic biomarker, influenced by energy balance, anabolic and nutritional status (Nindl & Pierce, 2010). Rarick et al (2007) reported a ~30% total IGF-I decline in the absence of body mass loss after 7 days of physical activity where energy expenditure was balanced with caloric intake (3,600-4,000 kcal/d) in a laboratory setting. This study investigated total IGF-I responses to a military operational stress scenario without calorie restriction. METHODS Thirty-three male military personnel (Mean±SD; 19.5±0.9 y; 1.75±0.06 m; 66.8±6.2 kg; 9.6±2.8 % body fat) participated in a 5-day military training course, which comprised of continuous physical activity with minimum sleep (total 1 h). Caloric intake was ~3,500 kcal/d. Measurements were taken a day prior and immediately following the course. Body composition was determined via skinfold measurement at 7 sites (chest, axilla, triceps, subscapula, abdomen, suprailiac and thigh). Body mass, serum IGF-I, tumor necrosis factor- $\alpha$ , interleukin-6 and creatine kinase were measured. Cognitive function was assessed as alertness, divided attention and decision making via the Vienna Test System. Upper body strength was determined by a JTECH force gauge. Vertical squat and countermovement jump height were assessed by a vertical jump yardstick. RESULTS There was no change in body mass (PRE: 66.8±6.2; POST: 66.8±6.0 kg;  $P=0.68$ ), fat mass (PRE: 6.5±2.5; POST: 6.3±2.5 kg;  $P=0.08$ ) and muscle mass (PRE: 33.5±2.7; POST: 33.1±2.9 kg;  $P=0.11$ ) following the course. Post course IGF-I decreased by 26% (PRE: 218±43; POST: 161±38 ng/mL;  $P<0.001$ ). There was an increase in interleukin-6 (330%;  $P<0.001$ ) and creatine kinase concentrations (1906%;  $P<0.01$ ) post course. Tumor necrosis factor- $\alpha$  levels remain unchanged ( $P=0.09$ ). Number of correct reactions decreased ( $P<0.001$ ) for alertness (14%), divided attention (26%) and decision making (18%) at the end of the course. Mean reaction time for correct reactions increased for alertness (38%;  $P<0.001$ ) but remained unchanged for divided attention ( $P=0.50$ ) and decision making ( $P=0.91$ ) at the end of the course. Average upper body strength and vertical squat jump height degraded by 22 and 35% ( $P<0.001$ ) respectively post course. No associations were found between IGF-I and the performance tests. CONCLUSION The decrease in IGF-I coincides with degradation of cognitive and physical performance and therefore established the intense physiological strain of the 5-day military course. Our findings further reinforced that decrease in IGF-I can occur in the absence of calorie deficit in actual military field settings. REFERENCES Nindl BC, Pierce JR (2010). ### LEPTIN AND OVERLOADING

Uusitalo, A.

Helsinki University Hospital

LEPTIN AND OVERLOADING Uusitalo, A.1,2, Tanskanen, M.3, Atalay, M.4, Häkkinen, K.3, Kyröläinen, H.3. 1: Helsinki University Hospital (Finland), 2: University of Helsinki (Finland), 3: University of Jyväskylä (Finland), 4: University of Eastern Finland (Kuopio, Finland) Introduction Leptin is a protein secreted by white adipose tissue. Its secretion decrease with energy deficit and increase with energy overloading and

obesity. It is unclear if physical overloading could influence leptin metabolism independently from energy homeostasis, and what is a role of leptin and energy deficit in the development of overtraining state (1). Leptin influences the stress response at every main level of HPA-axis, and it is suggested to reduce adrenal cortisol synthesis (2). Our aim was to study whether leptin level differed between overreached (OR) and no-OR conscripts during the first 9 weeks of military service. Correlation between leptin and cortisol levels were also analysed. Methods Fifty seven male conscripts (19.7  $\pm$  0.3 yrs) took part into the study. The blood samples were taken after one, 4 and 7 week's of service and after one week of recovery (9 wk) before and immediately after the 45-minute submaximal marching test. OR subjects had to fulfill three of five criteria; decreased VO<sub>2</sub>max, increased RPE in 45-min submaximal test or absence due to sickness from these tests, increased somatic or emotional symptoms of OR and high incidence of absence due to sickness from daily training (3). Results Out of 33 conscripts who were healthy on the test days and were able to perform the test scheme, 9 were classified as OR and 24 as no-OR subjects. Both OR and no-OR lost their weight and fat mass about 2 kg ( $p < 0.001$ ) during the service. Also their resting ( $p < 0.01$ ) and submaximal exercise related ( $p < 0.05$ ) leptin concentration decreased. There seemed to be significant leptin x fat mass interaction but overreaching had no significant effect on leptin behavior. Cortisol at rest was higher in OR than no-OR ( $p < 0.05$ ) especially at 9 wk time point, and it decreased during the service in the both groups. However, we did not find correlation with change in cortisol and leptin concentrations. Discussion Changes in leptin levels were related to change in fat mass but we did not find signs of independent effect of overreaching on leptin behavior. This, however, does not rule out it's possible role in pathophysiology of overtraining. Both leptin and cortisol decreased during the service, but we could not find linear relationship between cortisol and leptin changes, which, however, does not rule out the possible central interaction between leptin and HPA-axis. However, the effect may not be linear and strong and there are other even much stronger influencing factors. 1. Jürimäe J et al. (2011). *Metabolism Clinical and Experimental*, 60, 335-60. 2. ##### WEIGHT REDUCTION BY DIETARY INTERVENTION FOR THREE MONTHS DECREASED MEDICAL RISK IN HEAVY-WEIGHT FEMALE JUDO ATHLETES

Murata, H.1, Takata-Ishikawa, K.2, Higuchi, M.3, Taguchi, M.3

1: Japan women's College of physical education(Tokyo, Japan), 2: National Institute of Health and Nutrition(Tokyo, Japan), 3: Faculty of Sports Science, Waseda University(Saitama, Japan)

**Introduction** It is known that obese individuals have higher medical risk such as insulin resistance, hypertension and dyslipidemia. Previous studies reported that male athletes who possess heavier body weight such as American football players and Judo athletes have higher medical risk induced by excessive weight gain associated with excessive body fat accumulation. However, no information is available to evaluate medical risk concerned with excessive body fat accumulation for female Judo athletes categorized in heavy weight class. The purpose of the present study was to examine the effect of weight reduction by dietary intervention to aim the decrease in higher medical risk for female Judo athletes with heavier body weight. **Methods** Ten Japanese female Judo athletes categorized 78kg and over 78kg classes (age 20.3  $\pm$  1.9 years, height 166.4  $\pm$  4.1 cm, body weight (BW) 92.1  $\pm$  16.7 kg, % body fat 30.3  $\pm$  6.2% (%BF), fat-free mass (FFM) 63.4  $\pm$  7.2kg and body fat mass 28.7  $\pm$  10.3kg) completed a 12-week weight-loss intervention. Sports dietitian instructed to reduce their caloric intake through lipids intake control or sugar restriction. Before and after intervention, body composition was measured by dual energy X-ray absorptiometry (DXA). Physical fitness tests were performed before and after the intervention. Blood samples were taken after 12-hour over-night fasting. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), lipids, insulin, and glucose levels in blood were analyzed in all subjects before and after the intervention. Insulin resistance was assessed in terms of HOMA-IR. **Results** After the dietary intervention for 12-week, total body weight and fat content significantly reduced by 4.5kg (5.4%), and 2.5kg (10%), respectively, whereas no significant decrease was observed in FFM. Muscular and cardiorespiratory physical fitness was not changed in response to the intervention. Values of AST (26  $\pm$  11 vs. 18  $\pm$  5 U/L), ALT (29  $\pm$  17 vs. 17  $\pm$  5 U/L), total cholesterol (194  $\pm$  29 vs. 176  $\pm$  21 mg/dL) and glucose (92  $\pm$  10 vs. 87  $\pm$  9 mg/dL) in blood significantly decreased, respectively. HOMA-IR decreased significantly (3.3  $\pm$  2.0 vs. 2.6  $\pm$  2.1), but the three subjects still had abnormal insulin resistance. **Conclusion** This study suggested that long-term mild weight reduction by dietary intervention can reduce any medical risks without decreases of FFM and physical fitness for female Judo athletes categorized heavy weight class.

##### EXERCISE INTENSITIES AND DETERMINANTS IN BASIC AQUATIC MOVEMENTS

Kawano, H.

Waseda University

**BACKGROUND:** Aquatic (aqua aerobics) exercise is characterized in that exercise intensity can be easily adjusted with viscosity of water and reduction in load on knee joints is induced with buoyant force, in contrast to exercising on land. Although aquatic exercise program is mainly composed of basic aquatic movements such as Rocking, Jumping, Kicking, or Scissors, it remains unclear the exercise intensities of these aquatic movements. Moreover, because it is thought that, in the case of a body movement under the water environment, greater body surface area contacted on water may be associated with higher water resistance, aquatic exercise intensity may be accounted for by body size such as body surface area as well as physical fitness such as cardiorespiratory fitness. Therefore, the aims of this study were to determine the exercise intensity of basic aquatic exercises and to examine the determinants of the exercise intensities from physical characteristics such as body size or physical fitness. **METHODS:** A total of 38 healthy young men (11 sedentary, 15 endurance-trained, and 12 resistance-trained men) were participated in the study. Averages of age, height, body weight, percentage of body fat, body surface area, cross-sectional area in calf, and maximal oxygen consumption (VO<sub>2</sub>max) were 21.2  $\pm$  1.7 (19-27) yrs, 172.3  $\pm$  6.0 (158.6-183.5) cm, 68.2  $\pm$  12.7 (52.5-108.0) kg, 15.7  $\pm$  6.8 (5.0-33.7)%  $\pm$  1.80  $\pm$  0.15 (1.54-2.20) m<sup>2</sup>, 100.7  $\pm$  15.0 (80.5-151.1) cm<sup>2</sup>, and 50.0  $\pm$  11.2 (29.1-69.5) ml/kg/min, respectively. They randomly performed 4 basic aquatic exercises in a swimming pool for 5 min each, which the water depth was at the level of xiphoid process, and oxygen uptake was measured by a Douglas bag during final a minute of the

each exercise session. RESULTS and DISCUSSION: The highest intensity of aquatic exercises was in Kicking ( $61.7 \pm 15.0\% \text{VO}_{2\text{max}}$ ), followed by Scissors ( $49.4 \pm 13.7\% \text{VO}_{2\text{max}}$ ), Jumping ( $32.4 \pm 8.4\% \text{VO}_{2\text{max}}$ ), and Rocking ( $30.9 \pm 9.8\% \text{VO}_{2\text{max}}$ ). Multiple regression analysis revealed that body surface area was independently related with exercise intensity of Rocking ( $\beta=42.3$ ), and  $\text{VO}_{2\text{max}}$  was independently related with them of Scissors ( $\beta=-0.68$ ) and Kicking ( $\beta=-0.75$ ). In addition,  $\text{VO}_{2\text{max}}$  and cross-sectional area in calf were independently related with exercise intensity of Jumping ( $\beta=-0.38$  and  $-0.30$ , respectively). These results suggest that body size as well as cardiorespiratory fitness should be considered to determine the aquatic exercise intensity for constructing exercise program in water.

### PREDICTIONS DEVELOPMENTS OF MAXIMAL AEROBIC POWER BY GENERAL VARIABLES AND METABOLICAL RESPONSES IN SUBMAXIMAL EXERCISE FOR SOUTH KOREAN ADULT FEMALE

Lee, B.K.1, Kim, K.H.1, Shin, J.M.1, Im, J.H.2, Jeon, Y.J.2, Chang, H.K.3, Kim, H.J.4, Choi, D.H.5

1: SangMyung U(Cheonan, S Korea), 2: KAIST(Daejeon, S Korea) 3: Seoul Women's U(Seoul, S Korea), 4: ChoSun U(Gwangju, S Korea) 5: SeoGang U(Seoul, S Korea)

**Introduction** The purpose of this study was to develop the prediction model of maximal aerobic power by general variables and submaximal metabolic responses from the Bruce protocol for S Korean adult female, and to compare and analyse the validity of these prediction models. **Methods** The subjects were consisted of 198 South Korean adult female. They were participated maximal exercise testing with Bruce treadmill protocol(Bruce et al., 1973), and the general physical variables and the metabolic responses were measured in the end of the first(3 minute) and second stage(6 minute). Measurement items were Age, WT, HT, BMI, and  $\text{VO}_2$ ,  $\text{VCO}_2$ , VE, HR of 3 and 6 minute, time to HR 150 bpm. To determine the predicted model of  $\text{VO}_{2\text{max}}$ , multiple and simple regression analysis with stepwise methods analysis were applied. Results Analyzing with all variables using stepwise method, the multiple R of total variable model was 0.73( $p<.01$ ), SEE was 3.4 ml/kg/min, CV was 10.3%. The multiple R of 3 minutes model was 0.68, SEE was 3.6ml/kg/min, CV was 11.0%. The multiple R of 6 minutes model was 0.69, SEE was 3.6ml/kg/min, CV was 10.8%. The multiple R of general variables model was 0.59, SEE was 4.0ml/kg/min, CV was 12.2%. The R of HR 150 model were 0.16, SEE was 4.0ml/kg/min, CV was 14.8%. **Discussion & Conclusion** Cao, et al.(2009) reported the prediction of  $\text{VO}_{2\text{max}}$  model with daily step counts, BMI, Age for Japanese adult women, and R of this prediction was 0.81( $p<.001$ ). In conclusion, with considering usefulness and convenience through the validity of these prediction models, the prediction model of Maximal Aerobic Power recommended total model, general variables model, 6 and 3 minute model, and HR 150 model by tunes. **References** Bruce, R. ### RESTING ENERGY EXPENDITURE DOES NO CHANGE WITH OPTIMAL WEIGHT REDUCTION IN JAPANESE FEMALE HEAVY-WEIGHT CLASS JUDO ATHLETES

Taguchi, M.1, Murata, H.2, Ishikawa Takata, K.3, Higuchi, M.1

1) Faculty of Sports Sciences, Waseda University (Saitama, Japan), 2) Japan Women's College of Physical Education, 3) National Institute of Health and Nutrition (Tokyo, Japan)

**Introduction** Previous studies reported that treatment of body weight reduction in obese women with caloric restriction consistently induced lower resting energy expenditure (REE). It is not clear if REE is reduced caused by weight loss intervention in female heavy weight athletes. The aim of the present study was to examine whether body weight loss reduces REE of Japanese female Judo athletes who were categorized in heavy weight class. **Methods** Ten heavy-weight Judo athletes including Japanese elite class athletes (age 20.3 +/- 1.9 years, height 166.4 +/- 4.1 cm, body weight 92.1 +/- 16.7 kg, percentage of body fat 30.3 +/- 6.2 % and fat-free mass (FFM) 63.4 +/- 7.2 kg) completed a 12-week weight-loss intervention by the direction of the sports dietitian. REE was measured by indirect calorimetry, and body composition was estimated by dual energy X-ray absorptiometry (DXA) at pre- and post- intervention. Results The total weight loss was obtained by 4.5 +/- 2.1 kg (5.0 +/- 2.4 %) after the intervention. Only the weight of adipose tissue was decreased significantly by 10% ( $p<.01$ ), and FFM components (weight of skeletal muscle, bone mass, and residual mass) were maintained. Measured REE decreased significantly after the intervention, however, REE did not change after adjusting for FFM (pre;  $1767 \pm 46$  kcal/d, post;  $1702 \pm 46$  kcal/d,  $p=0.340$ ). **Discussion** REE reflects underlying tissue composition, mass, and metabolic rate, and FFM alone account for 45-50% of inter-individual variability of REE in Japanese female athletes. In the present study, athletes were required mild caloric restriction without reduction of protein and micro-nutrients intakes. Consequently, total body weight and fat mass were significantly decreased while FFM remained after the intervention. FFM including different resting metabolic rate such as muscles (13 kcal / kg /day) and organs (200 - 440 kcal / kg /day) maintenance was considered as the key factor of unchanging REE. **Conclusion** Optimal weight loss by reducing fat mass may conserve REE, and maintaining REE will be helpful for body weight management in heavy weight female athletes. **References** Taguchi M, Ishikawa-Takata K, Higuchi M et al. 2011 Resting energy expenditure can be assessed by fat-free mass in female athletes regardless of body size. *J Nutr Sci Vitaminol*, 57(1): 22-29.

### ESTIMATION OF $\text{VO}_2$ KINETICS FROM GRADED EXERCISE TESTS IN ENDURANCE RUNNERS

Sentija, D., Vucetic, V.

Faculty of Kinesiology, University of Zagreb

**Introduction** The kinetics of oxygen uptake are determined by computation of the time constant, or 'tau' ('tau'), from breath-by-breath  $\text{VO}_2$  data during square-wave work. In an incremental (ramp) test, presuming a linear increase of  $\text{VO}_2$  with increasing intensity (for the intensity range below the anaerobic threshold), tau can be estimated from the time delay ( $\tau=\Delta t$ ) needed to reach the  $\text{VO}_2$  that corresponds to the steady-state  $\text{VO}_2$  ( $\text{VO}_{2\text{ss}}$ ) at the same intensity (Whipp et al., 1981). We hypothesized that in treadmill tests with graded increases of intensity (step tests, no steady-state stages with short duration) the same estimation of tau can be performed from: 1) a single step test, if  $\text{VO}_{2\text{ss}}$  is known, or 2) two step tests with different speed increments. **Methods** 23 endurance runners completed 3 incremental treadmill tests to exhaustion with increase in running speed of: 1 km/h each min (T1), 1 km/h each 1/2 min (T05), and 2 km/h each 4 min (SS). Breath-by-breath  $\text{VO}_2$  data were averaged to 30 s, and centered to the corresponding running speeds for T1 and T05. The  $\text{VO}_{2\text{ss}}$  values at 8, 10 and 12 km/h were defined as the average  $\text{VO}_2$  values in the 4th minute of respective stages in the SS test, and were corrected to account for the  $\text{VO}_2$  difference between ramp and step protocols. The time constants ( $\Delta t$ ) were determined from linear regression parameters derived from the  $\text{VO}_2$ /running speed relationship in SS, T1 and T05. The analysis was performed within the aerobic speed range (8-12

km/h). The significance of differences between  $\Delta t$  were determined from 1) SS-T1, 2) SS-T05, and 3) T1-T05 test data ( $p < 0.05$ ). Results and discussion Similar  $\text{VO}_2$  kinetics were found for  $\Delta t$  determined from SS-T1, SS-T05 and T1-T05 data ( $32.5 \pm 26.6$  s,  $34.0 \pm 45.4$  s, and  $31.1 \pm 18.8$  s, respectively;  $p > 0.05$ ), and were consistent within the analyzed speed range. The increase of intensity in T05 (1 km/h/30s) is exactly twice the increase in T1 (1 km/h/60s). Therefore, for a certain  $\text{VO}_2$ , the  $\Delta t$  between T1 and T05 tests should be equal to  $\Delta t$  between T1 and SS, enabling estimation of  $\tau$  and  $\text{VO}_{2ss}$ . Indeed, the average error of  $\text{VO}_{2ss}$  and  $\Delta t$  estimated from the time delay between T1 and T05 was practically irrelevant (0.1-0.15 ml/min/kg, or 2-3 s). The  $\Delta t$  values of endurance runners in this study proved to be very variable (many of them outside of the physiological range for  $\tau$ ), reflecting accumulated effects of high biological variability and technical errors for repeated measurements. Also,  $\Delta t$  values were significantly higher compared to tau values measured directly from square-wave tests in previous studies. This difference may be explained by the delay time needed for transportation of blood from working muscles to the lungs (~ 10-20 s). An alternative explanation is that incremental exercise, unlike constant (square-wave) exercise, has more complex and slower  $\text{VO}_2$  kinetics. References Whipp BJ et al (1981). *J Appl Physiol* 50(1):217-21

## AN ANALYSIS OF THE TYPICAL DAILY PHYSICAL ACTIVITY PATTERNS OF JOCKEYS

Cullen, S.1, Mc Goldrick, A.2, O'Loughlin, G.1, May, G.1, Warrington, G.1

1: *Dublin City University (Dublin, Ireland)*, 2: *The Turf Club (The Curragh, Ireland)*

**Introduction** The specific physiological demands of horse racing remain largely unknown. Research suggests jockeys must perform close to their physiological limit in a race to be successful (Trowbridge et al., 1995), whilst maintaining the stipulated competition riding weight. This study aimed to characterise daily physical activity patterns of jockeys. **Methods** Apprentice jockeys ( $n=30$ ) completed a daily physical activity questionnaire. Trainee jockeys ( $n=11$ ; age  $16 \pm 1$  yr; height  $1.67 \pm 0.1$ m; body mass  $55.2 \pm 6.1$ kg; BMI  $19.7 \pm 1.8$ kg.m<sup>-2</sup>; % body fat  $7.62 \pm 0.09$ %) performed a maximal incremental cycle ergometer test starting at 60W, with 25W increments to volitional exhaustion to determine maximal aerobic capacity ( $\text{VO}_{2\max}$ ) and maximum heart rate ( $\text{HR}_{\max}$ ). Subjects subsequently completed a riding trial at a self-selected pace for different equine gaits: walk, trot and canter (3 minutes per gait). Each gait was performed in succession and the mean  $\text{VO}_2$  and HR were recorded for each gait. **Results** Questionnaire results revealed jockeys typically 'ride work'  $3.4 \pm 1.7$  days a week. The majority of riding time each day is spent at a walk, trot and canter with an average of  $6 \pm 3$  horses ridden each day for a period of  $36 \pm 15$  minutes per horse. Seventy three percent of jockeys ( $n=22$ ) reported undertaking additional exercise to riding when weight loss is necessary, with 40% ( $n=12$ ) reporting regular exercise. Mean  $\text{VO}_{2\max}$  for trainee jockeys was  $57.8 \pm 5.3$  ml.kg.min<sup>-1</sup> and  $\text{HR}_{\max}$  was  $191 \pm 11$  beats.min<sup>-1</sup>. During riding at a walk, trot and canter, mean  $\text{VO}_2$  corresponded to  $15 \pm 4\%$ ,  $38 \pm 6\%$  and  $47 \pm 9\%$  of  $\text{VO}_{2\max}$  and mean HR corresponded to  $48 \pm 6\%$ ,  $60 \pm 6\%$  and  $71 \pm 7\%$  of  $\text{HR}_{\max}$  respectively. **Discussion** The majority of an apprentice jockey's day is spent riding at a walk, trot and canter. These riding activities are associated with a relatively low physiological demand when compared to peak physiological data obtained from trainee jockeys. Limited training effects may occur at these intensities. To regulate weight for competition and maximise performance, riders must physically train for several hours per week in addition to typical daily riding. Questionnaire results reveal a small percentage of apprentice jockeys ( $n=12$ ) regularly undertake additional exercise. Further research is required to determine the specific physiological demands of horse racing during competition. This will provide a better understanding of the specific exercise training required to meet the stipulated competition riding weight and optimise performance. **References** Trowbridge E, Cotterill J, Crofts C. (1995). *Eur J Appl Physiol*. 70: 66-69.

## EFFECTS OF UPPER LIMB SWING ON THE LOWER LIMB MULTI-JOINT MOVEMENT

Yamauchi, J.1,2, Kobayashi, M.1

1: *Tokyo Metropolitan University*, 2: *Future Institute for Sport Sciences*

**[Introduction]** Many activities are performed using both upper and lower limbs in multi-dimensional movements. The integration of muscle activities in the extremities with those in trunk muscles is often required for activities of everyday life and better performance in sports. However, despite requiring the integrity of extremities in daily activity, there are only few researches on the study of the integration of extremities on the muscle force generating capacity in the dynamic movement. The present study investigated the effects of upper limb swing on the dynamic lower limb multi-joint movement. **[Method]** Twenty-one healthy young subjects (men=10, women=11; age,  $21.5 \pm 2.4$  year; height,  $165.5 \pm 8.1$ cm; body weight,  $58.6 \pm 10.7$ kg; mean $\pm$ SD) performed the knee-hip extension movement of one leg at their maximal effort on ergometer with an electromagnetic load control. Measurements were repeated three times with at least one-minute rest period between bouts, and the highest value among the measurements was used. Then, subjects performed the dynamic knee-hip extension movements with or without upper limb swing on the ergometer. During the dynamic movements, knee-hip extension movement velocity and foot pressure were measured with speedometer and pressure sensor mat, respectively. Subjects first performed a few submaximum efforts to familiarize themselves with the measurements, and then measurements were repeated five times with at least one-minute rest period between bouts and the highest value among the measurements was used. **[Result and Discussion]** The foot pressure during the dynamic knee-hip extension movements with and without upper limb swing was both average 80% of MVC and was not significantly different between two conditions. The movement velocity during the dynamic knee-hip extension movements tended to be faster in the leg movement with upper limb swing as compared to the movement without upper limb swing, but was not significantly different between two conditions. When men and women were separately analyzed, the movement velocity in men was significantly ( $p < 0.05$ ) faster in the leg movement with upper limb swing as compared to the movement without upper limb swing. The results indicate that because the knee-hip extension movements with upper limb swing changes leg movement velocity, the upper limb swing during the dynamic lower limb multi-joint movement interacts with force generating mechanism of lower limb.

## MUSCLE STRENGTH AND FUNCTIONAL CAPACITY IN PATIENTS WITH PARKINSON'S DISEASE

Paulista, H., Santos, T., Fonseca, R., Homem, R., Cruz, L., Santos, P., Moraes Filho, A., Silva, M., Oliveira, R.

*University of Brasilia*

**Introduction** Parkinson Disease (PD) is a progressive neurodegenerative condition related to decrease in muscular strength. The aim of this study was to correlate leg muscular strength with functional performance tests in patient with PD. **Methods** The sample was composed by 14 patients with PD from outpatient Parkinson's Hospital de Base and the Parkinson's Association members at Brasilia, Brazil, predominantly classified in stage 2.0 of Hohen & Yahr scale (mean and SD:  $63.5$  SD  $1.8$  years;  $1.69$  SD  $0.06$  m;  $74.7$  SD  $13$  kg;  $26.6$  SD  $4$  kg/m<sup>2</sup>). Muscle strength was measured by isokinetic knee extension (Biodex System 3) at  $90^\circ$  per second speed. Functional capacity was assessed by the Timed Up and Go Test (TUG). Statistical analysis was performed by Spearman correlation through BioEstat 5.0. **Results**

The Peak Torque (PT) was 143.25 SD 42.77 N/min., resulting in a relative torque (RT) of 196.12 SD 44.32% of body weight. The time needed for the TUG was 7:00 SD 1:54 seconds. PT was not correlated with TUG ( $p = 0.3137$ ), but it was possible to observe the correlation between RT and TUG ( $p = 0.0128$ ). Discussion The relative muscular strength of lower limbs was correlated with functional capacity, confirming the findings of Schilling et al. (2009). This result suggests that functional performance gains may depend on relative muscular strength increase as what was previously described by Sousa and Sampaio (2005). References Sousa N, Sampaio J. (2005). *Am J Hum Biol*, 17, 746–751. Schilling B, Karlage R, LeDoux M, Pfeiffer R, Weiss L, Falvo M. (2009). *Park Rel Dis*, 15, 776–780.

### FIVE DAYS SLEEP SHORTAGE ALTERED PHYSICAL FUNCTIONS

Kubota, C.1, Shioda, K.1, Morita, Y.1, Kojima, T.1, Sumitomo, J.1, Ganeko, M.1, Uchida, S.2

*Waseda University*

Introduction: Sleep loss has become an increasingly important issue in health science. Similarly in competitive sports, athletes sometimes cannot ensure enough sleep when they participate in a competition. A cause of sleep loss in athletes varies, from early morning workouts to jet-lag syndrome in international athletes. Sports-related activities need both physical and cognitive abilities. It has been studied that sleep shortage deteriorates cognitive performances. For sleep shortage situations, it is a concern that whether sleep shortage results in poor physical and cognitive performances. This study focuses on physical and vigilance performance to investigate how sleep shortage (SS) affects physical functions. Methods: Subjects were six healthy young students. They underwent two conditions (regular sleep condition: RSC, sleep deprivation condition: SDC). In order to measure regular sleep length, subjects wore wrist actigraphy for 14 days. After a regular sleep night, subjects slept five sleep shortage nights. In the SDC, sleep was shortened to 50% of regular sleep length for each subject. Exercise performances (EX) (aerobic capacity: VO<sub>2</sub>, VCO<sub>2</sub>, RER, VE, RPE during 5min pedaling exercise of a moderate intensity, anaerobic capacity: peak power during 7s maximum pedaling) and Psychomotor Vigilance Test (PVT) were examined on two conditions. EX was examined at 18:00 of the 1st, 3rd, 5th day, and PVT was examined at 9:00 and 17:00 every day. Standard PSG was performed on the regular sleep night and 1st, 3rd, 5th shortened sleep nights. Result: There were no significant differences in exercise performances. While PVT was impaired after three SS nights. Frequency analysis revealed that total delta density increased on the 3rd and 5th night ( $p < 0.05$ ). High frequency (25–40Hz) total power increased on 1st SS night. Moreover, rapid eye movement (REM) density increased on 1st SS night ( $p < 0.05$ ) and total number of REM tended to increase on 1st SS night ( $p = 0.057$ ). Conclusion: The present results suggested that five days of shortened sleep did not affect exercise performances. This may be because these experimentally measured physical performances are not much affected by sleep shortage. While PVT was impaired after three days of SS. Thus, increased delta recovery did not compensate after three nights. Increased high frequency (25–40Hz) total power could be related to increased REM, since high frequency (25–40Hz) total power and REM density and/or total number of REM increased on 1st SS night.

### PP-BN12 Sport Biomechanics 7 : Gait & Balance

#### MOTOR VARIABILITY AND ABILITY TO ADAPT IN BALANCE TASKS

Caballero, C.

*Miguel Hernández University*

Introduction Several works suggest that the complexity shown in the biological signal may be related to the system's ability to adapt to perturbation (Manor et al., 2010) but there is controversy about complexity results, performance and learning. The aim of our study is to analyze the relationship between movement complexity, performance and ability to adapt in a standing balance task. Methods Twenty-one volunteers took part in this study (Age  $27.82 \pm 7.03$  years; Height  $1.74 \pm 0.09$  m; Mass  $67.53 \pm 10.33$  Kg). Participants were asked to stand still (30s) both on a stable surface and on an unstable surface over a force platform. Eleven participants performed 10 trials on the unstable surface. Ten participants served as control group. Both groups performed a posttest. Dynamics of the center of pressure (COP) were measured through Sample Entropy (SampEn) and Detrended Fluctuation Analysis (DFA). Ability to adapt was measured as the change in performance (inverse of the standard deviation of COP) from stable to unstable condition and from pretest to posttest. Results In the stable condition, the correlation between performance and SampEn is positive ( $r = .709$ ;  $p < .01$ ). However, under the unstable condition, this relationship is negative ( $r = -.555$ ;  $p < .01$ ). In the stable condition, better ability to adapt is associated with greater SampEn ( $r = .708$ ;  $p < .05$ ). Ability to adapt is related to lower SampEn ( $r = -.844$ ;  $p < .01$ ), in the unstable condition. The DFA auto-correlation values are associated with the performance ( $r = .654$ ;  $p < .01$ ) and ability to adapt ( $r = .844$ ;  $p < .01$ ), as these are more persistent, which comes close to  $\alpha = 1$ . Discussion In the stable condition, a greater complexity in COP fluctuation is associated with a better performance and ability to adapt (Manor et al. 2010). In the unstable situation we have found an inverse correlation. These differences in the complexity of a behavioral system are found dependent on the nature of both the intrinsic dynamics of the system and the task demands (Vaillancourt & Newell, 2002). On the other hand, better performance and the ability to adapt are associated with DFA values close to 1. Goldberger et al. (2002) suggest that increased irregularity (SampEn) does not imply increased physiologic complexity. References Goldberger, AL, Peng, CK & Lipsitz, LA (2002) What is physiologic complexity and how does it change with aging and disease? *Neurobiology of Aging*, 23, 23–26. ## THE EFFECTS OF THE FELDENKRAIS METHOD ON MUSICIAN POSTURE

Forte, C.

*Forte Feldenkrais Training*

**Introduction** The Feldenkrais Method® is an activity based on the awareness through movement and recently has become very popular in the world. It is known that 15% of orchestral musicians frequently suffer of back and joint pain because of many hours engaged to study and play their instruments (Knishkowsky, 1986; Fishbein et al., 1988). The aim of our study was to examine whether the Feldenkrais Method can be used for treating the back pain in orchestral musicians and improving their performance and life quality. Methods Seventeen musicians were divided into two groups. One group, called Control, was composed by 8 participants (5 men and 3 women with  $34.63 \pm 4.81$  years,  $71.56 \pm 13.3$  kg weight and  $169.93 \pm 10.51$  cm height; BMI:  $24.78 \pm 3.2$ ) and did not participate to the treatment. The other group, called Feldenkrais, was composed by 9 participants (5 men and 3 women with  $34.78 \pm 8.50$  years,  $69.56 \pm 12.45$  kg weight and  $168.92 \pm 9.72$  cm height; BMI:  $24.38 \pm 2.4$ ) and were recruited to participate in a 4 sessions of Awareness Through Movement (CAM®) for 2 hours per week under the guide of the same teacher for all length of treatment period. This protocol consisted of movements of the pelvis, head, shoulders and eyes in sitting and in supine position coordinated to their breath. Before and after 4 weeks, Control and Feldenkrais groups were evaluated with sit and reach test, trunk lift and eye convergence test. In addition, we measured height in upright and sit position, shoulder symmetry in both groups. We used the visual rating scale (VRS) to select participants with a frequency of back pain ranging from 'occasionally' to 'always'. Significant differences ( $p < 0.05$ ) within group were analyzed with Wilcoxon Test, whereas differences between the two groups with Mann-Whitney Test. Results After 4 weeks of treatment, we found a significant increase in the upright position height and a significant decrease in eye convergence in the Feldenkrais group. Moreover, Feldenkrais group showed an increase in range of motion of spine compared with Control group. We did not observe any improvement in the Control group. These changes were associated with a bigger number of participants who showed a significant reduction of back pain frequency ( $p < 0.05$ ). Discussion The Feldenkrais Method® has positive effects in the treatment of the back pain in the orchestral musicians through an improvement of spine flexibility and the eye movement during and after the artistic performance. ## CHANGES IN POSTURAL MOVEMENTS AND MUSCLE ACTIVITY FOLLOWING THE LONG-TERM USE OF UNSTABLE SHOES

Uchida, Y.1, Ohbu, T.1,2, Iwata, H.1, Hazama, Y.2, Kanosue, K.1

*1: Waseda university (Saitama, Japan), 2: EVERNEW Inc. (Tokyo, Japan)*

**[Introduction]** It is important to maintain an appropriate upright standing posture in order to perform diverse movements. The stability of a natural standing has generally been considered as an index of ability in postural control. Masai Barefoot Technology Shoes (MBT®) have been developed to promote muscle activity by creating an unstable foot condition with the aims of training static and dynamic posture and postural control. This study examined changes in postural movements and lower-limb muscle activity following the long-term use of MBT. **[Methods]** Fourteen non-MBT users participated in this study. They wore MBT for three months. Experiments were done 4 times, just before the start of wearing MBT and 1, 2, and 3 months after the start. In total 27 markers were attached to the body surface for 3 dimensional analysis of body movements. Electromyograms (EMGs) were recorded with surface electrodes from 8 muscles (RF, VM, BF, TA, PL, GM, GL, and SOL). Subjects were instructed to maintain a natural standing position for 60 seconds per measurement under 2 different foot conditions: 1) barefoot and 2) wearing MBT. Head movement was analyzed based on the position of a marker attached to the parietal in both vertical and horizontal directions using EVaRT 5.0. Center of pressure excursion was also recorded using a force plate. EMG values were normalized with those of the MVC after full-rectification. **[Results]** The data obtained under the two conditions were compared, focusing on time-dependent changes in postural movements in the period of MBT usage. While no changes were observed in the head movements in both vertical or horizontal directions through the 3 month period under the barefoot condition, a significant increase in head movements was observed in both directions after 3 months under the MBT condition ( $p < 0.05$ ). A significant difference was observed in head movement in both directions after 0, 1, and 2 months ( $p < 0.05$ ). The EMG activities of the RF and BF significantly increased at 3 months under the MBT condition ( $p < 0.05$ ). In contrast, under the barefoot condition, no time-dependent changes in EMGs of any muscles were observed. Such a barefoot-MBT difference in EMG activities increased with the time-dependent changes in postural movements. **[Discussion]** An important role of MBT is promoting muscle activities even at standing position through inevitable or voluntary sway that would activate postural maintenance mechanism. The time-dependent increase in postural movements may indicate that the subjects adapted to the structure of MBT and developed the MBT-specific postural maintenance movements. The consequent increase in muscle activity suggests that the postural maintenance function is improved through the long-term use of MBT.

## BALANCE REACTIONS OF FEMALE BASKETBALL PLAYERS AFTER PERTURBATION IN THE SAGITAL PLANE

Ramazanoglu, N., Tatar, Y., Sayli, O., Uzun, S., Camliguney, F., Cotuk, B.

*Marmara University*

The female basketball players studied were reported to suffer a significantly greater number of knee and ankle injuries than male basketball players. During team sport activities, planned change of movement direction allow the athlete to anticipate, which allow these postural adjustments to be made much more easily. However, in the case of unpredictable postural perturbations or cutting movements, postural adjustments are harder to make, which affects loading of the lower limb joints and muscles, and causes balance loss. Objective: To investigate displacement of center of foot pressure (COF), recovery time and leg muscle activity pattern after perturbation in the knee joint and to compare female basketball players with sedentary subjects. Method: Twenty six young female students: 11 elite basketball players (age=  $17.55 \pm 0.52$  years, height= $178.36 \pm 5.90$  cm, weight= $67.14 \pm 5.86$  kg) with at least 3 training years and 15 sedentary subjects (age= $17.47 \pm 0.64$ , height= $159.53 \pm 5.68$  cm, weight= $61.93 \pm 12.04$  kg) were included in the study. Vertical jump was used to measure leg muscle strength. Assessment of balance was measured with Matscan (Tekscan, Boston, MA). The following balance tests were utilized: two feet eyes opened (EO), eyes closed (EC), right foot EO, and left foot EO both unperturbed and perturbed conditions. 13 N force was applied in the sagittal plane (anterior- posterior (A/P) direction) to the knee joint in order to produce balance loss during perturbation. Surface EMG (DELYSIS) measurements were taken from the quadriceps femoris, biceps femoris and tibialis anterior and gastrocnemius muscle to examine the order of muscle activation during unanticipated perturbation. Results: Female basketball players legs were stronger than sedentary students ( $p < 0.01$ ). No differences were found for COF in both perturbed and unperturbed condition for two feet eyes opened (EO), eyes closed (EC), right foot EO, and left foot EO between female athletes and sedentary subjects. However, there

were significant differences in terms of recovery time after perturbation (A/P direction) for two feet eyes opened (EO), eyes closed (EC), right foot EO, and left foot EO between the groups. Although female basketball players had longer height, athlete's recovery time was shorter than their sedentary peers ( $p < 0.05$ ). There was no difference in EMG muscle activation pattern for leg muscles between two groups during two feet OE. Discussion: Short recovery time may be important in providing early defense against loss of balance during unanticipated perturbation in the game. Unexpected perturbation training facilities should be addressed as part of the player's individualized program to improve postural balance.

### COORDINATION OF UPPER AND LOWER EXTREMITIES MOVEMENTS DURING THE GAIT OF WOMEN

Kalichova, M., Novotny, M., Korvas, P., Lukásek, M.

*Faculty of Sports Studies, Masaryk University, Brno*

**Introduction** Human gait is one of the basic human movement used to change place in the space. The aim of this study is to analyze the most important temporal and velocity parameters determining the movement of lower and upper limbs. Our purpose is to compare interindividually the coordination of these movements by evaluating these observed parameters of each proband. This research was implemented within the framework of the project 'Creating a research team for the purpose of determining the level of physical activity (inactivity) in selected age groups of the population of men and women in the Czech Republic' (CZ.1.07/2.3.00/20.0044). The project is financed by the European Social Fund and the state budget of the Czech Republic. **Methods** We did a 3D kinematical analysis of gait. For scanning the picture we used two high-frequency synchronized digital cameras SIMI MOTION Version 7. The gait cycle was performed by 16 women at the age of 20 – 45. On the basis of 3D kinematical analysis the characteristics of key phases of the gait cycle were evaluated. Results Walking speed was 1.2 m·s<sup>-1</sup> on average and the step duration 0.574 s on average. Swinging movement of arm took less, 0.508 s on average. We were mainly interested in speed parameters of ankles and wrists. The ankle speed oscillated between 0 m·s<sup>-1</sup> and 4.355 m·s<sup>-1</sup>, the average value of ankle speed of all probands was 1.805 m·s<sup>-1</sup>. The wrist speed ranged from 0.061 m·s<sup>-1</sup> to 3.790 m·s<sup>-1</sup>. **Discussion** The motion of the upper limbs is considered as a facultative component of human gait to reduce the energy cost of walking (Umberger, 2008). During human walking, arms normally swing in opposition to legs, which helps balance angular momentum generated in the lower body (Park, 2008). We observed temporal coordination of swinging phase of upper and lower limbs. The arm swing back ended a little bit earlier than the ipsilateral heel contacted the floor while the contralateral arm stopped its swing forward at the time of the initial contact of the heel with the floor. The chronology of moments at which the ankles and the wrists reached their maximum speed was the next observed parameter of limbs movement coordination. Every attempt showed that the minimum speed of the standing ankle and the contralateral wrist is reached approximately at the same moment. This temporal coordination wasn't proved in reaching the maximum speed of the lower and upper limb. The maximum speed of the swinging ankle is reached later than the maximum speed of the contralateral wrist swinging forward. **References** Park J (2008) Synthesis of natural arm swing motion in human bipedal walking. *J Biomech* 41:1417–1426 Umberger BR (2008) Effects of suppressing arm swing on kinematics, kinetics, and energetics of human walking. *J Biomech* 41:2575– 2580

### KINEMATICAL ANALYSIS OF GAIT

Lukásek, M., Kalichová, M., Novotný, M.

*Faculty of Sport studies, Masaryk University*

**Introduction** In nature is human walking unique and we can not find it in the same form in any other animal. Human gait and its details are individual. Minor differences in gait pattern may vary not only between different individuals, but may vary for a given individual in time. These facts complicate the definition of a standard 'normal' gait pattern. Nevertheless, based on the principle of cyclic walking its pattern is described, which deals with the description of one cycle (Ellis, 2005). Knowledge of the physiological characteristics of walking is necessary for a confrontation with pathological gait. Creating a population gait model is important for to assess the possibility of pathological gait and also can help to determine the causes of injury or wear skeletal muscle system. Results of work can help to prevent injury and also can be used in rehabilitation or orthopedics. **Methods** We used a 3D kinematical analysis of basic human walk. The research group consisted of 16 woman (age 20 – 45 years). For scanning the picture we used two high-frequency synchronized digital cameras SIMI MOTION Version 7. We evaluated kinematical characteristics of 13 body points that were in the performance marked with retro reflexive balls. Center of gravity was made by model of Gubitz. Most authors agree on the basic allocation step cycle into two phases. Stance phase is described as part of the step cycle when the foot is in contact with the ground. Swing phase is part of the step cycle when the foot is in the air (Rose and Gamble, 1994). On this basis, we follow the kinematic characteristics of body segments in each phase and at the moment of take-off and impact of the foot: center of gravity movement (horizontal, vertical), step length in relation to height, angle in the knee, ankle and elbow, comparison between left and right part of body, extremes and averages of flexion and extension, synchronization – the correlation between the angles dissenting limbs. Results We selected just one of the monitored parameters. The mean flexion in the joint of knee during impact – 161,5° on the right foot (min. 153,2°; max. 164,3°) and 157,6° (min. 148,9°; max. 163,1°) on the left foot. **Discussion** It is assumed that the whole movement is the reset of pre-prepared lunch of central motor program that is encoded in memory neural network. (Králíček, 1995). Our research has primarily descriptive character and serves as a pilot project of more comprehensive study of komplex gait analysis. On a small sample of respondents verify, if our procedure is correct. The aim of this work was based on a kinematic parameters and describe the gait pattern in a selected group of people without difficulty of neuro muscular and skeletal system. **References** Ellis, W. ### CHANGES IN COUPLING ON REAR FOOT, SHANK AND THIGH IN THE DIFFERENT SPEEDS DURING HUMAN WALKING

Lee, B.K., Shin, J.M.

*SangMyung UI Cheonan, S Korea*

**Introduction** Rear foot is contacted on the ground directly due to position the last lower extremities. Rear foot transfers the force which produced by contacting on ground to shank and thigh. In the processing transfer to force to upper segments, rear foot, shank and thigh are generated coupling. Therefore, the aim of this study was to analyse the changes of coupling on rear foot, shank, and thigh using vector coding technique. **Method** Subjects were selected 10 healthy college male students and 6 infra cameras were used for cinematograph. The walking speeds were determined fast (3.2 km/h), normal (4.0 km/h) and slow (4.8 km/h) speed. Coupling angles were by vector

coding technique (Chang, Van Emmerik & Hamill, 2008) of pronation/supination of rear foot and in/external rotation of shank and thigh. Changes of coupling were analyzed the amount of portion of in-phase and out-phase in the phase angle created by vector coding. Result There was no significance in the in-phase of pronation/supination of rear foot and in/external rotation of shank and hip each. There is significance in the out-phase of pronation/supination of rear foot and in/external rotation of hip. The out-phase portion in the fast walking was greater than normal and slow walking's in the rear foot ab/adduction and hip in/external rotation. The out-phase portion of rear foot ab/adduction and hip in/external rotation was greater than rear foot in/eversion and dorsi/plantar flexion's in the fast walking ( $p < .05$ ). Discussion Rear foot coupling appeared in the out-phase during support phase between ab/adduction of rear foot and in/external rotation of hip in the fast walking. Coupling of ab/adduction of rear foot and in/external rotation was more out-phased as walking speed was increased. This out-phase showed at the first half of support phase while in-phase appeared at the last half of it. Therefore hip extension and rear foot abduction were important feature producing out-phase during the first half of support phase between two segments. Reference Barton, C. ## **INFLUENCE OF A FOUR WEEK TREADMILL TRAINING TO IMPROVE POSTURAL CONTROL IN LOW BACK PAIN: A PILOT STUDY**

Schellendorfer, S., Stegen, C., Bauer, C., Kool, J.

*Zurich University of Applied Sciences*

Introduction Patients with lower back pain (LBP) are known to have reduced postural control (Dankaerts et al., 2009; Ruhe et al., 2011; Van Daele et al., 2009). Exercise and activity are an effective means of improving postural control (Henchoz and Kai-Lik 2008). The purpose of this study was to evaluate the influence of a treadmill-training on postural control and concurrent muscle activation. Methods 10 patients suffering from LBP were recruited. They received eight supervised treadmill training sessions (two times a week for four weeks) The following tasks were performed to measure balance and postural control before and after the training intervention: 1) narrow stance 2) tandem stance 3) one-leg stance 4) narrow stance on block of 9cm width 5) a dynamic balance test on the MFT® S3-check balance board The tests lasted 50 seconds and were performed barefoot and with eyes open and closed. 3D kinematics of the whole body, the centre of pressure (COP) and muscle activation of back muscles were recorded and analysed. Results Training resulted in no significant changes in the range of the COP excursion and in the angular range of motion, mean velocity and peak velocity in the pelvis-, hip-, thorax- and ankle-segments. Changes in kinematic variables and muscular activity were very heterogeneous. Variable movement strategies with different combinations of movement and muscular activity were observed. Challenging postural control tests such as standing on a block with eyes closed, one leg stance on a flat surface with eyes open and the MFT® S3-check balance board were useful assessment tests because they provoked some postural control movement and/or activation of the back muscles. The other tests were either too easy, with no movement provocation, or too challenging, so that they couldn't be performed by all the patients. Discussion The large variability in movement strategies and responses to the training-intervention observed in this study is considered to be the main cause for the non-significant results. Dynamic and challenging balance tests seem to be more meaningful than static tests. Focussing on pre-defined subgroups may be a more promising approach. Future research should identify subgroups of patients with LBP with different postural control strategies. These results support the statement of Dankaerts et al. (2009) who underline the importance of the need to identify and use subgroups in clinical research. References Dankaerts W., O'Sullivan P., Burnett A., Straker L., Davey P., Gupta R. ## **SIMPLIFIED PLANAR KINEMATIC CHAIN MODEL OF INITIAL START PHASES IN LUGING**

Fedotova, V.1, Pilipiv, V.2

*1: Riga Technical University (Riga, Latvia), 2: Latvian Olympic Team (Riga, Latvia)*

Introduction In the sport of luge the start plays an important role for an overall performance (Bruggemann et al., 1997). During the initial phases of the start, when an athlete is holding to the start handles, athlete's body and the sled are forming a closed kinematic chain. The aim of the present study was to develop and evaluate limitations of a planar kinematic chain model for two initial start phases in lugging. Methods The closed kinematic chain was modelled using SimMechanics(TM) computer modelling environment. Kinematic drivers for the model were obtained from motion capture data (Yeadon and King, 2008); motion capture performed with 3 high-speed cameras at 100 fps using Simi Motion software. Segment inertia parameters estimated as in (de Leva, 1996; Zatsiorsky et al., 1990). Results 4-, 5-, 6- (without leg segments) and 7-segment (with leg segments) models were developed. Testing of the models had shown that modelling the torso with one segment (4-segments model) is inappropriate for the selected movements. A model with two-segment torso gave a more realistic representation of the athlete's performance. It was possible to simulate the movement adequately without hand and foot segments (5- and 7-segment models), however, adding the hand segment (6-segment model) improved the simulation. Discussion During the initial start phases in the sport of luge movement of legs and arms is essentially three-dimensional; therefore modelling in-plane is an expected simplification. Nevertheless, the developed models can simulate the movement realistically in one plane. From the practical application perspective the planar models can be used as a first step in more sophisticated 3D modelling of the start phase in lugging. As standalone models they can be used as a visualization tool in movement optimization procedure. The developed models are purely kinematically driven, as no force data was available to use as drivers. Deriving kinetic data from movement simulation is theoretically possible, but validation of the results is challenging as long as no reference measurements are available. **KINEMATICS AND MOVEMENT VARIABILITY RELATED TO SERVICE PERFORMANCE IN YOUNG TENNIS PLAYERS**

Urbán, T., Hernández-Davó, H., Moreno, F.J.

*Universidad Miguel Hernández*

**Introduction** Recent studies have focused on analyzing kinematics related to performance in precision skills and in tennis service in particular (Reid, Whiteside & Elliott, 2011). Regarding kinematics variability, some studies have analyzed this topic in sport skills (Wagner, et al. 2011). Nevertheless, few researches have addressed this problem in tennis shots. The aim of this study is to analyze the relationship between kinematic variables, movement variability and performance of the tennis service in young players. **Methods** Twenty-nine young intermediate level tennis players (20 male, 9 female) (age  $12.9 \pm 1.64$ ) took part in the study. All participants carried out twenty services towards a target located on the service box. Kinematic variables from the dominant hand, arm, hip and the non-dominant hand were collected (Polhemus Liberty 240Hz update rate). Ball speed (RS3600 radar) and radial error of ball bounces (video digitized) were recorded to assess service performance. Correlation analysis was carried out to analyze the relationship between kinematics, variability and performance. **Results** Range of motion in the three axis correlated with higher velocity of the ball ( $r = .491$ ;  $p=0.007$ ; X axis, ( $r = .484$ ;  $p=0.008$ ; Y axis), ( $r = .608$ ;  $p<0.001$ ; Z axis). Right arm, hip and left hand position in Y axis also correlated with higher velocity values ( $r = .635$ ;  $p<0.001$ ;  $r = .517$ ;  $p=0.004$ ;  $r = .420$ ;  $p=0.023$ , respectively). Ball velocity correlated negatively with variability of the hand in the X and Z axis at the beginning of the movement ( $r = -.417$ ;  $p=0.024$ ;  $r = -.529$ ;  $p=0.003$  respectively). Radial error correlated with standard deviation of movement velocity of the hand during middle of the movement in the Y axis ( $r = .432$ ;  $p=0.019$ ) and the Z axis ( $r = .466$ ;  $p=0.011$ ). **Discussion** Higher range of motion and forward displacement of the dominant arm, hip and non-dominant hand has proved effective to increase the velocity of services. The variability of the movement affects the velocity of services only when this variability is observed at the beginning of the movement. Regarding service accuracy, the variability of the movement in the Y and Z axis reduces performance only if this variability is showed at the beginning or in the middle of the service movement. **References** Reid, M., Whiteside, D., & Elliott, B. (2011): Serving to different locations: set-up, toss, and racket kinematics of the professional tennis serve. *Sports Biomechanics*, 10:4, 407-414. **EFFECTS OF INCREASED VARIABILITY ON MOTOR LEARNING OF THE SHORT SERVE IN RECREATIONAL AND COMPETITIVE BADMINTON PLAYERS**

Jaitner, T., Schinz, F.

*TU Dortmund University, University of Kaiserslautern*

**Introduction** In recent years, a growing focus of motor learning research has been put on variability of practise. Based on the coordination dynamics theory variations are no more restricted on movement parameters as proposed by the Schema theory (Schmidt, 1975), but also extended to movement structures. As example, the differential learning approach tries to utilize the fluctuations and voluntarily variations in human motor behavior to induce a self-organising process to the athlete which takes advantage of individual movement and learning characteristics. Especially for goal directed movement, increasing the amount of variation to such an extent that no exercise is repeated during the learning process results in superior performance than repeating the same movement many times during acquisition (Frank et al, 2008). The purpose of this study was to investigate effects of differential learning on the short Badminton serve. **Methods** 51 Badminton players of two different levels of expertise (recreational vs. competitive players on regional/national level) participated in a learning experiment with 8 practice sessions. Subjects were divided into a differential (DT) and a traditional (TT) training group. The TT group started with basic exercises and increased complexity systematically during the experiment. Each exercise was repeated extensively, and feedback was given by demand. For the DT group variations with increasing complexity were implemented in a way that neither exercise was repeated, and no feedback on performance was given. In pretest, posttest and retention test two weeks after the posttest each participant performed 40 serves from two positions on a regular badminton court. All serves must be placed in the service area as closed as possible to the front and centre line. Net clearance and landing position of the shuttle were filmed and then rated on a ten point scale. A performance index was calculated as mean of both scores. Mann-Whitney-U-test was applied to analyze the performance of the subjects that completed all tests. **Results and discussion** The recreational as well as the competitive DT group improved performance from pretest to posttest significant, whereas as both TT groups showed no effect. From posttest and retention test the recreational players of the DT as well as of the DT decreased their performance significant. No effect was found for the competitive players. Therefore, a positive learning effect can only be stated for variable practise following the differential learning approach. Contrary to Frank et al. (2008) a further increase after the acquisition phase can not be observed in this study. Moreover, it can be assumed that only Badminton players on a higher level of expertise are able to maintain their level of performance during the retention phase. **References** Frank, T.D., Michelbrink, M., Beckmann, H. & Schöllhorn, W. I. (2008). *Biological Cybernetics*, 98, (1), 19-31. Schmidt, R.A., (1975) *Psychological Review* 82, 225-260.

**HANDEDNESS, FOOTEDNESS AND SKI-SIDE DOMINANCE IN ELITE CROSS-COUNTRY SKIERS**

Hébert-Losier, K.I, Holmberg, H.C.I, Stöggl, T.I,2

*Mid Sweden University, University of Salzburg*

**Introduction** Laterality in sports is researched in motor learning, injury prevention, and biomechanics. Handedness and footedness in sports is commonly addressed in isolation, and investigates tasks that are predominantly upper (baseball) or lower (soccer) body dependent. In contrast, cross-country skiing (XCS) is a whole-body exercise that relies on arms and legs. Although asymmetric techniques are used in XCS, and side preferences are observed; little research has explored lateralization in skiers. Thus, the aim was to investigate if handedness and footedness correlated with ski-side preference. **Methods** Eleven male elite XC skiers ( $28 \pm 5$  yrs) completed a standard

handedness (n=12 items), footedness (n=10 items), and ski-side dominance (n=11 items) questionnaire. Each item could be answered right, left, or either based on the side that was habitually used to perform a given task (i.e. write, kick a ball, preferred ski-curve). Each response was entered into a contingency table and measures of associations were expressed using correlation coefficients. Significance level was  $P < .05$ . Results Six of the 11 items on ski-side dominance were correlated to handedness or footedness items (all  $P < .05$ ), but no ski-side item correlated with hand/foot items simultaneously. The dominant side in steep uphill skating (V1) was associated with 3 handedness items ( $r = .63$ ). Using V1 at 15k race velocity, the dominant side was correlated to 9 of the 12 handedness items ( $r = .65$ ). At peak velocity, the dominant V1 side correlated with the leg used to balance on one foot ( $r = .82$ ). The leg used to accept weight when standing, stand on one foot, and step onto a chair or push a shovel into the group correlated with the dominant kick leg in kick double poling, preferred curve direction at a high velocity, and leg pushed forward at the end of a sprint race ( $r = .69$  to  $.91$ ), respectively. Discussion XCS is biomechanically complex, and relies on upper and lower body. Certain ski techniques favor one side of the body, and some were correlated with the sides used in daily tasks. Certain associations between ski-side and hand/foot dominance were more intuitive than others. For instance, several hand items were correlated with the dominant side in V1. Foot items were correlated with the preferred kick leg in kick double poling, which presumably reflects the need for the skis to grip to the snow. Correlations changed with skiing velocities, suggesting that velocity is an important factor in lateralization. This was a first attempt to address laterality in skiers using validated handedness and footedness questions, in addition to a ski-specific questionnaire. Standard, valid, and reliable ski-side questions should be used in future research to increase the understanding of lateralization in humans.

### DYNAMICAL SYSTEMS THEORY IN THE GOLF PUTTING PERFORMANCE

Mendes, R.1, Dias, G.2, Couceiro, M.3, Figueiredo, C.3, Luz, M.3, Clemente, F.2, Martins, F.4, Mendes, P.2

1: ESEC (Coimbra-Portugal), CIPER (Lisboa – Portugal), 2: FCDEF (Coimbra – Portugal), 3: ROBOCORP (Coimbra – Portugal), 4: IT (Covilhã – Portugal)

**ABSTRACT** Introduction Embodied within Dynamical Systems Theory, this study aimed to determine if the manipulation of constraints on the performance of golf putting, in different conditions of practice variability (distance, slope and angle), resulted in intra and inter-individual significant differences in amplitude, velocity, acceleration and duration of this movement (i.e., process variables), confirming a dynamic interaction between the practitioner, the environment and the task. Methods The sample consisted of 10 male golfers, adults ( $33.8 \pm 11.89$  years), volunteers, righties and experts ( $10.82 \pm 5.4$  handicap). On the first study, 30 practice trials were performed at 1, 2, 3 and 4 meters away from the hole without any constraints. On the second study, 30 trials were performed at 2, 3 and 4 meters away from the hole with a constraint imposed by a ramp. On the third and last study, 30 trials were performed at 2 meters away from the hole with a constraint imposed by a ramp and an angle of 25 degrees to the left and right of it. Results The ANOVA one-way test was used to accomplish a statistical analysis of the data. Moreover, a nonlinear analysis of the data was carried out, which included the Fourier series to determine players' behaviors (trends) at the level of product measures (i.e., radial error), as well as the approximate entropy and Lyapunov exponent to verify the periodicity and regularity of players in the performance of the putting. Discussion Given the constraints imposed in the task, the results demonstrate that the contextual information perceived by players was essential in accomplishing this movement. The intra and inter-individual variability resulting from a motor performance shows a 'signature putting' that is unique to each performer. The existence of significant differences in the process and product measures is confirmed.

### THE PRACTICE OF FOOTBALL 7 SOCIETY IMPROVES FINE MOTOR SKILLS OF LOWER EXTREMITIES IN CHILDREN BETWEEN 10 AND 11 YEARS OF AGE

Stecklow, M.V.1,2, Souza, A.C.B.1, Oliveira, J.C.F.1, Silva, T.A.1

1: UNIAEBU (Belford Roxo, Brazil), 2: PEB-UFRJ (Rio de Janeiro, Brazil)

**Introduction** The fine motor skills can be defined as the ability to produce and control small gestures. Football 7 society (F7S) is a variation of football very practiced in large cities, and their training methods include physical, technique and tactics training. It has been shown that motor tasks, as football training, increase the activity in cortical neurons and improve motor performance of lower extremities (Perez et al., 2004), but there are no studies on the effects of football training in fine motor skills of lower extremities. Therefore, this work aims at statistically assessing changes in fine motor skills of feet from children that play F7S. **Methods** The casuistry was composed of 60 health children between 10 and 11 years old, being 30 systematic practicing F7S twice a week during 60 min, and 30 children who did physical nonspecific activities to compose a control group (CON). The subjects seated on a chair, knees flexed at 90°, with the sole of the feet at 10 cm from the ground and a marker pen fixed in first digital fovea of left and right feet. The task was to follow as precisely as possible the shape of a 100 mm<sup>2</sup> square sketched in a millimeter paper after F7S training session, without time limit and the drawing error in mm<sup>2</sup> was calculated. The Kolmogorov-Smirnov test ( $\alpha = 5\%$ ) did not indicate data normality. The Wilcoxon simple and paired tests were respectively applied at significance level of 5% to assess error differences between groups or lower extremity sides. Results The median of error were 276 mm<sup>2</sup> to left and 249 mm<sup>2</sup> to right extremity in F7S, and 807 mm<sup>2</sup> and 776 mm<sup>2</sup> to left and right of CON respectively. Although the errors were higher in left than right extremity, the paired Wilcoxon intragroup tests indicated no statistical differences between lower extremities, both to F7S ( $P$  value = 0.508) or CON ( $P$  value = 0.684). The simple Wilcoxon intergroup tests indicated less error of F7S than CON in left ( $P$  value = 0.003) and right ( $P$  value = 0.006). Discussion The results pointed out that subjects of F7S presented a shape reproduction error smaller than CON subjects. Although there are no similar studies to be compared with, such findings may indicate the benefits observed in lower limbs undergoing training as reports of Perez et al. (2004). Since the ability to accurately control the ball is an important characteristic of good football players, perhaps this ability evaluation can help in the selection of future sports talents. According to our findings, we conclude that the F7S training promotes improvement in fine motor skills of children between 10 and 11 years of age. ### THE EFFECT OF CAFFEINE CONSUMPTION ON AROUSAL, ACTIVATION AND DART-THROWING PERFORMANCE AT DIFFERENT TIMES OF DAY

Ahmadi, P., Bhari, S.M., Azizi, M.

Share-Ray Branch, Islamic Azad University, Tehran, Iran

The Effect of Caffeine Consumption on Arousal, Activation and Dart-Throwing Performance at Different Times of Day 1Pezhman Ahmadi, 2Sydd Mohialdin Bhari, 3Mitra Azizi 1Department of Physical Education, Share-Ray Branch, Islamic Azad University, Tehran, Iran 2Department of Physical Education, Karaj Branch, Islamic Azad University, Karaj, Iran 3Department of Physical Education, Karaj Branch,

Islamic Azad University, Karaj, Iran Introduction It appears that many factors such as personal characteristics, time of day and medicines such as central nervous system stimulants may change the level of arousal and activation. The purpose of the present research was to study the effect of caffeine consumption on arousal, activation and dart-throwing performance at different times of day. Methods 24 volunteer participated in a randomized double-blind placebo-controlled repeated-measures crossover study and were studied for 6 weeks and 1 session per week in order to measuring arousal, activation and dart-throwing performance in the morning and evening. Results The results of repeated measures analysis of variance indicated that caffeine and placebo ingestion lead to increased arousal and activation but it does not affect dart-throwing performance. Further, time of day did not affect the results. Discussion The lack of a significant difference between caffeine and placebo conditions may be due to caffeine withdrawal effects. It can also be related to the psychological effects of placebo and caffeine (Schneider, 2006). Finally, the time limit can be pointed to placebo, because this effect tends to disappear in 20-30 minutes after taking a placebo (Adan, 2008). The results revealed that in comparison with control conditions, caffeine leads to increased SCL in the morning and evening. Fredholm showed that 250mg caffeine works by blocking adenosine receptors in the brain and other organs (Barry et al., 2008). It is natural that increased arousal due to caffeine leads to an increase in activation. However, greater increase in activation in comparison with arousal can be due to negative baseline SCL of some participants. Further, time of day did not affect the results. The reason could be related to the different effects of circadian rhythm on various components of performance. References Adan A, Prat G, Fabbri M, Sánchez-Turet M. (2008). ### EFFECT OF DIFFERENCE IN SHOT ANGLE ON SET SHOT BEHAVIOR IN BASKETBALL

Nagata, N., Inomata, K.

*Chukyo University*

Introduction Movement patterns in a motor task become more consistent with the skill development. However, it is assumed that the difference of task condition affect the variable of movement patterns while skill is same. Especially, motor programming may not consistent in the conditions for the relatively less experiences; therefore the variable of the movement patterns could be increased. The main purpose of this study was to examine the effect of difference in shot angle on set shot behavior in the basketball at semi-expert level. Method Participants of this study were two male Japanese college basketball players (Participant A: 170cm, 22 years age, 12 years experiment of basketball, Left hand shooter, Guard position. Participant B: 172cm, 20 years age, 10 years experiment of basketball, Right hand shooter, Guard position). In this study, Shot made percentage was measured and shot hand movement was recorded by 2 digital cameras. Shot movement was analyzed by three dimensions motion analysis system. Participants were took 10 shots from two locations, which were arranged at Free throw distances (4m from the free throw line to basketball ring) at two angles (Front, Side). Between each trial, we set 1 minute as the rest interval. Results In the front angle, Shot made percentage was Participant A = 60% and Participant B = 70%. In the side angle, Shot made percentage was Participant A = 60% and Participant B = 60%. In addition, the standard deviation of shot movement on the side angle was increased rather than the front angle. Discussion These results suggested that the whole movement pattern has been adjusted while variability of each joint increased, therefore participants was able to shoot successfully. ### TENNIS SERVE TOSS VARIABILITY UNDER THE CONSTRAINT OF ARTIFICIAL CROSS WIND

Mendes, R.1, Mendes, P.C.2, Fuentes, J.P.2, Martins, F.4, Clemente, F.5, Figueiredo, C.6, Couceiro, M.S.6, Dias, G.5

1: ESEC (Coimbra - Portugal), CIPER (Lisboa - Portugal), 2: CIDAF (Coimbra - Portugal), 3: FCD - UEX (Cáceres - Spain), 4: IT (Covilhã - Portugal), 5: FCDEF (Coimbra -

Introduction This study proposed to analyze the variability and stability of the toss in the tennis serve, on the x (side-to-side), y (back-to-front) and z (vertical), with 12 experienced players under the influence of lateral wind (induced aerodynamic flow), produced by a removable industrial ventilator. Methods The sample comprised 12 tennis players who were asked to perform 100 serves at the maximum speed and accuracy towards an intersection point between the central and the service lines ("T" point). In the practical procedure, an electronic variator of 11 positions, SEW Eurodrive, and a telescopic elevator, GUIL ELC - 506, were coupled to the industrial ventilator, METEC - HCT - 45 - 4T. Five practical conditions were previewed: without ISF; ISF1 (2,4m/s); ISF2 (4,3m/s); ISF3 (5,8m/s) and; Random ISF (random series of the 3 speed values used in this study). The players were analyzed individually after serving the maximum speed and accuracy to the intersection point of the center line and service line (point 'T'). The three positions of the tennis toss; Initial, Peak and impact, were recorded using two digital cameras to allow a 3D analysis. Results The results allow to conclude that the experienced players tend to stabilize the vertical dimension of the serve (z axis). Additionally, this study confirms the invariance of the player height ratio: height of impact (1:1.5) in experienced players even when constrained by the 'artificial crosswind'. Discussion Given the above, the vertical dimension of the tennis serve is assumed as an invariant feature, which is guaranteed in the remaining varying spatial and temporal dimensions (y and x axes) of the launch serve (compensatory variability). Thus, the variability should be seen as part of the solution and not as something to be avoided by players and coaches.

### INDIVIDUAL AND ENVIRONMENTAL FACTORS IN CHILDHOOD MOTOR PERFORMANCE: THE NEWELL'S' MODEL APPROACH

Mourao-Carvalho, M., Silva, E., Ramalho, H., Pinto, G., Coelho, E.

*Universidade Trás-os-Montes e Alto Douro*

Introduction: Newell's model (1986) is an excellent approach to study motor behavior across the life span. According to this model, motor behavior emerges from an interaction of individual constraints (structural and functional), the environment (physical and sociocultural) and the task (goals, rules and instruments). Therefore the main aim of this study was to verify the interaction of biological and sociocultural variables in motor performance. Methods: A cross sectional survey was conducted with a 142 Brazilian children, from 6 -10 years old

(8.03±1.05). TGMD-2 was used to evaluate the gross motor skill development. BMI was calculated and the cutoff of Cole et al. (2000) was used to estimate obesity. Parents completed a written survey in order to get information about free time activities and socioeconomic status. T test was applied to compare motor competence between obese and non-obese children. GLM was used to verify the interaction between biological and sociocultural variables in motor performance. Results: Significant differences were found between obese and non-obese children on motor performance: locomotor ( $p=.007$ ), object control ( $p=.004$ ) and gross motor quotient ( $p=.002$ ). Age and play outside interacted with the three motor quotients, age with a negative effect and play with a positive. Sport interacted with a positive effect on locomotor ( $\beta=.222$ ;  $p=.035$ ) and gross motor quotient ( $\beta=.352$ ;  $p=.003$ ). Time watching TV and video-games interacted with a negative effect with object control ( $\beta=-.040$ ;  $p=.034$ ;  $\beta=-.089$ ;  $p=.015$ , respectively) and gross motor quotient ( $\beta=-.242$ ;  $p=.012$ ;  $\beta=-.475$ ;  $p=.010$ , respectively). Discussion: Analyzing the motor competence, according to the underlying Newell's model, the results identified an interaction between individual and environment variables in motor performance, mainly the age and time playing outside. They also highlight the role of physical activity and of inactivity rather than obesity. The results emphasize the importance of a holistic theoretical model, as well as, the use of multivariate statistical techniques to understand the dynamic and the complexity of motor behavior, which characterize the human being. ##### **DO TEACHERS MATTER? INFLUENCE OF PERCEIVED TRANSFORMATIONAL TEACHING IN PHYSICAL EDUCATION ON STUDENTS' LEISURE TIME PHYSICAL ACTIVITY MOTIVATION AND BEHAVIOUR**

Spray, C.M., Manning, P.  
*Loughborough University*

Introduction Transformational leadership theory (Bass and Riggio, 2006) has recently been applied in the school physical education (PE) domain with the development of the Transformational Teaching Questionnaire (TTQ; Beauchamp et al., 2010). Beauchamp and colleagues provided support for the psychometric qualities of the TTQ and identified positive relationships between students' perceptions of transformational teaching and their sense of self-determination and experience of positive affect in PE classes. In line with theory and research into the potential transcontextual influence of the PE setting (Hagger and Chatzisarantis, 2007), this study examined relationships between perceived transformational teaching and adolescents' reported self-determination in leisure time physical activity (LTPA). Moreover, the utility of teaching perceptions in prospectively predicting reported physical activity behaviour was determined. Methods At time 1, students ( $N = 145$ ,  $M$  age = 13.25 years,  $SD = 1.88$ ) completed the TTQ and reported their reasons for engaging in LTPA. At time 2, students responded to two items assessing their involvement in LTPA over the previous four weeks. Results Hierarchical multiple regression analysis revealed that, at step 1, transformational teaching was a significant positive predictor of LTPA explaining 12% of variance. At step 2, a composite relative autonomy index was added to the model to represent students' (non) self-determined motivation for LTPA which explained a further 3% of variance. There was evidence of partial mediation of the relationship between perceptions of teaching and behaviour by relative autonomy. Discussion Current findings extend past work by establishing that adolescents' perceptions of transformational teaching in PE are associated with motivation and behaviour in the context of LTPA, providing support for the transcontextual model and the notion that teachers do matter. Future research should employ larger samples to tease out the effect of class average perceptions and supplement self-reports with objective measures of physical activity behaviour outside of school. ##### **EXAMINING THE RELATIONSHIP OF FLOW EXPERIENCE AND ATHLETES' TRAIT CHARACTERISTICS**

Stavrou, N.A.1,2, Karakasidou, E.1, Psychountaki, M.1  
*National & Kapodistrian University of Athens*

Introduction Flow experience has been used in psychology in order to describe an intrinsically rewarding experience that athletes feel during high levels of performance. Flow is experienced by an athlete when the goals are clearly set, when he/she is completely and concentrated on the task at hand, feels a sense of control over his/her actions, perceives the task as self-rewarding, and his/her actions look effortlessly and automatically (Jackson, 1992). An important issue associated with the generation of flow is whether particular situational or personal characteristics facilitate the experience of flow (Kimiecik & Stein, 1992). Based on that, the purpose of the study is to examine whether athlete's trait general and competitive characteristics constitute significant predictors of flow experience. Methods Three hundred and fifty one (351) (mean age =  $M = 18.14$ ,  $SD = 5.37$ ) athletes participated in the study. In non-competitive situations, based on how they usually felt, the athletes completed the following instruments: (1) Dispositional Flow Scale-2, (2) Trait Anxiety Inventory, (3) Self-Esteem Scale, (4) Sport-Competition Anxiety Test, (5) Trait-Sport Confidence Inventory and (6) Competitive Worries Inventory. Results General trait anxiety indicated negative correlations with flow experience, as well as, competitive trait anxiety. On the other hand, significant positive correlations revealed between self-esteem ( $r_{mean} = .33$ ) and trait self-confidence ( $r_{mean} = .39$ ) with athletes' flow experience. Hierarchical regression analysis (1st step: general trait characteristics, 2nd step: competitive trait characteristics) indicated that general ( $R^2$  adjusted = .437,  $F = 16.110$ ,  $p < .001$ ) and competitive variables ( $R^2$  adjusted = .422,  $F = 4.554$ ,  $p < .001$ ) constitute significant predictors of flow experience. Discussion Self-esteem and self-confidence suggested a close positive relationship to flow experience compared to the negative characteristics, such as general and competitive anxiety, as well as, competitive worries. Thus, if an athlete feels confidence about his/her sport ability, this is associated with achieving high levels of flow experience. On the other hand, the lack of relationship

between the trait anxiety ratings and the flow subscales suggests that this variable may not be as relevant to flow experiences as self-esteem. In addition, based on the regression analysis results, positive emotional characteristics constitute significant predictors of flow experience, while, negative emotional characteristics did constitute significant predictors of global flow factor. References Jackson S.A. (1992). *Journal of Applied Sport Psychology*, 4, 161-180. Kimiecik J.C., Stein, G.L. (1992). *Journal of Applied Sport Psychology*, 4, 144-160.

### THE RELIABILITY AND THE CONSTRUCT VALIDITY OF THE ACHIEVEMENT GOAL QUESTIONNAIRE-REVISED IN PHYSICAL EDUCATION SETTINGS AND THE GREEK LANGUAGE

Zourbanos, N., Argyropoulou, E., Papaioannou, A.

*University of Thessaly, Trikala*

**Introduction** In the last decade Elliot's achievement goals model (e.g., Elliot & McGregor, 2001) attracted the attention of several investigators in sport and exercise psychology. The 2x2 model included mastery approach, mastery avoidance, performance approach and performance avoidance goals. Recently they presented the Achievement Goal Questionnaire-Revised (AGQ-R; Elliot & Murayama, 2008). The purpose of the study was to examine the reliability and the construct validity of the AGQ-R in physical education and in the Greek language. **Methods** Participants were 313 students (151 females and 162 males) aged 12 (SD = .48) years old. The factor structure of the achievement goals were tested through CFA using the EQS 6.1 (Bentler & Wu, 2004). Three alternative models were tested. One where the original four-factor structure was tested, with the four factors allowed to correlate, then a trichotomous model (2), in which the performance-approach and performance-avoidance items load on their respective latent factors, and the mastery-approach and mastery-avoidance items load together on a third latent factor; and a trichotomous model (3) in which the mastery approach and performance approach items load on their respective latent factors, and the mastery-avoidance and performance-avoidance items load together on a third latent factor. **Measures** Achievement goals in PE. Following the stem "In the Physical Education class..." students responded to the items of the Achievement Goal Questionnaire-Revised (AGQ-R; Elliot & Murayama, 2008). Ratings are made on a five-point Likert scale from 1 (strongly disagree) to 5 (strongly agree). The alpha coefficients in the present study ranged from .54 to .70. **Results** Model parameters were estimated based on the covariance matrix and using the robust method, because examination of the descriptive statistics revealed moderate deviations from univariate normality for some of the items (kurtosis greater than 2.49). The results provided adequate support for the four-factor model (chi-square / df = 655.26 / 66, CFI = .97, IFI = .97, NNFI = .96, RMSEA = .04), which was superior to the trichotomous model (2) (chi-square / df = 655.26 / 66, CFI = .93, NNFI = .91, IFI = .93, RMSEA = .05) and the trichotomous model (3) (chi-square / df = 655.26 / 66, CFI = .70, NNFI = .62, IFI = .70, RMSEA = .10). Factor loadings for the four-factor model (1) ranged from .43 to .73. **Discussion** The results provided adequate support for the factor structure of the AGQ-R in the Greek language and the PE settings. **References** Bentler, P. M., & Wu, E. J. C. (2004). EQS 6 for Windows User's Guide. Multivariate Software, Inc., Encino, CA. Elliot, A. J., & McGregor, H. (2001). ### ELECTRONIC MEDIA-FREE ZONE IN THE BEDROOM! A GLOBAL STRATEGY NEEDED FOR IMPROVING HEALTH-RELATED BEHAVIOURS

Soos, I.1, Biddle, S.J.H.2, Hamar, P.3, Karsai, I.4, Ling, J.1, Li, S.5, Sandor, I.6, Simonek, J.7

*1 University of Sunderland, UK, 2 Loughborough University, UK, 3 Semmelweis University, Budapest, Hungary, 4 University of Pecs, Hungary, 5 Harbin University of Engineering, China, 6 Babes-Bolyai Univ*

**Introduction** Recent work has shown that if children have a television in their bedroom they are at increased risk of being obese or overweight (Delmas et al., 2007). Therefore, keeping television and computers out of young people's bedroom may be an effective strategy for preventing obesity and associated co-morbidities (Dennison et al., 2002). The aim of this study was to investigate the relationship between the presence of electronic media (TV sets and computers) in the bedroom and young people's TV viewing, computer use/games and snacking behaviours. **Methods** Eight hundred and twelve (11.9-17.9 years of age) students from five countries (UK, China, Hungary, Romania and Slovakia) participated in this study. Data were collected by self-report ecological momentary assessment (EMA). **Results** and **discussion** Results showed that along with the highest rate of TVs (83%) and computers (26%) in British students' bedrooms, they spent more time with TV/video viewing and computer use/games (167 mins/day) than youths in the other countries, with the Chinese spending significantly less (58 mins/day) than others, as only 4% of students have a TV set and 19% a computer in their bedroom. Also, more British students (60%) consume snacks than peers from other countries, with the Chinese youth consuming fewest (28%). **Conclusions** In conclusion, parents should play a vital role to establish an "electronic media-free zone" in children's and adolescents' bedrooms, which would meet with the recommendations of clinicians and public health practitioners (Nelson et al., 2006). This effort could contribute to a global strategy to assist with the reduction of non-communicable diseases associated with sedentary behaviour. **References** Delmas, C., Platat, C., Schweitzer, B., Wagner, A., Oujaa, M. & Simon, C. ### THE SHARED ENVIRONMENT EXPLAINS INDIVIDUAL DIFFERENCES IN CHILDREN'S EXERCISE BEHAVIOR: A TWIN STUDY

Huppertz, C., Bartels, M., van Beijsterveldt, C.E.M., Boomsma, D.I., Hudziak, J.J., de Geus, E.J.C.

*Vrije Universiteit Amsterdam*

**AIM:** The aim of this study was to investigate causes of individual differences in children's exercise behavior. Twin studies offer the unique opportunity to disentangle the relative contribution of genes, shared environment and unique environment to a trait. This is the first twin study on participation in leisure time exercise activities looking at children who are younger than 12 years old. **METHODS:** Data were collected as part of a longitudinal survey study of the Netherlands Twin Register. The twins were 7 (N=3,966 subjects), 10 (N=3,562) and 12 years old (N=8,687), with longitudinal data for 27% of the sample. Both mothers and fathers were asked to report on the children's regular participation in leisure time exercise activities, including frequency and duration. Resemblance between monozygotic and dizygotic twins for weekly MET hours spent on exercise activities was analyzed as a function of their genetic relatedness. **RESULTS:** Average weekly MET hours increased with age for boys [age 7: 14.0 (SD=11.8); age 10: 22.6 (SD=18.7); age 12: 28.4 (SD=24.9)] and girls [age 7: 9.7 (SD=9.5); age 10: 15.3 (SD=15.1); age 12: 19.3 (SD=19.8)]. Around 13% of boys and girls across all age groups did not participate in any

regular leisure time exercise activities. Tracking of exercise behavior from age 7 to age 12 was modest ( $.168 < r < .534$ ). For boys, genetic effects accounted for 24% (CI: 18-30%) of the variance at age 7, 66% (53-81%) at age 10 and 38% (32-46%) at age 12. For girls, this was 22% (15-30%), 16% (9-24%), and 36% (30-43%), respectively. Environmental influences shared by children from the same family explained 71%, 25% and 50% of the variance in boys (aged 7, 10, 12) and 67%, 72% and 53% in girls. Partly different aspects of the shared environment affected exercise behavior in boys and girls. CONCLUSION: Our analyses confirmed the important role of shared environmental factors for children's exercise behavior that gradually give way to genetic influences when they reach adolescence. The shared environment is made up of all environmental factors that make members of a family more similar to each other. Parenting behavior may be the most likely suspect to explain the strong shared environmental impact in the present study as parents often act as gatekeepers to their children's leisure time activities.

### **"WHAT DO COACHES DO" AND "HOW DO THEY RELATE": THEIR EFFECTS ON ATHLETES' PSYCHOLOGICAL NEEDS AND FUNCTIONING**

Felton, L., Jowett, S.

*Loughborough University*

"What do coaches do" and "how do they relate": Their effects on athletes' psychological needs and functioning Felton, L., & Jowett, S.11: School of Sport, Exercise, and Health Sciences, Loughborough University (Loughborough, UK) Introduction The sport psychology literature (e.g., Amorose & Anderson-Butcher, 2007; Bartholomew et al., 2011) has expressed the importance of coach behaviours, both supportive and controlling in various degrees, on athlete need satisfaction and ultimately well-being, however the importance of coach-athlete relationship quality on need satisfaction has hardly ever been explored. Grounded in self-determination theory, this study aimed to examine the links of the social environment, as defined by coach interpersonal behaviours and coach-athlete relationships, with athletes' perceptions of basic psychological needs and indexes of well-being. Methods Athletes (N = 300) completed a multi-section questionnaire assessing the study variables. Structural equation modelling was used to produce a path model with EQS 6.1 (Bentler, 2002) in order to analyse the hypothesised associations between the study variables. In order to determine the adequacy of the model fit to the data various goodness-of-fit indexes were used including; the Satorra-Bentler scaled  $\chi^2$  ( $S-B\chi^2$ ), Robust Comparative Fit Index (CFI), Non-Normed Fit Index (NNFI), and the Root Mean Square Error of Approximation (RMSEA). Results Structural equation modelling supported a model whereby coach behaviour of autonomy support and the quality of the coach-athlete relationship positively predicted athletes' satisfaction of needs, and in turn, satisfaction of needs predicted vitality, negative affect, and physical self-concept (self-descriptions of skillfulness and competence). Discussion The findings suggest that, athletes' perceptions of supportive coaching behaviours and positive coaching relationships may serve to fulfil important psychological needs. Subsequently, these manifested connections may promote athletes' well-being while thwarting their ill-being. These findings support theoretical assumptions and highlight that athletes' perceptions of what coaches do, and how they relate, are important to their psychological needs satisfaction and optimal functioning. ### **THE PRELIMINARY DEVELOPMENT AND VALIDATION OF THE COACH DOPING CONFRONTATION SCALE**

Sullivan, P., Feltz, D., LaForge-MacKenzie, K., Hwang, S.

*Brock University*

Many of the anti-doping interventions in sport target coaching as a mechanism of change (Laure, Thouvenin, & Lecerf, 2001). Typically, these interventions focus on coaches' knowledge with respect to doping. However, research has noted that coaches do not lack knowledge in this area, but do lack in confidence for how to act when they feel it is appropriate (Rockwell et al., 2001). The focus of this study was to design and validate a measure of coaches' confidence in doping confrontation abilities (i.e., coaching confrontation efficacy). The Coach Doping Confrontation Scale (CDCS) was based in the theoretical framework of Newell and Stutman's (1988) Social Confrontation Model. This framework supported a multi-factorial conceptualization of confrontation that includes five interrelated factors - Initiation, Intimacy, Legitimacy, Potential Outcomes, and Personal Resources. A review of the literature on interventions in other contexts resulted in a sample of items that could be used to measure coaches' confidence in sport doping situations which were reviewed by a panel of experts in intervention and coaching, resulting in a five-factor, 45 item Likert-type scale. The CDCS was then administered to a sample of 645 coaches of high school aged athletes. A Confirmatory Factor Analysis supported the five-factor model with minimal alternations. The resultant model showed excellent fit of the model to the data (CFI = .944, RMSEA = 0.29). The five factors also showed acceptable internal consistency. Correlations between these five factors and the factors of the Perceived Motivational Climate in Sport Questionnaire-2 (Newton, Duda & Yin, 2000) were also examined. Results showed that high scores in confrontation efficacy were positively related to task-involving ego orientation. The results of these analysis support that the CDCS is a psychometrically sound instrument for assessing coaching confidence in abilities to confront athletes. Future research will utilize this measure in a competency-based anti-doping coaching workshop.

### **AFFECTIVE RESPONSES TO SOCIAL COMPARISON WITH A CHOSEN INDIVIDUAL IN PHYSICAL EDUCATION**

Barnes, J.S., Spray, C.M.

*Loughborough University*

Objectives: To date, few studies have researched children's affective responses to social comparisons and none so far, have investigated these relationships in physical education (PE). Drawing on previous research, this study sought to determine the relationships between children's comparative evaluations with a chosen individual, friendship importance and eight emotions. Design: Cross-sectional. Method: Five hundred and forty-five children (264= males, 276= females, 5= undisclosed; Mage = 13.89, SD = 1.57 years) from two schools in England completed measures of perceived relative standing in comparison to an individual identified by them as someone they compare with (PRSI), importance of friendship with that individual and eight emotions; frustrated; proud; ashamed; inferior; disappointed; jealous; happy; inspired. Results: Hierarchical regression analysis demonstrated that the higher the PRSI, the more frequently children reported experiencing pride. Comparing upward with a friend (low PRSI) was associated with higher occurrences of feeling jealous. Individuals

who compared with someone who was considered an important friend reported higher frequency of inspiration. Those who compared with someone who was not a friend reported more frequent experience of frustration. Those who reported high levels of PRSI and friendship importance indicated more frequent experiences of happiness. No significant associations were identified for ashamed, inferior or disappointed. Conclusion: As the first study to assess the relationship between social comparison with a chosen individual in PE and emotions, this research indicates that children are affected both positively and negatively by the comparisons that they make. Different emotions are associated with social comparison with an individual in different ways, highlighting the complexity of social comparison processes. The results suggest that this avenue of inquiry is a valid and useful one when investigating emotions that children experience in an achievement setting. Future research is therefore needed, to ensure that our understanding of the role social comparison may play in the experience of different emotions continues to grow.

## A COMPARATIVE ANALYSIS OF MENTAL TOUGHNESS OF MALE AND FEMALE SCHOOL ATHLETES

Tomar, R., Antony, V.C.

*King Fahd University of Petroleum and Minerals//PHYSICAL EDUCATION DEPARTMENT*

A COMPARATIVE ANALYSIS OF MENTAL TOUGHNESS OF MALE AND FEMALE SCHOOL ATHLETES Tomar, Rakesh.1, Antony, Varghese C.2 1: KFUPM (Dhahran, Saudi Arabia), 2: KFUPM (Dhahran, Saudi Arabia) Introduction Acknowledging the essential need of mental toughness, coaches have come to agree that mental toughness is a factor that could determine the success of an athlete (Gould, Peterson and Petlichkoff, 1987). Therefore the objectives of study were to compare the mental toughness between; male & female school athletes; successful & non successful male athletes and successful & non successful female athletes. Methods Total 70 national level school athletes with age ranging from 16-18 years were selected randomly as subjects for study and were divided into two groups namely; male (N=47) & female (N=23). Further in the male category two sub-groups were formed namely; successful male athletes (N=10) & non successful male athletes (N=37). Similarly in female category two sub-groups were formed namely; successful female athletes (N=6) & non successful female athletes (N=17). Mental toughness questionnaire of Allan Goldberg was administered. Winning a medal in National Championship was considered as successful performance for this study. T- test was applied to compare means between the groups. Statistical significance was set at 0.05. Results Analysis of results revealed significant difference on mental toughness (MT) between male & female athletes ( $p = .011 < .05$ ), female athletes scored significantly higher ( $M \pm SD = 39.08 \pm 4.06$ ) than male athletes ( $M \pm SD = 35.72 \pm 5.48$ ). Significant difference was observed on MT between successful & non successful male athletes ( $p = .001 < .05$ ), successful male athletes scored significantly higher on MT ( $M \pm SD = 42.9 \pm 2.60$ ) than non successful male athletes ( $M \pm SD = 33.78 \pm 4.30$ ). No significant difference was found on MT between successful & non successful female athletes ( $p = .395 > .05$ ). Discussion Successful male athletes were more mentally tough than non successful and scored significantly higher on all subscales of mental toughness. Significant differences were observed between two groups (successful & non-successful male athletes) in handling pressure ( $p = 0.001$ ), concentration ( $p = 0.001$ ), mental rebounding ( $p = 0.016$ ) and winning attitude ( $p = 0.001$ ), which is supported by (Kuan & Roy, 2007) who also observed significant differences between medallist and non medallist athletes. (Alderman, 1974) suggested that successful athletes are thought of as being not only physically tough but mentally tough as well. (Rana, 2009) also reported that successful wrestlers scored significantly higher on all sub scales of mental toughness than non successful wrestlers. References Alderman R B. (1974). W.B Saunders Company, Toronto. Gould D, Hodge K, Peterson K, Petlichkoff L. (1987). *Sport Psychologist*, 1, 293-308. Kaun Garry, Roy Jolly. (2007). *Journal of Sports Science and Medicine*, 6, 28-33. Rana Munish. (2009). *Journal of Physical Education and Sports Science*, 4, 60-69.

## SELF ESTEEM AND BODY IMAGE IN INDIVIDUALS PRACTICING FITNESS ACTIVITIES

Bianco, A.1, Alesi, M.1, Paoli, A.2, Raccuglia, M.1, Spina, S.1, Pepi, A.1, Palma, A.1

*1: University of Palermo. 2: University of Padua*

Introduction There is a considerable body of recent studies in the literature to focus on the reciprocal enhancement of physical activity and psychological constructs such as self-esteem and body-image. Self-esteem is a fundamental aspect of a person's experience and quality of life. A positive self-evaluation and view of oneself are crucial predictors of one's general well-being. In particular self-esteem refers to the evaluative component of the Self, emerges precociously when the individual is required right to verify his evaluation of himself by comparing it with his actual performance on a variety of tasks such as physical or school tasks. Perceptions of body image play a pivotal role in the self-esteem. On this theoretical basis, the study aims to investigate two specific research questions: 1. Do gender and age influence the self-esteem and body-image of individuals practicing fitness activities? 2. To what extent are correlated fitness parameters, self-esteem level and body-image? Methods At the beginning of the research subjects were given a Fitness Test aimed at evaluating parameters such as weight, height, sit-up test, push-up test, squat-test... Then were administered Self-Esteem and Body-Image tests. The subjects' self-esteem was measured by the Self-Esteem Scale (Rosenberg, 1965) and body-image by the Body Weight, Image and Self-Esteem Evaluation Questionnaire. Results The sample consisted of 100 participants, with an average chronological age of 28.59 years, subdivided into three groups of age. With regard to gender, there were 50 females and males. The medium socio-economic level was predominant. On the whole, the findings show significant differences between males and females both for Self-Esteem ( $F 1.99 = 6.694$ ;  $p < .05$ ) and for Body-image ( $F 1.99 = 11.708$ ;  $p < .01$ ). In particular, males demonstrate higher levels of Self-Esteem and Body-image than females. Moreover the results point out significant correlations between weight and negative self-esteem and between Self-Esteem and Body-Image. Discussion Further research should be carried out to determine the clinical implications of the relationship of Self-Esteem and Body-Image considered as crucial factors that lead to the risk for developing eating disorders and body dissatisfaction. #### THE NARRATIVE ABOUT BECOMING A FEMALE ELITE JUDO PLAYER IN SOUTH KOREA

YEO, J.

*Yongin University*

THE NARRATIVE ABOUT BECOMING A FEMALE ELITE JUDO PLAYER IN SOUTH KOREA Yeo, J. 1, Kim, J.1, Park, I. 2 1:UYI(Yongin, South Korea), 2:UHN(Kwangju, South Korea) Introduction In South Korea, becoming a female elite Judo player is not common. Judo is not a popular sport for women in South Korea. Actually, most of female participants playing judo are not amateur players, and female Judo players open belong to a team, for instance school, university, or company. This research explored the process to be female elite Judo players. Method Qualitative research method was used for this study and four female elite judo players participated in the study as main informants. All participants of this study were judo players belonging to the different teams, respectively. During three months, three times interviews were operated each interviewees. Collected qualitative data was analyzed by three researchers through narrative inquiry. Result According to the information from four participants, playing Judo professionally was a process accepting their identity. Difference of gender was not an important problem to success as a superior judo player. Fulfillment as a Judo player was the best worth rather than beauty as a woman. Also, through the analysis of informer's transcription, it was revealed that the program for educating female judo players were not systematic and effective. The participants described that it was an accidental occasion for them becoming an elite Judo player. Discussion Denzin & Lincoln (2008) refers that narrative inquiry is one of the excellent method to study a life of woman. We tried to represent the experiences of female judo players. The analysis of this research was processed by the five steps of interpretation through analysis method suggested by Riessman(1993). The process to become a female elite judo player was rarely studied. Only one article handles with similar topic in South Korea, and it was an ethnological study about female elite player (Kim, 2006) References Denzin NK, Lincoln YS. (2008). *Collecting and Interpreting Qualitative Materials* (3rd Ed). Newbury Park, CA: Sage. Kim M. (2006). *The Korean Journal of Physical Education*. 45(4), 93-102. Riessman CK. #### OBESITY AND TRACKING OF PHYSICAL FITNESS IN ELEMENTARY SCHOOL CHILDREN

Watanabe, M., Kidokoro, M.

*College of Education*

Introduction Physical fitness (PF) in early teen years influences that in adulthood. Consequently, clarifying PF tracking at an early age is important. PF tracking during elementary school has shown a moderate correlation between lower and higher grades. However, although PF is related to obesity, its relation remains unclear. This study was conducted to elucidate the relation of first grade PF to sixth grade PF, and the influence of obesity. Methods We examined 501 sixth grade elementary school children (257 boys, 244 girls) using five-year longitudinal height, weight, and PF test data. PF tests consisted of scores of a 50 m run, standing jump, sit-and-reach, repeated side jump, hand grip, 20 m shuttle run, sit-up and softball throw. Obesity was assessed by the body mass index (BMI). The relation between first grade and sixth grade PF and the influence of obesity were assessed using Pearson's product-moment correlation coefficient. Results The 50 m run and softball throw showed high correlation ( $r > 0.60$ ). Standing jump, sit-up, 20 m shuttle run and hand grip showed moderate correlation ( $r = 0.40-0.50$ ). Sit-and-reach and repeated side jump showed low correlation ( $r < 0.40$ ). Relations between PF and BMI in the first grade were  $r < 0.20$ . Discussion Muscle strength and endurance ability should be intervened in the preschool period because tracking was moderately high in the first grade. Throwing skill acquisition was especially important. However, flexibility and agility can be acquired adequately during elementary school because the tracking was low. Furthermore, the influence of obesity on PF tracking is slight: the relation between obesity and PF in first grade is low. References Malina RM. (2001) *Am J Hum Biol*, 13,162-72. McMillan CS, Erdmann LD (2010) *Pediatr Exerc Sci*, 22, 231-244.

#### INTERRELATION BETWEEN THE MECHANISMS FOR THE CENTRAL REGULATION OF MOVEMENT AND THE COGNITIVE ABILITIES OF ADOLESCENT

Stankovic, V., Toskic, D.

*University of Pristina*

Introduction Determination of relations of motor abilities with other segments of anthropological status of sportsmen in particular sports nowadays, represents very current practical and theoretical issue. This issue is of a great importance firstly because of its possibility to form the most rational procedures in sport technology and sport training - sportsmen selection, training planning, programming and control as well as efficient monitoring of development of relevant anthropological characteristics (Stankovic, Malacko 2008). Methods We used a system of 9 tests of motor skills on a sample of 100 male participants, aged 17-18, along with 3 tests of cognitive abilities, with the aim of determining the statistically significant relations between the system of variables which were used to evaluate the mechanism of the central regulation of movement and cognitive abilities. The data were processed by means of the canonical correlation analysis (Popovic, 1993). Results Between the system of motor variables and the system of cognitive variables of the adolescents, a pair of significant canonical correlations ( $R_c = .52$ ) was obtained. The results of the research indicated that the adolescents showed better results for motor variables for the evaluation of the regulation of movement, if they had increased values for the cognitive variables of the effectiveness of the perceptive processor (IT-1) and the effectiveness of the parallel processor (S-1). Discussion On the basis of the results obtained in this study we can necessarily conclude that there are two-way relationships between cognitive mechanisms and motor functions. The obtained canonical factor indicates that, in the case of high school females, the results of the motor skills which were used to evaluate the mechanism of the central regulation of movement are undoubtedly dependent on the interrelations between the input processor, that is, the ability to receive and process information and solve problems whose elements are given in the field of perception, as well as on the ability which is formed during the process of acculturation (Milojevic, Stankovic 2010). Nevertheless, the relationships between motor and cognitive factors on their own do not play a decisive role in the success of a certain activity, and the overall relationship which includes the

remaining anthropological dimensions is necessary. References Milojevic, A., Stankovic, V. (2010). Development of motor abilities of younger adolescents. *Facta Universitatis. Series: Physical Education and Sport*, 8 (2), 107-113. Popovic, D. (1993). Programi i potprogrami za analizu kvantitativnih promena. ### THE EFFECTS OF CONTEXT ON DELIBERATE PRACTICE ORIENTATIONS IN YOUTH SPORT

Santos, A.1, Diogo, F.1, Goncalves, C.E.1

*University of Coimbra - NIF 501617582*

**Introduction** Different factors lead athletes to achieve high performances in sport. It's not just natural talent that affects the development of expertise in sport but also environmental influences (Lidor & Lavyan, 2002), namely the perspective of a professional sport career. The aim of the study is to analyze the effects of a sport season in three different contexts on the orientations for deliberate practice among adolescent athletes. **Methods** Forty-eight athletes under-17 years of age ( $15.7 \pm 0.99$ ), from a soccer academy (20), a volleyball club (14) and an elite volleyball centre (14) participated in the study. The adapted version of the Deliberate Practice Motivation Questionnaire/ DPMQ (De Bruin, Rikers & Schmidt, 2007) was used. The instrument has 21 items and 2 factors, Will to Compete and Will to Excel, and the athletes answered in the beginning of the season and in the end of the season. ANOVA analysis for the 2 factors was performed. Data about the training loads were collected. **Results** The training volume for soccer players was 7 hours/week, for volleyball players 6 hours/week and for elite volleyball players 19 hours/week. The scores for Will to Compete and Will to Excel of soccer players were higher than those of their volleyball peers and presented no significant effect of time for Will to Excel, but a significant increase in Will to Compete ( $p=0.03$ ). For both groups of Volleyball players a significant decrease in Will to Compete ( $p=0.01$ ) and Will to Excel ( $p=0.04$ ) was observed. **Conclusions** Despite the fact that elite Volleyball players practice and compete almost three times as much as their peers, it seems that it has a negative influence in their desire to become experts. The findings suggest that a context oriented to professionalization has the strongest influences in the level of engagement of adolescent athletes in a path to excellence. **References** De Bruin, A., Rikers, R., & Schmidt, H. (2007). The Influence of achievement motivation and chess-specific motivation on deliberate practice. *Journal of Sport & Exercise Psychology*, 29, 561- 583 Lidor, R., & Lavyan, N.-Z. (2002). ### THE SCHOOL NURSE'S TEACHING ABOUT MENSTRUATION AT ELEMENTARY AND JUNIOR HIGH SCHOOLS IN JAPAN

FUJIWARA, Y.1, MAKABE, C.2, KIMURA, K.3

*1: KAWASAKI UNIVERSITY OF MEDICAL WELFARE, 2: KUMAMOTO GAKUEN UNIV, 3: KOKUGAKUIN UNIV*

**Introduction:** The menstrual education in Japanese schools has been based on Government Course Guidelines. It includes contents about the growing body, hormonal mechanisms and the menstrual cycle. These contents are crucial for students to understand the many physiological changes in the adolescents. The school nurse is a key position to teach those contents in Japanese schools. The aim of this study was to investigate the practical guidance on menstruation of school nurses in Japan. **Methods:** We undertook the original questionnaire survey for the school nurses, and send the original questionnaire survey by post which was 1,200 each schools of elementary and junior high schools. The survey contained the following questions. Q1: Which of the following does your school include in practical guidance of menstruation? Q1-1: Coping with menstrual pain, YES or NO? Q1-2: Using tampons, YES or NO? Q1-3: Measuring basal body temperature, YES or NO? Q1-4: Teaching contents during menstruation in class of swimming and the other exercise out of water such as gymnastics, ball game and dance, YES or NO? Q2: Who is the leading teacher during guidance? Q3: How to teach the practical guidance? **Results:** The number of returned post from schools was 159 (13.3 %) elementary schools (ES) and 172 (14.3 %) junior high schools (JHS). The percentage of Q1-1 was 49.1 % (ES) and 64.0 % (JHS). The percentage of Q1-2 was 1.9 % (ES) and 1.7 % (JHS). For basal temperature, the percentage of Q1-3 was 5.7 % (ES) and 19.8 % (JHS). The percentage of Q1-4 was 37.7% (ES) and 23.3 % (JHS). For swimming in class during menstruation, the results were 50.3% (ES) and 31.3% (JHS). Q2: In most cases, leading teacher of practical guidance was the school nurse. However, menstruation guidance of physical education class of swimming and the other exercise out of water had been provided mostly by the physical education teacher in junior high schools, with result of 44.6 % for exercise out of water and 63.2 % during swimming. Q3: Firstly the situation of guidance at elementary school was in homeroom activities and secondly 'other time'. For junior high schools, the major situation was 'other time' and secondly was physical education class. The 'other time' was individual counseling when the students called at school nurse's room. **Discussion:** It was reported that measuring basal temperature is important for the self-control as a woman. Considering that, we discuss the guidance about basal temperature is more required. And it was reported that parents viewed school as a more appropriate setting than home for teaching physiological aspects of sexuality and providing accurate information. I would consider that the practical guidance agree with a stage of life and the situation of exercise.

### COMPARISON OF RESPIRATORY FUNCTIONS IN PHYSICAL EDUCATION CLASSES WITH PAST MEDICAL HISTORIES OF BRONCHIAL ASTHMA IN SUMMER AND WINTER

TAKAGI, Y.1,2, NAKASE, M.3, YOSHIZAWA, K.3, ANDO, Y.4, ONODERA, S.5

*1 RESEARCH FELLOW OF THE JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, 2 GRADUATE SCHOOL, KUMW, 3 KAGAWA NATIONAL COLLEGE OF TECHNOLOGY, 4 INSTITUTE OF DEVELOPING ECONOMIES, 5 KUMW*

**Introduction:** The purpose of this study is to investigate changes in indexes of respiratory functions in physical education classes with past medical histories of bronchial asthma in summer and winter. **Methods:** Eleven Japanese healthy male students (age:  $18.3 \pm 0.5$  years) with a past medical history of bronchial asthma (Asthma group) and Eleven healthy control students (Non-asthma group age:  $18.6 \pm 0.5$  years) volunteered to this study in physical education classes, in A National College. **Investigation I :** They played basketball games for two times, and each game was 10 minutes in summer (July). Atmospheric temperature was  $26.5$  °C, and relative humidity was 78.1 %. **Investigation II :** Subjects participated in the soccer games after warm-up in winter (December). They played soccer games for two times, and each game was 15 minutes. Atmospheric temperature was  $6.8$  °C, and relative humidity was 38.9 %. We took breaks for approximate 10 minutes between each game. Participant's FEV1.0, PEF, SpO2 and the degree of dyspnea sensation (DDS) were measured before the first game (Rest) and at the time 5 minutes after each game (After-1 • After-2) **Results & Discussion:** No significant differences were found on FEV1.0, PEF and SpO2 changes between the Rest and at After-1 • After-2 within groups in summer. There was no significance between the two groups in summer. On the other hand, significant reductions in FEV1.0, PEF and SpO2 were observed at the After-1 in

Asthma group in winter ( $p < 0.05$ ). No significant differences were found on measurement indexes in Non-asthma group. DDS at After-1 and After-2 were significantly higher than that at the Rest in each group in both seasons ( $p < 0.01$ ). As high intensity exercise of aerobic and anaerobic, basketball and soccer game increased stress on the respiratory system with apparent increases in oxygen demand. Especially, in Asthma group, it was considered that significant decrease in FEV1.0 and PEF after games indicated enhancing airway reactivity induced by additive effects of increase of oral-breathing from high-intensity exercise and exposure to cold environment (6°C) from classroom (22°C). Though conditions in Asthma group after the games indicated mild asthma attack in clinical estimation, it was in safety range of exercise in Japan. Conclusion: These data suggest that stress on respiratory system indicated greater during playing a soccer game for 15 minutes in physical education classes under cold environment in individuals with past medical histories of bronchial asthma.

### TEKO - PROMOTING SAFETY IN SCHOOL SPORTS VIA INTERNET AND EDUCATION

Oksanen, R., Jussila, A.M., Ojala, A., Parkkari, J.

*UKK Institute for Health Promotion Research*

Introduction Sports injuries are the most common injury type in Finland, over 350 000 injuries occurred in year 2009. Sports injury numbers have increased considerably during the past decades. In Finnish basic education sport injuries happen mostly in PE classes, in recess and on the way to school or home. Football, floorball, basketball and skating are the most common activities causing injuries during PE class sports. Most injuries are mild, but the treatment can be time consuming and expensive. Especially knee, low back and head injuries may cause long-term pain and disabilities. A remarkable part of these injuries can be prevented by enhancing pupils motor skills and awareness of injury risks, by increasing quality and contents of PE and health education classes, and taking care of safety equipment and environment in sports. Methods The Sports and Exercise Safety in Finland program (LiVE 2006-) and its nationwide implementation project among teachers, Safety in School Sports (TEKO 2010-), is producing educational material to the internet to promote physical activity levels in general and to promote safety of sports and exercise in a nationwide setting. The main focus is to deliver national and international research findings to the schools by communication via website [www.tervekoululainen.fi](http://www.tervekoululainen.fi) and to support this communication with education methods. The main target group for TEKO is secondary school teachers (grades 7 to 9). Results In TEKO project the sports safety promotion is focused on ten different segments; physical activity, sports skills, maturation, nutrition, rest and sleep, environment and equipment, health care, atmosphere and rules, sports injuries and support network. These 10 different segments compose a model, "Element wall", which teachers can leverage to build up the safety in sports in school context. TEKO builds up information packages and practical toolkits e.g. diaries, videos and ppt slides for teaching. The education material has been developed precisely to adolescents by using their language, style and information channels. These materials are available free of charge for all users in the projects websites. During 2010-2011 TEKO project has completed 7 of the 10 Element wall segments. TEKO has been presented annually in about 10 different events (e.g. PE and Health Education teachers' national seminars) and organized several education sessions to improve safety in PE classes. TEKO websites (in Finnish) have attracted 3000 visitors and 80 000 hits per month. Discussion Successful development and implementation of preventive strategies against sports and exercise related injuries are likely to result in large reduction in the absolute number of health problems, a reduction in school absenteeism, decrease in long-term disabilities and medical costs. The true effects of the preventive measures through TEKO project will be seen within five to ten years. To support the common goals LiVE program is promoting sports safety also for sport clubs and coaches via Healthy Athlete project: [www.terveurheilija.fi](http://www.terveurheilija.fi).

### TRIAL AND RESULTS OF HOMEWORK IN A UNIVERSITY PE CLASS

Kita, T.1, Hattori, Y.2, Yoshihara, S.3, Yamamoto, T.1, Asai, T.4, Horie, S.5

*1: Musashino Art University (Tokyo, Japan), 2: Seisa University (Hokkaido, Japan), 3: St.Marianna Univ. (Kanagawa, Japan), 4: Nagasaki Univ. (Nagasaki, Japan), 5: Tokai Univ. (Kanagawa, Japan)*

Introduction: In recent years, the educational benefits of using video delay units in university physical education classes have been reported. However, physically attending classes to personally instruct students in real time can be rather difficult in terms of time constraints. Therefore, we tried assigning the evaluation of a sports video as homework for this research. Subject of Research were 20 students taking a "basketball" class in a physical education class in a university in Tokyo. Of those 20, 17 of the students who participated in the homework assignment were used as subjects for analysis. Methods: The students were given a DVD with videos of themselves playing sports (one hand set shot / free throws), along with notes to check. The students were instructed to evaluate and analyze the video, and to turn it in by a set date along with their notes. Also, a practical test was conducted before and after starting the homework assignment, and one hand set shot / free throws accuracy was evaluated. The students were given a DVD with videos of themselves playing sports, along with notes to check. The students were instructed to evaluate and analyze the video, and to turn it in by a set date along with their notes. Also, a practical test was conducted before and after starting the homework assignment, and one hand set shot / free throws accuracy was evaluated. Results: Most of the students noted that "it was my first time objectively watching myself play and evaluating myself, and my form was different from how I'd imagined it," and that they were able to find concrete points to fix among the various checkpoints. A one hand set shot / free throws accuracy test was also conducted before and after the homework assignment. Results of having the students basketball one hand set shot / free throws the five times each showed that more than 40% of the students improved their goal rate after the homework assignment. Discussion/Conclusion: Most of the students noted that "it was my first time objectively watching myself play and evaluating myself, and my form was different from how I'd imagined it," and that they were able to find concrete points to fix among the various checkpoints. A one hand set shot / free throws accuracy test was also conducted before and after the homework assignment. Furthermore, in regards to improvement in physical performance after the homework assignment, male and females felt that they had "improved" one hand shot abilities. [Postscript] :This research was conducted as part of the Kanagawa Society of Physical Education and Sports Science 2010 grant program to "Testing the introduction of homework to a university physical education class" (Principal researcher: T. Kita).

### 1000M. RUN TEST PERFORMANCE DURING YEARS: FOURTEEN URBAN STUDENTS RESULTS.

Fratini, G., Vago, P., Casolo, F., Bruseghin, P., Lovecchio, N., Merati, M.

*Catholic University of Milan, Italy*

Introduction During adolescence (A) individuals experiment a great number of changes in their own body. At the same time, physical activity represents an important element for health and physical efficiency. Unfortunately, PA practice often ceases at the start of high school. The purpose of this study was to investigate the performance of 14 y old students during their first week in high school. Data were

collected for 7 consecutive years (2005-2011). Material and methods Every year in September the students of an high school (Milano city) performed the 1000m run test. All students followed the same path and were assessed by the same teacher. Over than 500 students (228 M and 280 F) were tested during the first lesson of Physical Education (PE). Thus, every year 72 students (on average) were tested about physical efficacy during the transition from middle to high school. Thus a useful baseline could use to set the educational programs. All students lived in the city (I) since their birth. Results These tests show a different trend between boys and girls. In particular, boys increased the performance during years while girls are fluctuating. Boys students run the test in 293sec  $\pm$  34 (data pooled within years) while girls in 338sec  $\pm$  32. The best performances were 210 and 251 sec (M and F respectively) while the worst 416 and 445 sec. In 2005, male run the test in 318 sec while during September 2011 the 14y old students took only 285 sec. Indeed boys decrease, every years, the time spent to run the test of about 5,5 sec. Girls were not constant or regular following a decreasing or increasing trend. Their were, always, more slow than their same age mates: from 5 sec (in 2005) to 71 sec (in 2006) of difference. The best years for girls was 2005: mean speed about 3,1 m/sec. Girls shown a minor variability (each years) while boys group obtained variation close to 45 sec. Discussion The use of motor fields tests allows a valuable monitoring about physical skills. The repetition of 1000m run test during years shown a general decreasing (boys) or a fluctuating performances (girls). Other factors could influence the physical practice: i.e. world events of national team for boys and a cultural drop-out during A for girls. The PE course (2) that are compulsory throughout the country are the only common element that could improve the physical efficiency especially in an urban environment where play sport is not always easy. ### A COMPARATIVE STUDY OF BONDING WITH PHYSICAL EDUCATION AT SCHOOL AMONG 11-18 YEAR-OLD HUNGARIAN AND TRANSYLVANIAN STUDENTS

Hamar, P.1, Versics, A.1, Adorjänné, O.A.1, Volák, A.1, Karsai, I.2, Soós, I.3

*1Semmelweis University Budapest, HU, 2University of Pécs, HU, 3University of Sunderland, UK*

Introduction Bonding with school subjects is an attribute of affectivity. Studying bondings throws light upon which subjects students prefer and to what extent in addition to showing which subjects they prefer more and which ones to a lesser degree (Báthory, 1989). A survey conducted at the end of the twentieth century in Hungary (Gombocz, 1999) shows that physical education teachers think the popularity of physical education is falling among students. This tendency is particularly true at secondary but also at primary schools. The aim of this research is to find out about the attitudes of 11-18 year-old Hungarian and Transylvanian boys and girls towards physical education and sports at school and whether the positive and negative attitudes towards physical education at school are manifest according to geographical units, sex and age. Methods The sample was made up of 3941 students, including 2840 Hungarian and 1101 Transylvanian boys and girls. The method applied with the cross-section test was a questionnaire survey. Data collection and filling in the questionnaires took place in the academic year 2006/2007. Factors were created from the questions of the questionnaire. Nine questions belonged to the factors relevant to our study. Factors were created from the items of the questionnaire. Nine items belonged to the factor relevant to our study which measured the positive attitude to the physical activity and PE classes. The values of the factor were expressed using the percentages of the positive answers in the factor. After descriptive statistics the three way 2\*2\*3 ANOVA was used (country\*gender\*age) to test the main effects and Bonferroni Post Hoc test for checking the group differences. We accepted the results as significant difference when  $p < 0.05$ . Summary The majority of the 11-18 year-old Hungarian and Transylvanian students participating in the study had a positive attitude towards physical education and sports at school. Our test results confirmed that Transylvanian boys and girls showed a more favourable attitude to physical education at any age than their Hungarian counterparts. Boys, except for the Transylvanian age group of 11-12, had a more positive attitude to physical education at any age than girls. Positive emotional attitudes towards physical education show a decreasing tendency. References Báthory, Z. #### AN ALTERNATIVE WAY TO DEVELOP THE TEACHING COMPETENCE IN THE PRE-SERVICE TEACHER EDUCATION FOR PHYSICAL EDUCATION

Shin, K.

*Jeonju National University of Education*

Introduction In Southern Korea, the elementary school teachers are raised mainly from the national universities of education. But there are limitations to teach them sufficiently to teach physical education. First of all, the required courses toward Pre-service Teachers (PTs) are uniformly organized. Second, PTs are obligated to cover the all of subjects. Third, there is a lack of time to learn content knowledge sufficiently. The motive of this study is that it is needed to find alternative way to overcome the limitations of Physical Education Teacher Education (PETE) programs. So this study aimed not only to investigate what activities the PTs' experience of sport club as an alternative way to develop the teaching competence for physical education, but also to interpret the educational meaning inherent in their experiences in the sport club. Methods This Study was designed by the qualitative method. Participants in this study were selected from PTs attended eagerly in the sport club on the campus. Eight PTs who have been taking the role of the executives in their club participated in this study. Data were collected by participant observation and in-depth interviews. Inductive analysis and constant comparison were used to analyze the data by go through the stages of transcription, the development and application of codes for each participants. Results The findings are as followings: First, the factors affect the PTs to choose and become the members of the sport club among other various clubs are linked separately to intrinsic motivation (such as 'the favorite exercise', 'the new experience') and extrinsic motivation (such as 'the recommendation of others'). Reinforcing the intrinsic motivation is the ultimate task in education process. Therefore it is needed to create conditions that stimulate pre service teachers' intrinsic motivation for doing physical activities so that they perform and challenge

continuously. Second, the main activities in the sport club are categorized as making relationship, doing exercise, strengthening the unity, and entering sport event. In contrast to other general clubs, the organic relationship existed in sport club. The difference is presumably based on the properties of sport and exercise. Participants are easily able to take something new in the site through seniors' advices which can be recognized as an apprentice. Lastly, the educational meaning of these sport club activities are interpreted as an extra-curricular activities, internalization of values in physical activities. Discussion Based on the results, It is very important to vitalize the sport club on the campus in that this sport club activities give the participants the chance to enrich their teaching expertise and teacher socialization. Therefore, It is necessary to give the administrative and financial help to the sport clubs, so that they attracts a lot of PTs to participate in. This abstract is a modified version of my published research in Korean Association of Sport Pedagogy Journal(Vol. 18(4), 19-38).

### **EXPECTATIONS OF PARENTS PARTICIPATION OF THEIR CHILDREN IN PHYSICAL EDUCATION LESSONS LIVING IN DIFFERENT REGIONS IN TURKEY**

Atan, T., Eliöz, M., Polatcan, İ.

*Ondokuz Mayıs University*

EXPECTATIONS OF PARENTS PARTICIPATION OF THEIR CHILDREN IN PHYSICAL EDUCATION LESSONS LIVING IN DIFFERENT REGIONS IN TURKEY Atan, T.1, Eliöz, M.1, Polatcan, İ.1. 1 Ondokuz Mayıs University, Yaşar Doğu Physical Education and Sports High School (Turkey) Introduction Parents decide for their child to participate in sport. Today, parents have more positive approaches to participate sports events than ever before (Tel, 2009). Therefore purpose of this study was to determine the expectations of parents from participation of their children in physical education lessons according to several variables (living city, living place and parents' gender). Methods For this purpose in 2010-2011 academic year, parents of second grade of primary school students participated the study whom live in Bursa and Diyarbakır, in Turkey. 120 and 116 parents live in Bursa and Diyarbakır respectively, totally 236 subjects filled the expectation questionnaire. The number of male and female parents was 143 and 93 respectively. Expectation Questionnaire (Öncü, 2007) was used to determine the expectation of parents from physical education lessons. Results Expectations of parents from physical education lessons were compared between Bursa and Diyarbakır city and 8 of the 18 expression were found significantly different. The expectations of parents were compared between the living place and significant differences were found in some items, especially between cities and villages. No significant differences were found between gender (mother and father) expectations except one expression. In this expression, female parents reported no sweating and easy exercise in physical education lessons more than males. Discussion All the parents' expectations from physical education lessons were positive. However, in some cases their expectations differ according to rural-urban settlements. In modern societies, sport is an integral part of social life while backward communities have ignored the importance of sports (Yetim, 2000). Due to urbanization, industrialization socio-cultural structure and economically developed places have more positive expect from physical education lessons. Living in the city has a positive effect on participation in sports (Pepe, 2003). Male and female parents' thoughts were parallel for physical education lessons. References 1. Tel, M. (2009). ### **POSTURE AND BEHAVIOURAL DISORDERS IN INFANCY AND ADOLESCENCE: PEDAGOGICAL POINT OF VIEW AND POSSIBLE EDUCATIONAL AID**

Costantino, D.

*University of Palermo*

Introduction Posture is "attitude or position of the body", the way in which a person holds himself as he stands, walks or sits. Harmony in movements originates with a contraction of different skeletal muscles, all coordinated by "one nerve control tower". If there is a gap in this nerve-muscular connection, there is twist of correct postures. Science is improving knowledges, but it hasn't reached final goal. In research's field, it is very important to join medical with pedagogical competences, to field possible educational aids for young at primary and secondary school. Improving «education at movement» in our schools is health-conscious practical teaching, that aims at helping young to become aware of their bodies. Methods It is necessary to increase curricular time dedicated to «education at movement» in primary and secondary schools. On one hand physical trainer must follow gymnastic exercises of pupils, on the other he must increase and extend knowledges of pupils about nutrition and health. There are postural disorders originated with malfunction of eyes, and others originated with feet's malfunction. Expert physical trainer will adjust carefully physical exercises with skeletal structures of his pupils. To every man his due. Results Let's show two paradigmatic situations: 1. pupil in the last desk in the classroom. If he is nervous and follow lessons with effort (moving himself from left to right), maybe he has malfunction of eyes, that obstructs him in learning well. Physical trainer is under the obligation to contact pupil's parents and to suggest them to bring their son to doctor to have eye test; 2. pupil with a very frail skeleton structure goes to school with enormous school-bag on his shoulders. Physical trainer is under the obligation to talk to him, explaining that heavy weights must put down his young and frail back, and suggesting to use trolley-bag. Discussion Physical trainer, rich in medical and pedagogical competences, can help young at school in improving their wellness. Simple remarks, made at the right time, are able to cause health-conscious changing in habits and postures. The more physical trainer will use «pedagogical tact», the more his action will be incisive and successful. References AA.VV. **PHYSICAL ACTIVITY AND ITS BUDGETARY CONSEQUENCES ON A SAMPLE OF THE SWISS POPULATION**

Rey, D.

*University College Thim van der Laan*

Physical activity and its budgetary consequences on a sample (n = 87) of the Swiss population Rey, D.1, Taeymans, J.2, Poortmans, J.3 1: Thim (Landquart, Switzerland), 2: BUAS (Berne, Switzerland), 3: ULB (Brussels, Belgium) INTRODUCTION: The last Swiss health survey testified that only 41% of the Swiss population showed sufficient regular physical activity (HEPA, 2007). If the health benefits of physical activity (PA) are well elaborated, the impact of PA on direct health care costs is less clear. The aim of this study was to compare the average costs to preserve capital-health between 'physically active' and 'physically inactive' Swiss adults. METHODS: Eighty-seven French and German-speaking Swiss participants (age = 51.0 ± 10.4 years and body mass index (BMI) = 24.9 ± 4.3 kg.m<sup>-2</sup>) with stable health status, volunteered in this cross-sectional stratified study. PA, gender, BMI, injuries associated with PA, lifestyle habits (such as fruit and vegetable intake (F&V), smoking status, alcohol consumption status and yearly health care costs were assessed using a questionnaire, administered by interview between November 2010 and 2011. Data were analysed using a linear regression analysis with health care costs as the dependent variable. In addition odds ratio's (OR) and 95% Confidence Intervals [95%CI] were calculated. Therefore, data were dichotomised using following cut-offs: BMI = 25 kg.m<sup>-2</sup>, F&V = 5 portions per day, alcohol consumption = 10 standard drinks per week and PA = 30 minutes moderate PA 5 times per week or 75 minutes vigorous PA once per week, smoking status = 0 cigarettes and PA-associated injuries was expressed as 0=no or 1=yes while for age and health care costs the mean was used as cut-off value. RESULTS: The average annual direct health care costs were 4333 ± 1580 CHF (3580 ± 1306 EUR) for the 'physically active' and 6559 ± 2638 CHF (5422 ± 2181 EUR) for the 'physically inactive' volunteers (p = 0.028). The best linear regression equation for health care costs was established as {-126.0 + (1815.7xPA) + (49.5xAGE) + (273.8xSMOKING)} (R<sup>2</sup> = 0.3413; RMSE = 1808; n = 87; p < 0.0001). OR for health care costs was for PA status = 0.2 [95%CI = 0.1 - 0.7], smoking status = 5 [95%CI = 1.2 - 19.2] and age = 2.9 [95%CI = 1.2 - 7.1] respectively. None of the other variables under investigations showed significant correlations with health care costs. DISCUSSION: These results suggest that the mean difference in the direct health care costs between the 'physically active' and the 'physically inactive' people may be confounded by age and smoking status (Pronk et al., 1999; Pratt et al., 2000). CONCLUSION: Independently of gender, BMI, alcohol consumption, injuries associated with PA or F&V intake the model showed that low physical activity, older age and smoking are risk factors for increased health care costs in this sample of Swiss inhabitants. **STANDARDS OF CARE IN YOUTH SPORT IN ENGLAND AND WALES: EVALUATING LIABILITY**

Greenfield, S., Osborn, G.

*University of Westminster*

Sport, like many areas of civil society, has had to face up to the threat posed by claims for negligence brought on behalf of children injured whilst participating in sport. The potential for negligence claims to impact upon sport more broadly is well established; witness for example the case of Watson v BBC that effectively bankrupted the British Boxing Board of Control. The notion of the duty of care owed is an important one, and one that has been extended by case law in recent years to embrace match officials for example (Smoldon v Whitworth). In addition to this legal duty of care, the CPSU (2009) also talks of a moral duty of care that further develops what is expected of adults in positions of power and control. Whilst the notion of duty is important, it is in fact the extent of this duty, and whether those who owe a duty fall below the standard of care they ought to show, that is the fundamental question that forms the focus of this paper Using the seminal case of Caldwell v Maguire [2001] EWCA Civ 1054, as its point of departure, the paper will analyse the meaning and extent of the standard of care owed. In particular it will consider the impact of issues such as the sport's object, demands and dangers, but will in particular explore the impact of its rules, working culture, conventions and customs, to evaluate the factual matrix that must be considered in determining the standard of care owed in children's sport. CPSU (2009) 'Duty of Care' CPSU Briefing, available online via [www.cpsu.org.uk](http://www.cpsu.org.uk)

**SUPPORT FOR ELITE SPORTS STUDENTS IN HONG KONG SCHOOLS**

Sum, K., Ma, M.

*The Chinese University of Hong Kong*

The purpose of this study is to investigate schools policy or practices in helping Elite Sports Students (ESSs) and how ESSs manage their school/personal lives. The study aims at inductively developing a grounded theory of how ESSs manage their school/personal lives in relation to a conceptual framework based on the following interrelated concepts – such as: identity, socialization and training experiences. An inductive grounded theory methodology will be employed. Use of the techniques and procedures outlined by Strauss and Corbin (1998) enables the researcher to explore the richness and complexity of experiences of ESSs as expressed in their own words, their descriptions of their experiences and exploring the meanings of those experiences for them. Data for grounded theory methods will be collected, coded and related, with the intention of developing a theoretical understanding of the phenomenon, that is, how ESSs make sense of their schools' practices. Purposive sampling will be employed in the open coding stage so that ESSs with different personal and organizational backgrounds can be included. The sample (ten to twenty local schools) will be drawn from different secondary and primary schools in Hong Kong. The researcher can meet the student participants face-by-face and interact with them through semi-structured interviews and focus group interviews. This method allows for differences that unfolded between participants to be maximized, and consequently for relationships between categories to be more robustly tested and verified in the construction of theory. In addition, theoretical sampling will be used to maximize opportunities to enrich the theoretical development of the thesis and to tell the storyline. Two pilot interviews will be conducted to ensure that the interview questions are appropriate and to test the duration of each interview. After pilot interviews, feedback from participants will be collected and the interview questions will be refined and modified. All the interviews will be tape-recorded and transcribed. As triangulation will also be implemented in this study, memos will be used for validating the incoming data from the interviews. As already mentioned, the researcher will write memos to record suggested questions, thoughts, hypotheses and relationships, and diagrams will be drawn to track back through the emerging theory. Through systematic record-keeping and ongoing evaluation of theories and findings, confirmability of the research findings will be considered.

## MUSLIM MAGHREBIAN WOMEN IN CATALONIA INTERPRETING THE POSITION OF ISLAM INTO THE WOMEN'S PARTICIPATION IN SPORT

Nasri, K., Soler, S.

*Inefc - Barcelona*

So much the religious values like the procedure and traditional practices influence the muslim girls and women's daily lives, leisure and participation in sport (Pfister, 2004). On the other hand, many Muslims and not Muslims think that the woman cannot play sports for a wrong belief that Islam prohibits it. But, in effect, the Islam promotes it, the Prophet Muhammad was encouraging always the people to do any physical exercises (Jawad, 2011). From the religious Maghrebian vision, it is accepted and even he promotes the participation of the women in the physical activity (PA), but it conditions how muslim men and women have to do it, banning them to go out semi naked and /or to do it mixed (Nasri, Soler, Serra & Gaztelu; 2010). Departing from all that, we have dedicated to it a part of the fieldwork of the PhD, with the aim to know what the muslim maghrebian women (MMW) believe that it is the position of the Islam into the feminine practice in PA and how it influences in their attitudes and conduct. Which I will present it in this presentation. The data is gathered by a qualitative interviews to MMW in addition to a field-observation in a program of PA, when participate MMW. The results were that all the women believe that the Islam does not prevent them from playing sports, upside-down, it encourages them to do it. Likewise, they speak about the conditions that the Islam puts with regard to the clothes or the type of group. In this point there are different interpretations and positions, ranging from the consideration that if the men in the group are not muslims, it would be not so relevant, until to the coverage of the body even when there are only women. #### RELEVANCE OF ABSOLUTE KNEE LOADING DURING VERTICAL JUMP IN ELITE FEMALE ATHLETES

Malfait, B.1, Dingenen, B.1, Staes, F.1, Vanrenterghem, J.2, Verschueren, S.1

*1: KU Leuven (Leuven, Belgium), 2: LJMU (Liverpool, UK)*

**Introduction** Knee injuries are very common in dynamic sports such as football (FB), handball (HB) and volleyball (VB), particularly in women. Anterior cruciate ligament (ACL) injury is a debilitating injury which often influences the further career of athletes. ACL injury risk appears to be associated with knee abduction loading in tasks such as the drop vertical jump (DVJ), which is therefore commonly used as a functional screening test (Hewett 2005). However, previous research provides no clear consensus about the use and interpretation of either absolute or relative knee joint moments during DVJ tests. Therefore, the purpose of this study was to examine differences in absolute knee loading during DVJ tasks between athletes from different sports and whether these differences remain after normalization for anthropometrics. **Methods** 43 injury-free female athletes (22 FB, 11 HB and 10 VB) volunteered to participate (mean age=21.1±3.4yrs). All subjects performed 3 DVJs from 30cm after a warm-up protocol. Kinematics and kinetics were measured according to the lower limb trunk model (Vanrenterghem 2010) using a 6 camera motion analysis system (Vicon) and 2 separated force plates (AMTI). Peak external knee abduction moments (eKAM), external knee flexion moments (eKFM) and peak vertical ground reaction forces (vGRF) were calculated for each leg between touchdown and take-off. Jump height (JH) was calculated using the vertical displacement of the center of mass. **Results** Jump height was significantly higher in VB than in FB ( $p<0.001$ ) and HB ( $p<0.001$ ). In frontal plane, absolute dominant eKAM was significantly higher in VB compared to HB ( $p=0.034$ ). In sagittal plane, absolute dominant eKFM was significantly higher in VB compared to FB ( $p=0.014$ ). No significant differences in peak vGRF between groups were found. After normalization of eKAM and eKFM for body weight and height (%Nm), no significant differences in relative external knee moments between groups were found. Jump height was not significantly correlated with the external knee moments in all groups. **Discussion** The non-significant correlation between JH and external knee moments in FB, HB or VB suggests that jump height is not related to knee loading during a DVJ task. Body weight and height had a clear effect on knee loading. The VB showed a significant greater absolute eKAM and eKFM compared to the other groups and can therefore be considered to be at higher risk for ACL injury. This may, with respect to injury prevention, suggest that the absolute knee loading remains an important variable due to the strain produced by these loadings on static and dynamic restraints of the knee. **References** Hewett et al (2005). *Am J Sports Med* 33,492 Vanrenterghem et al (2010). *Gait&Posture* 31,517-521

#### THE EFFECTIVENESS OF A SPECIFIC WARM-UP PROTOCOL TO ENHANCE STATIC AND DYNAMIC POSTURAL CONTROL IN FEMALE TEAM HANDBALL PLAYERS

Steib, S.1, Zahn, P.1, Zech, A.2, Pfeifer, K.1

*1 University of Erlangen-Nuremberg, 2 University of Hamburg*

**Introduction:** Lower extremity (LE) injuries are very common in team handball, especially in female athletes. The risk of sustaining a LE injury has been associated with several internal factors, including poor postural control (Willems et al. 2005). The aim of this study was to investigate the effectiveness of a specific warm-up programme to enhance static and dynamic postural control abilities in female team handball players. **Methods:** An adapted version of 'The 11+' (Soligard et al., 2008), a warm-up programme for injury prevention in soccer,

was implemented in three German female handball teams (4th division). A total of 41 players were randomized into a control (n=20, age = 24.00 ± 5.59 years, height: 168.95 ± 4.57 cm, mass: 65.90 ± 6.77 kg) and an intervention group (n=21, age: 23.95 ± 6.27, height: 171.43 ± 7.02, mass: 65.52 ± 7.69). Subjects in the intervention group (IG) carried out the adapted protocol instead of their regular warm-up routine for 11 weeks. The programme consisted of seven exercises targeted at increasing joint and trunk stability as well as postural control, and was performed prior to each training session and before competition. The control group (CG) kept their regular training regime. The main outcome measures were: COP velocity (vCOP) in single-leg-stance, mean reach distance in the 'star excursion balance test' (SEBT) and the 'dynamic postural stability index' (DPSI) calculated from a unilateral jump-landing task. A two factorial linear mixed model (random intercept and slope) was specified for each of the main outcomes with 'group' and 'time' as fixed factors. Results: No significant differences existed in group demographics at baseline. After 11 weeks of training, subjects in the intervention group significantly (p<.05) improved in the SEBT (5.6%) compared to the control group (3.6%). The same trend existed for the reduction of vCOP (IG: -16.1%, CG: -7.1%) but this was not statistically significant. No significant changes were seen for the DPSI (IG: 2.9%, CG: -0.8%). Conclusions: A specific warm-up programme regularly incorporated prior to training and competition can be effective to enhance some aspects of postural control in female handball players. ## CHANGES IN POSTURAL SWAY IN GOLF PUTTING AMONG CHILDREN WITH AND WITHOUT DEVELOPMENTAL COORDINATION DISORDER

Chen, F., Wu, S., Tsai, C., Perng, W.

*National Pingtung University of Science and Technology*

**Introduction** Developmental coordination disorder (DCD) refers to developmental impairments of coordination and difficulties in movement skills that children exhibit, that are not derived from general intellectual, sensory or motor neurological impairment (APA, 2000). Previous research has reported group differences in the control of postural sway during stance (Geuze, 2003) when comparing children with DCD to typical developing children (TDC). More important, the differences in postural sway between the two groups was more noticeable in more challenging conditions (Tsai et al., 2008). Children with DCD frequently encounter difficulties while engaging in physical activities which demands on postural control. The present study assessed the effects of postural sway in golf putting among children with and without DCD. **Methods** Eight 11-to-12-year-old children with DCD and TDC participated in golf putting on an indoor practice green while standing on a force platform. There were two conditions of difficulties: Low (LD) and High (HD). The putting distance were 1.5 and 3.5 feet in the LD and HD conditions, separately. Postural sway data were collected using a Nintendo Wii balance board. Putting performance were recorded as the measured distance (cm) between the ball and the hole once the ball had come to a complete stop after being putted (successful shots recorded as 0 cm). **Results** Averaging across groups, postural sway in anterior/posterior axis decreased significantly from the LD to the HD condition. In addition, a Group × Task Difficulty interaction was significant for positional sway in the AP axis,  $F(1, 6) = 19.15, p < .05$ . The interaction effects revealed that children with DCD reduced less postural sway from LD to HD condition in anterior/posterior axis compared to TDC. That is, the effect of task difficulty (HD vs. LD) on postural activity differed for the two groups. **Discussion** Stoffregen et al. (2000) proposed a functional integration between postural activity and a suprapostural task: control of postural motion is not an aim in itself, but is valuable to the extent that it promotes success of other behavioral goals. Postural control is tuned to positively mediate performance of suprapostural tasks. Our experiments suggest that children with DCD seem less able to modulate their postural sway than their typically developing peers, when engaged in golf putting. It support the notion that and postural sway are not autonomous systems but are linked to the performance of physical activity. Our experiments bolster the proposition that DCD is a perceptual motor deficit characterized by a diminished perception-action coupling when a motor response is linked to tasks that demand increased perceptual effort. **References** American Psychiatric Association. ## EFFECT OF PARTICIPATION IN BOXING ON POSTURAL STABILITY AND COGNITIVE FUNCTION

Otomo, M.1, Iida, Y.2, Nakamura, C.2, Torii, S.2

*1) Graduated School of Sport Sciences, Waseda University 2) Faculty of Sport Sciences, Waseda University*

**Introduction** Brain concussion is considered as relatively mild type of head injury. Assessment of postural stability and cognitive function are often used to evaluate the severity of concussion. As boxing is the competition to damage the head and trunk of the opponent, head injuries including brain concussion occur frequently. Head blows are repeatedly given to boxers in training and matches, even if they are not diagnosed as concussion. Until now, there are few studies investigating the effects of repetitive blows on the brain of boxers. This study investigated the change of postural stability after the training and matches of boxing. In addition, we also investigated a one-year change of postural stability and cognitive function of boxers. **Methods** Participants were 25 collegiate boxers. Nine boxers were assessed by Balance Error Scoring System (BESS) before and after the training of boxing, eight boxers were assessed by BESS before and after matches, and 21 boxers were assessed as one-year survey by BESS and Standardized Assessment of Concussion (SAC). All boxers were surveyed their competition history and injury history by questionnaire. Moreover, we counted number of hit given to the participants from recorded video of the matches. **Analyses** A two-way analysis of variance was used to examine the relationship about the changes of BESS scores before and after training or matches (the timing factor). A Pearson's product-moment correlation coefficient was used to examine the relationship between the number of blow and BESS score, rate in the matches. A t test was used to compare one-year change of BESS score and SAC score. Statistical significance was set at  $P = .05$  for all analyses. **Results** A two-way analysis showed significant increase of BESS scores in the timing factor, suggesting decreased postural stability only after matches. The more blows given, the more increase in BESS scores. There was no significant difference in one-year change of both BESS and SAC. **Discussion** The training of boxing is conducted at conditional knock up and thus include few dangerous blows, resulting in no decrease in postural stability. On the other hand, the intensity of the blow in the match is considered stronger than training, bringing down decrease in postural stability. In addition, players given many blows to the head in the match demonstrated more decrease in postural stability, suggesting transiently decreased neural function even if they were not diagnosed as concussion. One-year survey showed that participation in boxing did not affect neural function such as postural stability and cognitive function.

### KNEE BIOMECHANICS DURING SIDE-STEP MANEUVERS IN ANTICIPATED AND UNANTICIPATED CONDITIONS

Saho, Y.1, Fukubayashi, T.1, Sakaguchi, M.1, Sanomura, M.1, Nakamura, C.1

1: Waseda University

**Introduction** In their video analysis, Koga et al. (2010) reported that non-contact anterior cruciate ligament (ACL) injuries occur 40 msec after foot contact. ACL injuries often occur during reactive movements, such as an unanticipated (UN) side-step, which are known to exert higher peak knee loads than those occurring during anticipated (AN) maneuvers (Besier 2001a,b). However, it is unclear whether UN situations produce higher initial loads that cause ACL rupture. This study aimed to investigate whether the UN condition is more risky than the AN condition during side-step tasks, with particular focus on the initial phase of foot contact. **Methods** Nine healthy male athletes performed 3 maneuvers after a standing broad jump—side-steps at 45° (S45) and 90° (S90) and crossover-steps at 45° (C45)—under AN and UN conditions. By using 3 LED signals, subjects were given cues for 1 of the 3 maneuvers in both conditions. Subjects received the cues before the trial during AN. During UN, subjects received a visual cue after jumping and before reaching the step position. Three-dimensional motion analysis system and force plate were used to record the three-dimensional marker positions of lower extremity and ground reaction forces. We calculated the knee joint angle by using the joint coordination system and external knee moment by using inverse dynamics. All subjects performed the stepping task with their right leg. Only S45 and S90 were analyzed in this study. **Results** During S45 maneuvers, the external knee abduction moment in UN until 40 msec after foot contact was significantly higher than that in AN ( $0.16 \pm 0.10$  Nm/kg vs.  $0.08 \pm 0.09$  Nm/kg,  $p < 0.05$ ). During S90, the external knee internal rotation moment in UN until 40 msec after foot contact was significantly higher than that in AN ( $0.28 \pm 0.49$  vs.  $0.12 \pm 0.08$ ,  $p < 0.05$ ). Knee flexion/extension, abduction/adduction, and internal/external rotation angle at the foot contact and peak values did not differ between conditions. **Discussion** Knee abduction and internal rotation moment are risk factors for knee ligament injury. Koga et al. (2010) reported that knee internal rotation and knee abduction angle increased until 40 msec, at which point ACL rupture has already occurred. Our results indicate that UN steps increase knee abduction and rotational moment at the initial phase and at peak value. This indicates that UN tasks may help identify the risk of knee ligament injury. Perhaps ACL rupture occurs in the early phase of foot contact. Therefore, it is important to note the early phase of foot contact and peak value. **References** Koga et al. (2007). *AM J Sports Med*, 38, 2218-2225. Besier TF et al. ### INCREASE IN CONTACT LENS USE BY WATER POLO PLAYERS DUE TO A CHANGE IN PRODUCT QUALITY: A 20-YEAR STUDY OF JAPANESE COLLEGE PLAYERS

Komori, Y., Kobayashi, D., Murase, Y., Enomoto, I., Takagi, H., Kono, I.

Doshisha University

**Introduction** Water polo is a heavy contact team sport, which is why it is also regarded as rugby football being played in water. According to the rules of water polo, players shall remove any articles likely to cause injury before taking part in a game. Therefore, wearing eye-glasses or swimming goggles is prohibited in principle. This rule forces players with low visual acuity to use contact lenses during play. However, the consequences of contact lens use by water polo players have not been reported. The purpose of this study was to investigate contact lens use by competitive water polo players from Japanese colleges in 1991, 1996, 2001, 2006, and 2011. **Methods** We investigated the following 5 groups of male water polo players from Japanese colleges: a group of 114 players in 1991, 118 players in 1996, 121 players in 2001, 118 players in 2006, and 130 players in 2011. Information about the use of contact lenses during play, the different types of contact lenses, and any previous cases of ophthalmopathy was obtained through a self-report questionnaire. **Results** Fifty-four percent of the players were using contact lenses during water polo play in 1991 ( $p < 0.01$ ); more than 74% in 1996; 89% in 2001; 84% in 2006; and 86% in 2011. While 96% of the contact lenses used by the players in 1991 were soft type (SCL), 74%, 92%, 86%, and 88% of the contact lenses used in 1996, 2001, 2006, and 2011, respectively, were disposable type (DSCL). The problem was that the players using contact lenses during play had sustained significantly higher corneal and conjunctival damage than players using vision correction devices in their daily lives and players without vision correction devices ( $p < 0.01$ ). **Conclusions** These findings demonstrate that a high percentage of players were using vision correction devices while playing water polo between 1996 and 2011. This may be correlated with the fact that many players were DSCL users. DSCL is currently considered the optimal vision correction device for water polo players. This study suggested that increasing contact lens use for water polo players may induce beneficial effects in terms of maintaining good vision. **References** 1) Komori Y, et al. (1998). ### THE IMPLEMENTATION OF LATERAL TRUNK MOTION IN TWO-DIMENSIONAL VIDEO ANALYSIS DURING UNIPODAL FUNCTIONAL SCREENING TESTS IN ELITE FEMALE ATHLETES

Dingenen, B., Malfait, B., Verschueren, S., Staes, F.

KU Leuven

**Introduction** Two-dimensional (2D) video analysis is a valid and reliable method to measure knee valgus (KV) during functional screening tests (Munro et al., 2011). However, focusing only on this angle may be too limited and may lead to misinterpretations when assessing knee injury risk, as it is recognized that the lower extremity acts as a linked system of interdependent segments. Increased ipsilateral trunk motion (LTM) during unipodal tasks may influence hip adduction (HA) and knee abduction loading and therefore increase knee injury risk in female athletes (Hewett and Myer, 2011). The purpose of this study was to implement the measurement of LTM in 2D video analysis, and to examine the relationship between LTM, HA and KV during unipodal functional screening tests. **Methods** A total of 63 elite female athletes (35 soccer, 16 handball and 12 volleyball) who were injury- and pain free were tested (age:  $21.28 \pm 3.36$  years). LTM, HA and KV were measured during the deepest phase of the single-leg drop vertical jump (SLDVJ) and single-leg squat (SLS) with a standard digital camera. Smaller angles represent more LTM, HA and KV. Pearson correlations coefficients were calculated between angles within and between tests. **Results** In the SLDVJ test, LTM was significantly correlated with HA ( $r = -0.537$ ;  $p < 0.001$ ) and KV ( $r = -0.254$ ;  $p = 0.045$ ). In the SLS test, LTM was significantly correlated with HA ( $r = -0.527$ ;  $p < 0.001$ ) and KV ( $r = -0.367$ ;  $p = 0.004$ ). Furthermore, LTM ( $r = 0.315$ ;  $p = 0.015$ ), HA ( $r = 0.396$ ;  $p = 0.002$ ) and KV ( $r = 0.407$ ;  $p = 0.001$ ) were significantly correlated between SLS and SLDVJ. **Discussion** The results of the present study show that more LTM is significantly correlated with less HA and KV during unipodal screening tests, suggesting that LTM can be used as a compensation mechanism for poor hip and knee control. As a consequence, focusing only on KV angles can mimic knee injury risk, as an increased LTM can increase knee abduction load. The combination of more LTM and more KV, may lead to the

highest knee injury risk (Hewett et al., 2009). Furthermore, the amount of LTM, HA and KV was significantly correlated between the SLS and SLDVJ. This indicates that in general the same strategy was used to complete both tasks. These results support the fact that the knee does not function as an isolated joint, but as a part of the kinetic chain. Therefore, we suggest to implement the measurement of LTM in the 2D video analysis of functional screening tests. References Munro A, Herrington L, Carolan M. (2012). *J Sport Rehabil*, 21, 7-11. ### THE INFLUENCE OF PHYSIOLOGICAL LOAD ON POSTURAL CONTROL- IS THERE A BALANCE THRESHOLD?

Ruzic, L.1, Prpic, T.2, Tudor, A.2

1: Faculty of Kinesiology (Zagreb, Croatia), 2: Clinic for Orthopaedic Surgery-Lovran (Rijeka, Croatia)

**Introduction** The postural control is an essential factor in prevention of falls and consequently prevention of injuries and an important ability for success in many sports. The aim of the study was to evaluate the influence of the physiological load on postural control. Special attention was directed towards the identifying the intensity level in which the major deterioration in static and dynamic balance abilities occurs. **Methods** Thirty subjects were randomly divided into two groups. We conducted multistage all-out exertion protocol of spiroergometric testing on cycle-ergometer until exhaustion with continuous measurement of objective ventilatory-metabolic as well as subjective parameters of fatigue. The each level of the protocol lasted for three minutes and was followed with three minute breaks during which the subjects underwent the static and the dynamic balance testing. In a control group, the protocol encompassed only balance testing procedures followed by 3 minute rest periods. After the completion of the testing procedures, the five intensity zones were determined according to the ventilatory-metabolic parameters at different loads. **Results** The significant differences in both static and dynamic balance tests were found in experimental, exercising, group between the test stages. The post-hoc analyses revealed the significant negative effect of fatigue on the static balance with three visible „balance thresholds“. The first threshold was at the rest to work transition, the second at the anaerobic threshold and the third at the maximal exertion level. The dynamic balance was also negatively affected with fatigue, however no „balance thresholds,“ were clearly identified. No significant changes in neither static nor dynamic balance abilities were observed in the control group so the changes in the experimental group could have been attributed to the fatigue. **Discussion** As already at the intensity 60-65% of HRmax the significant decrease of balance ability was found, that is the intensity level at which the patients in rehabilitation process should train their proprioceptive/balance. However, as in athletes the demands of the sport are usually higher and considering that the next decrease in balance was identified just above the anaerobic threshold, we could advise that in order to obtain the most of their balance training the athletes should aim to train intensity zones above the anaerobic threshold. **References** Yaggie JA, McGregor SJ.(2002). *Arch Phys Med Rehabil*,83,224-8. ### COMPARATIVE AND RELIABILITY STUDIES OF NEUROMECHANICAL LEG MUSCLE PERFORMANCES BETWEEN ELITE AND RECREATIONAL ATHLETES

Yin, N.H., Wang, H.K., Un, C.P., Lin, K.H., Shiang, T.Y., Chang, E.C., Su, S.C.

*School and Graduate Institute of Physical Therapy*

**Introduction** The aim of this study is to compare the neural profiles of leg muscles between elite and recreational athletes and to analyse the reliability and correlations between their profiles and biomechanical performances. **Methods** Two types of volleyball players were recruited to include 10 elite and 20 recreational athletes. The outcome measures were compared between the groups, including soleus H-reflex, first volitional (V) wave, normalised rate of electromyography (EMG) rise (RER) in the triceps surae muscles, and RER ratio for the tibialis anterior and soleus muscles, normalised root mean square (RMS) EMG in the triceps surae muscles, antagonist co-activation of the tibialis anterior muscle, rate of force development (RFD), and maximal plantar flexion torque and jump height. **Results** Neural profiles in the elite group showed greater normalised V waves, normalised RER 0–75 ms in the medial and lateral gastrocnemius, RER ratio, and normalised RMS EMG of the soleus and lateral gastrocnemius muscles and less antagonist co-activation of the tibialis anterior. The elite athletes showed greater maximal torque, absolute RFD at 0–100 ms and 0–200 ms and less in the normalised RFD at 0–30 ms, 0–50 ms and 0–100 ms of plantar flexion when compared to the results of the recreational group. Neural profiles correlated to fast or maximal muscle performances, except for RER ratios. **Discussion** There are differences in the descending neural drive and activation strategies in leg muscles during contractions between volleyball athletes competing at different levels (Aagaard et al., 2002; Holtermann et al., 2007). These measures are reliable and correlate to biomechanical performances. **References** Aagaard P, Simonsen EB, Andersen JL, et al. (2002). *J Appl Physiol*, 93,1318-1326. #### EFFECTS OF ENDURANCE TRAINING AND COMPETITION IN THE URINARY FUNCTION OF MARATHONERS

Puggina, E.F., Machado, D.R.L., Tourinho Filho, H., Barbantij, V.J.

*University of Sao Paulo*

**Introduction** Marathon is the longest running event in the Olympic calendar. The endurance training and competitions lead to many physiological changes and some of the least investigated are the kidney function and urine changes in endurance athletes during the training season and competitions. The aim of this study was to verify the renal function and urine changes induced by endurance training and a marathon using urine indicators. **Methods** Nine male marathoners (34.78±10.62 years, 70.54±7.88 Kg, 170.15±8.06 cm) participate in the study. Urine samples were collected in two moments of training (M1- beginning of the training program and M2- after 10 weeks of training) and in two moments of the competition (M3- before the competition and M4- after the 2010 São Paulo Marathon). Urine pH was

measured using reagent tapes, urine density with manual refractometer. Proteinuria was assayed by colorimetric method and red and white blood cells by microscopy. Results were analyzed using Kolmogorov and Smirnov test, One Way Anova and Tukey-Kramer to detect differences,  $p < 0.05$ . Results For urine pH and density were found values of  $6.62 \pm 0.51$  and  $1011.87 \pm 2.58$  in M1,  $6.61 \pm 0.50$  and  $1011.86 \pm 2.56$  in M2,  $6.63 \pm 0.53$  and  $1011.88 \pm 2.60$  in M3 and  $5.37 \pm 0.50$  and  $1030.62 \pm 1.76$  respectively. For the cell counts were found  $1.150 \pm 350.51$  and  $2087.5 \pm 180.77$  units/mL in M1,  $1087.5 \pm 180.77$  and  $2.150 \pm 226.78$  in M-2,  $1275 \pm 452.77$  and  $2137.5 \pm 199.55$  in M3 and  $56625 \pm 42.14$  and  $6437.5 \pm 4065.9$  for erythrocytes and leucocytes respectively. Finally, urine protein excretion revealed  $5.11 \pm 2.33$  mg/dL in M1,  $7.87 \pm 1.95$  in M2,  $6.53 \pm 2.44$  in M3 and  $30.75 \pm 12.73$  in M4. Differences were found when M4 was compared to the other collection moments for all variables studied. Discussion The changes in urine pH and density are indicators of dehydration during the marathon, as well indicators of acid metabolites excretion induced by the effort. Indicating that the hydration strategy adopted during the race was not effective. Proteinuria was observed after the marathon and this effect was probably due to changes in the glomerular permeability to plasmatic proteins and endocrine factors. For blood cells, the excretion of erythrocytes in urine is attributed to changes in the glomerular permeability and urinary tract damage caused by the successive strides during the race. Conclusion The training program for the São Paulo Marathon did not interfere in the hydration status and renal function of the athletes, probably due to the 24h rest between the last training session and the collections performed in M1, M2 and M3. However, the results found in M4 show an important impact of the competition in the hydration and in the kidney function and glomerular permeability to the macromolecules and cells.

### HEART RATE KINETICS DURING SYNCHRONIZED SWIMMING SOLO ROUTINES IN RELATION TO BREATH HOLDING AND BODY POSITION

Iglesias, X., Rodríguez-Zamora, L., Barrero, A., Chaverri, D., Erola, P., Irúrtia, A., Rodríguez, F.A.

*INEFC-Barcelona, University of Barcelona*

Introduction Performance times for synchronized swimming (SS) solo routines range from 2min for the technical solo (TS) to 3min for the free solo (FS) (FINA, 2009-2013). Homma (1994) found that the, on the average, 62.2% of this time is spent underwater, while Alentejano et al. (2008) reported a lower value (46%). It is known that synchronized swimmers experience diving bradycardia during breath holding (BH) bouts underwater (Gemma and Wells, 1987; Rodríguez-Zamora et al., 2012). This study aims to determine the frequency and duration of face immersion periods in relation with body position, and to characterize heart rate response in technical and free solo SS routines. Methods Eight elite synchronized swimmers ( $20.8 \pm 4.9$  years, 3 Olympic medalists) were monitored while performing a total of 11 routines during an official national championship in the technical (TS,  $n=5$ ) and free solo (FS,  $n=6$ ) programs. Heart rate (HR) was continuously monitored using a waterproof beat-by-beat monitor. All routines were recorded using a digital video camera (Panasonic AG-DVX100BE 3-CCD Mini-DV Cinema Camcorder, 50i PAL) at a rate of 50Hz and a frame rate of 50 frames•s<sup>-1</sup> with an interlaced resolution of 720x576, which allows a time resolution of 0.02s. By frame-by-frame video analysis, two face immersion conditions (face-in and face-out), and three body positions (horizontal, upright, and inverted position) were identified and timed. Results and discussion Mean HR during the 11 solos was  $153.2 \pm 16.4$  beats•min<sup>-1</sup>. HR peak was  $190.0 \pm 13.2$  beats•min<sup>-1</sup> with frequent interspersed bradycardic events down to  $80.7 \pm 31.3$  beats•min<sup>-1</sup>. Mean face-in HR (beats•min<sup>-1</sup>) was lower ( $150.1 \pm 31.7$ ) than face-out ( $156.1 \pm 28.0$ ) ( $P < 0.000$ ). HR range during the whole routine was  $109.4 \pm 27.3$  despite the high intensity of the exercise performed underwater. Mean HR at horizontal position ( $156.0 \pm 27.6$ ) was higher than at upright ( $155.2 \pm 28.1$ ) and inverted ( $147.4 \pm 33.6$ ) body position ( $p < .0001$ ). The time spent underwater (face-in) was longer (67.0%) than in previous reports (62.2%; Homma, 1994). Conclusions The autonomous nervous system plays a fine tuned regulation of HR in this unique type of exercise in which sympathetic and parasympathetic activation and inhibition are continuously interplaying according to the swimmer's body position, breath holding condition, and intense exercise. Our main finding is that the main cardiovascular response to face immersion (i.e. bradycardia) is powerful enough to counteract exercise tachycardia during the breath holding phases of intense exercise. ### DISTRIBUTION OF BONE AND MUSCLE MASS IN WATER POLO PLAYERS

Iizuka, S.I, Suguru, T.2, Yukako, I.2

*1: GRADUATED SCHOOL OF SPORT SCIENCES, WASEDA UNIVERSITY, 2: FACULTY OF SPORTS SCIENCES, WASEDA UNIVERSITY*

Introduction There are many previous studies demonstrating that different types of sports activity induce different distribution of bone and muscle in athletes. The knowledge about the composition of the elite athletes helps to build and maintain the body of young athletes. However, there is no report about the water polo players in Japan. In order to clarify the distribution on body composition of water polo players, we were compared with those in handball player and competitive swimmer. Methods 20 male water polo players (WP;  $19.7 \pm 1.3$  years) and 29 male competitive swimmers (SW;  $20.2 \pm 0.8$  years) and male handball players (HB;  $20.4 \pm 1.0$ ) were recruited to this study, all of them were collegiate athletes. Body composition was assessed using dual X-ray absorptiometry (DXA). We compared their bone mineral content (BMC), bone mineral density (BMD) and lean mass (LM). Bone mineral mass and lean mass was adjusted by body height. Results Bone mineral mass and density of the dominant arm of SM was significantly lower than those of WP and HD. However, those of the non-dominant were similar between three athlete groups. Thus, the side-to-side difference in arm BMC and BMD was lower in SM. For lean mass, there is no difference in each arm between the three athlete groups, and side-to-side difference in lean mass of the arm in WP was significantly larger than those of SW. On the other hand, BMC, BMD and LM of the leg of HD were significantly higher than those of SW and WP, and side-to-side difference in BMD of the leg was significantly larger in HD than those of WP. Discussion It is considered that the higher BMC, BMD and lean mass in dominant arm of WP and HD were gained by their throwing motion. However, the higher lean mass in legs of HD seemed to be attained by weight bearing activity such as running and jumping, those not involved in activity of WP and SW. These results suggest that the mechanical stress imposed to specific body sites stimulate site-specific modeling and accumulation of bone and muscle.

## CARDIAC TROPONINS IN YOUNG MARATHON RUNNERS

Traiperm, N., Gatterer, H., Wille, M., Burtscher, M.

*Department of Sport Science, Medical Section, University of Innsbruck*

**Introduction** Increases of troponins have been shown to be relatively common among adult marathon finishers with levels typically diagnosed in acute myocardial infarction (Fortescue EB et al., 2007). Especially less marathon experience and younger age seem to be associated with more pronounced elevations of serum troponins (Tian Y et al., 2006). Data on adolescent runners have only been reported for prolonged running in laboratory-based settings and after 21 km running (Fu F et al., 2009, Tian Yet al., 2006, Nie J et al., Frank H Fu et al., 2010) and are practically missing for a whole marathon distance. Therefore, the aim of this study was to investigate cardiac troponins in young marathon runners of both sexes. **Methods** Forty young Asian runners (20 healthy males and 20 females) aged between 13-17 years participated in this study. Blood samples were taken before, immediately after and 24 hours after a standard marathon race for determination of cardiac troponin T and troponin I. All participants had to undergo a routine physical examination, electrocardiogram (ECG) and provided a detailed training history. The experimental protocol was approved by the Khon Kaen University Ethics Committee for Human Research, and was performed as a PhD thesis at the Department of Sport Science of the University of Innsbruck. Results Thirty seven runners completed the race. In 30 out of 37 participants the levels of troponin T and/or troponin I exceeded the upper reference limit of 0.01 and 0.1 ng/mL immediately after the race and in 3 participants these levels were even higher than the reference range for acute myocardial infarction (>0.1 ng/mL and >0.5 ng/mL for troponin T and I, respectively). Twenty four hours after the marathon troponin levels of all participants returned below the upper reference limit. Troponin T values of male participants were negatively related to their training history (35±15 months of training). **Discussion** These findings imply also for young runners that elevated cardiac troponin levels after finishing a single marathon might rather be a physiological than a pathological response and that a preceding long period of regular running may be protective at least in young male runners. **References** Fortescue EB, Shin AY, Greenes DS, Mannix RC, Agarwal S, Feldman BJ, Shah MI, Rifai N, Landzberg MJ, Newburger JW, Almond CS. ## CHANGES IN PERIPHERAL BLOOD CELL SUBPOPULATIONS IN ELITE KAYAKERS DURING A TRAINING SEASON

Borges, G.F.1,4, Rama, L.1, Alves, F.2, Pedreiro, S.3, Paiva, A.3, Teixeira, A.M.2

*1:FCDEF-UC (Coimbra-Portugal), 2: FMH-UTL (Lisbon, Portugal), 3:HC (Coimbra,Portugal), 4: ISB-UFAM (Brazil).*

**Introduction** Prolonged strenuous exercise has been associated with a depression of immune function. The aim of this study was to investigate if changes in training load could affect peripheral blood leukocyte counts and percentage, including B, T, TCD4+, TCD8+ and Natural Killer (NK) lymphocytes in elite kayakers during a training season. **Methods** The sample comprised 8 male elite canoeists, 22±4.0 years old, 78.5 ±6.9kg body mass and 178.0±5.6cm stature. The control group were 6 health males, 18.1±5.0 years old, 73.0± 6.6kg body mass and 172.5±4.6cm stature. Blood samples were collected at different moments of the training season: at the beginning, after an off training period of 6 weeks (t0), at the 11th week after the application of high weekly training volumes (t1), at week 26 after a cycle of intense training (t2), at the 31th week at the end of a tapering phase (t3). Blood samples were collected from the non-athlete group at 3 time points: t1 early November, t2 late February and t3 early April. Lymphocyte subpopulations were determined by flow cytometry (FACSCalibur; BD, USA). Statistical analysis was done using ANOVA. Significance was set at P<0.05. **Results** At the time of increased training volume (t1) granulocytes counts decreased and remained lower until the end of the training season. The number of lymphocytes decreased at the time of higher intensity training (t2) but recovered to baseline values at t3. On the other hand no changes were for the lymphocyte subpopulations between baseline and the other time points, except for the CD3+CD56+CD8+ subpopulation that showed an increase at t2 and t3. However, at the end of the taper period (t3) total cell numbers in the CD3+, CD3+CD4+, CD3+CD8+, CD3+CD8-CD4-, CD3-CD19+, CD3-CD56+, CD3-CD56+CD8- and CD3-CD56+CD8+ subpopulations increased when compared to t1. No differences for the non-athletes were observed between the time points studied. At the beginning of the training season, both CD3+ and NK cell counts were lower in the kayakers than in the non-athletes. **Discussion** Our data suggests that increased training load leads to a decrease in lymphocyte counts at the periods of high training loads. When compared to the non-athlete group, lymphocyte numbers were lower in the kayakers at t0, t1 and t2. Although not significant we see a decrease in all the lymphocyte counts subpopulations when volume reaches it's highest values (t1). When the training season reaches the high intensity phase (t2) values are already increasing and will do so until the end of the season. Periods of heavy training have been associated with immune depression (t1) normally reversible by a tapering period. **References** 1. Gleeson M. & Bishop NC. (2005) *Ann Transplant*, 10: 43

## CORRELATION BETWEEN STRETCH RESISTANCE AND MUSCLE STRENGTH OF THE TRICEPS SURAE MUSCLE

Kudo, H., Sano, F.

*Mejiro University*

**Introduction** A tendon is known as a poor tensility tissue, and convey muscular tension to a bone. In recent years, it also turned out that a tendon generates power like muscles (Fukunaga,2005, 2009). On the other hand, it is not easy for many patients to return to the original athletic ability, although the sport return rate after an Achilles tendon rupture is high. Moreover, it has also been reported that viscoelasticity (resistance torque of passive ankle dorsiflexion) of Achilles tendon decrease in postoperative case (Kurata, 2010). Therefore, the purpose of this study was to elucidate that correlation between stretch resistance (resistance torque of passive ankle dorsiflexion) and muscle strength of the triceps surae muscle. **Methods** This study comprised 30 healthy college student volunteers (15 male and 15 female). In all volunteer, the muscle strength of the triceps surae muscle and the resistance torque of passive ankle dorsiflexion were measured using Isokinetic dynamometer BIODEX SYS-TEM 3 (Sakai medical co., Tokyo, Japan) in prone position with knee straight position. A correlation coefficient between the muscle strength of the triceps surae muscle and the resistance torque of passive ankle dorsiflexion was calculated in statistically analysis. **Result** In male volunteer, the correlation coefficient between the muscle strength of the triceps surae muscle and the resistance torque of passive ankle dorsiflexion had shown 0.546 in the right side, and 0.542 in the left side (p<0.05). The correlation coefficient in female volunteer had shown 0.552 (Rt.), and 0.534 (Lt.) respectively (p<0.05). Moderate positive correlation coefficient was shown both in male and female volunteer between muscular strength and resistance torque in calf muscle. **Discussion** The viscoelasticity in a muscle tendon complex is known that the viscoelasticity contributed to a sports performance via the stretch-shortening cycle. It is reported that viscoelasticity of the intramuscular tendon decrease due to disuse, and that also reported difficult to recover by retraining. The important factor to get high sport performance is not only muscle strength, but also the viscoelasticity

of the muscle tendon complex. On the other hand, the stretch resistance of the triceps surae muscle often decreased in postoperative case of Achilles tendon rupture. Therefore, it is not only muscle strength but also stretch resistance important to restore triceps surae muscle to a comfortably functioning state. References Fukunaga T. (2005). ### CHANGES IN CARDIAC INJURY BIOMARKERS IN RUNNERS AFTER ENDURANCE EXERCISE AND THE RELATIONSHIP WITH BIOMARKERS OF DEHYDRATION

Sierra, A., Ghorayeb, N., Dioguardi, G., Francisco, R.C., Benetti, M., Gabriel, E.A., Kiss, M.A.P.D.

*University of Sao Paulo*

**Introduction** The training can be considered the combination of negative influences (fatigue) with positive influences (conditioning). Some studies show, after endurance exercises, an increase of cardiac injury biomarkers such as BNP (brain natriuretic peptide) and troponins; however its physiopathology is not completely clarified as the changes in these biomarkers are usually related to cardiovascular disease. This study aims at analyzing the changes of these biomarkers, and their possible relationship with creatinine, weight, and water % after a marathon. **Methods:** We evaluated 32 male runners of São Paulo International Marathon, average age  $41.03 \pm 6.54$  years. A blood collection was performed 24 hours before and immediately after (imed) the marathon for dosing of troponin T, BNP, urea, and creatinine; and another dosing of troponin T 18 hours after the marathon. The bioelectrical impedance analysis was performed before and after the run to check the amount of water lost. For statistical analysis we used ratio, t-Student test, and Pearson's correlation. **Results:** Troponin T (TT) ( $\mu\text{g/L}$ ), BNP (pg/mL), creatinine (mg/dL) and urea (mg/dL) - (ratio; average  $\pm$  STDEV): TT 24h before - 6.25%;  $0.00187 \pm 0.0078$  TT imed - 34.37%;  $0.07531 \pm 0.30104$  -  $P < 0.01$  TT 18h after - 9.37%;  $0.02312 \pm 0.08618$  -  $P > 0.05$  BNP before - 0%;  $7.825 \pm 15.356$  BNP imed - 21.87%;  $71.021 \pm 80.217$  -  $P < 0.0001$  Creatinine before - 0%;  $0.921 \pm 0.087$  Creatinine imed - 53.12%;  $1.403 \pm 0.202$  -  $P < 0.0001$  Urea before - 9.37%;  $29.812 \pm 6.432$  Urea imed - 40.62%;  $39.031 \pm 7.756$  -  $P < 0.0001$  Water % and weight (Kg) (Average  $\pm$  STDEV) % of water before -  $66.48 \pm 1.823$  % of water imed -  $65.856 \pm 1.750$  -  $P > 0.05$  Weight before -  $70.24 \pm 9.185$  Weight imed -  $67.77 \pm 8.88$  -  $P > 0.05$  Weight loss -  $2.46 \pm 0.943$  Pearson's Correlation between Creatinine and BNP imed =  $+0.1415$  Creatinine and Water % =  $-0.3229$  Creatinine and Weight loss =  $-0.0045$  Urea and BNP imed =  $-0.0326$  Urea and water % =  $+0.1189$  Urea and weight loss =  $-0.2625$  **Conclusion:** We found significant changes in troponins imed, but these changes were not kept after 18 hours, as it happens in patients after acute myocardial infarction. Regarding BNP the imed had a significant increase, being that 21.87% had levels above 100 pg/mL, values which normally don't exclude heart failure. We found statistical difference between the levels of creatinine and urea imed and after the run, but no statistical difference between levels of water % and weight imed and after the run. There was a positive correlation between creatinine and BNP, and between urea and water % imed, a negative correlation between creatinine, water % imed and weight loss, and between urea, BNP and weight loss.

### THE EFFECTS OF AEROBIC TRAINING ON COGNITIVE FUNCTION IN ALZHEIMER'S DISEASE PATIENTS – A REVIEW OF RECENT LITERATURE

Praetorius, A.

*Ruhr Universität Bochum*

The effects of aerobic training on cognitive function in Alzheimer's Disease (AD) patients – a review of recent literature Praetorius, A.1, Hanakam, F.2, Platen, P.1 1Department of Sports Medicine and Sports Nutrition, Ruhr-University Bochum 2Department of Training and Exercise Science, Ruhr-University Bochum **Introduction** This literature review is evaluating the potential benefit of aerobic training on cognitive function in early stage AD patients. We hypothesized that aerobic training improves cognitive functioning in these patients. **Methods** We conducted systematic literature review from sources in Medline, Web of Science, PubMed and Biosis databases relating to AD and aerobic training. Recent studies published 2003-2012 and featuring pre- and post-tests, randomized and controlled study design, aerobic training intervention and assessment of cognitive functions have been selected for review. Studies were analyzed to answer the question whether the intervention group improved in cognitive function (outcome measure) compared to control group. The search query included the terms "aerobic", "fitness", "Alzheimer", "exercise", "training", "cognition", and "cognitive functioning". Results 7 studies met all inclusion criteria and were selected for further analysis. Duration of intervention ranged from 6-52 weeks. Training sessions were held from once per week up to once per day lasting from 30-120 minutes. All studies featured walking or moderate aerobic training exercises as intervention. Cognitive function tests used in the studies were Mini Mental State Examination (MMSE) (n=2), Alzheimer's Disease Assessment Scale (ADAS) (n=1), Rapid Evaluation of Cognitive Function (ERFC) (n=1), Cambridge Neuropsychological Test Battery (CANTAB) (n=1), Wechsler Adult Intelligence Scale (WAIS-R) (n=1), and Neuropsychiatric Inventory (NPI) (n=1). MMSE scores stabilized over 24 weeks in one study while controls deteriorated, but there were no improvements in MMSE in the second study. In the third study the exercise group scored better on the ERFC compared to the control group. Improvements in language abilities could be seen in the ADAS cognitive subscale in the training intervention group in the one investigation using this score. Attention and memory skills improved significantly in the training group in the one study utilizing CANTAB. WAIS scores remained stable during training intervention in the one selected study. NPI scores showed no significant changes during training in the respective study. **Conclusion** Aerobic training seems to positively influence progression of AD. Gains in language, orientation, memory, and attention skills could at least partly be achieved by aerobic training in 3 out of 7 trials although only moderate improvements were achieved. 2 further trials reported stabilization of cognitive function compared to control groups, while only one trial could not find any effect. Therefore, aerobic training should be recommended as therapeutic measure in AD.

### HIGH INTENSITY INTERVAL TRAINING INCREASES SKELETAL MUSCLE GLUCOSE UPTAKE

Eskelinen, J.J.1, Hannukainen, J.1, Savolainen, A.1, Heinonen, I.1, Virtanen, K.1, Kapanen, J.3, Nuutila, P.1, Knutti, J.1, Kalliokoski, K.1

*University of Turku*

**Introduction** Muscle insulin resistance and triglyceride content are strongly associated with obesity and type 2 diabetes. Aerobic exercise training (AET) is known to improve both whole-body and skeletal muscle insulin sensitivity. Recently, anaerobic high-intensity interval training (HIT) has gained popularity to get the benefits of exercise with less time commitment. It has been shown that HIT improves whole-body insulin sensitivity, but less is known of tissue-specific effects and of fat metabolism. In the present study we investigated the effects of high intensity interval training (HIT) on skeletal muscle glucose and fatty acid uptake (GU and FFAU) using positron emission tomogra-

phy (PET). In addition the effect of HIT on the amount of muscle triglyceride content was studied using magnetic resonance spectroscopy (MRS). Methods Eighteen healthy sedentary middle-aged men were recruited into the study. They were randomly divided into HIT group (n=9) and AET group (n=9). Within two weeks, the subjects in HIT group finished six training sessions each consisting of 4 to 6 times 30-seconds "all out" sprints (Wingate-type) with 4 min rest between sprints. Correspondingly the subjects in AET group did six training sessions consisting of 40-60 min of cycling at the intensity of 60% of max workload in VO<sub>2</sub>max -test. Quadriceps femoris muscle GU and FFAU were measured using PET and 18F-FDG and 18F-FTHA tracers before and after the exercise intervention. Intra- and extramuscular triglycerides (EMTG and IMTG) were measured from tibialis anterior muscle using MRS. VO<sub>2</sub>max-test until volitional exhaustion was performed before and after the last training session. Results All subjects managed to finish the exercise intervention well and without any complications. HIT enhanced VO<sub>2</sub>max by 5 % (from 33.9 ± 3.8 ml/kg/min to 35.5 ± 3.7 ml/kg/min, p = 0.019) and the maximal workload by 8 % (224 ± 31 W to 241 ± 31 W, p = 0.010) in the VO<sub>2</sub>max-test. Skeletal muscle GU during euglycemic hyperinsulinemic clamp increased by 38 % (4.4 ± 1.1 μmol/100 g/min to 6.0 ± 1.8 μmol/100 g/min, n = 6, p = 0.004), while whole-body glucose uptake increased by 11 % (p = 0.21). FFAU, EMTG and IMTG data are still under analysis. Discussion This preliminary data shows that skeletal muscle glucose uptake is increased more than the whole body glucose uptake after two weeks of HIT. Indirectly this suggests that HIT may decrease glucose uptake in other organs, but this needs confirmation.

### BLOOD LACTATE CONCENTRATION AT REST AS AN INDICATOR OF A CORRECT TRAINING LOAD IN YOUNG ATHLETES

Marinovic, M., Loncaric-Katusin, M.

*Faculty of Kinesiology, Split; Intensive Medicine and Pain Medicine, Karlovac*

Introduction "The practice of sport is a human right. Every individual must have the possibility of practicing sport in accordance with his or her needs" (Olympic Charter, Fundamental Principles). As coaches of young children we need to ensure that every child or young person who takes part in sports should be able to participate in a fun and safe environment and be protected from neglect and abuse. There is a large volume of research suggesting that the blood lactate response to exercise can be a good indicator of endurance performance, as well as indicator of homeostasis. Methods During sport diagnostics procedure 151 young athletes from three sports (tennis, swimming and soccer) from 10 to 14 years old were measured. All tests were performed in the morning, before the school or any exercise, expecting the young athletes to be rested. At the beginning of testing procedure finger-prick blood lactate samples were collected and analyzed using Accutrend lactate analyzer. Results Results of blood lactate concentration at rest were in range of 1.0 to 6.4 mmol/l. Only 16 (10.5%) young athletes had concentration less or equal to 1.6 mmol/l while 35 (23%) examinees had concentration between referential values. It is very interesting that 76.8% of the measured athletes had markers of acidosis at rest. Among them 24 (15.8%) had the same value higher than 3.5 mmol/l. Discussion Obtained results of blood lactate concentration very much differs of those expected at rest and presented in numerous articles. Only 35 (23%) examinees completed equilibrium between lactate concentrations in working muscles and blood. The lactate level depends on the intensity of exercise bouts, aerobic and anaerobic capacity of an athlete and the duration of rest intervals. Thus, knowing aerobic and anaerobic capacities and changing other two components it is possible to speed up or speed down lactate accumulation in the blood. These findings lead us to conclude that the training load can be incorrect, which can produce fatigue as well as the possibility for sport injuries. #### PRO-ANTIOXIDANT RESPONSE TO INCREMENTAL EXERCISE AFTER INGESTION OF ANSERINE AND CARNOSINE

Zembron-Lacny, A.2, Slowinska-Lisowska, M.1, Kopec, W.3, Ostapiuk-Karolczuk, J.2, Kasperska, A.2, Rynkiewicz, M.2, Rynkiewicz, T.2

*1:USPE (Wroclaw, Poland), 2:USPE (Poznan, Poland) 3:UELS (Wroclaw, Poland)*

Introduction Dipeptides anserine and carnosine are contained in the skeletal muscles or brains of vertebrates in high concentrations. These substances may reduce muscle fatigue and improve learning ability because of an antioxidative effect, sarcoplasmic reticulum Ca<sup>2+</sup> regulation and buffering capacity. In spite of the large number of studies investigating the effects of pure anserine and/or carnosine, only a few studies concern the effectiveness of the natural extract containing dipeptides (Goto et al. 2011, Mishima et al. 2008, Sato et al. 2008, Suzuki et al. 2006). The present study was designed to evaluate the effects of supplementation with chicken breast meat extract (CBEX) containing anserine and carnosine on pro-antioxidant response during intense exercise. Methods Fourteen healthy untrained men and women at 21.3 ± 0.2 yrs were assigned to a CBEX drink group (CBEX containing total 2 g of carnosine and anserine) or a placebo drink group. The subjects ingested the prescribed drink (100 ml) twice daily for 16 days. The blood samples were collected on the first day of CBEX ingestion (initial study), and then on the fourteenth day immediately before incremental exercise and at 1 min, 30 min, 24 h and 48 h after exercise. In blood, hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), nitric oxide (NO), 8-isoprostanes (8-iso), antioxidant potential (AOP) and redox status (GSHTotal-2GSSG/GSSG) were determined. Myoglobin (Mb) concentration was measured as a marker of skeletal muscle damage. Results CBEX reduced H<sub>2</sub>O<sub>2</sub> concentration at rest and at 1 min and 30 min after exercise trial. No significant differences in NO and 8-iso concentrations were observed. AOP increased after CBEX ingestion and maintained on high level after exercise. CBEX elevated 2-fold redox status before and after exercise through reduction of oxidised glutathione (GSSG) level. CBEX did not effect on reduced glutathione (GSH) concentration. CBEX had not any effect on muscle damage induced exercise. Discussion/Conclusion These results confirm the antioxidant properties of extract containing anserine and carnosine, and suggest its use for modulation of blood antioxidant potential and redox status during intense exercise. ### THE EFFECT OF A CAFFEINE CONTAINING ENERGY DRINK ON MUSCLE PAIN PERCEPTION, PERCEIVED EXERTION AND READINESS TO INVEST EFFORT DURING SUBMAXIMAL CYCLING

Hankey, J., Duncan, M.J.

*Coventry University*

**Introduction** The beneficial effect of caffeine ingestion on exercise performance is well established. Caffeine has been shown to attenuate leg pain during cycling (Gliottoni and Motl, 2008) and positively influence psychophysiological variables including readiness to invest effort during exercise (Duncan and Oxford, 2011). Caffeine containing energy drinks can also improve aerobic performance and the volume of training an individual can undertake (Hoffman et al., 2008). However, the data pertaining to psychophysiological responses to such energy drinks during exercise is limited. This study examined the effect of a caffeinated energy drink on leg pain perception and perceived exertion during and readiness to invest effort pre and post 60 minutes cycling exercise. **Method** Fourteen participants (7 males, 7 females, mean age 23.5, s = 3.5 years), completed 60minute cycling trials at 60% VO<sub>2</sub> max preceded by ingestion of solutions containing either a caffeinated energy drink (absolute dose of caffeine 179mg) or placebo using a double-blind design. During exercise, RPE (6-20 scale), leg pain (0-10 scale), heart rate (HR) were recorded. Pre ingestion, post ingestion/pre exercise and post exercise, participants completed measures of readiness to invest physical effort (RTIPE). Repeated measures ANOVA was used to assess differences in all variables and across time and treatments, with gender used as a between subjects variable. Results HR was significantly higher (P = .002) from 30-60minutes and RPE (P = .0001) and pain perception (P = .0001) were significantly lower from 20-60minutes in the energy drink condition compared to placebo. RTIPE (P = .001) increased significantly more from pre ingestion to post ingestion pre exercise, in the energy drink condition compared to placebo. No gender differences were evident (P > .05). **Discussion** Ingestion of a caffeine containing energy drink can favourably influence perceptual responses (RPE and leg pain) during 60minutes cycling at 60% VO<sub>2</sub> max, agreeing with previous research (Gliottoni and Motl, 2008). The greater RTIPE reported following energy drink ingestion, may also result in participants feeling more able to provide greater effort compared to placebo. This study assumes that caffeine is the most likely ingredient to explain these results, in line with other studies (Hoffman et al. 2008). However, the other ingredients within the energy drink may have contributed to these results. Overall, it can be suggested that energy drink ingestion has a positive effect on psychophysiological responses during submaximal cycling. **References** Duncan MJ, Oxford S. (2011) J Strength Cond Res, 25, 178-185. Gliottoni RC, Motl RW. (2008) Int J Sports Nut Exerc Metab, 18, 103-115. Hoffman et al.(2008) J Strength Cond Res, 22, 874-882.

### EFFECTS OF CAFFEINE ON FLUID BALANCE AFTER EXERCISE-INDUCED DEHYDRATION

Veniamakis, E.E.1, Nikolaidis, P.2

*Technological Education Institute of Crete*

The study assessed the effectiveness of caffeine compared with water on whole body rehydration during 5 hours of recovery after exercise-induced dehydration. Eight young subjects, 6 habitual caffeine users (200 – 300mg/d) and 2 occasional caffeine users (mean 23.3 ± 2.6yr and 77.5 ± 6.6kg), undertook a cycling exercise at 2w/kg in a warm environment (32.3 ± 1.3oC; 57.3 ± 2.7 % r.h) until 1.8% of their body weight was lost. An average of 1.63 ± 0.26kg was lost during the water trial and 1.59 ± 0.26kg during caffeine trial. After exercise subjects sat in a thermoneutral environment (24.8 ± 1.3oC; 50.2 ± 8.9% r.h) and consumed fluid volumes equal to 150% of body weight lost during exercise. Fluids were consumed in 4 boluses at 0min, 15min, 30min and 45min of the 5 hours rehydration period. The average amounts consumed were 2.44 ± 0.4L for the water trial and 2.38 ± 0.4L for the caffeine trial. The mean caffeine concentration in the drink was 455.5 ± 37mg. Urine samples were collected prior, immediately after, and once every hour for 5 hours after exercise, in order to assess fluid net balance and fluid retention. Urine production during the rehydration period was observed to be significantly greater during caffeine intake immediately (116.6 ± 81.4ml), 1 hour (689.3 ± 106ml), and 3 hours (164.5 ± 153.7ml) after the rehydration period compared to the water trial (57.5 ± 22.1ml, 452.2 ± 172.7ml, and 250.1 ± 188.3ml respectively: p<0.01). As a result, the cumulative urine output was significantly greater in the 2nd (806 ± 177ml vs. 509.7 ± 192.6ml: p<0.01), 3rd (1357 ± 296.2ml vs. 1033.3 ± 300ml), 4th (1521.8 ± 412ml vs. 1283.5 ± 379ml), and 5th (1624.4 ± 430ml vs. 1381.5 ± 423ml: p<0.05) hour of the rehydration period during the caffeine trial compared to the water trial. The volume of fluid retention after 5 hours of fluid replacement was lower during the caffeine trial compared to the water trial (32 ± 13.1% vs. 44.1 ± 11.5%, respectively; p=0.018). Subjects returned to a negative fluid balance 1 hour after water consumption and immediately at the end of the rehydration period following intake of caffeine. The findings suggest that caffeine is less effective than water as a post exercise rehydration drink. This remains the case even when the volume of fluid intake is greater than fluid loss. Subjects in both trials did not reestablish a positive net fluid balance. During the trial inappropriate electrolyte replacement occurred suggesting opportunities for further research to investigate the effects of caffeine in relation to sodium after exercise induced dehydration.

### THE INFLUENCE OF CARBOHYDRATE/PROTEIN SUPPLEMENTATION ON CENTRAL FATIGUE AND REACTION TIME

Seifert, J.G., Bloemendal, A.

*MSU (Bozeman, MT, USA)*

**Introduction** It has been well established that caloric supplementation can enhance endurance performance. However, it has not been clearly established if such feedings can enhance indices of central fatigue during exercise. Thus, the purpose of this study was to compare the effects of a carbohydrate/protein/caffeine sports gel (GEL) to a non-caloric placebo (PL) on reaction time and muscle power output. **Methods** Following IRB approval, 7 trained cyclists completed 2 - 70 min cycling trials followed by a 2 min power test (PT). Central fatigue was assessed by two auditory reaction time tests (RTT), completed pre and post exercise, and RPE. The simple RTT (RTTs) consisted of pushing a switch upon hearing an auditory beep. Subjects completed a specific movement pattern with their arms before they stopped the timer for the second RTT (RTTc). Treatments were a non-caloric PL or a sports GEL. Dosage for the GEL was 50.4g CHO, 8.4g PRO, and 280 mg caffeine/hr and was administered in equal doses following each 10 min interval. Subjects ingested 140 mL of the PL or of water + the GEL following each 10 min interval. Exercise consisted of cycling in intervals at 70% of maximal power output (MPO) for 8 min followed by 2 min at 90% MPO for a total of 70 min. Following the post exercise RTT, subjects completed a cycling PT for 2 min at 5% of BW, similar to a Wingate. Blood glucose was measured pre and post exercise. RPE and HR were recorded during each 70% interval. All subjects ingested their pre-exercise meal 3 hrs prior to exercise. Data were analyzed with t-tests and ANOVA with repeated measures. Data are listed as mean (+/-SD). Alpha level of significance was p<.05. **Results** The RTTs was significantly faster for the GEL (.171 (.029) sec) than the

PL (.180 (.022) sec). RTTc was also faster for the GEL (.565 (.111) sec) compared to the PL (.593 (.115) sec). Mean RPE during the GEL (11.7 (2.0)) was lower than PL (12.7 (1.7)). Mean HR was significantly lower during the GEL (142.9 (13.6) bpm) compared to PL (145.8 (13.8) bpm). There was a trend ( $p=.1$ ) for the GEL (5.10 (.49) W/kg) to produce greater relative power during the 2 min PT test than the PL (4.88 (.67) W/kg). No statistical differences were observed between trials for blood glucose (GEL: 4.7 (.4) mM/L; PL: 4.5 (.3) mM/L). Discussion Ingestion of the sports GEL led to significantly faster simple and complex reaction times and lower RPE and HR than PL. The 5% faster reaction times are comparable to improvements in endurance performance when CHO are ingested. In fed subjects, blood glucose levels did not impact reaction time following 70 min of exercise. The results of this study demonstrate that supplementing with carbohydrate, protein, and caffeine can improve reaction time and reduce perceived effort following endurance exercise.

### EFFECTS OF WHEAT GLUTEN HYDROLYSATE SUPPLEMENTATION WITH EXERCISE ON MUSCLE SIZE OF LEG IN MICE.

Shimmura, Y.

*Nisshin Pharma Inc.*

Effects of wheat gluten hydrolysate supplementation with exercise on muscle size of leg in mice. Yuki Shimmura<sup>1,2</sup>, Ichiro Goto<sup>1</sup>, Nobuhiro Yahata<sup>1</sup>, Junichiro Yamauchi<sup>2,3</sup> 1. Health care research center, R&D division, Nisshin Pharma Inc. 2. Graduate School of Human Health Sciences, Tokyo Metropolitan University, JAPAN 3. Future Institute for Sport Sciences, JAPAN [Introduction] Glutamine is an amino acid, involving as a substrate in many physiological processes as well as acting as a physiological regulator. It has been known that glutamine has effects of immunomodulatory, anti-catabolic and anabolic, intestine mucosal barrier-protective and antioxidant actions. Also, glutamine is known as an increase in the secretion of anabolic hormones, i.e. insulin and growth hormone. A beneficial anabolic action has been demonstrated in several pathological conditions associated with muscle loss. Therefore, glutamine supplementation may be of a potential interest to modulate muscle protein metabolism and to maintain muscle mass. Large amounts of glutamine are contained in wheat protein known as gluten. Because glutamine in wheat gluten hydrolysate (WGH) is bonded to other amino acids with peptide bonds, it is more stable and better utilized by the body as compared with free form L-glutamine. However, there is no research on the study of WGH supplementation with exercise on the muscle size. In this study, we investigated the effects of supplementation of WGH derived from wheat protein with exercise on muscle size of leg in mice. [Methods] Male mice (BALB/c CrIcrij) at 7 months age were randomized into three groups: 1) 10% casein with 4% WGH (WGH group), 2) 14% casein (CA group) and 3) 10% casein (CON group) diet. Mice were fed with a free wheel cage for 28 days. Voluntary exercise was provided by free access to running wheels fitted with odometers. Before and after the trial, body mass, exercise volume, liver mass, muscle mass of leg (quadriceps, triceps surae) and serum concentration of protein and amino acids were assessed, and they were then compared with each group. [Results] The mean food intakes of WGH, CA, CON groups were  $6.45 \pm 0.13$  g/day,  $6.57 \pm 0.08$  g/day and  $6.24 \pm 0.12$  g/day respectively, and not significantly different. Body weight and exercise volume of WGH and CA tended to be higher than that of CON, although there were no significant differences. WGH and CA significantly increased muscle volume of quadriceps as compared with CON, and these increases represent  $0.575 \pm 0.007$  g,  $0.576 \pm 0.0016$  g and  $0.523 \pm 0.013$  g ( $p<0.05$ ), respectively. Serum TP and albumin of WGH and CA were not significantly different from those of CON. [Conclusion] WGH is a good candidate for protein supplementation to increase skeletal muscle volume and may help to prevent catabolic effects of muscle with aged population.

### EFFECTS OF SHORT TERM GINSENG SUPPLEMENTATION ON GLYCOGEN SYNTHESIS IN EXERCISED HUMAN SKELETAL MUSCLE

Chen, H.W., Lu, H.C., Cheng, I.S.

*National Taichung University of Education*

Introduction The active components of ginseng are considered to be ginsenosides, a group of steroidal saponins. The root of ginseng is a commonly used as herbal medicine (Wang et al., 1998). Little studies are available regarding to whether 28 days ginseng supplementation can enhance muscle glycogen synthesis in exercised human skeletal muscle. Methods Nine healthy male subjects (aged:  $21.87 \pm 0.87$  yrs) completed crossover trials after a 60-min cycling exercise at 70–75%  $VO_2$  max separated by 28 days. Subjects consumed 400 mg of ginseng or placebo for 28 days. On the 29th morning, they consumed 400 mg of ginseng or placebo with high carbohydrate meals (2 g carbohydrate/ kg body weight, 80 % carbohydrate, 8 % fat, 12 % protein) for a 24-hour recovery following exercise. Muscle biopsy samples were collected from vastus lateralis immediately after exercise and 3h, 24h during recovery (Bergstrom et al., 1962). Blood samples were collected before the exercise, every 30 minute within 3 hours after the exercise and 24h. Results We found 28 days ginseng supplementation significantly lowered post-meal insulin and glucose response with similar carbohydrate meal supplementation compared to placebo. The synthesis rate of glycogen during the 3-hour recovery is significantly higher compared to placebo ( $P<0.5$ ). Discussion These results demonstrated the rate of glycogen synthesis in exercised human skeletal muscle was enhanced during 3h during exercise recovery accompanied with improvement in post-meal insulin sensitivity. The results of this are beneficial for athletes, who are training for competition, on muscle glycogen synthesis after exercise. References Bergstrom J. (1962). Scand J Clin Lab Invest, 68, 11-13. Engels H J, Kolokouri I, Cieslak T J, Wirth J C. (2001). The Journal of Strength & Conditioning Research, 15(3), 290. Wang L, Lee T. (1998). Planta medica, 64, 130-133.

### WHETHER ORAL FAT BURNER SUPPLEMENTATION CAN ENHANCE GLYCOGEN SYNTHESIS IN EXERCISED HUMAN SKELETAL MUSCLE

Tsao, J.P.1, Chiu, Y.C.1, Cheng, I.S.2

1: NTUPES (Taichung, Taiwan), 2: NTCU (Taichung, Taiwan)

Introduction The term 'fat burner' is used to describe nutrition supplements that are claimed to enhance fat oxidation, increase weight loss, or somehow cause long-term adaptations that promote fat metabolism (Jeukendrup et al., 2011). The most popular 'fat burner' supplements include caffeine, carnitine, green tea, conjugated linoleic acid, hydroxycitrate, forskolin, chromium, kelp and fucoxanthin. Little studies were found regarding to whether fat burners administration is expected to enhance glycogen synthesis in exercised human skeletal muscle. As glycogen serves as a main fuel source in the skeletal muscle for endurance performance (Ivy et al., 1988), the present study is to investigate whether hydroxycitrate, carnitine caffeine, and conjugated linoleic acid supplementation separately can enhance fatty acid oxidation, attenuate glucose utilization and results in more glycogen content in exercised human skeletal muscle. Methods Eight healthy male volunteers (age,  $22.0 \pm 0.3$  years) completed a 60-min cycling exercise at 70–75%  $VO_2$  max and received hydroxycitrate, carnitine, caffeine and placebo supplemented separately in a crossover design repeated after a 7 d washout period. They consumed fat

burners or placebo with a high-carbohydrate meal (2 g carbohydrate/kg body weight, 80% carbohydrate, 8% fat, 12% protein) for a 3-h post-exercise recovery. Muscle biopsy samples were obtained from vastus lateralis immediately and 3 h after the exercise (Bergstrom et al., 1962). Simultaneously, blood glucose, insulin, non-esterified fatty acid and glycerol, and expired gas analysis will be performed before and after exercise. Results The main findings of the study are: (1) oral Hydroxycitrate, carnitine, or caffeine supplementation significantly accelerated the rate of glycogen synthesis to twofold in exercised human skeletal muscle compared to placebo; (2) Hydroxycitrate and carnitine increase occurred in parallel with increased whole-body insulin sensitivity, evidenced by reduced post-meal insulin response. Discussion The results of the present study suggested that the greater glycogen synthesis rate were found in exercised human skeletal muscle after fat burners supplementation are mediated by either reduced carbohydrate utilization and increased fat utilization (glycogen sparing effect), evidenced by lower in respiratory exchange ratio during 3h recovery. The fruitful outcome from this study may suggest that fat burners may influence metabolic consequence, which in turn affects the glycogen re-synthesis in exercised human skeletal muscle. Since muscle glycogen is the main energy source for endurance competition, the results of this study will certainly benefit to athletes, who are training for competitions. ### ENERGY SUPPLEMENTATION INFLUENCED ENERGY AVAILABILITY, BUT NOT PHYSICAL ACTIVITY DURING 8 DAYS OF SUSTAINED PHYSICAL EXERTION

Tanskanen, M.6, Westerterp, K.R.2, Uusitalo, A.L.3, Atalay, M.4, Häkkinen, K.1, Kinnunen, H.5, Kyröläinen, H.1

Introduction Energy balance is an important factor in sustaining training load and maintaining high performance during strenuous military training. Previous studies have shown an energy deficit during a strenuous military field-training course (TC). The purpose of this study was to determine the effects of energy bar supplementation on energy balance, physical activity (PA), physical performance and well-being and to define whether ad libitum fluid intake is sufficient during a wintertime 8-day military TC. Methods Twenty-six men (age  $19 \pm 1$  yr.) were randomly divided into two groups: The control group (n = 12) had traditional field rations and the experimental (Ebar) group (n = 14) had the same field ration plus additional energy supplement of 4.1 MJ/day. Food and water intake was recorded. Fat-free mass and water loss were measured with deuterium dilution and elimination, respectively. The energy expenditure (EE) was calculated using the intake/balance method and energy availability as (energy intake/estimated basal metabolic rate). PA was monitored using an accelerometer. Physical performance was measured and questionnaires of subjective well being were recorded before, during and after TC. Results During TC, Ebar had a higher energy intake and energy availability than the controls ( $p < 0.05$ ). However, decreases in body mass ( $-1.8 \pm 1.0$  kg) and fat mass ( $-2.1 \pm 0.7$  kg) were similar in both groups representing an energy deficit ( $p < 0.001$ ). No differences were observed between the groups in PA, water intake and changes in physical performance and fat-free mass. Water balance was negatively related to PA. The present study further demonstrated that a negative mood state before TC associated negatively with energy availability and PA. Discussion An easy-to-use energy bar of 4 MJ/day did not prevent energy deficit nor influence PA during an 8-day strenuous military TC. A satiation effect of the high content of protein in the bars might have induced a decreased energy intake from field rations. During strenuous TC, PA seems to be primarily affected by other factors than energy supplementation such as mood state.

### CORRELATION BETWEEN HYDRATION AND BASKETBALL PERFORMANCE

Vukasinovic-Vesic, M.1, Dikic, N.1,2, Andjelkovic, M.1, Radivojevic, N.1, Curcic, D.J.1, Antic, T.1, Baralic, I.1, Turner, R.2, Stokes, R.2, Gunter, H.2

*Sports Medicine Association of Serbia*1, *FIBA Europe*2

Introduction Many study results suggest that inadequate hydration is influencing sports performance by: impairing mental/cognitive performance, decreasing the motivation to exercise, increasing the rating of perceived exertion and decreasing the time to exhaustion. In basketball dehydration is correlated with overall basketball performance, jumps, shooting and number of shots that were attempted and made. The aim of our study was to analyze the influence of hydration on basketball performance. Method Ninety-six basketball players of eight national teams have assessed during official FIBA Europe U20 Championship Men 2011 - Division B held in Sarajevo in July 2011. In order to detect a correlation between hydration and basketball performance we measured body mass of all players before and after one game. This correlation was evaluated by percentage of dehydration (body mass loss/pre exercise body mass) x 100. Results Players age was  $19 \pm 0.79$  years. After the game percentage of dehydration was  $0.99 \pm 0.7\%$  ( $-1.25 - 2.95\%$ ). We found statistically significant negative correlation between percentage of dehydration with most valuable player index (MVP) ( $p < 0.01$ ), points scored ( $p < 0.01$ ), total rebounds ( $p < 0.01$ ), shooting percentage for 3 points ( $p < 0.05$ ), shooting percentage for 1 points ( $p < 0.05$ ), assists ( $p < 0.05$ ). Discussion We have found that dehydration considerably impaired basketball performance. Dehydration significantly impaired points scored, total rebounds, shooting percentage for 3 points, shooting percentage for 1 point, assists, except steals balls, turnovers and shooting percentage for 2 points. Most importantly, there is a significant negative correlation between hydration and the category of the most valuable player index (MVP). We decided to use the method of percentage of dehydration because we consider that this parameter can be used most efficiently and effectively on the spot by trainers to measure hydration level of players. The result of this study showed that dehydration is not only a physiological state, but also a very important factor for the total performance of one team, which requires sports personnel to be educated in order to be able to help contribute to a better overall sports performance. ### DOES CARBOHYDRATE SUPPLEMENTATION MAXIMIZE TENNIS MATCH PLAY PERFORMANCE?

Capitani, C.D.1, Gomes, R.V.2, Fernandez-Fernandez, J.3, Mendez-Villanueva, A.4, Moreira, A.2, Aoki, M.S.2

1University of Campinas, Campinas, Brazil; 2University of Sao Paulo, Sao Paulo, Brazil; 3Ruhr-University Bochum, Germany; 4 ASPIRE Academy for Sports Excellence, Doha, Qatar.

Introduction: The aim of the present study was to assess the effect of carbohydrate (CHO) supplementation on tennis match performance. Twelve young tennis players ( $18.0 \pm 0.8$  years) with national rankings among the top 50 in Brazil agreed to participate in the study. Methods: This study was conducted over a 5 day period in which each player completed 2 games of 3 hours simulated tennis match play

either supplemented with a CHO or placebo (PLA) drinking solution. A randomized, cross-over, double blind research design was used. The activity profile of each match was determined by filming each match with two video cameras. Each player was individually tracked for the entire duration of the match. Two experienced researchers watched the matches and performed a match analysis. The following variables were calculated: (1) games won or lost; (2) rally duration (s); (3) strokes per rally; (4) rest time between rallies (s); (5) effective playing time (%); (6) changes of direction per rally; (7) aces; (8) double faults; (9) first service in; (10) second service in; (11) first return in and (12) second return in. Results: There were no between-condition differences in any of the variables analysed. Conclusion: In summary, the key finding of this study was that CHO supplementation did not improve tennis match play performance.

#### **EVENING WEIGHT-LIFTING PERFORMANCE AFTER TWO NIGHTS PARTIAL SLEEP DEPRIVATION; ARE "POWER NAPS" ON THE DAY OF COMPETITION USEFUL?**

Edwards, B.J., Moseley, S.E., Robertson, C., Waterhouse, J.

*Liverpool John Moores University*

Maximal gross muscular performance is unaffected by partial sleep deprivation, effects on repetitive gross muscular tasks (i.e. weightlifting) is unknown. Power naps have been reported to improve mood and physical performance following reduced sleep. Therefore, the purpose of this study was to determine the effects of partial sleep-deprivation (3h sleep for 2 consecutive nights) on weight-lifting and whether the use of a short post-lunch power nap could improve performance. Eight untrained males (Mean±SD: age, 20 ± 1.5 yrs; height, 184±6cm; body mass, 94±10kg; Bench Press 1 Rep Max (1RM), 81.25±10.7 kg; Leg Press 1RM, 270±27.8 kg) volunteered for the study. The subjects were familiarised before undertaking the main protocol, which consisted of completing 3 conditions administered in a counter-balanced fashion. The three conditions were: 1) Normal (N) retiring at 23:00 and rising at 06:30h, 2) Partial sleep deprivation (SD) retiring at 03:30 and rising at 06:30h; and 3) Partial sleep deprivation with 1h nap at 13:00h (SDN). Measurements of rectal and skin temperatures, tiredness and alertness, and Profile of Mood Scores (POMS) were made at 08:00, 11:00, 14:00 & 17:00h. At 17:00h subjects also performed 3 attempts (with 3-min rest between each attempt) at progressive sub-maximal (40, 60, 80% 1RM) Bench and Leg Press. A linear encoder (Muscle Lab) was attached to an Olympic bar (20kg, resting on steel racks, for bench press; 40kg and tilted for leg press). Perceived effort and ratings of perceived exertion for breathing, muscle effort and overall feeling were measured after each lift. Average force, power, velocity time-to-peak velocity and distance were also recorded for each lift. Data were analysed using ANOVA models with repeated measures. Alertness, tiredness, sleepiness and bench press (power, force and average velocity) was lower in SD than N and SDN. RPE for breathing and muscle feeling increased during SD for bench and leg press. General body feeling additionally increased in leg press (subjects perceived the task to be harder). Mood states for vigour, calm were lower and anger, tension depression and fatigue were higher in SD compared to N. A significant load (%1RM) effect was observed for bench and leg press (force, average velocity, time to peak velocity); similarly 'distance' increased (at 80% 1RM) and leg press power increased as load (%1RM) increased. Further, RPE for breathing, muscle and general body feeling increased between loads. Alertness, tiredness and sleepiness demonstrated a significant time of day effect and interaction with a 1-h power nap increasing alertness and reducing tiredness and sleepiness. Furthermore, rectal temperature values were lowest at 08:00 and highest at 17:00h (P<0.05). All other variables were insignificant (P>0.05). In summary, this study suggests that the use of a short post-lunch nap may improve performance to levels of that of normal sleep by increasing evening alertness, reducing tiredness and sleepiness and improving aspects of mood.

#### **THE EFFECTS OF RESISTANCE TRAINING OF THE ROTATOR CUFF ON SUBACROMIAL SPACE IN HEALTHY PEOPLE**

Kaji, K.1, Watanabe, H.2, Takahashi, M.2, Takahira, N.1

*1:Graduate School of Medical Science, Kitasato University (Kanagawa, Japan), 2: Kitasato University (Kanagawa, Japan)*

**Introduction** The rotator cuff (RC) of the shoulder contributes to stabilize and center the humeral head in the glenoid at the glenohumeral joint. A weakness or abnormal functions of the RC are associated with the shoulder injuries (Byram et al., 2010). In the RC, the supraspinatus has a one of the important functions to avoid inferior instability that is evaluated with subacromial space (SAS) as loaded to inferior direction (Cheng et al., 2008). The resistance training of the RC is also needed to prevent the shoulder injuries. However, there is little study that focuses on the effects of only resistance training of the RC. The purpose of this study is to investigate the effects of resistance training of the RC during 6 weeks on SAS. **Methods** 19 participants (3 men, 16 women) aged from 19 years to 25 years (mean age 21.1±1.4 years) with normal shoulder were examined. SAS was measured with the ultrasonography. The ultrasonographic measurement of the SAS was defined as the distance between the tip of acromion and the nearest aspect of humeral head. The subjects were seated with their arm drop to their sides in internal rotation, and were loaded to inferior direction by heavy bob (3kg or 5kg). The examiner measured SAS at rest, 3kg loaded or 5kg loaded. All subjects performed the resistance training of the RC during 6 weeks and abducted their shoulder from 0 degree to 30 degrees in scapular plane with external rotation. The resistance applied at the wrist with Thera-Band. Each of SAS (when rest, inferior loading of 3kg or 5kg) was measured both before and after resistance training of the RC. Results SAS before resistance training was 13.3±0.7mm at rest, 15.0±0.7mm at 3kg loaded or 15.7±0.8mm at 5kg loaded. On the other hand, SAS after resistance training was 13.9±0.7mm at rest, 15.5±0.8mm at 3kg loaded or 16.2±0.9mm at 5kg loaded. In all of the conditions, SAS was significantly increased after resistance training. **Discussion** A functional depression of the RC is associated with the shoulder injuries (Byram et al., 2010). We intended to identify the utility of resistance training of the RC to prevent the shoulder injuries for healthy people. In this study, SAS was widened after the RC training. The inability of the RC against the deltoid that pulls the humeral head proximally relates to superior migration of the humeral head (Weiner et al., 1970). Therefore, the results may be indicative to improve the balance between the RC and the deltoid. However, we couldn't confirm whether the balance of these muscles become altered actually. **Conclusion** The resistance training of the RC during 6 weeks widens SAS at rest and inferior loaded in healthy people. ## RUNNING VERSUS CYCLING: IN WHICH MODE IS THE LACTATE THRESHOLD MORE USEFUL IN TRIATHLETES?

Fisher, S., Jenkins, D., Skinner, T., Osborne, M., van Rosendal, S., Emmerton, L.

*University of Queensland*

**RUNNING VERSUS CYCLING: IN WHICH MODE IS THE LACTATE THRESHOLD MORE USEFUL IN TRIATHLETES?** Fisher, S.I, Jenkins, D.I, Skinner, T.I, Osborne, M.I, van Rosendal, S.I, Emmerton, L.I 1: School of Human Movement Studies, The University of Queensland (Brisbane, Australia) 2: Queensland Academy of Sport (Brisbane, Australia) 3: School of Pharmacy, Curtin Health Innovation Research Institute, Curtin University (Perth, Australia) Introduction The weight of available evidence suggests that endurance performance is better predicted by the lactate threshold (LT) than by maximal oxygen uptake (VO<sub>2</sub>max). However, it is not clear whether exercise intensity at the LT is equal to the maximal exercise intensity able to be sustained during a time-trial (TT), nor whether exercise at either of these work rates elicits a 'maximal lactate steady state'. The purpose of the present investigation was to examine the relationships between the LT, constant-load exercise at the LT and TT performance in running and cycling. Methods Ten highly-trained male triathletes (age 27.5 ± 4.4 years, cycle VO<sub>2</sub>max 61.5 ± 3.8 mmol•L<sup>-1</sup>, run VO<sub>2</sub>max 59.9 ± 6.8 mmol•L<sup>-1</sup>) completed three trials for both cycling and running: 1) incremental tests to determine their LT; 2) 30 min constant-load (cycle) or speed (run) tests at their LT intensity; and 3) TT (40 km cycling and 10 km running). Results Strongest predictors of TT performance for running were LT speed (r = -0.92; p < 0.01) and VO<sub>2</sub>max (r = -0.89; p < 0.01), while for cycling, LT power output was the only significant predictor (r = -0.68; p < 0.05). Only four out of nine participants were able to run for 30 minutes at their LT speed; in contrast, all 10 participants were able to maintain their LT cycle power output for the same duration. During the running constant load trial, the average plasma [La] between 10 and 30 minutes was not in steady state; in contrast, during the cycle constant load trial, plasma [La] was in steady state between minutes 10 and 30. In the running trials, the LT speed (15.6 ± 1.2 km•hr<sup>-1</sup>) was significantly greater than the average TT speed (14.8 ± 2.0 km•hr<sup>-1</sup>) (p < 0.05) whereas in cycling, there was no difference between power output at LT (243.5 ± 35.2 W) and average TT power output (251.6 ± 33.5 W). Discussion The present data demonstrate that the run LT predicts 10 km TT performance yet over-predicts the highest sustainable running speed over a 30 minute duration. In contrast, the cycle protocol more accurately predicts the highest sustainable cycling workload over 30 minutes, in addition to predicting 40 km TT performance. The cycling LT protocol is more useful than the running protocol since it predicts a sustainable workload over 30 minutes in addition to the workload and performance time during a TT. References Faude, O., W. Kindermann, et al. (2009). 'Lactate Threshold Concepts How Valid are They?' *Sports Medicine* 39(6): 469-490.

## AEROBIC PARAMETERS IN FREE AND SEMI-TETHERED FIELD RUNNING TESTS

Ribeiro, L.F.P.1,2, Sousa, F.A.B.3, dos Reis, I.G.M.3, Belli, T.2, Beck, W.R.3, Papoti, M.4, Cunha, S.A.3, Martins, L.E.B.3, Gobbato, C.A.5

1: DCS/UESC (Ilhéus, Brasil), 2: IB/UNESP (Rio Claro, Brasil), 3: FEF/UNICAMP (Campinas, Brasil), 4: FCT/UNESP (Presidente Prudente, Brasil), 5: FCA/UNICAMP (Limeira, Brasil)

Introduction Resisted running is a common practice in sprinter's daily routine, but despite prior literature on its acute kinematic effects (Maulder et al., 2008; Paulson & Braun, 2011), the physiological consequences of such practice are largely unknown. In this study we investigated the effects of resisted running on aerobic parameters by comparing data derived from free (FR) and semi-tethered running (STR) tests in well trained athletes. Methods Nine male runners (21.1 ± 3.4 yrs; 70.6 ± 6.6 Kg; 180 ± 5 cm) volunteered to take part in this investigation and underwent graded exercise tests in both FR and STR conditions on a synthetic 400 m track using a portable gas analyzer (K4B2, Cosmed, Italy). In the STR athletes were attached by their waists to a specific apparatus that enabled a 4% body weight resistance to be set by means of a mechanical break. Studied variables included peak oxygen uptake (VO<sub>2</sub>PEAK), velocity at VO<sub>2</sub>PEAK (vVO<sub>2</sub>PEAK), peak heart rate (HRPEAK) and ventilatory threshold (VT). Comparisons were performed using t-tests and effect sizes (ES) were calculated. Results Although velocity at VT (12.59 ± 0.50 vs 11.42 ± 0.65 Km/h; ES = 2.0) and vVO<sub>2</sub>PEAK (16.9 ± 1.0 vs 14.8 ± 0.4 Km/h; ES = 2.5) were significantly greater in FR (P < 0.01), t-tests revealed no significant differences (P > 0.05) between FR and STR for VO<sub>2</sub>PEAK (3216 ± 306 vs 3377 ± 318 L/min; ES = -0.5), HRPEAK (194 ± 3 vs 192 ± 6 bpm; ES = 0.4) and VO<sub>2</sub> at VT (2792 ± 306 vs 2929 ± 250 mL/L; ES = -0.5). Discussion Extending previous findings showing deterioration in running mechanics in resisted sprinting (Maulder et al., 2008; Paulson & Braun, 2011), our data suggest semi-tethered running against a 4 % body weight resistance to reduce velocities at VO<sub>2</sub>PEAK and VT without changing metabolic rates at these intensities. In addition, these results provide initial support to the STR system as an interesting tool for evaluation and training purposes in resisted running. ## RESPIRATORY MUSCLE ENDURANCE TRAINING WITH NORMOCAPNIC HYPERPNEA IMPROVES VENTILATORY FUNCTION AND EXERCISE PERFORMANCE IN TRIATHLETES.

Bernardi, E., Melloni, E., Pomidori, L., Mandolesi, G., Cogo, A.

*post graduate student in sport medicine*

**RESPIRATORY MUSCLE ENDURANCE TRAINING (RMET) WITH NORMOCAPNIC HYPERPNEA (NH) IMPROVES VENTILATORY FUNCTION AND EXERCISE PERFORMANCE IN TRIATHLETES.** Bernardi E.I, Melloni E.I, Pomidori L.I, Mandolesi G.I, Cogo A.I 1: Biomedical Sport Studies Center (University of Ferrara, Italy). Introduction: Recent studies show that RMET reduces dyspnea perception, improves endurance performance and decreases ventilation during exercise (Verges, 2008). At the best of our knowledge no information about the changes of oxygen consumption (VO<sub>2</sub>) and ventilation (VE) during incremental test is available in healthy subjects after RMET. Aim: To evaluate the effect of 5 weeks of RMET with NH by means of Spirotiger on respiratory function, cycling and running performance in triathletes. Materials and Methods: 15 M triathletes were randomly allocated to 2 groups: RMET (10 subjects; age 28 ± 6) and control (5 subjects; age 29 ± 4) group. At baseline (T0) all subjects underwent: pulmonary function tests (forced expiratory volume in first second, FEV<sub>1</sub>; forced vital capacity, FVC; maximal inspiratory pressure, MIP; maximal voluntary ventilation, MVV) and exercise tests (maximal incremental and endurance cardiopulmonary tests performed with both cycle ergometer and treadmill). Then, RMET group trained at home for 5 weeks: 20 min daily, with Spirotiger, at the same ventilation level measured at the respiratory compensation point (roughly corresponding to 50% of MVV) during incremental test. The same tests were repeated after 5 weeks (T1). Between T0 and T1 all subjects maintained the same level of daily physical activity. Result: No change was found in control group (data not reported). In RMET group MIP (T0: 93±29; T1: 97±25 cmH<sub>2</sub>O\*) and MVV (T0: 213±17; T1: 231±18 l/min\*) significantly increased. No differences were found in FEV<sub>1</sub> and FVC. Incremental test: maximum watt on cycle ergometer (T0: 389±106; T1: 429±119 watt\*) and maximum speed on treadmill (T0: 18±2; T1: 19±2 Km/h\*) signifi-

cantly increased. The trend of  $\text{VO}_2$ , VE and respiratory rate (RR) showed values significantly lower after RMET ( $p < 0.05$ , ANOVA test). The dyspnea Borg score during endurance tests on treadmill (T0: 7,2/10; T1: 6,5/10\*) and on cycle ergometer (T0: 7,3/10; T1: 6,7/10\*) showed a significant lower score. No differences were found in ventilatory pattern during both endurance tests. After RMET a significantly lower weight (-1 Kg\*) was measured. (\*  $p < 0.05$ ; T test) Conclusion: RMET significantly improves MIP and MVV in triathletes and increases exercise performance during incremental test. Furthermore the VE becomes more efficient as shown by the reduction of VE and RR during incremental test and by the lower dyspnea Borg score. Reference: Verges S, Boutellier U, Spengler CM. (2008). *Respir Physiol Neurobiol*, 161(1):16-22.

### EFFECT OF STAGE DURATION ON THE RELATIONSHIP BETWEEN PEAK RUNNING SPEED AND ENDURANCE PERFORMANCE

Machado, F., Kravchychyn, A.C.P., Peserico, C.S., da Silva, D.F., Mezzaroba, P.V.

*State University of Maringá*

**Introduction** It has been reported that the peak running speed ( $V_{\text{peak}}$ ) obtained during an incremental treadmill test is a good predictor of endurance performance (Noakes et al., 1990; Scott and Houmard, 1994; Stratton et al., 2009). However, the most appropriate protocol for the  $V_{\text{peak}}$  determination is still not established. Therefore, the purpose of this investigation was to examine the relationship between the  $V_{\text{peak}}$  determined during incremental tests of different stage durations and the endurance performance. **Methods** Thirty male, recreational, endurance trained runners (age:  $39 \pm 13$  years) of regional and local level participated in this study. Participants performed three continuous incremental exercise tests of different stage durations on a motorized treadmill until volitional exhaustion. Each protocol started at 8 km/h with increments in speed of 1 km/h every 1 min for the first protocol (P1), every 2 min for the second protocol (P2) and every 3 min for the third protocol (P3). The  $V_{\text{peak}}$  was defined as the highest speed that could be maintained for more than 90% of the stage duration during the incremental test. Thereafter, all the participants undertook two 5-km and two 10-km time trials on a 400-m track, which took place within a 15-day period after the laboratory testing. The best 5-km and 10-km time for each individual was recorded and their mean 5-km running speed ( $S_{5\text{km}}$ ) and 10-km running speed ( $S_{10\text{km}}$ ) from the best trials were calculated in km/h. **Results** The correlations between  $V_{\text{peak}}$  and  $S_{5\text{km}}$  were 0.86 (P1), 0.91 (P2) and 0.93 (P3). The correlations between  $V_{\text{peak}}$  and  $S_{10\text{km}}$  were 0.81 (P1), 0.87 (P2) and 0.88 km/h (P3). **Conclusion** The  $V_{\text{peak}}$  obtained during the incremental test with increments every 3 min presented the highest correlation with both  $S_{5\text{km}}$  and  $S_{10\text{km}}$ . Thus, the 3-min stage duration protocol is preferred than the 1-min and 2-min stage duration protocols for the determination of the  $V_{\text{peak}}$  to predict long distance running performance. **References** Noakes TD, Myburgh KH, Schall R. ### BODY COMPOSITION, HABITUAL PHYSICAL ACTIVITY AND BONE MEASUREMENTS IN MALES

Szmodis, M., Szóts, G., Bosnyák, E., Trájer, E., Tóth, M., Farkas, A.

*Semmelweis University, Faculty of Physical Education and Sports Sciences*

**Introduction** Osteopenia and osteoporosis are well known common diseases worldwide. The bone degeneration could be prevented or decreased and slowed down by regular physical activity. The aim of this study was to analyze relationships between sport events, some anthropometric parameters and bone stiffness in males. A quantitative ultrasound measurements could be easily used as a non-invasive method for evaluating bone status. **Methods** The subjects were Hungarian elite athletes (kayak-canoe,  $n=42$ ; triathlon/biking,  $n=16$ ) and non-athletic ( $n=48$ ) males of the same age range. In the anthropometric data collection the suggestion of the International Biological Program (Weiner and Lourie 1963) was considered. Body fat percentage was assessed by Pařízková's (1961) method, body composition by Drinkwater and Ross (1980), nutrition status was calculated by BMI. Calcaneal QUS parameters were examined with a Sonost 3000 bone densitometer. The measurements included speed of sound (SOS, m/s), broadband ultrasound attenuation (BUA, dB/MHz) and calculated the bone quantity index ( $BQI = \alpha \text{SOS} + \beta \text{BUA}$ ,  $\alpha, \beta$ : temperature corrections). We analysed the relationships of anthropometric variables and bone characteristics of total sample and subgroups. Differences of the respective subgroup means were tested by Tukey's post-hoc tests at the 5% effective level of random error when the overall F-test of one-way ANOVA was significant. **Results** There were moderate significant correlations between fat percentage, BMI and BUA, BQI in total sample. Compared the kayakers to the triathlete and non-athlete males the bone parameters did not differ but there was a constant tendency: triathlons and cyclists had the highest, non athletes had the lowest values. The differences of SOS and BQI means of triathlons and controls were significant: SOS ( $1512,91 \pm 20,80$  vs.  $1499,60 \pm 14,65$ ), and BQI ( $84,76 \pm 9,63$  vs.  $73,41 \pm 15,84$ ). **Discussion** The fact that active lifestyle can prevent degradation process of bones is proved in many international reports. Two of the bone parameters were different between triathlons and the controls but did not differ in kayakers and controls. It seems the quantity bone characteristics are highly dependent on sports events. The greater the mechanical load on the lower limbs the influence is stronger on bone stiffness or structure.

### INTRA-SESSION RELIABILITY OF RESPIRATORY PARAMETERS MEASUREMENT DURING SUBMAXIMAL EXERCISE ON CYCLE ERGOMETER IN AEROBICALLY TRAINED ADULTS

Dvorák, M., Balás, J.

*Charles University in Prague*

**Introduction** The aim of the study was to assess the intra-session reliability of the oxygen consumption, the carbon dioxide production and the expired minute volume during submaximal exercise test on cycle ergometer during repeated measures with the PowerLab/8M (ADInstrument Pty Ltd., Australia). **Methods** Eight aerobically trained participants (age  $24 \pm 3$  years) performed the submaximal exercise test on cycle ergometer. The first load was  $1.5 \text{ W} \cdot \text{kg}^{-1}$  (4 min) the second load  $2.5 \text{ W} \cdot \text{kg}^{-1}$  (4 min). The participants undertook 3 repetitions with 15 minutes recovery. The oxygen consumption, the carbon dioxide production and the expired minute volume were recorded by PowerLab/8M during the exercise and analysed with LabChart 7 (ADInstrument Pty Ltd., Australia). The average scores over the last minute in both loads were used for the calculations. Intra-class correlation coefficient ICC2.1 (Shrout & Fleiss, 1979) and standard errors of measurement SEM were used to address relative and absolute reliability. Repeated measures ANOVA were used to assess the systematic error between the three measurements. **Results** The ICC2.1 for the oxygen consumption was 0.92, for the carbon dioxide production 0.90, for the expired minute volume 0.94 at the first load ( $1.5 \text{ W} \cdot \text{kg}^{-1}$ ). The ICC2.1 for the oxygen consumption was 0.98, for the carbon dioxide production 0.98, for the expired minute volume 0.98 at the second load ( $2.5 \text{ W} \cdot \text{kg}^{-1}$ ). SEM for the oxygen consumption was 0.05

$L \cdot \text{min}^{-1}$ , for the carbon dioxide production  $0.05 L \cdot \text{min}^{-1}$ , for the expired minute volume  $1.28 L$  at the first load ( $1.5 W \cdot \text{kg}^{-1}$ ). SEM for the oxygen consumption was  $0.04 L \cdot \text{min}^{-1}$ , for the carbon dioxide production  $0.04 L \cdot \text{min}^{-1}$ , for the expired minute volume  $1.16 L$  at the second load ( $2.5 W \cdot \text{kg}^{-1}$ ). Discussion The coefficients of reliability ranged between 0.90 and 0.98. The values 0.90 and higher are considered as a good indicator of reliability in sport science literature (Baumgartner et al., 2006). The value of ICC is, however, influenced by the heterogeneity of the research sample. The indication of absolute reliability coefficient should be calculated. We choose the SEM which is one of the most used coefficients along with coefficient of variation and limits of agreement. We agree with Eng et al. (2004) who stated similar values of ICC and SEM for  $\text{VO}_2$  at submaximal load ( $1.1 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ ). In conclusion, we found high reliability of ventilatory parameters measurement during submaximal cycle ergometry measured by PowerLab 8/M. References BAUMGARTNER, T. A., JACKSON, A. S., MAHAR, M. ## COMPARISON OF UPHILL SPRINT TRAINING TO CYCLE SPRINT TRAINING

Jakeman, J.R.1, Lorimer, R.2, Babraj, J.A.2

1. Oxford Brookes University; 2. SPEC, University of Abertay, Dundee

High intensity training (HIT) involving 30sec sprints is an effective approach to improving aerobic performance. However much of this research is based on cycle ergometry, with access to equipment difficult, and the protocol non sport-specific. We investigated whether 30sec uphill running sprints could deliver similar improvements in aerobic performance as cycle HIT and the similarity of metabolic demand. Methods: Eleven recreationally active males ( $35 \pm 8$  y, weight  $82 \pm 10$  kg, BMI  $26 \pm 3$   $\text{kg} \cdot \text{m}^{-2}$ ) were recruited and allocated to either a cycle training group (CT n=5) performing two weeks of HIT, or a run training group (RT n=6) performing 2 weeks of uphill sprints on a 1:10 slope. The sprint intervention for both groups involved 4 x 30 sec sprints separated by 4 min active recovery, 3 x per week (totalling 6 sessions, with a total exercise time of 12 min). Before and after 2 weeks of training participants performed a  $\text{VO}_2$  max and time to exhaustion (TTE) test on a cycle or treadmill ergometer, with protocols seeking to produce similar TTE. On separate occasions 6 participants performed 2 uphill or cycle sprints with portable breath by breath analysis and blood lactate taken 1 minute after each sprint. Results: Two weeks of HIT resulted in an 11% increase in TTE in the RT group and a 6% increase in TTE in the CT group ( $p = 0.014$  and  $p=0.05$  respectively). The improvement in TTE was associated with an increase in the %  $\text{VO}_2$  max where  $\text{VCO}_2$  excess occurred (RT- pre  $66 \pm 10\%$ , post  $78 \pm 5\%$ ;  $p<0.01$  pre versus post; CT- pre  $53 \pm 2\%$ , post  $64 \pm 4\%$ ;  $p<0.05$  pre versus post). Further, blood lactate was significantly lower after the first uphill sprint compared to the first cycle sprint ( $5.1 \pm 2.4$  versus  $10.2 \pm 1.3$   $\text{mmol} \cdot \text{l}^{-1}$ ,  $p<0.001$ ). However blood lactate levels were similar after the second sprint ( $12.5 \pm 2.2$  versus  $14.1 \pm 1.7$   $\text{mmol} \cdot \text{l}^{-1}$ , NS). The first uphill sprint produced a greater area under the curve for heart rate,  $\text{VO}_2$  and  $\text{VCO}_2$  than the cycle sprint during the sprint and 4 minute recovery ( $p<0.05$  for all). However, only area under the curve for  $\text{VO}_2$  was greater for uphill sprinting compared to cycle for the second sprint ( $p<0.05$ ). Discussion: In the present study we demonstrate that uphill sprints can improve aerobic performance to a similar extent as a cycle HIT protocol. The magnitude of change in  $\text{VCO}_2$  excess is similar following RT and CT suggesting both protocols produce similar adaptations in lactate metabolism. There is a greater oxygen demand in the first uphill sprint which results in a lower blood lactate concentration suggesting a higher aerobic contribution to an uphill sprint compared to a cycle sprint. In conclusion uphill sprints are as effective as traditional cycle high intensity training to improve aerobic performance in recreationally active males.

##### EFFECT OF 6 WEEKS OF REPEATED SPRINT ABILITY TRAINING ON HEART RATE RECOVERY.

Sarabia, J.M.1, Sánchez-Sánchez, E., Torres, G.2, Guillen, S.1, Aracil, A.1, Moya, M.1

1: Research Group on Healthy Physical Conditioning, Centro de Investigación del Deporte, UMH (Elche, Spain).

Introduction Tennis is characterized by repeated explosive movements, followed by recovery periods of around 20-25 s. Post-exercise recovery is a key factor to determine the optimal training load in athletes. Heart rate recovery (HRR) is been used as a marker of post-exercise recovery (Lamberts et al., 2010). The aim of this study was to describe the HRR evolution during 6 weeks of a repeated sprint ability (RSA) training period in young tennis players. Methods During a 6-week intervention period, 9 young male tennis players performed two RSA training sessions per week in addition to their regular training schedule. Each RSA training session consisted in performing three series -of six repetitions each- of a high-intensity circuit, including hits, with 20-s self-paced recovery periods among repetitions and 3 min among series. Intensity was controlled by means of heart rate (HR) monitors (RR interval -Polar Team2-). For each session, HRR was estimated by measuring the HR after the last repetition of the last series immediately at the end of the repetition, and after 30", 1' and 2' of recovery. For each individual a sixth polynomial regression line was calculated for the whole intervention period, and after a post hoc analysis individuals were grouped depending on HRpeak tendency. Results Two groups were identified: a first group that showed stability in HRpeak (SP), and a second group that showed a decrease in HRpeak (DP). HRR range tended to maintain stable along the whole intervention period in SP group in comparison with DP group, in which HRR tended to decrease. These differences were found to be statistically significant at every moment studied (30",  $p = .011$ ; 1',  $p = .007$ ; 2',  $p = .005$ ; ANOVA). Discussion According to previously published work (Lamberts, et al., 2010) at the present report homogeneous groups based on their HRR tendency after high-intensity training could be identified. The fact that RSA training may produce different responses in a homogenous sample suggests that this type of training should be monitored and individualized. ## COMPARISON OF DIFFERENT METHODS FOR ESTIMATING TOTAL ENERGY EXPENDITURE FOR BRIEF BOUTS OF HIGH INTENSITY INTERVALS

Kilian, Y.1, Koehler, K.2,3, Wahl, P.1, Zinner, C.1, Sperlich, B.4, Mester, J.1,3

*German Sport University Cologne*

1 Institute of Training Science and Sport Informatics, German Sport University Cologne, Germany 2 Institute of Biochemistry, German Sport University Cologne, Germany 3 The German Research Centre of Elite Sport, Cologne, Germany 4 Department of Sport Science, University of Wuppertal, Germany Introduction: O<sub>2</sub> uptake remains the most popular method to estimate energy expenditure. Although O<sub>2</sub> uptake provides an excellent representation of aerobic ATP turnover, it does not represent the energy expenditure (EE) by rapid anaerobic glycolytic ATP turnover. The quantification of total EE for exercise and recovery includes the measurement of exercise O<sub>2</sub> uptake and excess post oxygen consumption (EPOC) along with anaerobic glycolytic ATP turnover. Scott et al. (2006) used and critically discussed these measurements to determine EE for a single brief bout of high intensity intervals. However the problems emerging with the used of these parameters might be even bigger when estimating the EE of several bouts of high intensive work due to the estimation of anaerobic EE from  $\Delta$ blood lactate levels. The aim of the present study was to compare the anaerobic and total EE calculated by different methods. Methods: Nine healthy competitive young cyclists took part in this study (14.4  $\pm$  1.1 years; VO<sub>2peak</sub>: 59.6  $\pm$  9.1 mL\*kg<sup>-1</sup>\*min<sup>-1</sup>; peak power output (PPO): 4.2  $\pm$  0.5 W\*kg<sup>-1</sup>). The high intensity training consisted of 4x4 min intervals at 90-95 % PPO separated by 3 min of active rest. Capillary blood from the earlobe was collected for the analyses of blood lactate pre, post warming-up (WU) and after each 4 min exercise bout. O<sub>2</sub> consumption was recorded continuously during the exercise. Aerobic, anaerobic EE and EPOC were calculated according to Scott et al. (2006).  $\Delta$ blood lactate was obtained by a) subtracting WU lactate from peak interval lactate concentration, b) subtracting the previous interval lactate from peak interval lactate, c) treating  $\Delta$ blood lactate obtained the first interval as representative for all intervals. In addition, EE of the first interval was multiplied by 4 (d). Results: Total energy expenditure was a) 1824  $\pm$  512 kJ, b) 1752  $\pm$  522 kJ, c) 1781  $\pm$  531 kJ and d) 1801  $\pm$  564 kJ. Significant differences were found between method a) and b). Based on a total work 334  $\pm$  73 kJ, average cycling efficiency was between 18.3% (b) and 19.1% (a). Conclusion: For estimating EE for repeated bouts of high intensity intervals it is possible to treat the first interval as representative for total EE. Even though there are significant differences between a) and b), these differences (72 kJ) are clinically not relevant. References: Scott, C.B. (2006). Estimating energy expenditure for brief bouts of exercise with acute recovery. *Appl. Physiol. Nutr. Metab.* 31: 144-149

## ENHANCEMENT OF POWER IN TAKE-OFF PHASE OF JUMPS ON FIRM AND FOAM SURFACE

Zemková, E., Vilman, T., Jelen, M., Hamar, D.

*Faculty of Physical Education and Sport, Comenius University*

Introduction It has been shown that activation of stretch-shortening cycle (SSC) during countermovement jump (CMJ) enhances power production in concentric phase as compared to squat jump (SJ). Such an enhancement of power in take-off phase of CMJ may be ascribed to utilization of energy accumulated in elastic tissues due to increase of braking force during eccentric phase. To some extent it may be also attributed to activation of stretch reflex by stimulation of proprioceptors by rapid increase of force in eccentric phase. However, it is unknown whether this enhancing effect is influenced by stability of support base. Therefore, the study compares the difference in peak power in take-off phase of CMJ and SJ on firm and foam surface. Methods A group of 34 physical education students (age 20.8  $\pm$  2.1 y, height 187.6  $\pm$  7.5 cm, weight 86.7  $\pm$  9.2 kg) performed in random order CMJ and SJ on force platform and on foam (Airex Balance Pad) placed on force platform, respectively. The strain gauge force platform (FITRONiC s.r.o., SK) with electronics, 12 bit AD convertor and software was used. Analytical software module was used for calculation of acceleration, velocity, vertical center of mass displacement, and power from force-time curve. Vertical force applied to the plate includes weight (product of body mass and gravitational constant) and inertia component (product of body mass and vertical acceleration). As a parameter of the capability to utilize elastic energy, the difference in peak power in take-off phase of CMJ and SJ was considered. Results Peak power in take-off phase of CMJ was significantly ( $p < .05$ ) higher on firm than on foam surface (1923.3  $\pm$  208.7 W and 1793.7  $\pm$  191.4 W, respectively). On the other hand, there were no significant differences in peak power in take-off phase of SJ on firm and foam surface (1710.7  $\pm$  143.1 W and 1635.7  $\pm$  117.8 W, respectively). Consequently, the difference in peak power between CMJ and SJ was significantly ( $p < .05$ ) higher on firm than on foam surface (212.6  $\pm$  39.2 W and 158.0  $\pm$  31.2 W, respectively). Further analysis showed that subjects produced significantly ( $p < .05$ ) higher peak force during CMJ on firm than on foam surface (4160.3  $\pm$  324.7 N and 3892.0  $\pm$  317.8 N, respectively) at maximal velocity of 2.9  $\pm$  0.08 m/s and 2.8  $\pm$  0.06 m/s, respectively. Discussion These results showed that the enhancement of power in concentric phase of jump due to CM is greater on firm than on foam surface. Similar finding has been shown in beach volleyball players during jumps on stable support base and unstable sand (Zemková et al., 2011). Taken this fact into account, in some sports such measurement of take-off power in jump under unstable conditions may provide additional information on force-velocity characteristics and may complement existing methods. ## POWER PRODUCTION IN CONCENTRIC PHASE OF SQUATS ON UNSTABLE SURFACE AT DIFFERENT RANGES OF MOTION

Zemková, E., Hamar, D.

*Faculty of Physical Education and Sport, Comenius University*

Introduction It has been reported (Escamilla, 2001) that peak quadriceps EMG activity occurring at approximately 80-90° of knee flexion. Quadriceps activity remained fairly constant beyond 80-90° of knee flexion, hence descending beyond 90° flexion, may not enhance quadriceps strength. Therefore, practitioners are instructed to begin the up-phase once the upper leg is at a position parallel to the ground. Furthermore, the load of 80% of the maximum muscular strength is required for its enhancement in trained individuals (Kraemer et al., 2002). However, these requirements might not be met during instability resistance exercises. Full barbell squats on unstable support base are rather difficult to perform for subjects without experience in instability resistance training. Using higher weights during squats on Bosu ball may also lead to anxiety of falling, which might compromise the proper technique of movement. It has been suggested that velocity and range of motion (ROM) might be affected to an even greater degree than force by an unstable platform. Drinkwater et al. (2007) have found meaningful effect sizes when evaluating squat-depth changes moving from stable (floor) to unstable (foam and Bosu ball) conditions at most resistances. This study compares mean power in concentric phase of squats on Bosu ball at a knee angle of 90° and 135° while lifting different weights. Methods A group of 23 PE students (age 21.4 $\pm$ 1.8 y, height 176.9 $\pm$ 8.1 cm, weight

78.0±9.6 kg) performed in random order 3 reps of barbell squats on Bosu ball while lifting 40%, 60%, and 80% 1RM, respectively. Squats were performed from full extension to a knee angle of 90° or 135° using maximal effort in concentric phase of lifting. Since the depth of squats was determined from visual inspection, only trials with vertical range of 0.55-0.60 m and 0.35-0.40 m has been taken for the evaluation. A PC based system FITRO Dyne Premium was used to monitor force and velocity and to calculate power. Results There were no significant differences in mean power in concentric phase of squats with 40% 1RM at 90° and 135° of knee flexion (322.4±42.7 W and 305.5±41.4 W, respectively). Similarly, its values did not differ significantly during squats with 60% 1RM at 90° and 135° of knee flexion (394.6±45.8 W and 364.5±43.1 W, respectively). However, mean power in concentric phase of squats with 80% 1RM was significantly ( $p < .05$ ) lower at 90° than at 135° of knee flexion (429.4±50.2 W and 507.5±59.1 W, respectively). Discussion Power in concentric phase of squats on unstable Bosu ball was more profoundly compromised at knee angle of 90° than at 135°, however, only at higher weight lifted (80% 1RM). To avoid this drawback, smaller ROM when using higher weights or lower weights when exercising at greater ROM should be preferred. References Drinkwater et al. (2007). *Int J Sports Physiol Perform*, 2: 400-13 Escamilla R (2001). *Med Sci Sports Exerc*, 33: 127-41 Kraemer WJ et al. (2002). *Med Sci Sport Exerc*, 32: 364-80

## ACCURACY OF THE T2MINUTE METHOD FOR MEASURING ELITE ROWING TRAINING

Tran, J.I., Main, L.C.I., Rice, A.J.2, Gastin, P.B.1

1: Deakin University (Melbourne, Australia); 2: Australian Institute of Sport (Canberra, Australia).

Introduction Elite rowers undertake a combination of rowing-specific and non-specific modes of training, incorporating bouts of continuous and interval efforts, and low- and high-intensity work (Steinacker 1993). However, current training load measures are not suitable for measuring load in certain modes and intensities, e.g., heart rate monitoring is not valid during intermittent work (Achten & Jeukendrup 2003). To address these limitations, the T2minute method was developed to quantify rowing training loads. The method incorporates a modal weighting factor to account for differences in load imposed by training in various modes. The measure also includes intensity weighting factors based upon intensity zones standardised by the Australian Institute of Sport. The purpose of this study was to examine the accuracy of the T2minute method for quantifying elite rowing training loads, by comparing the method to Banister's TRIMP (Banister et al. 1975) and the Session-Rating of Perceived Exertion method (S-RPE; Foster et al. 2001) as criterion measures. Methods Fourteen elite Australian rowers (12 males, 2 females) participated in this study. Training load data was collected from 4 weeks of routine training. Athletes completed varied training, including rowing-specific (on-water and ergometer rowing) and non-specific sessions (cycling, running, swimming). Spearman's correlation coefficients ( $\rho$ ) with 90% confidence limits [CL] were calculated to examine the relationship between the criterion measures and the T2minute method. Inferences were drawn from effect sizes, calculated from the correlation coefficients. Results A strong correlation was observed between the T2minute and Banister's TRIMP ( $\rho \pm 90\% \text{ CL} = 0.59 \pm 0.43$ ,  $p < 0.05$ ). A moderate correlation was observed between the T2minute and S-RPE ( $\rho \pm 90\% \text{ CL} = 0.42 \pm 0.41$ ,  $p < 0.05$ ). The true effect was likely positive for both comparisons (92.1% likely for T2minute vs. Banister's TRIMP; 86.4% likely for T2minute vs. S-RPE). Discussion The T2minute method is sufficiently accurate for field measurement of elite rowing training loads from varied training. This method improves upon existing measures, providing a novel means to measure overall training and sessions of variable intensities. Future research should focus on incorporating the measurement of strength training loads, and on examining the method's applicability to other sports. References Achten, J., Jeukendrup, A. ## TRUNK AND KNEE MUSCLE PERFORMANCE OF ROWERS

Grosdent, S., Demoulin, C., Gauthier, S., Croisier, J.L., Vanderthommen, M., Crielaard, J.M.

University of Liege

Purpose: The aim of this study was to assess trunk extensor and limb muscular performance of rowers. Methods: 12 rowers involved in national or international competitions (male, mean age  $22.8 \pm 8.5$  years, weight  $74.0 \pm 7.6$  kg, height  $181.4 \pm 6.0$  cm), 12 non-rowing athletes (male, mean age  $21.4 \pm 2.6$  years, weight  $70.7 \pm 6.7$  kg, height  $179.8 \pm 6.4$  cm) and 12 healthy sedentary males (mean age  $22.6 \pm 1.9$  years, weight  $71.6 \pm 7.7$  kg, height  $177.8 \pm 6.0$  cm) were included in the study. Trunk extensor performances were assessed by means of a maximum static strength test [consisting in maximal voluntary contractions (MVC)] and a dynamic endurance test [consisting in performing as much flexion-extension movements as possible using a load corresponding to 40 percent of MVC test] performed with a specific trunk dynamometer (David International Ltd., Vantaa, Finland). Moreover, a static endurance test [modified Sorensen test] was also performed. Knee flexors and extensors strength peak torques (PT) of the dominant leg were assessed, using a Cybex Norm dynamometer (Henley Healthcare, Sugar Land, Texas), at 60°/s and 240°/s in concentric and 30°/s in eccentric exertions. Muscle fatigue resistance was also measured (30 maximal concentric contractions at 180°/s). Results: Regarding trunk muscle performance, rowers had significant higher PT than sedentary males ( $P < .01$ ) and non-rowing athletes ( $P < .05$ ). By contrast, static and dynamic endurance did not differ between groups. However, during the dynamic endurance test, rowers moved a total load (number of repetitions accomplished x load) significantly higher than control subjects ( $P < .05$ ). Regarding knee muscles, rowers had higher extensors concentric PT at 60°/s ( $P < .05$ ) and flexors total work at 180°/s ( $P < .05$ ) than sedentary males. In contrast, no difference was shown between groups regarding flexors strength and agonists/antagonists ratios. Conclusion: This study showed some difference in trunk and knee extensors strength between rowers and control subjects as well as between rowers and non-rowing athletes. The increased performances of extensor muscles in elite rowers appear to be probably related to the specificity of this sport. In the drive phase of rowing, rowers sequentially push with the legs and then pull with the arms and lower back, requiring both muscular strength and endurance. However, no difference was shown between groups regarding dynamic and static trunk extensor endurance. Further study is required to clarify if trunk and knee muscle strength and/or endurance are related to rowing performance.

## EFFECT OF STAGE DURATION ON PHYSIOLOGICAL RESPONSES AT FIXED AND MODELLED PLASMA LACTATE MARKERS DURING INCREMENTAL TREADMILL RUNNING

Gavin, J.P., Myers, S.D., Clements, R.E., Willems, M.E.T.

University of Chichester

Introduction Incremental exercise with measurement of physiological responses at workloads equivalent to lactate threshold (LT) can be used to estimate training adaptation and endurance performance. Incremental protocol design has been extensively reviewed (Beniley et

al., 2007), yet the effect of stage duration on physiological responses corresponding to speeds at plasma lactate markers for incremental running of 4- and 8-min stages has not. Methods Fifteen men ( $23 \pm 4$  yr,  $178 \pm 5$  cm,  $73 \pm 11$  kg) performed repeat treadmill running trials of 4- and 8-min stages at a 1% gradient. Running commenced at  $8 \text{ km} \cdot \text{h}^{-1}$  with an incrementation rate of  $1 \text{ km} \cdot \text{h}^{-1}$ . Breath-by-breath oxygen uptake (VO<sub>2</sub>), and heart rate (HR) (Cosmed K4b2, Italy) were recorded for the final 30s of each stage with ratings of perceived exertion (RPE) and plasma lactate. Fingertip blood samples were analysed for plasma lactate (2300 STAT Plus™, YSI Life Sciences, USA) and analysis software (Newell et al., 2007) used to derive treadmill speed, HR, VO<sub>2</sub> and RPE at the markers: fixed 4.0 mmol.L<sup>-1</sup>, the initial 1 mmol.L<sup>-1</sup> rise, Dmax, LT and log-log LT. Differences between 4- and 8-min stages were analysed by paired samples t-tests. One-way repeated measures ANOVA with pairwise comparisons was used to assess mean plasma lactate and VO<sub>2</sub> for 4-min, 4-min at 8-min, and 8-min stages. Results Mean maximal running speed was faster for 4-min ( $14.4 \text{ km} \cdot \text{h}^{-1}$ ), in comparison to 8-min stages ( $12.6 \text{ km} \cdot \text{h}^{-1}$ ) ( $P=0.001$ ). There was no effect of stage duration on speed, HR, VO<sub>2</sub> and RPE at fixed lactate markers ( $P>0.05$ ). For 8-min stages, the treadmill speed was lower at modelled markers: Dmax, ( $-1.1 \text{ km} \cdot \text{h}^{-1}$ ;  $P=0.001$ ), LT ( $-0.9 \text{ km} \cdot \text{h}^{-1}$ ;  $P=0.008$ ) and log-log LT ( $-0.8 \text{ km} \cdot \text{h}^{-1}$ ;  $P=0.006$ ), yet RPE was higher and VO<sub>2</sub> lower for LT ( $1.1$ ,  $P=0.023$ ;  $-270.7 \text{ mL} \cdot \text{min}^{-1}$ ,  $P=0.013$ ) and log-log LT ( $1.4$ ,  $P=0.027$ ;  $-293.3 \text{ mL} \cdot \text{min}^{-1}$ ,  $P=0.002$ ). Mean plasma lactate and VO<sub>2</sub> were greater at  $8 \text{ km} \cdot \text{h}^{-1}$  for 4-min ( $P=0.008$ ), then similar until  $11 \text{ km} \cdot \text{h}^{-1}$  for 4- and 8-min stages ( $P=0.05$ ). At subsequent speeds, there was a trend towards higher plasma lactate concentrations for 4-min, in comparison to 8-min stages. Discussion These findings suggest that incremental treadmill running tests using stage durations of 8-min have the effect of reducing the speed, but increasing the perception of exercise intensity at the LT and log-log LT. When assessing physiological responses for incremental treadmill running, the use of these markers with protocols of longer stage duration may underestimate marker running speed. ### EFFECTS OF LONG-TERM MILITARY FIELD TRAINING ON THE PHYSICAL PERFORMANCE OF CONSCRIPTS ON THE EXAMPLE OF A UNIT IN THE ESTONIAN ARMY

ANTSON, H., MÄRK, H.

*Tallinn University, Estonian Defence Forces*

Introduction Several studies indicate that the end of the soldiers' basic training course is the break-point in the progress of freshmen physical performance. The period following it is dedicated to practising specific military skills and knowhow not only in the habitual barracks environment but also in outdoor conditions. Conscripts' physical performance and fitness standard is especially influenced by long-term field training (with the duration of a week or more). Predominantly, body mass and waist circumference of the recruits have a tendency to shift upwards quite quickly. Therefore, soldiers' endurance and strength indicators cannot be maintained in accordance with the requirements of physical fitness test (PFT) any more. The current follow-up study continues the recent research among conscripts. The paper aims at eliciting influence of one-week military field training on comparative body mass and waist circumference and on conscripts' physical performance. Methods 727 male conscripts at the start of service in 2010 (mean age 21.5) participated in the study of the training cycle in years 2010-2011. Individual PFT (was taken before and after one-week field training period) results as well as their body measurement records were collected and stored in the data base and analyzed. Results The current study revealed the fact that both body mass and waist circumference of a significant number of conscripts tended to expand during the period of military field training. The rise of BMI is related either to the growth of muscle mass (then, waist circumference is not increasing) or the progression of fat mass (in that instance, waist circumference is increasing). Individuals' mean body mass increment was 3-5 % throughout a week. The decline in average 3.2-mile run results was 10-15 %. Discussion The field training period is characterized by irregular activities and outdoor nutrition regime without comfort. All major factors – health, weather, eating, ground difficulties etc – influence any conscript in the field over a week. The other key causes for the rise in conscripts' body mass are related to increased consumption of high calorie and nutrient-poor packed food and the method of cooking. There is an indirect evidence that the long-term absence of ordinary military environment may cause mental and bodily stress, which influences recruits' physical performance indicators (stamina, strength) towards decrease. Such trend might impose an unwanted influence on the conscripts' defence capacity and deployability during allied missions or war time. It is important, according to the present investigation, that field instructors should encourage conscripts to do appropriate relaxation exercises during training as well as during recreation time.

### INFLUENCE OF IVO<sub>2</sub>MAX DETERMINATION ON TIME SPENT AT VO<sub>2</sub>MAX DURING CONTINUOUS CYCLING TO EXHAUSTION

Merry, K.L.

*Loughborough College of Higher Education*

INFLUENCE OF IVO<sub>2</sub>MAX DETERMINATION ON TIME SPENT AT VO<sub>2</sub>MAX DURING CONTINUOUS CYCLING TO EXHAUSTION Merry, K.L.1, Glaister, M.2, Howatson, G.3, Van Someren, K.4 1: Loughborough College (Loughborough,UK), 2: St Mary's University College, (Twickenham,UK), 3: Northumbria University, (Newcastle Upon Tyne, UK), 4: English Institute of Sport, (Twickenham, UK) Introduction The minimal exercise intensity that elicits VO<sub>2</sub>max during a maximal incremental test (iVO<sub>2</sub>max) may allow the longest time spent at a high VO<sub>2</sub> ( $\geq 95\%$  VO<sub>2</sub>max) during continuous exercise to exhaustion (Billat et al., 1999). The purpose of this study was to compare the time to exhaustion (TTE) and time spent at a high level of oxygen uptake (VO<sub>2</sub>) during two continuous cycle ergometer exercises to exhaustion at iVO<sub>2</sub>max Methods Nine male triathletes (age  $31.6 \pm 10.2$  years, body mass  $73.3 \pm 6.1$  kg, height  $1.79 \pm 0.07$  m, VO<sub>2</sub>max  $3.52 \pm 0.49 \text{ L} \cdot \text{min}^{-1}$ ) attended the laboratory on four separate occasions over a period of 4 weeks. During trials 1 and 2, in a random order, participants performed two maximal incremental cycle ergometer tests with different stage durations (1 min and 3 min) for the determination of iVO<sub>2</sub>max(1 min) and iVO<sub>2</sub>max(3 min). During visits 3 and 4, participants performed two continuous cycles to exhaustion at iVO<sub>2</sub>max(1 min) (CONT1) and iVO<sub>2</sub>max(3 min) (CONT3) also in a random order. Results iVO<sub>2</sub>max(1 min) was significantly greater ( $P < 0.05$ ) than iVO<sub>2</sub>max(3 min) ( $337 \pm 36 \text{ W}$  vs.  $292 \pm 43 \text{ W}$ ) ( $P < 0.05$ ). There was no significant difference ( $P > 0.05$ ) between iVO<sub>2</sub>max(1 min) and iVO<sub>2</sub>max(3 min) for VO<sub>2</sub>max ( $3.59 \pm 0.48 \text{ L} \cdot \text{min}^{-1}$  vs.  $3.52 \pm 0.51 \text{ L} \cdot \text{min}^{-1}$ ). The mean TTE measured during CONT3 was significantly longer ( $P < 0.05$ ) than CONT1 ( $511.7 \pm 189.2 \text{ s}$  vs.  $224.9 \pm 54.2 \text{ s}$ ). The mean time spent at VO<sub>2</sub>max (T@VO<sub>2</sub>max) was significantly longer ( $P < 0.05$ ) during CONT3 than CONT1 ( $199.3 \pm 220.0 \text{ s}$  vs.  $11.6 \pm 26.8 \text{ s}$ ), and the mean time spent above 95% VO<sub>2</sub>max (T@95%VO<sub>2</sub>max) was significantly longer ( $P < 0.05$ ) during CONT3 than CONT1 ( $306.4 \pm 238.0 \text{ s}$  vs.  $64.3 \pm 61.2 \text{ s}$ ). Discussion In conclusion, these results show that when exercising continuously to exhaustion at iVO<sub>2</sub>max time spent at a high level of VO<sub>2</sub> is significantly longer when iVO<sub>2</sub>max(3 min) is used to determine iVO<sub>2</sub>max References Billat, V.L., Blondel, N., and Berthoin, S. (1999). *Eur J Appl Physiol*, 80, 159-161.

**EFFECT OF POLAR TRAINING LOAD-GUIDED VERSUS NON-GUIDED TRAINING IN RUNNERS**

Bruch, A., Kinnunen, H., Stapelfeldt, B.

*Albert-Ludwigs-Universität Freiburg*

Introduction Practical methods to quantify the individual training dose of an athlete have been studied earlier (1). Polar Training Load (TL) feature (Polar Electro Oy, Finland) aims at determining the balance between training and recovery. Input information for TL are gender, weight, VO<sub>2</sub>max, HRmax, HRrest, lactate threshold (LT), and anaerobic threshold (IAT). The training software (PPT.com) guides daily training based on individual cumulative TL values (CTL) with a colour based system (green, yellow, red). The purpose of this study was to quantify the effects of TL guidance and performance parameters among regularly training runners. Methods 24 male runners were randomised into a study group (PPT.com) and a control group (PPT). The average VO<sub>2</sub>max was 59 ml/min/kg in PPT.com group and 61 ml/min/kg in PPT group. Average weekly training time before the study was 7 h in both groups. The training was followed up for 8 weeks. PPT.com group trained with TL guidance and PPT group without guidance. At the beginning and end of the study a standardized incremental maximal exercise test was performed on a treadmill (h/p/cosmos sports & medical GmbH, Germany) with respiratory gas analysis. Test measurements included LT, IAT and VO<sub>2</sub>max. One subject was left out the analysis due to training data loss. Results Both groups trained 8.4 h/week, PPT.com with an average HR of 135 bpm, PPT group with an average HR of 133 bpm. Average CTL values before a training session were 43 and 60 in PPT.com and PPT groups, respectively, indicating a tendency towards better recovery status in PPT.com group when starting an exercise session ( $p = 0.08$ ). No differences were found in any other CTL values. Lab-tests showed no significant differences between groups in any performance markers. Discussion In runners who had been training 7 h weekly, users of TL feature didn't train differently compared to non-users. In contrast to this, a previous study (2) showed significant changes in training among cyclists who trained 15 h weekly. One reason for the present finding may be that most runners did not train too extensively in terms of TL parameters: even without using the TL feature their own training routines did not include high intensity sessions with poor recovery status. Additionally, three subjects in PPT.com group did not adapt their training according to the TL-rules which underlines the importance of personal motivation factors. References 1 BANISTER E.W., et al. (1992): Dose/Response Effects of Exercise Modelled from Training: Physical and Biochemical Measures. *Ann. Physiol. Anthropol.*; 11(3): 345-356. 2 BRUCH, A.; KINNUNEN, H.; STAPELFELDT, B. **EFFECTS OF COMPRESSION SOCKS ON PAIN AND PERIPHERAL RESPONSES DURING AND FOLLOWING MARATHON RUNNING**

Babault, N.1, Deley, G.1, Gardon-Mollard, C.2, Benigni, J.P.2, Allaert, F.A.3

*Université de Bourgogne*

EFFECTS OF COMPRESSION SOCKS ON PAIN AND PERIPHERAL RESPONSES DURING AND FOLLOWING MARATHON RUNNING. Babault, N.1, Deley, G.1, Gardon-Mollard, C.2, Benigni JP.2, Allaert, FA.3 1: CEP (Dijon, France), 2: Phlebologists (France), 3: CEN (Dijon, France) Introduction Compression garments are now commonly used by athletes during training and competitions to delay fatigue, reduce pain during efforts (Chatard et al., 2004) and also to optimise recovery (Kraemer et al., 2001). They may favour peripheral circulation, blood flow return and therefore decrease metabolic toxin stasis. If many athletes regularly reported these effects, few data are available concerning their effects during marathon runs. Therefore this study aimed to assess the effects of wearing class II elastic socks (18-21 mmHg) on subjective ratings and peripheral circulation when applied during marathon runs. Methods This study was conducted during the "Marathon de Paris". Eighty-six comparable subjects (i.e., males/females proportion, marathon performance, body mass index, internal gastrocnemius vein diameter) were considered in this study ( $n = 43$  in each group). Their mean age  $\pm$  SD were  $43 \pm 8$  years old and none reported any venous insufficiency. Compression socks (18-21mmHg) were proposed to marathoner who accepted to wear them during the race (Compression Sock Group CSG) and compared to a control group who did not wear them (Control Group CG). Marathoners had a Doppler examination before and after the race and described their feeling at the end of the race and during the 4 following days using a visual analogic scale (from 0 to 100). Results At the end of the race and compared to CG, the CSG group described lower muscular pain  $33 \pm 25$  vs.  $49 \pm 28$  ( $p < 0.01$ ), lower muscular leg tiredness  $44 \pm 21$  vs.  $57 \pm 25$  ( $p < 0.01$ ) and lower leg swelling  $9 \pm 18$  vs.  $18 \pm 22$  ( $p < 0.01$ ). The diameter of the internal gastrocnemius vein was also lower  $5.1 \pm 1.4$  mm vs.  $5.7 \pm 1.5$  mm ( $p < 0.05$ ). While pain decrease was comparable during the 4 following days, recovery of muscular leg tiredness was significantly improved in the CSG group ( $p < 0.01$ ). Discussion These results clearly demonstrate the positive effects of wearing elastic compression socks during long duration efforts. The pain reduction during the marathon may reduce the risk of a premature stop and may contribute to the last supplementary effort at the end of the race. The additional positive effects on the recovery kinetic is also important for the runners' comfort and especially in elite athletes which may have to practice frequently with short recovery delays. In conclusion, wearing compression socks may contribute to increase muscular adaptation and recovery. References Chatard JC, Aïlaoui D, Farjanel J, Louisy F, Rastel D, Guezennec CY. (2004). *Eur J Appl Physiol*, 93, 347-352. Kraemer WJ, Bush JA, Wickham RB, Denegar CR, Gomez AL, Gotshalk LA, Duncan ND, Volek JS, Putukian M. (2001). *J Orthop Sports Phys Ther*, 31, 282-290.

**14:45 - 15:45****Poster presentations****PP-PM73 Physiology 19****RECOVERY KINETICS IN SOCCER GOALKEEPERS AND FIELD PLAYERS**

Nédélec, M.1, Berthoin, S.1, Dupont, G.1

*1: Université Lille Nord de France, UDSL, EA 4488, Lille, France*

Introduction During a soccer match, goalkeepers and field players perform running activities and actions leading to muscle damage which may impair physical performance (Byrne et al., 2004). In addition, a soccer match induces mental activities for both goalkeepers

and field players (Williams, 2000), and mental fatigue has been shown to reduce physical performance (Marcora et al., 2009). The purpose of this study was to analyze the recovery kinetics of physical and cognitive performance, as well as subjective ratings in goalkeepers and field players after a soccer match. Methods Eight goalkeepers (age:  $18.5 \pm 2.5$  yr; height:  $182.3 \pm 4.6$  cm; body mass:  $75.9 \pm 8.8$  kg) and eight elite field players ( $17.1 \pm 0.9$  yr;  $180.9 \pm 5.8$  cm;  $70.5 \pm 6.8$  kg) were tested immediately, 24 and 48h after a soccer match. The battery of test included squat jump (SJ) and countermovement jump (CMJ) on a force plate; mean power output (MPO) and mean speed (MS) during a 6-s sprint on a non-motorised treadmill; reaction and motor time during Vienna Reaction Test; number of stimuli, correct responses, incorrect responses and omitted responses during Vienna Determination Test; perceived level of recovery rating. Results Squat Jump and CMJ were both significantly ( $p < 0.01$ ) decreased 24h after the match, while only CMJ remained significantly ( $p < 0.05$ ) lower 48h after the match. Mean power output and MS showed no change ( $p > 0.05$ ) for goalkeepers throughout the protocol whereas MPO and MS were significantly altered for field players immediately after the match ( $p < 0.01$ ). No significant interaction was found for other variables between position and time ( $p > 0.05$ ). There was a main effect of time ( $p < 0.05$ ) for fatigue and muscle soreness. Fatigue increased immediately ( $p < 0.001$ ) and 24h after the match ( $p < 0.05$ ), whereas muscle soreness was increased immediately after the match only ( $p < 0.05$ ). Discussion A significant decrease in sprint was found only for field players. The different running profile of goalkeepers compared to field players (Rampinini et al., 2007; Di Salvo et al., 2008) could explain this finding. The decrement in jumps found in both goalkeepers and field players could be explained by activities leading to muscle damage (diving, tackling, changes of direction, jumps, deceleration). Results from the tests assessing some aspects of cognitive function did not show any change in goalkeepers and field players after a match. ### MUSCLE RECOVERY TIME FROM EXHAUSTIVE WORK IN THE HEAT

Oksa, J., Rissanen, S., Mäkinen, T., Hyrkäs, H., Lusa, S., Lindholm, H., Rintamäki, H.

*Finnish Institute of Occupational Health, Oulu*

Introduction Insufficient recovery time from work may lead to a state of cumulative muscle fatigue which may be regarded as a precursor for musculoskeletal symptoms and disorders. The purpose of this study was to evaluate the time needed for wrist flexor muscles to recover from heavy work in the heat. Methods Fifteen voluntary firefighters participated in the study. They performed three 15 minute work bouts at  $35^{\circ}\text{C}$  (separated with 10 minute break at  $20^{\circ}\text{C}$ ). The work simulated smoke diving and clearance work and induced significant fatigue to wrist flexors. At baseline and at each time point maximal wrist flexion force and muscle tissue reoxygenation rate were measured. Recovery from fatigue was followed at 0, 20, 40, 60 minutes and 2, 4, 22 and 30 hours after cessation of work. Results Muscle reoxygenation rate had two recovery peaks, first occurring after 2 and second after 22 hours. Maximal wrist flexion force recovered after 4 hours but force production velocity did not recover during the 30 hour follow-up. Discussion In conclusion, muscle recovery time from heavy work in the heat is different depending on the measured parameter and may be longer than time between consecutive work days.

### THE EFFECT OF THREE DIFFERENT RECOVERY METHODS ON CYCLE PERFORMANCE IN THE HEAT

De Pauw, K., Roelands, B., Meeusen, R.

*Vrije Universiteit Brussel*

Introduction/purpose: Although the scientific information on recovery and cycle performance is abundant, little is known about the influence of recovery between consecutive cycle performances in the heat. Therefore the aim of this study is to determine the influence of active recovery (AR), passive rest (PR) and cold water immersion (CWI) on repeated simulated time trial performance in the heat. Methods: Nine trained male subjects (age:  $22.7 \pm 3.4$  yrs;  $\text{VO}_{2\text{max}}$ :  $62.1 \pm 5.3$  ml.min<sup>-1</sup>.kg<sup>-1</sup>) participated in this randomized crossover study, and they performed a max test, familiarization trial and 3 experimental trials interspersed by a 6-d rest period. Each trial consisted of two cycle performances in a warm environment ( $30^{\circ}\text{C}$ ; 45-55%) separated by one hour. The first cycle performance included a 60 min constant load trial (at 55%  $\text{W}_{\text{max}}$ ), followed by a 30 min simulated time trial (TT1). The second cycle performance comprised a 12 min simulated time trial (TT2) that started at 85%  $\text{W}_{\text{max}}$ . Immediately after TT1 AR (cycling at 80W), PR or CWI (water temperature set at  $15^{\circ}\text{C}$ , subjects immersed until sternum) was applied for 15 minutes. Outcomes: TT performance was used as primary outcome measure. Heart frequency (HF), blood lactate concentration [BLa], rating of perceived exertion (RPE), thermal comfort (TC), rectal temperature (T<sub>rect</sub>) and skin temperatures (T<sub>skin</sub>) were measured. Results: Compared to PR ( $13.23 \pm 1.25$  min) and AR ( $13.27 \pm 1.05$  min), CWI ( $12.71 \pm 0.71$  min) resulted in a 30 seconds faster TT2. It is noteworthy that after CWI [BLa] was significantly higher during TT2 compared to PR at 6 min ( $p = 0.011$ ), and compared to PR and AR at 9 min ( $p = 0.021$ ,  $p = 0.044$  respectively). HF on the other hand was significantly lower compared to AR at 0 min ( $p = 0.000$ ) and 3 min ( $p = 0.002$ ), and compared to PR at 0 min ( $p = 0.000$ ) and 6 min ( $p = 0.038$ ). CWI significantly reduced T<sub>rect</sub> and T<sub>skin</sub> during the recovery period and lower T<sub>rect</sub> and T<sub>skin</sub> were sustained during rest and TT2. Discussion/Conclusion: In a previous study from our lab (De Pauw et al, 2011) we observed no differences in a second cycle performance after applying different recovery interventions (PR, upper leg cooling, AR, AR + upper leg cooling). An interesting finding was the faster decrease of [BLa] during AR combined with upper leg cooling ( $15^{\circ}\text{C}$ ). In this study we immersed subjects until the chest and found better TT2 performance that can be contributed to an increased heat storage capacity. Subjects performed better during TT2 with a lower HF and a higher [BLa]. Thus, the present study provides evidence for the ergogenic effect of CWI as a recovery intervention between two exercise bouts in the heat. Effect of five different recovery methods on repeated cycle performance. *Med Sci Sports Exerc* 2011; 43(5): 890-897.

### NOVEL COMPRESSION STOCKINGS INCREASE TISSUE RE-OXYGENATION IN RECOVERY BOUTS DURING PROGRESSIVE INCREMENTAL EXERCISE

Hunter, S., James, D.C., Mileva, K.N.

*London South Bank University*

Introduction Investigations have shown equivocal benefits of wearing graduated compression garments for exercise performance (Sperlich et al 2010; Ali et al 2011; Menetrier et al 2011). New technology incorporated into compression stocking design has been developed. Therefore, the aim of the present investigation was to evaluate its effect on parameters relating to cardiorespiratory and lower limb tissue oxygenation indices during progressive incremental exercise. Method Twelve club runners participated in a 2-trial randomized protocol consisting of 5-stages (4.5min, 30s recovery) of incremental (1km/h) treadmill running (1% incline) wearing either compression

stockings (STO) or commercially available (PLAC) garments under standard football socks. Standard cardiorespiratory measures ( $\dot{V}O_2$ , HR, [BLa-]) were taken in parallel with continuous records of tissue haemoglobin indices (THI, TOI, HbO<sub>2</sub>, HHb) from the calf and the thigh using near-infrared spectroscopy (NIRS). The final 30s of stages corresponding to steady-state, threshold and maximal exercise, along with 30s recovery after these stages were analysed and subjected to 2-way repeated measures ANOVA corrected with Holm-Sidak post-hoc tests. An alpha level for statistical significance was set at 0.05. Results During exercise, cardiorespiratory and NIRS parameters showed significant change over time ( $p < 0.05$ ); but were not different between conditions ( $p > 0.05$ ). In the 30s recovery period between stages, significantly steeper changes in calf HHb and TOI were observed in STO ( $p < 0.05$ ) compared to PLAC, indicating faster muscle re-oxygenation during recovery. No condition effects ( $p > 0.05$ ) were observed in thigh muscle oxygenation rates. Discussion The findings of the present study demonstrate that wearing novel compression stockings during incremental intermittent exercise enhances tissue re-oxygenation during the recovery periods. This finding is in agreement with the observations of Menetrier et al. (2011) who reported increased calf tissue oxygen saturation during exercise recovery. They also support the findings of Ali et al (2011) and Sperlich et al (2010) in reporting that STO resulted in no cardiorespiratory or performance benefit during exercise. These findings merit further investigation into the effects of faster recovery tissue re-oxygenation on high intensity intermittent exercise performance. References. 1. Ali, A. et al. (2011). *J. ### EVALUATION OF HYDROTHERAPY, USING PASSIVE TESTS AND POWER TESTS, FOR RECOVERY ACROSS A CYCLIC WEEK OF COMPETITIVE RUGBY UNION

Higgins, T.

*Australian Catholic University*

Evaluation of hydrotherapy, using passive tests and power tests, for recovery across a cyclic week of competitive rugby union Trevor R. Higgins 1, Mike Climstein 1, Melaine Cameron 1, Aaron Coutts 2 1)Australian Catholic University, Australia 2)University of Technology Sydney, AUSTRALIA Introduction In team sports, a cycle of training, competition, and recovery occurs weekly during the competitive season. This research evaluates hydrotherapy for recovery from a simulated game of rugby union and a week of recovery and training. Methods Twenty-four male players (mean age 19.46 SD± 0.82, weight 82.38kg SD± 11.12, height in centimeters 178.54 SD± 5.75) were divided into three groups: one received (n=8) cold water immersion therapy, another (n=8) received contrast bath therapy, and the control group (n=8) received neither. The two forms of hydrotherapy were administered following a simulated game of rugby union. Testing was conducted one hour prior to the game and at five intervals after it: one hour, 48 hours, 72 hours, 96 hours, and 144 hours. Dependent variables included countermovement jump (CMJ), 10 and 40 meter sprints, sessional rating of perceived exertion (RPE), flexibility, thigh circumference, and delayed onset muscle soreness (DOMS). Results A significant difference in DOMS was found at 72 hours post ( $p=0.03$ ) and 96 hours post ( $p=0.04$ ) between the control and contrast bath groups, and at 48 hours post ( $p=0.02$ ) between cold water immersion and contrast bath groups. Cold water immersion and contrast baths scores for Sessional RPE showed a significant difference at time points 72 hours post and 96 hours post ( $p=0.05$ ) between the two groups. Discussion Athletes' perceptions of muscle soreness and sessional RPE scores for training were greater in the contrast bath group after the simulated game and throughout the training week. Although results from passive and power tests were inconclusive in determining whether cold water immersion or passive recovery was more effective in attenuating fatigue, they showed that contrast baths had little benefit in enhancing recovery during a cyclic week of rugby union. Trends identified through effect sizes indicated that cold water immersion offered more in attenuating the effects of fatigue when athletes' perceptions of muscle soreness and perceptions of training loads were measured. Indications are that cold water immersion offer more for players in terms of recovery from the cyclic activity of game and training associated with rugby union. References Alexiou, H. and A.J. ### EFFECT OF COLD WATER IMMERSION USED BETWEEN GAMES ON MUSCLE POWER AND BIOCHEMICAL PARAMETERS ON RUGBY PLAYERS

Takeda, M., Sato, T.1, Kawamoto, A.1, Aizawa, S.1, Kato, H.1, Suhara, Y.1, Yamaguchi, Y.2, Radak, Z.3

*Laboratory of Exercise Physiology, 1: Doshisha Univ. (Kyoto, Japan), 2: Yamaguchi Orthopedic Hospital (Kyoto, Japan), 3: Semmelweis Univ. (Budapest, Hungary)*

Introduction Recently, cold water immersion (CWI) has been used in many athletes to facilitate recovery from the fatigue after the athletic training or competition. However, despite the facts that there are some evidences demonstrating the positive effects of CWI on athletic performance (Eston, 1999; Vaile, 2008), there are pros and cons regarding the effect of CWI on athletic performance. Particularly, effect of CWI on muscle power after the athletic competition accompanied by muscle damage with severe body contact like rugby game has not been clarified. This study examined the effect of CWI used between 7th rugby simulation trainings including severe body contact on muscle power and biochemical parameters on rugby players. Methods Thirty top level of Japanese university rugby players aged 21.0 ± 1.8 years old randomly assigned to any of 3 groups, i.e. 5 minutes CWI group (5-min. CWI, n = 10), 10 minutes CWI group (10-min. CWI, n = 10) and no CWI group (control, n = 10). Seventh rugby simulation training was performed including 1 severe tackle within 20 m dash, totally 12 tackles with 1,300 m dash. Total time of this training was 16 minutes (two 7 minutes consecutive training including 2 minutes half time rest). Ten seconds maximum bicycle pedaling power, 10 m dash time, vertical jump, grip strength, reaction time, and 20 seconds side step and biochemical parameters such as lactate dehydrogenase, creatine kinase,  $\gamma$ -glutamyltranspeptidase, creatinine, sodium, chlorine, potassium, and white blood cell, and subjective fatigue were measured at pre training, post training, and post CWI with 2 hours rest. Results Analysis of variance revealed no significant deteriorated effect of 7th rugby simulation training (pre training vs post training) in all variables in all 3 groups. As to the changes from post training to post CWI, only creatinine significantly reduced from post training to post CWI in 10-min CWI (-0.138±0.041) group compared 5-min CWI (-0.097±0.041) and control (-0.075±0.037) groups. There were no significant differences in any of other variables. Discussion Although significant decrease in creatinine at post CWI in 10-min CWI group might be positive effect of CWI in 2 hours break between 7th rugby simulation training. However, our study strongly demonstrated that there no positive physiological and subjective effects of CWI used in 2 hours break time between 7th rugby games. References Eston R, Peters D. (1999). *J Sports Sci*, 13(7), 231-238. Vaile J, Halson S, Gill N, Brian D. (2008). *J Sports Sci*, 26(5), 431-440.

## THE EFFECT OF ACTIVE RECOVERY AND COLD WATER IMMERSION ON THE SUBSEQUENT KNEE EXTENSION AND FLEXION STRENGTH

Strejcova, B., Konopková, R.

*Faculty of Physical Education and Sport*

**Introduction** It is generally accepted that good recovery enables better performance and decreases the number of injuries in athletes. Athletes routinely employ post exercise strategies or practices in a bid to speed up recovery (Bleakley & Davison, 2010). Currently cold-water immersion recovery and active recovery have emerged as one of the most popular intervention enabling faster recovery. The aim of the study was to compare the effect of three kinds of recovery (active recovery, cold water immersion, passive recovery) on the medium-term knee strength in the extension and flexion. **Methods** Fourteen athletes at the age of  $26.6 \pm 4.4$  years performed, in a random cross-over design, 3 sessions with 3 repeated medium-term isokinetic tests. As active recovery we used walking for 10 minutes on the treadmill of  $5.5 \text{ km}\cdot\text{h}^{-1}$  speed and a gradient was depended on the HR to achieve 60-65% of individual HRmax. As cold water therapy the participants were immersed up to their hips in the cold bath ( $13 \pm 1^\circ\text{C}$ ) for  $3 \times 2, 5 \text{ min}$  with 2 min out of the bath, repeated twice as intermittent protocol. The effect of active recovery, passive rest and cold water immersion were assessed by the  $3 \times 3$  (time x recovery) repeated-measure ANOVA, respectively. **Results** We found significantly lower absolute differences between first and third trial in knee extension for peak torque after the active recovery ( $\uparrow 0.9 \text{ N}\cdot\text{m}$ ) than after the cold water immersion ( $\downarrow 14.6 \text{ N}\cdot\text{m}$ ) or the passive recovery ( $\downarrow 13.9 \text{ N}\cdot\text{m}$ ). The decrease of the average power was significantly lower differences after the active recovery ( $\downarrow 5 \text{ W}$ ) than after the cold water immersion ( $\downarrow 23.7 \text{ W}$ ) or passive recovery ( $\downarrow 25.9 \text{ W}$ ). Maximal heart rate (HRmax) was significantly higher during the active recovery than during the cold water immersion and the passive recovery ( $173 \pm 14, 166 \pm 14$  and  $167 \pm 14 \text{ bpm}$ ). We have found significant differences in the average heart rates (HRavg) during active recovery, cold water immersion and passive recovery ( $124 \pm 8, 97 \pm 9$  and  $107 \pm 12 \text{ bpm}$ ). **Discussion** The active recovery was the only method which showed lower decrease of knee strength in extension compared to passive recovery and cold water immersion. The fact that the current literature is not consistent in this topic is probably caused by the different localization of load and its subsequent effect on the blood circulation (Draper, Bird, Coleman, & Hodgson, 2006). **References** Bleakley, C. ## EFFECT OF COOLING DURING THE RECOVERY FROM CYCLING ON PHYSIOLOGICAL AND COGNITIVE RESPONSES.

Gaetz, M., Brandenburg, J.P.

*University of the Fraser Valley*

**Introduction** During the recovery from exercise, particularly when the time is limited (e.g. half-time), cooling strategies are utilized to accelerate the recovery of physiological variables (e.g. body temperature) and aid subsequent performance. This study examined the effects of cooling following 30 minutes of vigorous cycling on the recovery of brain function, measured using the electroencephalogram (EEG), and cognition, measured using the Stroop test. **Methods** Nine active males ( $21 \pm 3 \text{ y}$ ;  $76.9 \pm 7.7 \text{ kg}$ ;  $179.6 \pm 3.8 \text{ cm}$ ) completed two trials in a randomized order: control recovery (CTL) and cooling recovery (COOL). In each trial, subjects performed 30 min of cycling at a constant power output ( $2.4 \pm 0.2 \text{ W}\cdot\text{kg}^{-1}$ ). Following the cycling protocol subjects either received cooling (from a combination of a cooling vest, neck collar, and fan) (COOL) or received no cooling (CTL) throughout a 30-min recovery period. Heart rate (HR), core (TC) and tympanic (TTY) temperatures, Stroop test, and EEG were assessed pre- and immediately post-cycling as well as throughout the recovery period. In both trials subjects ingested water to match sweat losses while cycling. Air temperature ( $\sim 23^\circ\text{C}$ ) and humidity ( $\sim 50\%$ ) were similar in both trials. **Results** HR, TC, and TTY at the end of the 30 minutes of cycling were similar in CTL and COOL ( $165 \pm 15$  vs.  $164 \pm 17 \text{ b}\cdot\text{min}^{-1}$ ;  $38.1 \pm 0.5$  vs.  $38.1 \pm 0.4^\circ\text{C}$ ;  $37.2 \pm 0.2$  vs.  $37.2 \pm 0.3^\circ\text{C}$ , respectively) as was the change of body mass ( $-0.1 \text{ kg}$ ). During recovery, HR decreased by  $81 \pm 10$  and  $85 \pm 9 \text{ b}\cdot\text{min}^{-1}$  in CTL and COOL. TC decreased by about  $0.7 \pm 0.2^\circ\text{C}$  in both trials. TTY recovered by  $0.9 \pm 0.2^\circ\text{C}$  in CTL and  $1.0 \pm 0.3^\circ\text{C}$  in COOL. There were no differences between CTL and COOL in the degree of recovery of any of these variables. Mean blood glucose levels during recovery ( $\sim 4.8 \text{ mmol}\cdot\text{l}^{-1}$ ) were also similar between trials. No differences were observed for Stroop test variables (errors and reaction time) or EEG between CTL and COOL trials. A multivariate ANOVA did reveal differences in EEG ratios of low/high frequency over the 30-min recovery period (e.g. theta/beta1 activity  $F(2,7) = 6.74, p=0.023$ ). **Discussion** The combination of a cooling vest, cooling collar, and fan did not significantly improve the cardiovascular, thermal, or cognitive recovery from 30 min of vigorous cycling. Changes in EEG ratios of low/higher frequency activity were sensitive to, and paralleled, the changes in physiology that occurred during recovery but were not aided with the use of cooling strategies. Perhaps the degree of thermal strain during cycling was not sufficient for the cooling strategies to be effective. Alternatively, the combined cooling strategies may have been excessively cold, thus inducing peripheral vasoconstriction and blunting any potential cooling and subsequent benefits.

## PARADOXICAL EFFECT OF RESISTANCE TRAINING AND HIGH PROTEIN DIET ON PLASMA MYOSTATIN RESPONSE TO EXERCISE

Paoli, A.1, Pacelli, Q.F.1, Toniolo, L.1, Bianco, A.2, Faggian, D.3, Plebani, M.3, Reggiani, C.1

*University of Padova and University of Palermo*

**Introduction** In recent years, a mounting amount of evidence has suggested that contracting muscle can act as a cytokine producing organ that may influence metabolism (Pedersen 2010). Myostatin (MSTN) relationship with body fat amount, training status and nutrition has been widely investigated but with conflicting results. Although MSTN inhibits the Akt/mTor pathway some studies have shown also an counterintuitive positive correlation between MSTN and muscle mass (myostatin paradox). Moreover MSTN has been shown to reduce IGF-1 stimulated AKT phosphorylation in a dose-dependent manner. We investigated the influence of two months of resistance training (RT) and high protein diet on plasma myostatin, IL1, IL6, TNF- $\bullet$  and IGF-1. **Methods** Eighteen healthy volunteers participated in an upper limbs progressive resistance training. Subjects were divided in two groups: an high protein group (HP;  $1.8 \text{ g/Kg bw/day}$ , n. 9) and normal protein group (NP  $0.9 \text{ g/Kg bw/day}$ , n. 9). MSTN, IGF-1, IL1, IL6 and TNF- $\bullet$  were analyzed before and after the first training session and before and after the last training session (after 8 weeks). Lean body mass and muscle mass were analyzed through skinfolds methods, arm muscle area with MNR, strength with 1 RM test and an isometric pullgrip. ANOVA statistical analysis and linear regression were performed. **Results** MSTN showed an unexpected significant increase ( $p < 0.001$ ) after the last training in the HP group ( $\text{ng/ml}$ ) compared to NP group ( $\text{ng/ml}$ ) and to the samples taken after the first training ( $\text{ng/ml}$ ). There were no significant differences (time x treatment) in IGF-1, IL1, IL6 and TNF- $\bullet$ . Interestingly IGF-1 showed a positive correlation with MSTN in HP after the last training ( $r^2=0.6456$ ;  $p=0.0295$ ). No

correlation were found with other blood parameters nor with muscle mass and muscle strength changes. Moreover no significant differences were found between treatment group in strength performance and muscle mass. Conclusions Taken together this findings indicate a "paradoxical" response of plasma myostatin to high protein diet after 8 weeks of RT. It is noteworthy that IGF-1 which activity is down regulated by MSNT is increased in HP group after the last training and it correlates significantly with MSNT increase. This double increase of opposite mediators could explain the substantial overlapping of muscle mass increases in the two groups. We can argue that high protein diet influence metabolic regulation of IGF-1 and MSNT upstream the same pathway. Our findings are not in agreement with those of Hulmi et al (2009) that found a decrease in MSNT with protein ingestion whilst instead are in line with those of Dalbo et al (2011) that found a paradoxical MSNT response to RT in older individuals compared to younger individuals. Taken together this data show a complex and not yet well understood MSNT release mechanism. More studies are needed to explain this paradoxical response to nutrition and RT exploring also muscle signalling molecules as mTor and Akt.

### EFFECT OF RESISTANCE TRAINING UNDER SYSTEMIC HYPOXIA ON GENE EXPRESSIONS IN HUMAN SKELETAL MUSCLE

Kon, M., Ohiwa, N., Honda, A., Matsubayashi, T., Ikeda, T., Suzuki, Y., Akimoto, T., Hirano, Y.

*Japan Institute of Sports Sciences*

Introduction: It has been reported that resistance training under hypoxic condition caused greater increases in muscle size and strength compared with that of normoxic condition (Nishimura et al. 2010). We recently demonstrated that resistance exercise induced a greater anabolic hormone response under hypoxia than that under normoxia (Kon et al., 2010). However, the influence of hypoxic resistance training on skeletal muscle gene expressions related to muscular hypertrophy is still not clarified. Here, we examined the effect of resistance training under systemic hypoxia on gene expressions in human skeletal muscle. Methods: Sixteen healthy male subjects were randomly assigned to either the normoxic resistance training group (n = 7) or the hypoxic (14.4% oxygen) resistance training group (n = 9); they performed 8-wk resistance exercise training. The resistance exercise consisted of two consecutive exercises (bench-press and bilateral leg-press), each with 10 repetitions for 5 sets at 70% of one-repetition maximum. All the sets and exercises were separated by 90-s rest intervals. Muscle biopsy samples from the vastus lateralis muscle were analysed for insulin-like growth factor 1 (IGF-1), IGF-1 receptor (IGF-1R), myostatin, androgen receptor (AR) mRNA expressions. Results: There were no significant differences in the mRNA expressions of IGF-1, IGF-1R, myostatin, and AR between the groups, although the mRNA expressions of IGF-1 and AR were significantly increased, and the mRNA expression of myostatin was significantly reduced after training in both the groups (P < 0.05). The IGF-1R mRNA expression was unchanged after training. Discussion: Present results are consistent with the results of the previous studies (Kim et al. 2007, Lamon et al. 2009). However, resistance training under hypoxic condition did not affect IGF-1, IGF-1R, myostatin, and AR mRNA expressions in human skeletal muscle compared with that of normoxic condition. Hypoxia may not influence the responses of IGF-1, IGF-1R, myostatin, and AR mRNA expressions to resistance training. References Nishimura A, Sugita M, Kato K, Fukuda A, Sudo A, Uchida A. ### DEVELOPMENT OF FORCE-VELOCITY CHARACTERISTICS IN SOCCER PLAYERS

Nikolaidis, P.T.1, Veniamakis, E.E.2

*1: Laboratory of Human Performance and Rehabilitation, Hellenic Army Academy (Athens, Greece), 2: Department of Nutrition and Dietetics, Technological Educational Institute of Crete (Sitia, Greece)*

Introduction Although the contribution of anaerobic power in soccer performance is widely recognized, this parameter of physical fitness has not been well studied in young players. The aim of this study was to investigate the force-velocity (F-v) components of anaerobic power across adolescence. Methods Male adolescent players (n=561; aged 10-22 yr), classified in six two-year age groups, all members of competitive soccer clubs, performed the F-v test. The participants performed four sprints, each one lasting 7 sec, against incremental braking force (2, 3, 4 and 5 kg) on a leg cycle ergometer (Ergomedics 874, Monark, Sweden), interspersed by 5-min recovery periods. Results Positive correlation between age and theoretical maximal velocity (v0, r=0.57, p<0.001), theoretical maximal force (F0, r=0.53, p<0.001), maximal anaerobic power in absolute (Pmax, r=0.68, p<0.001) and relative to body mass values (rPmax, r=0.47, p<0.001) was found, while there was negative correlation between age and v0/F0 (r=-0.37, p<0.001). With regard to Pmax, rPmax, v0 and F0, each age group had higher score than the respective younger and lower score than the older groups, while there was no difference between the age group under 18 yr (U18), U20 and U22. Conclusions An important finding was that while force and velocity increased across adolescence, the ratio v0/F0 decreased significantly (e.g. from 19.5 rpm.kg<sup>-1</sup> in U12 to 11.8 rpm.kg<sup>-1</sup> in U18), indicating changes in the force-velocity profile of soccer players. The v0 to F0 ratio decreased with age, but there was no difference between U16, U18, U20 and U22 with regard to this trait. While our results about the development of anaerobic power across adolescence were in general agreement with previous studies, we identified different patterns of development of the F-v components of anaerobic power, which was a novel finding.

#### DOSE ACUTE MODERATE-INTENSITY 7:30 PM EXERCISE AFFECT FOLLOWING SLEEP?

Ganeko, M.1, Shioda, K.1, Kojima, T.1, Uchida, S.2

*Waseda University*

Introduction Although many studies investigated the effect of acute exercise on sleep EEG, it had only a small effect. Recently many interests are focused more on peripheral parameters such as heart rate or core body temperature during sleep after exercise. The purpose of the study was to simultaneously record EEG sleep and peripheral physiological parameters, and to investigate their relationships. Meth-

ods 6 Healthy young male subjects, who are sedentary nonsmokers, underwent the 2 experimental conditions (no-exercise, exercise) consisting of 2 nights. The first night was an adaptation for both conditions. Sleep time was 8 hours (11pm-7am). On the exercise condition, subjects started 60-minutes cycle ergometer exercise at 60%VO<sub>2</sub>max at 7:30pm. On the no-exercise condition, subjects relaxed by watching TV and reading books. We recorded PSG including sleep-EEG, heart rate, respiratory rate, and rectal temperature. In addition, blood glucose level, blood lactate level, sleepiness, and subjective fatigue were measured before and after exercise and sleep. Results There were no significant differences in any PSG sleep parameters. Heart rate was higher during the first 2 sleeping hours in exercise condition than in no-exercise condition. On the blood glucose level before and after sleep, a significant main effect for condition was observed. Discussion Although no significant differences were observed in PSG sleep parameters, heart rate was significantly increased. This result indicates that night moderate exercise may increase sympathetic nerve system during sleep without having an impact on sleep quality. Furthermore the statistical results on the glucose level seem to indicate that night moderate exercise may have an impact on carbohydrate metabolism during sleep. Now we have finished six subjects. Complete results and discussion will be presented at the meeting

### **INFLUENCE OF SMOKING STATUS ON PHYSICAL PERFORMANCE ADAPTATION AND ENDOCRINE AND INFLAMMATORY MARKERS DURING INITIAL MILITARY TRAINING**

Siddall, A., Bilzon, J., Thompson, D., Greeves, J., Izard, R., Stokes, K.

*University of Bath*

Influence of smoking status on physical performance adaptation and endocrine and inflammatory markers during initial military training Siddall, A.1, Bilzon, J.1, Thompson, D.1, Greeves, J.2, Izard, R.2, Stokes, K.1. 1: Department for Health, University of Bath, BA2 7AY, UK. 2: Department of Occupational Medicine, Army Recruiting and Training Division, SN9 6BE, UK Habitual smoking has been associated with reduced physical performance adaptation, increased risk of injury and failure to complete military training, but the underlying mechanisms remain unclear. We examined physical performance and resting endocrine (cortisol, testosterone, insulin-like growth factor-1) and inflammatory (C-reactive protein (CRP), interleukin-6) markers in British infantry trainees during 14 weeks of military training. A validated lifestyle questionnaire was administered to 46 male trainees (age 21 ± 4 yr; mass 76.3 ± 8.3 kg; height 1.78 ± 0.07 m) for determination of smoking status. Waking fasted blood samples and physical performance measures (chest press, seated row, leg press, static lift and jump exercises) were obtained at weeks 1, 5 and 10 of training. Performance in military physical fitness tests (press ups and sit ups in two minutes, 2.4-km run) at weeks 1 and 14 were also recorded. At weeks 1 and 10, lower-leg muscle and adipose cross-sectional area (CSA) and density were measured by peripheral Quantitative Computed Tomography (pQCT, XCT2000L, Stratec Pforzheim, Germany). Two-way repeated measures ANOVA was used to identify differences over time between non-smokers (NS, n=22) and habitual smokers (S, n=24). There were no significant differences in endocrine and inflammatory markers, or in physical performance measures (main group effect; P>0.05). Higher CRP concentrations in S approached significance (mean (SD); NS, 1.80(2.06); S, 2.83(3.29) mg•L<sup>-1</sup>; P=0.059). Military training, irrespective of smoking status, significantly improved physical performance in all parameters (main time effect; P<0.05) except vertical jump height. An interaction effect existed whereby improvement in bench press performance was significantly greater in S than NS (P=0.031). Performance in 2.4-km run improved more in S than NS, but this was not significant (P=0.069). There were significant changes from weeks 1 to 10 in muscle CSA (8232(831) and 8604(901) mm<sup>2</sup>; P<0.001), total density of muscle and fat (66(4) and 67(4) mg•cm<sup>-3</sup>; P<0.001) and fat/muscle CSA ratio (22(8) and 20(7)%; P=0.012) as a result of training. No effect of smoking was evident on muscle and adipose characteristics of the lower leg (P>0.05). Physical performance improved with 10 weeks of military training irrespective of smoking status, with the exception of greater improvement in bench press performance in smokers. Therefore, it appears that smoking, while chronically elevating resting CRP, does not have a marked effect on physical performance improvement in the early stages of military training.

### **ALTERED CIRCADIAN RHYTHMICITY IN BLOOD PRESSURE WITH SPINAL CORD INJURY IS NOT EXPLAINED BY DIFFERENCES IN PHYSICAL ACTIVITY**

Jones, H.1, Groothuis, J.T.2,3, Verheggen, R.H.M.2, Thompson, A.1, Hopman, M.T.E.2, Atkinson, G.1, Thijssen, D.H.J.1,2

1. *Liverpool John Moores University*; 2. *Department of Physiology, Radboud University Nijmegen Medical Centre*; 3. *Department of Rehabilitation, St Maartenskliniek, Nijmegen*

Introduction: Individuals with spinal cord injury (SCI) demonstrate attenuation or absence of nocturnal reductions in blood pressure (BP) and heart rate (HR) (Rosado-Rivera et al., 2011; J Spinal Cord Med, 34, 395). Diminished rhythmicity is associated with increased incidence of cardiovascular disease and mortality (Verdecchia et al., 1993; Circ, 88; 986). Differences in the levels of physical activity (PA), due to impaired motor functioning in SCI, may contribute to these findings. Therefore, the purpose of this study is to examine the impact physical activity on the circadian rhythms in BP and HR in paraplegics and tetraplegics. Methods: Ten healthy able-bodied controls, 9 paraplegic (spinal cord lesion between T4-T12) and 6 tetraplegic (spinal cord lesion between C4-C7) SCI individuals underwent simultaneous 24-h ambulatory BP, HR and activity monitoring. Blood pressure and HR were measured every 15 min and a diary of events was kept throughout this period which included time of sleep and time of waking. Ambulatory accelerometry was used to measure changes in PA across 15 min periods preceding each BP/HR-measurement. Data were then averaged hourly and re-ordered to the time of waking for each individual. Systolic (SBP) and diastolic (DBP) and HR were analyzed with within-subject generalized estimating equations, and then covariate controlled for changes in PA. Data are presented as mean±SD. Results: Significant interactions between time of day and group factors were evident for SBP, DBP, HR and PA. Generally, SBP was 14±8 mm Hg and HR 15±4 beats.min<sup>-1</sup> lower in tetraplegics compared to paraplegics. Significant interactions remained for SBP, DBP and HR after controlling for physical activity (P<0.05). SBP was significantly lower in tetraplegics compared with paraplegics 5, 6, 13, 14 and 21 hrs post-waking (range 13-20 mmHg) and controls 5, 6, 9 and 13 hrs post-waking (range 16-35 mm Hg). DBP was significantly lower in tetraplegics than paraplegics 6, 9, 11, 22 and 23 hrs post-waking (range 8-14 mmHg) and controls 1, 22 and 24 hrs post-waking (range 10-12 mmHg). Importantly, Paraplegics and controls were not different following covariate control for activity. Conclusions: Differences in the level of physical activity between SCI individuals compared with healthy controls do not explain the altered circadian rhythmicity of BP and HR. The elevated cardiovascular incidence is likely due to inherent changes in the autonomic nervous system as a direct result of the injury.

## INFLUENCE OF PHYSICAL TRAINING ON COLD-INDUCED VASODILATION OF FINGER

Sugawara, M.

*Nagasaki University, Faculty of Education*

INFLUENCE OF PHYSICAL TRAINING ON COLD-INDUCED VASODILATION OF FINGER SUGAWARA, M.1, TAIMURA, A.2 1:Department of Exercise Physiology, Faculty of Education(Nagasaki, Japan) 2:Natural Environmental Conservation, Faculty of Environmental Studies(Nagasaki, Japan) [Introduction] The following two aspects will be considered in this paper. First, in order to elucidate the effects of experimental increase of heat production on the cold-induced vasodilation(CIVD), we examined 20males in CIVD before and after each exercise. Second, in terms of the difference in CIVD between trained and untrained individuals, 160 trained and 34 untrained males were examined. [Methods] The CIVD test was performed by Yoshimura's method: A thermister was attached to the dorsal side of the distal phalanx of the middle finger of the non-dominant hand, and the finger skin temperature was measured during immersion (30 minutes) in iced water. [Results] The CIVD after one hour's outdoor exercise was enhanced in comparison with that before exercise. After exercise, the temperature before water immersion(TBI), mean skin temperature(MST) and temperature at first rise(TFR) during immersion were significantly higher, and the time to temperature rise(TTR) during immersion was significantly shorter. The amplitude of temperature(AT) was likewise significantly higher. These scores were calculated into resistance indices(RI) by Yoshimura's method and Nakamura's method(3 point method and 5 point method). As a result, the RI by Yoshimura's method was significantly higher after exercise while that by Nakamura's method showed no difference. This suggests that a transient increase of heat content by physical exercise is ignored in the latter method. In regard to the features of CIVD in the trained as compared with the untrained, TBI, MST, TFR and AT were higher, and TTR was shorter and RI was significantly higher. There was a significant positive correlation between the years of experience of sports and RI. The CIVD was higher in those trained in outdoor sports than in indoor sports. The RI, classified by sport events was the highest in swimming followed in decreasing order by rowing, karate, baseball, track and field, judo, tennis, rugby, basketball, soccer, kendo, badminton, volleyball and table tennis. [Conclusion] This order was almost the same even after eliminating the effects of the years of experience of sports. Thus, it follows from this observation that the RI was higher in the trained in outdoor sports than in the trained in indoor sports. This result may be attributed to the fact that outdoor sportsmen have more opportunities to be exposed to outdoor cold as compared with indoor sportsmen. [References] Lewis T. (1930). *Heart*, 15, 177-208. Yoshimura H, Iida T. (1950), *Jap. J. Physiol*, 1, 147-159.

## EVIDENCE OF HIGH BODY TEMPERATURE DURING MEN'S STAGE-RACE CYCLING IN TEMPERATE ENVIRONMENTAL CONDITIONS

Ross, M.L.R.1,2, Stephens, B.1, Abbiss, C.R.2, Martin, D.T.1, Laursen, P.B.2,3, Burke, L.M.1

*Australian Institute of Sport*

EVIDENCE OF HIGH BODY TEMPERATURE DURING MEN'S STAGE-RACE CYCLING IN TEMPERATE ENVIRONMENTAL CONDITIONS Ross, M.L.R.1,2, Stephens, B.1, Abbiss, C.R.2, Martin, D.T.1, Laursen, P.B.2,3, Burke, L.M.1 1:AIS (Canberra, Australia), 2:ECU (Joondalup, Australia), 3:HPSNZ (Auckland, New Zealand) Introduction Hyperthermia, hypohydration and carbohydrate (CHO) depletion have been recognized as likely factors influencing fatigue during prolonged endurance cycling. However, there is currently limited field-based research examining the occurrence of hyperthermia and real-life fluid and fuel practices of athletes, especially during exercise in temperate conditions. Therefore, the aims of this study were to observe the thermoregulatory stress, fluid balance and voluntary CHO intake of highly competitive road cyclists during a multiday multiple-stage race in temperate conditions. Methods Ten internationally competitive male cyclists competed in two cycling stage-races (2009 Tour of Gippsland; n=5, and 2010 Tour of Geelong; n=5) in temperate conditions (15.8±1.4°C; 54±12%r.h., and 13.2±2.1°C; 80±8%r.h., respectively). Body mass (BM) was recorded immediately before and after each stage. Peak gastrointestinal temperature (TGI) was recorded throughout each stage. Cyclists recalled the types and volumes of fluid and food consumed throughout each stage. Results Overall general classification of cyclists ranged from 1st to 97th placing with 5 stage wins in the Tour of Gippsland, and 3 stage wins in the Tour of Geelong. The mean change in BM during stages of the Tour of Gippsland, was -1.3±0.2%, with only 5 out of 43 occasions where subjects were observed to exceed a deficit of >2% BM. There was a very large negative correlation (r=-0.8) between fluid deficit and stage finish time. Mean fluid consumption was 771-1658 ml (0.41-0.64 L/h) during road, and 210-432 ml (0.24-0.27 L/h) during criterium stages. There was a large correlation (r=0.95, and r=0.88) between fluid intake and stage distance observed in both tours. Mean CHO consumption was 85-200g (44-77 g/h or 1.18-2.84 g/kg BM) during road, and 24-37 g (28-29 g/h or 0.34-0.52 g/kg BM) during criterium stages. 67% and 73% of peak TGI observed during the Tour of Gippsland (mean peak TGI=38.9±0.7°C) and the Tour of Geelong (39.3±0.4°C) were >39°C. Discussion This study captured novel and insightful data on the thermoregulatory stress, fluid balance and voluntary CHO intake of highly competitive cyclists during a multiday multiple-stage road race performed in temperate conditions. In the present study we consistently observed TGI associated with hyperthermic-induced fatigue. Further, cyclists in this study experienced only mild fluid deficit and matched recommended rates of CHO consumption during exercise, however interpretation of fluid balance on cycling performance is made difficult by race tactics. Further research is required to determine the impact of elevated body temperature on cycling performance in temperate conditions.

## CRITERION VALIDITY OF A PORTABLE URINE REFRACTOMETER AND THE EFFECTS OF SAMPLE STORAGE

Sparks, S.A., Close, G.L.

*Edge Hill University*

Introduction: The assessment of urine osmolality has been used extensively as an index of hydration status. In applied sport settings, such measurements are regularly made before and after training. Over the past decade the use of a portable means of testing the osmolality of urine samples has been widespread, but no studies have assessed the validity of this means of measurement. Furthermore, where samples are collected and stored at -80 degrees C prior to analysis, it is unclear what effect this may have on osmolality. Method: 68 males and 18 females of mean (±SD) age 24.5±7.6yrs, height 1.76±0.1m and weight 77.4±12.2kg, gave informed consent to take part in this study. Participants were required to attend the laboratory in either a well hydrated state or following an overnight nil by mouth fast. Mid flow urine samples were then collected and analysed via both freeze point depression (FPD) and refractometry (RI). Once analysis had taken place, 68 of the samples were frozen at -80 degrees C and then thawed prior to re-analysis using both analytical techniques. Differences between analytical methods and storage were determined using Wilcoxon's Signed Rank test. Confidence intervals (CI) typical error (TE) and 95% limits of agreement (LoA), were used to determine validity. The effects of storage was further analysed using Spearman's Rank Correlation Coefficient, Chronbach's  $\alpha$  and TE. All statistical procedures were performed using PASW 18 for Windows. Results: A significant difference in urine osmolality between FPD and RI (p=0.008) was observed (678.6±328.1 and

657.9±312.1mOsm/l respectively). The mean (±SE) difference was 20.67±48.83mOsm/l with CI of 75.72 and 117.72 for lower and higher levels respectively. TE was 0.24 and LoA were ±156.6 mOsm/l. Storage at -80 degrees C significantly reduced the mean osmolality of urine samples for both the FPD (629.7±338.7 pre and 618.9±331.4mOsm/l post storage, p=0.002, CI=3.69 and 17.86 for lower and higher respectively) and the RI methods (611.3±322.5 pre and 620.0±326.2mOsm/l post storage, p=0.017, CI =-18.80 and 1.45 for lower and higher respectively). Despite these effects of storage, samples were still highly related to their pre-freezing values (r=0.996, p<0.001, α=0.998, TE=0.06 and r=0.992, p<0.001, α=0.996, TE=0.09 for the FPD and RI methods respectively). Conclusion: Despite mean differences between methods and as a result of storage, the small differences observed although statistically significant, are physiologically trivial and therefore the use of RI appears to be a valid measurement tool to determine urine osmolality.

## THE EFFECTS OF ISCHEMIC PRECONDITIONING ON SKELETAL MUSCLE DEOXYGENATION DURING AN EXHAUSTIVE CYCLING TEST.

Jenner, W.J., Gyori, A., Fallan, C., Cunniffe, B., Montgomery, H.E., MacAllister, R.J., Cardinale, M.  
*University College London, British Olympic Medical Institute*

**Introduction** Ischemic preconditioning (IPC) is a physiological phenomenon whereby non-lethal intermittent ischemia induces protection against lethal ischemic episodes. IPC also improves tolerance to intense exercise resulting in improved power output and increased VO<sub>2</sub> max (de Groot et al. 2010). Based on the potential of IPC to modulate blood vessel and skeletal muscle function, we aimed to study whether IPC improves muscle oxygenation during incremental exercise in well-trained individuals. **Methods** Thirteen well-trained male club cyclists (aged 33±6 years, height 180±6cm, weight 78.5±4.0kg, [mean±s.d.]) were randomised to IPC or sham IPC using a crossover design. IPC was induced using three 5-minute cycles of inflation and deflation of a blood pressure cuff on the thighs to suprasystolic blood pressure. Sham IPC was induced using a subdiastolic cuff pressure, and the crossover interval was 7 days. The inflations were followed by an incremental exercise test on a cycle ergometer; 4 minutes of warm-up at 150W followed by 50W/min increases at a constant cadence until exhaustion. Muscle oxygenation was assessed in-vivo by means of near-infrared spectroscopy (NIRS - InSpectraTM 650, Hutchinson Technology). From the NIRS signal, the ratio of oxygenated haemoglobin to total haemoglobin in the micro-circulation was calculated and used for analysis (StO<sub>2</sub>). Repeated measures ANOVA was used to analyse the data (P<0.05 deemed significant). Results IPC reduced StO<sub>2</sub> to a higher degree than sham during cuff inflations (P=0.001). StO<sub>2</sub> was significantly reduced during exercise in both treatment groups (P<0.0001). There was a trend for IPC to preserve muscle oxygenation during exercise compared with the sham intervention, which was observed in 11 of the 13 subjects (P=0.07). **Discussion** The IPC protocol employed in this study was effective in producing ischemia and reperfusion in the vastus lateralis muscle. Despite not reaching statistical significance, IPC showed potential to ameliorate the reduction in StO<sub>2</sub> during exercise in an incremental cycle ergometry exercise compared with sham. Whether IPC improves oxygen delivery to skeletal muscle or increases metabolic efficiency remains to be determined. Further work aims to identify whether IPC can influence additional outcomes of sporting performance. Reference de Groot PCE, Thijssen DHJ, Sanchez M, Ellenkamp R, Hopman MTE. (2010). *Eur J App Phys*, 108(1), 141-146

## A CONCENTRIC/ECCENTRIC KNEE EXTENSION/FLEXION PROTOCOL UNTIL EXHAUSTION – PILOT STUDY

Sousa, M.1, Brito, J.1, Carvalho, P.2, Guimaraes, J.T.3, Teixeira, V.H.2,4, Soares, J.1

1: CIFI2D (Porto, Portugal), 2: FCNAUP (Porto, Portugal), 3: FMUP (Porto, Portugal), 4: CIAFEL (Porto, Portugal)

**Introduction** The aim of this study was to test if a protocol until exhaustion on an isokinetic dynamometer is intense enough to induce alterations in muscle functional and biochemical variables and monitor these alterations for 24 h. **Methods** Six trained male participants (25.2±7.0 years; 176.2±6.8 cm; 70.0 kg, 65-94 kg) completed 3 maximal eccentric repetitions at a constant angular velocity of 60°/s to determine the maximal peak torque of the knee extensors (PTE). Afterwards, a exhaustion protocol was conducted which consisted of 3 bouts of a concentric/eccentric knee extension/flexion exercise at 60°/s with a 200-sec rest time between sets. The 1st and 2nd sets were composed by 100 repetitions; in the 3rd set, subjects performed n repetitions until the PTE of 3 consecutive repetitions fall below 25% of the initial value. The range of motion was from 50° to 110° flexion in the knee (0° = full knee extension). Maximal eccentric PTE was also determined after the exhaustion protocol to evaluate force decrease. Blood samples were collected before (moment 1), 2 h (moment 2) and 24 h (moment 3) after the exhaustion protocol and analysed for lactate dehydrogenase (LDH), creatine kinase (CK), C-reactive protein (CRP) and aspartate aminotransferase (AST). A visual analogue scale (VAS; 0-100) was used to determine the delayed onset muscle soreness (DOMS) before the exercise, immediately after, and 2 and 24 h after the protocol. Data were analyzed by one-way repeated-measures ANOVA and by paired sample t-test. One participant was excluded from data analysis due to high initial value of CK (622 U/L). **Results** There were significant changes in LDH levels with the exercise protocol (p=0.010), being the differences between moments 1 and 2 (165.8±14.7 vs. 193.4±16.1 U/L; p=0.009). There was no significant changes in serum CK activity (p=0.077). No differences were found for AST (p=0.063), and for CRP (p=0.173). There was a significant decrease of the eccentric PTE after the protocol (352.0±57.1 vs. 181.1±61.4 N m; p=0.007). For DOMS (p<0.001), differences were found between the reported values before and immediately after the protocol (2.0±4.5 vs. 64.4±22.6; p=0.039) and before the protocol and 24 h after (2.0±4.5 vs. 48.8±12.3; p=0.003). **Discussion** Taking into account that there were significant changes in LDH, DOMS and eccentric PTE, it can be concluded that this exhaustion protocol is capable of inducing muscle damage. It is known that CK has a high biologic range of response; therefore, the CK non-significant result may be due to the small number of subjects. As no differences were found for AST, liver damage can be excluded. Regarding the results for CRP, probably there is a need for a more specific inflammatory biomarker.

## 2-MINUTES BOUTS OF PHYSICAL ACTIVITY ARE BETTER ASSOCIATED WITH CARDIORESPIRATORY FITNESS THAN LARGER IN CHILDREN AND ADOLESCENTS

Lopez, I.1, Raya, J.F.1, García-Fernandez, J.C.1, Barrera, J.E.1, Torres, G.2, Dorado, M.G.1, Chinchilla, J.M.1, Carnero, E.A.1

1. University of Malaga. 2. University of Jaén.

**Background** A high cardiorespiratory fitness (CF) is an important determinant of health for children and adolescents. Physical activity (PA) is the main stimulus to promote an increase of CF. Although, there is some PA specific recommendations for children and adolescents, mainly regarding the volume of moderate-vigorous PA (MVPA); there are not guidelines focused on patterns (bout time) and optimal doses of PA to improve CF. Accelerometers (ACL) can assess all parameters of external load of PA, so they are useful tools to analyze the relationship between patterns and doses of PA and CF. The primary purpose of this study was to explore the relationship between CF and patterns of PA assess with ACLs. **Methods** Ninety-three children and adolescents were included in this cross-sectional analysis (age,

13.8±2.1 ages; 21.2±3.6 kg/m<sup>2</sup>; VO<sub>2</sub>max, 37.1±7.0 ml/kg/min). Body mass index (BMI) was used as adiposity index. One week of total daily physical activity was recorded using ACLS. Cardio-respiratory fitness (CF) was assessed with a progressive step test until volitional fatigue. Data collections of PA with 2, 4, 5, 6, 8, 10, 12 and 14 bouts (B2, B4, B5, B6, B8, B10, B12 and B14) were calculated (minutes/day), also time expended on moderate and vigorous PA (MVPA) was integrated. Partial correlations were carried out in order to analyze the association between CF and bouts of PA; MVPA was used as control variable. Results Our data showed that shorter bouts better association with CF (B2, r=0.43; B4, r=0.33; B5, r=0.23; B6, r=0.24; P<0.001), after control for total minutes per day of MVPA. Also, the time expended on 2 minutes bouts and CF were the only variables, which had got a negative correlation with BMI (r=-0.23 and r=-0.24, p<0.05; respectively). Finally, Pearson's correlations between daily time for vigorous PA and bouts, were positive and higher for shorter bouts than larger bouts (B2, r=0.36; B4, r=0.30; B5, r=0.29; B6, r=0.29; P<0.001). Conclusions Our main finding was that the shorter bouts of PA had got higher correlations than larger bouts with CF and BMI. We speculated that it should be related with the higher intensities of PA performed during shorter bouts. These results may be important to analyze the relationship between health variables and PA guidelines; so they suggest that short (<2 minutes) and intense PA should be a recommendation for a improved CF. Moreover, bouts shorter than 5 minutes may be explored in future researches in order to clarify completely this issue.

### EFFECT OF 4 WEEKS SWIMMING TRAINING WITH CHEST WALL RESTRICTION ON AEROBIC POWER, CARDIO-RESPIRATORY FUNCTIONS AND SWIMMING PERFORMANCE OF ELITE FEMALE SWIMMERS

Azizi Masoule, M., Razmjou, S., Rajabi, H., Ahmadi, P.

*Department of Physical Education, Karaj Branch, Islamic Azad University, Karaj, Iran.*

Effect of 4 weeks swimming training with chest wall restriction on aerobic power, cardio-respiratory functions and swimming performance of elite female swimmers. Mitra Azizi\*, Sahar Razmjou\*, Hamid Rajabi\*\*, Pezhman Ahmadi\*\*\*\* \* Department of Physical Education, Karaj Branch, Islamic Azad University, Karaj, Iran. \*\* Department of Physical Education, Tarbiat Moalem University, Tehran. \*\*\* Department of Physical Education, Share-Ray Branch, Islamic Azad University, Tehran, Iran Introduction Respiratory muscle fatigue is a physiological effect which has been witnessed in both maximal and submaximal exercises [1]. Therefore, considerable attention has been paid to the potential benefits that respiratory muscle training may have in improving athletic performance. Some studies have reported variations in blood lactate, heart rate and ventilation following respiratory muscle training [2]. Some studies, however, reported no variations in these factors [3, 4]. Therefore, this study is aimed to evaluate the effect of 4 weeks swimming training with chest wall restriction on aerobic power, cardio-respiratory functions and swimming performance of elite female swimmers. Method 24 elite female swimmers volunteered to participate in this study and were randomly divide into two groups: experimental group 1 (swimming training without chest wall restriction) and experimental group 2 (swimming training with chest wall restriction). Both groups were in a monthly swimming program (they trained 3 times a week for a total of 4 weeks). They swam almost 3.5 to 4 km/d with 70–85% of HRmax. Carotid test, Spirometry, Modified Balk test and T-20 were used to measure aerobic power, pulmonary parameters, time to exhaustion and swimming performance respectively. To analyze data, student t test was used. Result The results showed that Time to exhaustion increased in group training with chest wall restrictor (P=0/012). T-20 test results showed improvements in group 2 (average speed (P=0/028), average time for each 100 m (P=0/012), average distance (P=0/018)). No significant difference was observed in VO<sub>2</sub>max, MVV, FVC, and FEV1/FVC in two groups. Also there was no significant difference between the groups. Discussion The results showed that using chest elastic band (chest wall restriction) in order to impose more stress on respiratory muscles during exercise leads to some adaptations in these muscles and it is associated with some improvements in exercise performance. Respiratory muscles, like skeletal muscles, respond to specific training so that training increase respiratory muscles strength and endurance. References [1] M. E. Lomax, A. K. #### RUNNING ECONOMY AND STRIDE FREQUENCY IN EXPERIENCED AND NOVICE RUNNERS

de Ruijter, C.J.1, Werker, W.A.N.1, Zuidema, M.J.1, Verdijk, P.W.L.1, de Haan, A.1,2

*1 Research Institute MOVE, VU University Amsterdam, The Netherlands*

Running economy and stride frequency in experienced and novice runners. C.J. de Ruijter<sup>1</sup>, W.A.N. Werker<sup>1</sup>, M.J. Zuidema<sup>1</sup>, P.W.L. Verdijk<sup>1</sup>, A. de Haan<sup>1,2</sup> <sup>1</sup> Research Institute MOVE, VU University Amsterdam, The Netherlands <sup>2</sup> Institute for Biomedical Research into Human Movement and Health, Manchester Metropolitan University, Manchester, United Kingdom It is believed that self-optimization of the stride frequency improves with running experience. At optimal stride frequency (SF<sub>opt</sub>) oxygen consumption is minimal, at least for speeds below anaerobic threshold. For most experienced endurance runners their preferred stride frequency (SF<sub>pref</sub>) is also the most economical stride frequency. We hypothesized that the difference between SF<sub>pref</sub> and SF<sub>opt</sub> would be larger in inexperienced compared to experienced runners. Ten physically active men who were not involved in regular running exercise (23.8±1.7 yr.) and ten trained runners (25.0±3.3 yr; 10 km times: 34min 53s ± 85s) participated. The anaerobic threshold speed (RER=1) was determined for each subject. They subsequently ran on the treadmill at 80% of this speed, at 7 imposed stride frequencies (2 min bouts) ranging from -18% to +18% of SF<sub>pref</sub> with steps of minimal 6% applied in random order. All frequencies were imposed with a metronome and assessed with an acceleration sensor (1000 Hz) taped on the right foot. SF<sub>opt</sub> was determined by fitting a second order polynomial function through the data points of measured oxygen uptake (second minute of each bout) during the runs at different imposed frequencies, with the minimum signifying SF<sub>opt</sub>. This oxygen consumption was subsequently compared to the oxygen consumed at SF<sub>pref</sub>, also taken from the fitted function. On a different day this protocol was repeated keeping the order of stride frequencies the same within participants. Between days coefficients of variation (%) for SF<sub>opt</sub> were 2.5±2.2 for inexperienced and 1.4±1.3 for trained runners. Those for SF<sub>pref</sub> respectively were 1.0±0.6 and 0.7±0.5. Trained runners ran at (averaged values across days) a speed of 12.6±1.0 km/hour and were more (p<0.05)

economical ( $1.90 \pm 0.13$  VO<sub>2</sub> ml/kg/m) at SF<sub>pref</sub> than inexperienced runners ( $1.239 \pm 0.031$  VO<sub>2</sub> ml/kg/m) who ran at  $9.6 \pm 1.0$  km/hour. As hypothesized, for inexperienced runners SF<sub>pref</sub> ( $77.8 \pm 2.8$  strides/min) was significantly different from SF<sub>opt</sub> ( $84.9 \pm 5.0$ ), whereas both values were similar for trained runners:  $84.5 \pm 5.3$  and  $87.1 \pm 4.8$  strides/min ( $p > 0.05$ ). The improvement in economy while running at SF<sub>opt</sub> instead of SF<sub>pref</sub> did not differ between inexperienced ( $1.3 \pm 1.9\%$ ; range: 0.0-5.2%) and trained runners ( $0.6 \pm 0.5\%$ ; range: 0.0-1.4%). In conclusion, trained runners selected a stride frequency closer to the frequency that minimized cost of running than inexperienced runners. Moreover, although some inexperienced runners clearly reduced oxygen consumption when they increased their stride frequency, others already ran at optimal stride frequency.

### THE EFFICIENCY OF J-STEP FOOTWEAR ON INDOOR WET FLOOR

Moon, K.D.1, Chae, H.J.1, Shin, K.O.2, Kim, C.H.3, Cha, J.H.2, Cho, J.Y.4, Cho, I.H.2

1. *J Step Incorporation*, 2. *Korea National Sport University*, 3. *Korea National Sport University*, 4 *Korea National Sport University*

The footwear including unique out sole made by J step footwear shows two distinct features such as weight dispersion and non-slip function, which prevent slip or/and fall related injuries on indoor wet floor. However, this footwear still has not been tested as ergogenic aids. Therefore, the purpose of this study was to investigate the effects of J-step footwear on power output of lower extremities and aerobic capacity on indoor wet floor. Eight female handball athletes (age:  $20.0 \pm 1.31$  yrs, height:  $171.38 \pm 2.70$  cm, weight:  $63.0 \pm 3.07$  kg, career:  $10.37 \pm 3.24$ ,  $n = 8$ ) were participated and underwent a dynamic electromyography (EMG). During side step, power output of lower extremities was significantly higher in J-step handball footwear compared to normal handball footwear ( $p < 0.05$ ). In addition, running time in J-step handball footwear was much shorter than that of normal handball footwear. Finally, HR and VO<sub>2</sub> were significantly higher in J-step footwear compared to normal handball footwear in 1000 m running ( $p < 0.05$ ). These results indicated that wearing J-step footwear could be possible for handball athletes to increase their performance or prevent knee or ankle injuries via slip and fall on wet floor.

### ALTERED RELATIONSHIP BETWEEN R-R INTERVAL AND HEART RATE VARIABILITY IN OVERTRAINED ENDURANCE ATHLETES

Kiviniemi, A.M.1, Tulppo, M.P.1, Hautala, A.J.1, Vanninen, E.2, Uusitalo, A.L.T.2,3

1: *Verve Research (Oulu, Finland)*, 2: *Kuopio University Hospital*, and *University of Eastern Finland (Kuopio, Finland)*, 3: *University of Helsinki and Helsinki University Hospital (Helsinki, Finland)*

**Introduction** The correlation between R-R interval length (RRi) and vagally mediated heart rate variability (HRV) varies in young healthy subjects within 24-hour recording ( $R^2: 0.31 - 0.97$ , Kiviniemi et al., 2004). It is not known whether overtraining syndrome (OT) affects this relationship. Thus, the aim of the present study was to assess the relationship between RRi and HRV over 24-hour recording among OT and control endurance athletes. **Methods** Ambulatory 24-h ECG monitoring was performed for 9 OT (age:  $28 \pm 7$  years, 5 women) and 10 control endurance athletes (age:  $27 \pm 6$  years, 5 women). Overtrained athletes 1) had suffered from an unexplained long-term decrement in physical performance and fatigue, the symptoms being continued even after a recovery time of weeks to months, 2) were otherwise healthy, and 3) had a suitable training history for overtraining (Uusitalo et al. 2006). Ambulatory 24-h ECG monitoring was successfully repeated for 8 OT and 10 control athletes after 6 months. The power of low (LF, 0.04-0.15 Hz) and high frequency (HF, 0.15-0.4 Hz) oscillations of RRi were analyzed in 5-min epochs over the whole 24-hour recording. The 5-min values of HF power were transformed into natural logarithm (ln) and plotted against corresponding mean RRi. Due to the expected saturation of HRV at time of long mean RRi, quadratic regression was performed between RRi and HFln to obtain  $R^2$  between these measures separately for each subject. **Results** The mean RRi, HFln and LFln were similar between OT and control athletes ( $865 \pm 73$  and  $867 \pm 79$  ms;  $7.4 \pm 0.6$  and  $7.2 \pm 0.8$  ln ms<sup>2</sup>;  $7.6 \pm 0.6$  and  $7.7 \pm 0.5$  ln ms<sup>2</sup>, respectively,  $p = ns$  for all). LF/HF-ratio tended to be lower in OT compared with control athletes ( $1.2 \pm 0.3$  vs.  $1.8 \pm 0.8$ ,  $p = 0.063$ ). The  $R^2$  between RRi and HFln was higher in OT athletes compared with controls ( $0.87 \pm 0.04$  vs.  $0.78 \pm 0.11$ ,  $p = 0.031$ ). This difference was vanished 6 months later ( $0.78 \pm 0.12$  and  $0.78 \pm 0.07$ , respectively,  $p = ns$ ). **Discussion** The overtraining strengthens the relationship between RRi and vagally mediated HRV without altering the mean RRi and HRV in endurance athletes. This indicates prevailing RRi being more tightly controlled by vagal activity in overtrained athletes compared with control athletes. Lower correlation between RRi and HRV in control athletes manifests other mechanism, potentially sympathetic activity as suggested by slightly higher LF/HF-ratio, affect the prevailing RRi more in non-OT than in OT athletes. **References** Kiviniemi AM et al. ### ANAEROBIC POWER AND CADENCE CHARACTERISTICS OF ELITE CROSS-COUNTRY AND DOWNHILL MOUNTAIN BIKERS

Hurst, H.T., Swarén, M., Hébert-Losier, K., Ericsson, F., Holmberg, H.C.

*University of Central Lancashire; Mid Sweden University; Swedish Cycling Federation*

**Introduction** Mountain biking (MTB) is composed of several sub-disciplines, with Olympic Cross-Country (XCO) and Downhill (DH) being the most popular. Much of the current research on MTB pertains to the aerobic demands of XCO racing, with comparisons often made to road cycling. No studies have compared elite level XCO and DH bikers. Therefore, the aim of this study was to investigate the anaerobic power and cadence characteristics of elite XCO to DH riders. **Methods** Twelve male elite mountain bikers ( $n=6$  XCO,  $n=6$  DH; age  $21.83 \pm 3.71$  yrs; stature  $179.67 \pm 4.40$  cm; mass  $72.50 \pm 5.45$  kg) took part in this study. An inertial load cycling test was performed as described in previous studies(3), on an SRM cycle ergometer instrumented with a scientific version SRM Powermeter. Inertial load was adjusted to ensure riders achieved 130-150 revs.min<sup>-1</sup> within 4-7 s. Peak power (W<sub>peak</sub>), cadence at W<sub>peak</sub> (CAD<sub>opt</sub>) and power to weight ratio (W.kg<sup>-1</sup>) were calculated for each rider as the mean from 3 trials. Statistical differences between XCO and DH were determined using independent t-tests with significance set at  $p \leq 0.05$ . **Results** A significant difference between DH and XCO was found for CAD<sub>opt</sub> ( $114.93 \pm 5.41$  and  $107.96 \pm 4.63$  revs.min<sup>-1</sup>,  $p < 0.05$ ), respectively. No other differences were revealed between groups. The mean recorded values for DH and XCO were  $1137.76 \pm 135.84$  and  $1113.86 \pm 75.22$  W for W<sub>peak</sub> and  $15.21 \pm 2.05$  and  $15.95 \pm 0.75$  W.kg<sup>-1</sup> for power to weight ratio, respectively. **Discussion** The findings of comparable W<sub>peak</sub> between groups may indicate that high anaerobic power is not a prerequisite for success in elite DH. However, significant differences were found in CAD<sub>opt</sub>, where DH riders had a higher cadence when producing W<sub>peak</sub> compared to XCO riders. This may reflect training specificity and the greater emphasis on repeated accelerations in DH(2) and the lower cadences elicited by XCO riders(1). Further research is therefore warranted to compare laboratory and field-based performance in these two population groups. **References** 1. Gregory, J., Johns, DP. and Walls, JT. ### RELATIONSHIP BETWEEN STRENGTH QUALITIES AND 800 M PERFORMANCE IN FEMALES

Argeitaki, P., Katsikas, C., Douskas, T., Kesoglou, I., Smirniotou, A.

*National & Kapodistrian University of Athens*

**Introduction** The aim of this study was to investigate the relationship between strength and power parameters and 800m performance as well as to explore if these relationships varied between the first and the second 400m of the race distance. **Methods** One hundred eight university female students of physical education (age 19, 2±0, 6 years, height, 167, 9±0, 6 cm, body mass 59, 6±0, 7 Kg and BMI 21,1±0,2) were timed over the distance of 800m and also the intermediate lap-400m was considered (photocells, Microgate, It). The following tests were evaluated: countermovement jump (CMJ), 15 second repeated jump (RJ) and power output (PO) (Ergojump, Bosco) To examine the relationship between strength qualities and the 2 laps of 800m performance, a correlational approach was used (SPSS). Results CMJ and RJ showed low but significant correlations ( $r = -0,24$  and  $-0,27$ ,  $p < 0,05$  respectively) with the 800m performance times. However, both CMJ and RJ showed moderate correlations in the first 400m of the race ( $r = -0,26$  and  $-0,30$ ,  $p < 0,01$  respectively). In addition, no significant correlation was found between CMJ, RJ and performances in the second 400m of the race. The power output (PO) was not significantly correlated either with 800m or both laps of the race. From the anthropometric characteristics only the BMI was significantly correlated with the 800m performance ( $r = -0,26$   $p < 0,01$ ). **Discussion** The present findings suggest that CMJ and RJ affect only the first 400m of the race but not the second therefore strength qualities as tested in the present study proved to be poor predictors of 800m performance. These preliminary results should be validated in future research using trained athletes of different levels and both genders. **References** Bosco C, Luhtanen P, Komi PV. ### DETERMINATION OF GLUCOSE THRESHOLD USING BLOOD GLUCOSE METER AND COMPARISON OF THE LACTATE THRESHOLD

Togashi, G.B.1,2, Sousa, N.M.F.1,3, Ferraresi, C.3, Rodrigues, M.F.C.3, Arakelian, V.M.1,3, Pieroni, R.P.3, Oliveira, J.C.3, Azevedo, P.H.S.M.3,4, Perez, S.A.3, Baldissera, V.1,3

*1: Programa de Pós Graduação Interunidades Bioengenharia/USP; 2: Faculdade Anhanguera de Bauru; 3: Universidade Federal de São Carlos; 4: Universidade Federal de São Paulo*

**Introduction** The objective of the present study was to determine and to compare the lactate threshold (LT) and glucose threshold (GT) during treadmill running. **Methods** 14 individuals were selected for the study, with mean age of  $29.7 \pm 8.8$  years, mean weight of  $74.2 \pm 9.4$  kg, mean height of  $174.9 \pm 5.9$  cm, and mean body fat of  $21.1 \pm 2.8\%$ . Incremental treadmill test was applied, and the initial speed was  $8.0 \text{ km}\cdot\text{h}^{-1}$  followed by increment of  $1.0 \text{ km}\cdot\text{h}^{-1}$  every 3 minutes until the subject became exhausted. Blood samples were collected from the earlobe for determining both glycaemia and lactaemia. LT and GT were determined through visual inspection. Initially, Shapiro-Wilk test was applied for analysing the normality of the sample. Because data were found to be normal, parametric statistic test was used. Data are expressed as mean values and standard deviation. Results No statistically significant difference was found between the velocity values ( $\text{km}\cdot\text{h}^{-1}$ ) for LT ( $10.3 \pm 1.7$ ) and GT ( $10.3 \pm 1.9$ ) ( $P > 0.05$ ). A strong correlation was found between LT and GT velocities ( $r = 0.93$  and  $R^2 = 0.87$ ). A high concordance was observed between methods (Bland and Altman analysis). One may conclude that the glucose threshold may substitute the lactate threshold. **Discussion** The main finding observed in the present study was that it is possible to assess the aerobic capacity by determining the glucose threshold with a portable glucose meter. Such a methodology was made more accessible due to the use of low-cost devices, thus allowing this important physiological marker for both functional evaluation and exercise intensity to be more easily determined. Thus, it was possible to determine the lactate and glucose thresholds during incremental test on a treadmill. No statistically significant differences were found between LT and GT velocities, thus demonstrating that LT determination may be substituted by GT as long as the same methods are applied in a comparable group of healthy subjects. **References** Gladden LB (2008). *Med Sci Sports Exerc*, 40, 477-85. ### VALIDATION OF A PROTOCOL OF HIIT WITH HYDROBIKE: TRIATHLETES VS GROUP CONTROL

COLLU, G., MILIA, R., ROBERTO, S., MIGLIACCIO, G.M.

*LABORATORIO FISILOGIA DELLO SPORT*

**Introduction:** Based on international scientific literature (ref 1-2) which indicates HIIT as an excellent method for improving  $\text{VO}_2\text{max}$ , and continuing with a research effected in precedence with Triathletes (ref 4), it was decided to propose the same protocol to a new group of Triathletes (TA) and to a Group of Control (CG). **Methods** 16 male Italian Triathletes at national level agreed to participate in this study. They was divided in two groups from 8: TA (age  $37.2 \pm 2.9$  years, weight  $68.5 \pm 5.9$  kg, height  $170 \pm 4.99$  cm) and CG (age  $40.8 \pm 6$  years, weight  $75.5 \pm 7.2$  kg, height  $180 \pm 5.33$  cm). At first both groups performed an incremental test up to exhaustion using a Hydro Bike (HydroRider Italy). The test consisted of a linear increment of pedaling frequency (RPM) every 2 mins. During the test they wore a portable metabolic device ( $\text{VO}_22000$  MedicGraphics USA) able to collect data of maximal oxygen uptake ( $\text{VO}_2\text{max}$ ,  $\text{VO}_2/\text{Kg max}$ ), maximal heart rate (HRmax) and to calculate anaerobic threshold (AT),  $\text{CO}_2$  Excess, VE max and Wmax. The TA then participated in 12 sessions of Hydro Bike HIIT (training: 30 mins- frequency: 3 times /week - duration: 4 weeks) following a well-established protocol of training: 4 mins 90% HR max + 3 mins 70% HR max for 4 times. The CG followed a free training reducing and limiting the volume and the loads of training. After such a period both groups repeated the incremental test up to exhaustion. **Results** The statistic analysis effected with t Student for coupled data, has statistically underlined a significant reduction of the  $\text{VO}_2/\text{Kg max}$ ,  $\text{VO}_2 \text{ max}$  on the CG after e period of a month of reduced activity, while the other variables have not statistically meaningful differences in both the groups in the two moments of the tests. **Discussion** The element underlined in the CG, in which a reduction of the ability of performance is observed reveals that a protocol of training with Hydro Bikes performed with HIIT- low duration protocols, can be recommended to Triathletes as an alternative practice in

low activity phases or in times of reduced training and to contrast some common detraining effects. ### INCIDENCE OF BACK PAIN IN TRACK AND FIELD ATHLETES: A TRASVERSAL STUDY

Mondoni, M.

*Università Cattolica Sacro Cuore*

INCIDENCE OF BACK PAIN IN TRACK AND FIELD ATHLETES: A TRASVERSAL STUDY Mondoni M.1, Casolo F.1, Bottini L, Negrini S. 1, Ajani A.1, Scirè S. 1 Faculty of Education Science: degree in physical education and sport - Università Cattolica del Sacro Cuore di Milano INTRODUCTION AND OBJECTIVES Back pain is better localized at the lumbar spine and sciatica can become if not prevented or cured. The purpose of this research is to identify if the incidence of back pain is more common in athletes who practice different disciplines in Track and Field (throwing, jumping, speed and middle distance race), compared to persons who do not practice this sport. MATERIALS AND METHODS The groups examined are: track and field group (TaFg), mean age 23.5 years, comprising 160 athletes (m and f) and control group (CP), mean age 26.5 years, comprising of 80 persons (m and f) that do not practise TaF. All subjects were given an anonymous questionnaire to assess the incidence of back pain in physical activity. RESULTS The data collected showed that 65% of throwers and jumpers suffer from back pain and that 68% have never suffered from sciatica and has never stopped the pain. The TaF group suffers most from low back pain (60.56%), compared with the CP (39.44%) and both groups said they were not suffering from sciatica pain and it never stopped the pain. The 76.92% of TaFg said they did not suffer from back pain while filling out the questionnaire and 60% said they had back pain over the last 30 days and the throwers said to suffer more back pain than other athletes. The TaFg said to suffer back pain once every 6 months, especially the jumpers and throwers have reported suffering from back pain more than once a month. Confronted with the CP, showed that the TaFg undergoes more medical visits for low back pain resulting in rehabilitative therapy. In the TaFg 69% said they had never suffered back pain before starting the competitive activity, 74% of the 'test sample' thinks that the sporting activity has been affected quite to develop of back pain, 58% said they suffer from back pain during training before the competitive season. CONCLUSIONS The research shows that in TaF increasing incidence of low back pain, especially in males. The disciplines that cause more back pain are the throws and jumps. Comparing the TaFg with the CP, we can say that competitive athletes suffer more back pain than the CP. The throwers and jumpers said they frequently suffer from back pain, more often than once a month. From our observations we found that the TaFg underwent further medical examinations and treatments (drugs or otherwise), especially the throwers and jumpers, compared to the CP. The last part of the research, dedicated only to TaFg, it was found that subjects had never suffered from back pain before the race and think that has influenced the start of racing onset of back pain, especially for the sprinters, jumpers and throwers, also claimed to suffer more back pain during athletic training in the competitive season. ### REST INTERVAL BETWEEN JUMPS DURING TRACK AND FIELD JUMPING COMPETITIONS

VELIGEKAS, P., BOGDANIS, G.C., STABOLITIS, C., FRANTZIS, D.

*University of Athens, GREECE*

Introduction Field jumping events may be categorized as horizontal jumps (long and triple jump) and vertical jumps (high jump and pole vault). In the horizontal jumps each athlete performs three jumps and the eight athletes with the best valid performances are allowed three additional trials. Vertical jumps are "open ended", and an athlete may commence at any height and may continue to any subsequent height, until failure (IAAF, 2012). Analysis results from Olympic Games and World Championships (IAAF competition archive, www.iaaf.org) showed that high jumpers and pole vaulters performed on average  $9 \pm 2$  jumps and  $8 \pm 1$  vaults. However, it is now known if the recovery time between the jumps is always adequate. The aim of this study was to record the time interval between trials during official competitions in the four field jumping events (long, triple, high jump and pole vault). Methods Data acquisition was performed during three different indoor competitions (one of them was the National Championships). The total number of athletes in all three competitions was 63 males and 61 females for the horizontal jumps and 54 males and 52 females for the vertical jumps. The time elapsed from the end of each trial until the start of the next was recorded for every athlete by two observers. Results In the long and triple jump, the rest interval between the first three jumps was  $10.0 \pm 0.2$  min, while it increased to  $12.5 \pm 0.5$  min between jumps 3 and 4. This was due to the change in the order that the athletes jumped after the third trial, where only 8 athletes continued to compete. The rest intervals before the last two jumps were decreased to  $6.85 \pm 0.2$  min. In the high jump and pole vault, the rest interval between the first two jumps was on average  $6.8 \pm 0.5$  min and declined steadily until the sixth jump to about  $4.0 \pm 0.4$  min. Thereafter, the rest interval declined by a small amount, depending on the number of participants left. Discussion The main findings of this study were that there is significantly less time between trials in the horizontal compared with the vertical jumps. Thus, athletes who compete in the vertical jumps have about 40% less time for recovery between their jumps while every subsequent trial must be done at a higher height. The relatively short recovery time in the vertical jumps indicates that some athletes may not be metabolically ready to perform maximally during the later stages of the competition (Dawson et al., 1997). These findings may have implications for the design of specific training programs that simulate competition, especially in the vertical jumps and also for competition tactics. References IAAF (2012). ### THE RELATIONSHIP BETWEEN MAXIMAL FAT OXIDATION RATES AND BLOOD LACTATE THRESHOLDS IN RUNNERS.

Orme, D., Relph, N., Sparks, S.A.

*University of Cumbria*

The relationship between maximal fat oxidation rates and blood lactate thresholds in runners. Orme<sup>1</sup>, D., Relph<sup>1</sup>, N., and Sparks<sup>2</sup>, S.A. 1 Sport and Physical Activity, University of Cumbria, Lancaster, UK 2 Department of Sport and Physical Activity, Edge Hill University, Ormskirk, UK. Introduction: As aerobic exercise increases in intensity the relative oxidation rates of carbohydrate and fat have been shown to change (Van Loon et al., 2001). The rate of maximal fat oxidation (Fatmax) has been shown to be closely related to the increase in plasma lactate during incremental cycle ergometer exercise (Achten and Jeukendrup 2004). To date no studies have looked at this relationship in whole body exercise. The aim of this study was to evaluate the relationship between the exercise intensity which elicits Fatmax and three

methods of determining blood lactate thresholds during treadmill running. Method: Fifteen moderately endurance trained male recreational runners of mean ( $\pm$ SD) age  $35.0 \pm 8.98$  yr, body mass  $75.2 \pm 5.21$  kg and height  $1.76 \pm 0.05$  m, completed a discontinuous graded exercise test to exhaustion on a treadmill, using 1km/h increments every four minutes. Respiratory gases were measured throughout the test and used to calculate Fatmax via indirect calorimetry. Capillary whole blood lactate samples were collected at the end of each stage for the determination of the exercise intensity (speed in km/h and % of VO<sub>2</sub> peak) at which three thresholds LT, D-max (DM) and Modified D-max (MDM) occurred. Correlation analysis was performed using Pearson's and Spearman's rank correlation coefficients for parametric and non-parametric data respectively. Differences were determined using t-tests. Significance was accepted at  $p < 0.05$ . Results: No significant correlations were observed between the speed at Fatmax and the speed at which LT, DM or MDM occurred. There was however a significant correlation between Fat Max Speed and Fat Max % of VO<sub>2</sub> peak ( $r = 0.608$ ,  $p = 0.016$ ). Fat Max % of VO<sub>2</sub> peak was significantly correlated to DM % of VO<sub>2</sub> peak ( $r = 0.534$ ,  $p = 0.04$ ) and MDM % of VO<sub>2</sub> peak ( $r = 0.622$ ,  $p = 0.013$ ). There were significant differences between the speed at Fat Max and LT ( $p = 0.011$ ) and Fat Max and LT % of VO<sub>2</sub> peak ( $p = 0.011$ ). Conclusion: In moderately trained endurance runners Fatmax is significantly correlated with the % of VO<sub>2</sub> peak at both DM and MDM, but not at LT. ##### COMPARISON OF TWO BALANCE TESTS TO PREDICT INJURY RISK IN A MILITARY SETTING

Wyss, T., Roos, L., Wunderlin, S., Mäder, U.

*Swiss Federal Institute of Sports Magglingen SFISM*

**Introduction** A negative association between balance ability and injury risk during physical training or sport has been shown in college students and athletes [1, 2]. The same association can be expected in a military setting, where a large number of physical activities on uneven surfaces and with heavy loads take place. Therefore, the aim of this study was to investigate the discriminative power of two different balance tests to predict injury risk during basic military training. **Methods** The study was conducted with 298 volunteering male recruits of an infantry training camp in Switzerland. Balance was assessed in the first week of basic military training using a one-leg standing (OLS) test [3] and the MFT S3 Check test [4]. In OLS participants had to close their eyes after 10s and lay their head back after 20s. The sum of time on each leg was valued. For the MFT S3 participants had to balance for 30s on a disc connected to a computer that calculated two indexes: sensorimotor function (S3 SMF) and symmetry (S3 SYM). Injury occurrences were recorded during 13 weeks of basic military training. Discriminative power of volunteer's balance ability for predicting risk of injuries were calculated using receiver operating characteristic curve (ROC) analysis. Results Correlation between OLS and MFT S3 performances were low but significant ( $r = .11$  for S3 SMF and  $-.27$  for S3 SYM,  $p = .05$  and  $.00$ ). Overall, 8.4 overuse injuries and 10.6 acute injuries per 100 recruits per month were registered. The area under the ROC curve to predict overuse injuries for OLS, S3 SMF and S3 SYM and to predict acute injuries for S3 SYM was small and not significant ( $p = .17 - .67$ ). However, to predict acute injuries by OLS and S3 SMF it was  $.57$  and  $.58$  ( $p = .06$  and  $.04$ ). A combination of both tests (OLS + 8\* S3 SMF) resulted in a ROC area of  $.61$  ( $p = .00$ ) to predict acute injuries. **Discussion** S3 SYM was not correlated to S3 SMF, negatively correlated to OLS and not related to injuries. This index does not appear to add any relevant information to a balance ability assessment in a military setting. OLS and S3 SMF are both related to acute injury incidences in infantry training, but correlate only to a small extent with each other. Therefore, we conclude, that a combination of the OLS and S3 SMF gives a more powerful index of balance ability to predict acute injuries in a military setting. **References** 1. ##### DEVELOPMENT OF AN ENERGETIC DEMAND PROFILE IN FIGURE SKATING

Hermisdorf, M.1, Hartmann, U.1, Spiegel, S.2, Knoll, K.3, Ehrig, A.3

*University Leipzig*

**Introduction** Existing data for the metabolic background and the endurance skills in figure skating are very incomplete and primarily based on an 'old rating system' of the 70s and 80s. They show a high participation of anaerobic and low share aerobic energy for a free skating of four minutes [1, 2]. The aim of this study is the development of a complex sport-specific energetic demand profile for figure skating competition. **Methods** Eleven competitive figure skaters (five males, six females) with the following physical characteristics took part in the study: mean age  $16.4 \pm 2.5$  yrs, mean height  $164.5 \pm 6.9$  cm, mean body weight  $56.9 \pm 7.5$  kg. Ventilation, gas exchange and heart rate (HR) were measured during the free skating presentation for a minimum of four minutes with a portable spirometry system (MetaMax 3B, Cortex, Germany). Lactate concentration (LA) was assessed before and after the exercise (Biosen S\_line, EKF-diagnostic, Germany). Additionally, free skating presentation was recorded on video for quantitative analysis. Covered distance and velocity of the figure skater were measured with an local indoor position system (LPM, Inmotio, Netherland, frequency 1.000 Hz, measurement accuracy of 5 cm). Laboratory tests were carried out to determine maximum oxygen uptake (VO<sub>2</sub>max), HR and LA during a treadmill (Saturn, h-pocosmos, Germany) all-out-test with an increasing workload (start by 3.25 m/s, increase 0.25 m/s every 30 s, inclination 1 %) until exhaustion (vita-maxima-test). Results All athletes reached their individual maximum HR and VO<sub>2</sub>max during the four minutes free presentation on ice. In average VO<sub>2</sub>max ( $n=6$ ) was  $3.21 \pm 0.69$  l/min on ice and  $3.19 \pm 0.68$  l/min on treadmill, corresponding to  $59.0 \pm 7.4$  ml/kg/min and  $58.3 \pm 6.1$  ml/kg/min respectively. HR was  $194.0 \pm 7.7$  min<sup>-1</sup> on ice and  $198.0 \pm 4.1$  min<sup>-1</sup> on treadmill and LA  $9.7 \pm 2.5$  mmol/l and  $10.1 \pm 3.1$  mmol/l. The analyses of the gas exchange parameters indicate a distribution  $74.1 \pm 5.1$  % of aerobic,  $11.6 \pm 2.9$  % anaerobic

lactic and  $14.3 \pm 3.6$  % anaerobic alactic energy shares. Discussion The results point out to a very high aerobic metabolic rate in free skating for top competitors. All athletes showed very high physical strain during free skating. However, the data of the acyclic activity profile on ice implies that aerobic metabolism is the dominant source of energy. Compared to traditional perspectives, as mentioned in the introduction, the anaerobic shares take up a minor influencing factor. References (1) Dal Monte A. (1983): The functional values of sport. ### **HIGH INJURY PRONENESS IN PHYSICAL EDUCATION TEACHERS: A RATIONALE FOR INJURY PREVENTION**

Goossens, L., Cardon, G., De Clercq, D.

*Ghent University, Department for Movement- and Sports Sciences*

Teaching Physical Education is physically very demanding due to long-time standing, replacement and storage of materials, aid by and demonstrations of specific techniques and exercises (1). Sandmark (2) observed physical work load for PE teachers is considerable with high load on the lower extremities. In line with these results, Sandmark (3) found more injuries and osteoarthritis of the knees and a higher prevalence of low back pain in PE teachers between 53 and 65 years of age compared to referents. Updated information with reference to PE teachers of all ages in Flanders is needed for working towards sports injury prevention in this specific population. Study design 129 PE teachers (69 m, 60 f;  $42.95 \pm 10.25$ y) signed in to take part in this study. All teachers received a weekly email through which they reached the online registration. Time of exposure was questioned and whether or not an injury occurred during the last week. In case of injury, specifications were questioned. Results After 22 weeks of follow-up, injury prevalence was 51 injuries (28 in females, 23 in males) suffered from by 39 teachers. Injury incidence was 41 injuries in 32 teachers, incidence rate was 1.3 injuries/1000h of exposure. The absolute risk for having an injury was 31.7%. The injured teachers were  $41.18 \pm 9.95$ y of age. The majority of all injuries were acute (68.6%) and non-contact (76.5%). The amount of new and recurrent injuries was more or less the same (52.9% Vs 47.1%). Injuries happened during teaching activities in 43.2% of the cases whereas in 37.3% while practicing extracurricular sports. 71.5% of all injuries happened to the lower limbs with mostly affected body parts the lower leg and knee (13.7% each). Concerning the upper body, the lower back (7.8%) and shoulder (5.9%) were mostly affected regions. Mostly injured tissues were muscles (17.6%), followed by ligaments and joints (9.8% each). Discussion We observed that PE teachers are at considerable risk for having a sports injury and teaching activities are an important reason for this. As expected following the results by Sandmark (2), the majority of all injuries involved the lower limbs. Regarding the upper body, also in line with the results by Sandmark (3) we observed most injuries to the lower back. These epidemiological data will be used to refine a specific sports injury prevention program in PE teachers in Flanders. References (1) Lemoyne J, Laurencelle L, Lirette M, Trudeau F. ### **SAFETY IN SPORTS – DEVELOPMENT OF A METHODOLOGY FOR GUIDELINES ON INJURY PREVENTION AND SAFETY PROMOTION IN SPORTS**

Henke, T., Luig, P.

*Ruhr-University Bochum*

Introduction Sport is an important cultural element and one of the most widespread activities. There is a global consensus that health protection and health promotion are important potentials of sport. However, approximately 20% of all injuries result from sporting activities. In particular with regard to popular sports, the benefit for health can be increased by reducing the frequency of sports injuries. The general aim of the project, which receives funding from the European Commission, is to contribute to the reduction of sports injuries by elaborating general guidelines and recommendations for injury prevention and safety promotion in sports with absolute high numbers of participants and injuries. Methods Based on an up-to-date inventory, a consensus on best injury prevention measures and implementation strategies for handball and basketball was reached using a web-based evaluation tool in combination with multiple expert consultation meetings. Additionally, surveys among trainers measuring opinions, attitudes, needs and knowledge on prevention topics were carried out. Results Prevention toolkits were elaborated that consist of media and information to convey preventive contents to stakeholders and target groups in handball and basketball communities. In collaboration with the European Handball Federation and the FIBA Europe these toolkits have been pilot-tested in four national associations with special focus on acceptance and applicability. In the light of the test implementations, general guidelines on how to develop, implement and sustain injury prevention and safety promotion in a sports setting have been drawn up. Major task areas are: (1) Topic selection, (2) Resources, targets and realistic planning, (3) Methods for developing injury prevention measures and safety promotion strategies (4) Dissemination and sustainability (5) Evaluation, and (6) Updating and continuous improvement. For each area we developed a kind of checklist with instrumental advices for its successful realization but leaving enough space for individual adjustment to the specific demands and needs of the respective implementation setting. Conclusions The guidelines and recommendations are built on experiences from the pilot project "Safety in Sports" and may assist sports organisations during future safety approaches. To bridge the evidence-to-practice translation gap it is obligatory to involve the respective target communities from the very first process step and to acknowledge the specific demands, interests and settings of each sports community. Moreover, it is essential to analyse the sports communities' perception and knowledge of the injury problem itself as well as their perspectives of handling the problem within their own organisational structures and with regard to their capacities.

### **HEALTH REPORT BY STUDENTS FOR STUDENTS**

Simi, H., Grach, D., Neuhold, B., Wallner, D.

*FH JOANNEUM*

HEALTH REPORT BY STUDENTS FOR STUDENTS Simi, H.1, Grach, D.2, Neuhold, B. 3, Wallner, D.1 1:FH JOANNEUM Uni. App. Sci., Sport Science Laboratory (Bad Gleichenberg, Austria), 2:FH JOANNEUM Dietetics (Bad Gleichenberg, Austria), 3:FH JOANNEUM Health Management in Tourism (Bad Gleichenberg, Austria) Introduction Female students aged 15 to 17 years from four Austrian schools for food and agriculture worked on a health report by students for students. The goal was to gain data from and by female scholars to increase their interest in research in the disciplines of sport science, dietetics & social sciences. This article presents the results of the sport science component. The involvement of health oriented reports of citizen is recommended (Böhm, 2009). Methods 93 volunteer female students participated in this project. Workshops on the basics of the scientific method supported by experts like literature searching, quotation,

protocol implementation, exercise testing and interpretation, basic statistics were conducted. The students applied this knowledge by gathering data in a project week of four sport motor skill tests (Endurance: 2000m Walking Test, Coordination: Kasten-Bumerang-Lauf (KBL), Rapidity: 20m Sprint and Bounce: Standing Long Jump (SLJ)). To get valid data students collected data through a series of tasks including construction of the test, protocol implementation, explanation of the test & measurements. An additional workshop was held to interpret and analyze the results. Based on the results the students made recommendations for themselves and for their schools. Results 20m Sprint  $3.91\text{sec} \pm 0.33\text{sec}$  and SLJ  $1.58\text{m} \pm 0.23\text{m}$  was in average ( $3.75\text{sec}-4.15\text{sec}$  &  $1.58\text{m}-1.78\text{m}$ ), KBL  $20.73\text{sec} \pm 5.52\text{sec}$  was below average ( $>19.5\text{sec}$ ) in Austrian school students (bm:bwk, 2003). For the 2000m Walking Test  $18:52\text{min} \pm 09:30\text{min}$ , no reference data are available. Conclusion There should be more observance paid to the coordination exercises. This fact is also mentioned by the students in the recommendations on school level: More varied sport and hours in physical education and therefore an increased communication with their teacher should be given. Recommendations on personal level: Doing more sport, the sport needs to be enjoyed (e.g. with friends and pets) and better time management skills (e.g. using a bicycle instead of a bus). Experience The implementation of interactive workshops had a positive impact on the working behavior. The research process appeared complex for the students though the sport motor skill tests were handled well. References Bm:bm.k. (Hg). (2003). Klug & Fit. ## RELATIONSHIP BETWEEN LIFESPAN AND STRENGTH LEVELS FROM FORCE TESTS IN COLLEGE STUDENTS

Pessoa Filho, D., Bravo, V.A., Siqueira, L.O.C., Neiva, C.M., Verardi, C.E.L.

*São Paulo State University*

RELATIONSHIP BETWEEN LIFESPAN AND STRENGTH LEVELS FROM FORCE TESTS IN COLLEGE STUDENTS Bravo, V. A.1, Siqueira, L. O. C.1, Neiva, C. M.1, Verardi, C. E. L.1, Pessoa Filho, D. M.1. 1: UNESP (Bauru-SP, Brazil) Introduction The practice of physical activities from college students leading to damage level when not properly assisted, and worse it is when considering the practice of resistance exercise. To overcome this condition it is necessary to plan exercise programs taking into account anthropometric references, muscle level of fitness and lifespan information. The objective was to analyze the profile of college practitioners of resistive exercise from body composition, strength levels and lifespan. Methods 24 college students, 12 men ( $23.4 \pm 3.5$  years,  $75.2 \pm 6.5$  kg of body weight) and 12 women ( $21.2 \pm 3.2$  years,  $60.2 \pm 12.2$  kg of body weight) from UNESP at Bauru (SP) were subjected to body composition measurement from bio-impedance (Tanita, BC-553), that was classified following ACSM recommendation. The force was assessed from one repetition to maximum protocol (1RM) in bench press (BP), leg press (LP), arm curl (AC), lat pull down (PD), leg extension (LE) and leg curl (LC). The global index of force made possible a categorization of force into five levels ranging from poor to excellent for the performance in BP, LP, AC, PD, LE and LC. Lifespan information was analyzed from SF36 questionnaire, categorized into functional capacity (FC), physical constraints (FCo), pain (P), health status (HS), vitality (V), social features (SF), emotional features (EF), and mental health (MH). Results The body fat in men ( $14.96 \pm 3.29\%$ ) and women ( $21.95 \pm 6.99\%$ ) were considered below and at mean, respectively. The values of force from 1RM protocols for men (BP:  $0.89 \pm 0.20$  kg.kg<sup>-1</sup>; AC:  $0.51 \pm 0.14$  kg.kg<sup>-1</sup>; PD:  $0.85 \pm 0.24$  kg.kg<sup>-1</sup>; LP:  $1.38 \pm 0.28$  kg.kg<sup>-1</sup>; LE:  $1.32 \pm 0.34$  kg.kg<sup>-1</sup>; and LC:  $0.81 \pm 0.12$  kg.kg<sup>-1</sup>) and women (BP:  $0.44 \pm 0.12$  kg.kg<sup>-1</sup>; AC:  $0.29 \pm 0.08$  kg.kg<sup>-1</sup>; PD:  $0.51 \pm 0.06$  kg.kg<sup>-1</sup>; LP:  $1.16 \pm 0.30$  kg.kg<sup>-1</sup>; LE:  $0.93 \pm 0.17$  kg.kg<sup>-1</sup>; and LC:  $0.55 \pm 0.16$  kg.kg<sup>-1</sup>) were categorized into good after global force index analysis. From the percentage of each level of the categories, 64% of the men and 73% of the women were even at good level. However, the performance at BP, PD and AC was considered above the mean for men and women. But the general level of force was in concert to the eight categories of lifespan, in such all subjects were located at high percentiles: 89(+/-15) to FC; 94(+/-25) to FCo; 75(+/-21) to P; 77 9(+/-16) to HS; 66(+/-17) to V; 85(+/-18) to SF; 84(+/-26) to EF and 72(+/-37) to MH. Conclusion The analyzed college students show an adequate profile of body fat, strength level and lifespan when related to the health patterns. However, a deficit of force for upper limbs was observed, and must be considered when planning an exercise program with resistance exercise. References GRIFFIN, J. C. ## EFFECT OF LOW-INTENSITY STRETCH EXERCISE ON RECTAL TEMPERATURE, STRESS, AND MOOD IN MIDDLE-AGED WOMEN IN JAPAN

Nagamatsu, T., Kitabatake, Y., Sensui, H.

*Meiji Yasuda Life Foundation of Health and Welfare*

Introduction Moderate exercise has been suggested to promote sleep onset and increase slow-wave sleep. We have also reported that low-intensity stretch training is effective in promoting greater improvement of sleep-related problems by shortening sleep onset latency. However, the mechanisms underlying such effects remain unclear. This study aimed to investigate the effects of low-intensity stretch exercise on physiological and psychological responses in relation to sleep. We examined changes in rectal temperature, stress, and mood states in response to acute exercise in middle-aged women. Methods Eight subjects (mean age,  $49.4 \pm 5.8$  years) who were not taking any medications affecting sleep volunteered to participate in this study. The exercise program required 10 min of stretching according to yoga techniques and poses. Exercise and control programs were randomly performed in a cross-over trial in each subject. Rectal temperature was measured before and after stretching. Cortisol in saliva was examined 5 min before and 5 min after each trial. Mood states (pleasantness, relaxation, anxiety) in response to stretching were also examined 30 min before and 5 min after each trial using a self-reported questionnaire. Results Significant interactions in the two factors (trial and time progress) were identified for rectal temperature, cortisol, and pleasantness score. A greater degree of change in rectal temperature was seen with the exercise program than with the control program. The rise in mean rectal temperature after stretching was approximately 0.1 deg C. Cortisol levels increased slightly in the control program and decreased in the exercise program. Pleasantness score increased over time in both programs, but the degree of change was greater in the exercise program than in the control program. Discussion Sleep onset is reportedly improved with peripheral heat dissipation at bedtime after a rise in core temperature of less than 0.5 deg C. This study found a suitable rise in core temperature was achieved after stretching. Stress response and pleasantness also improved with stretching. These changes after exercise may contribute to improved emotional condition at bedtime. In conclusion, performance of low-intensity stretch exercises immediately before bedtime may promote improvement in sleep-related problems by causing a suitable rise in core temperature, reduction of stress, and improved mood status in middle-aged women in Japan.

## SECULAR GROWTH CHANGES IN ATHLETIC BOYS - A PILOT STUDY

Farkas, A., Szmodis, M., Szots, G., Bosnyák, E.

*Semmelweis University, Faculty of Physical Education and Sport Sciences*

Introduction: Studies upon secular trend can show us the nature of changes in a population over time. We can get a common view into the essential effects of the socio-economical background – and also of the genetic components in different age groups and in active and non-active groups. The aim of this study was to analyze the trend and relationships, if any, between anthropometric characteristics over time in prepubertal and pubertal ball game players, so that to register any form of manifestation of the secular growth trend. Methods: The subjects were Hungarian basketball player boys living in Budapest, between 1993 and 2002, aged 9 to 16 (N=400). In taking all 24 anthropometric measurements the suggestions of the International Biological Program (Weiner and Lourie 1969) were considered. Body fat percentage was assessed by Pařízková's (1961) method, for body composition assessment the Drinkwater and Ross (1980) body fractionation method was used. We analysed the relationships of anthropometric variables and the changes of the trend over the time. Basic statistics, interrelationships and Student t-test were ( $p < 0,05$ ) used by Statistica Statsoft Version 9 computer programme. Differences of the respective subgroup means were tested by Tukey's post-hoc tests at the level of 5% random error. Results: There was an obvious constant age-dependent increase in the basic anthropometric measurements for the whole sample along the studied time period. When grouping the boys by age and by the studied years, we could only prove a definite, clear significant trend over time in some anthropometric measurements as most data followed oscillating manner of change. When considering the starting and the final time point of the 12 year old group they differed in their mesomorphy and in plastic index values, significantly. However there were interesting trend-like changes by age e.g. in the order of the magnitude in skinfolds by body regions. The relatively low subgroup numbers by age and by the subsequent years was a limitation factor in our present study. Discussion: When observing the growth trends we need really large sample of a population to check the consequent changes. Even when tendencies could be demonstrated no statistically proved results are existing. In the studied sample of basketball player boys the tendencies and trends of growth changes should be affected and modified by the factors of selection and their training history besides other socio-economical factors. We need to add further number of subjects to get more realistic picture on the quality of changes, if any, in respect of the secular growth trend.

#### CHEST AND ABDOMINAL CIRCUMFERENCE VARIATION ACCOMPANYING INCREASED VENTILATION IN INCREMENTAL-LOAD EXERCISE

KIMURA, M.1, YAMAMOTO, M.1, BAN, Y.2

*1:Tokyo Polytechnic University(Japan), 2:Musashino Junior College(Japan)*

Introduction The mode of diaphragm and respiratory-accessory muscle participation during high-intensity exercise has been reported to differ from the mode during rest or low-intensity exercise (Grimby et al.,1976; Johnson et al.,1993). The activated state of the respiratory muscles is manifested not only in increased ventilation, but also in accompanying variations in chest and abdominal movement (expansion and contraction). The present study therefore investigated the amplitude of cyclic variation in chest and abdominal circumference with rising ventilation during incremental-load exercise on a bicycle ergometer. Method Twelve healthy male subjects (age, 19-22 years) were participated in this study. With a pedaling speed of 50 rpm, the initial bicycle pedaling load of 50 W was increased by 10 W each minute until the subject exhibited total exhaustion. Mean values for minute ventilation (VE) and chest (chest-cir) and abdominal (abdominal-cir) circumferences during the 20 sec period from 40-60 sec at each load were obtained and the relationship between VE and chest-cir and abdominal-cir was analyzed. Results During the incremental-load exercise, the 12 subjects exhibited maximum VE of 89-143 L/min (mean, 113.9±17.6 L/min), maximum oxygen uptakes of 33.5-56.6 mL/kg/min (mean, 45.4±7.2 mL/kg/min), and peak heart rates of 179-207 beats/min (mean, 191.1±8.4 beats/min). All subjects exhibited the amplitude of cyclic variations in chest-cir, which increased linearly with the VE throughout the incremental-load exercise ( $r=0.818-0.974$ ). In contrast, the amplitude of cyclic variation in abdominal-cir increased with VE throughout the time to moderate exercise intensity (48-77% of maximum VE), but in some subjects declined relative to the VE with further increases in exercise intensity and in others continued to rise in positive linear correspondence with the VE in the same manner as chest-cir. Discussion These results indicate that during intense exercise, the respiratory and respiratory-accessory muscles in the chest work more strongly on the VE than do the muscles of the abdominal region. The decline in abdominal-cir variation relative to VE in high-intensity exercise that was found in several subjects may be attributed to fatigue of abdominal muscle (Bryan et al.,2006) and diaphragm (Johnson et al.,1993;Babcock et al.,1988). #### VALIDITY OF TRIAXIAL ACCELEROMETER FOR ASSESSMENT OF TOTAL ENERGY EXPENDITURE IN PRIMARY SCHOOL CHILDREN AGAINST DOUBLY LABELED WATER METHOD

Hikihara, Y., Midorikawa, T., Ohta, M., Tanaka, S.

*Chiba Institute of Technology*

Validity of Triaxial Accelerometer for Assessment of Total Energy Expenditure in Primary School Children against Doubly Labeled Water Method Hikihara Y. 1, 2, Midorikawa T. 3, Ohta M. 4, Tanaka S. 2 1:CIT (Chiba, Japan), 2:NIHN (Tokyo, Japan), 3:J.F.OU (Tokyo, Japan) 4:KSN (Ishikawa, Japan) Introduction Most of accelerometers underestimated total energy expenditure (TEE) compared with the value by doubly labeled water method (DLW). We speculate that it is because accelerometer cannot accurately evaluate nonlocomotive activities (Hikihara et al., 2012). Therefore we proposed algorithm and equations which differentiate locomotive activities from nonlocomotive using

triaxial accelerometer for children and adults (Oshima et al., 2010; Ohkawara et al., 2011; Hikiyama et al., under review). Moreover, we found that the equations for adults overestimate energy expenditure (EE) in children against EE evaluated by Douglas bag method. We examined the validity of triaxial accelerometer with algorithm and equations that we proposed for the assessment of TEE in children. Methods Twenty two primary school students (13boys, 9girls) participated in this examination. We measured TEE for 9 days using DLW method. We followed the standardized way of DLW in our previous study (Ishikawa-Takata et al., 2008). Simultaneously we asked them to wear triaxial accelerometer on left waist. This device memorized synthetic acceleration of a 10-s epoch length within a measurement range of  $\pm 6$  G and with a resolution of 3 mG. The synthetic acceleration was converted into metabolic equivalents through two equations of locomotive and nonlocomotive activities. Additionally, we asked subjects to record the time and duration when they detach the device from waist. Results Average TEE evaluated by DLW was  $2203 \pm 356$  kcal/day. Physical activity level (TEE/basal metabolic rate) was  $1.63 \pm 0.20$ . Meanwhile, TEE estimated from triaxial accelerometer was  $2223 \pm 311$  kcal/day. We did not find a significant difference between DLW method and triaxial accelerometer. Moreover, there is a significant relationship ( $r=0.83$ ,  $P<0.01$ ) between them. We also found a contribution of energy expenditure during nonlocomotive activities to TEE ( $r=0.67$ ,  $P<0.01$ ). Discussion Triaxial accelerometer that we proposed has better estimation accuracy than previous accelerometers. It might be because the equations in this accelerometer based on children's energy cost. Furthermore, we believe that we can evaluate nonlocomotive activities exactly as well as locomotive ones. We confirmed that it is important to focus on nonlocomotive activities because children have long time of such activities in their lifestyle. Conclusion Our results indicate that triaxial accelerometer with our unique algorithm can exactly estimate TEE in children.

### HOW IMPORTANT IS THE USE OF A LOGBOOK IN ADDITION TO ACCELEROMETER TO ASSESS THE PROPORTION OF INSUFFICIENTLY ACTIVE 13-YEAR-OLD GIRLS?

Titze, S.1, Stücker, M.1, Matouschek, S.1, Pedisić, Z.1,2

1 *Institute of Sport Science (Graz, Austria)*, 2 *Faculty of Kinesiology (Zagreb, Croatia)*

Introduction It is strongly recommended to use objective measurements for the assessment of physical activity among children and adolescents. However, as some activities such as bicycling/inline skating/scooter are incorrectly recorded by accelerometer, assisting methods are needed to obtain correct data. The aim of the study was to examine the proportion of insufficiently active girls based on data from accelerometer only compared to data from accelerometer combined with a logbook. Method In the city of Graz and in the rural surroundings 178 13-year-old girls filled in a logbook. Of those, 125 girls wore an accelerometer (GT3X+) for at least four days. In the logbook we particularly asked about the duration of cycling/inline skating/scooter for transport per day as this is recorded with the accelerometer as light-intensity physical activity. We calculated the average minutes of at least moderate-intensity physical activity (MVPA) per day as well as the average minutes of cycling/inline skating/scooter per day of each individual. Finally, we divided the girls into insufficiently (less than 60 min of MVPA per day) and sufficiently active groups. McNemar chi-squared test was applied. Results Cycling/inline skating/scooter for transport were performed at least once a week by 49% of the girls with a median duration of 36 min per day. Based on the accelerometer data 84% of the girls were insufficiently active. After adding the minutes of MVPA assessed by accelerometer and the minutes of cycling/inline skating/scooter derived from the logbook the proportion of insufficiently active girls was reduced statistically significantly to 53%. Discussion In our sample of young girls the prevalence of cycling/inline skating/scooter at least once a week was almost 50%. As long as accelerometers do not appropriately measure e.g. non weight bearing physical activities such as bicycling, it is strongly recommended to additionally apply methods to capture those activities. Without taking cycling/inline skating/scooter into account, the prevalence of insufficiently active girls would have been overestimated considerably in our study. Furthermore, correct information about such activities is important to assess relationships between MVPA and active transport or for tracking of cycling/inline skating/scooter over time (Carver et al., 2011). ### HANDGRIP STRENGTH SEEMS TO BE AN IMPORTANT PREDICTOR OF PHYSICAL FITNESS REGARDLESS OF PUBERTAL STATUS

Matsudo, S.M.M.1, Rezende, L.F.M.1, Matsudo, V.K.R.1, Raso, V.2,3

1: *CELAFFICS (SP, Brazil)*; 2: *UNOESTE (SP, Brazil)*; 3: *UNIBAN (SP, Brazil)*

Introduction Numerous tests and measures have been used to physical fitness assessment. Handgrip (HG) dynamometry is one of the simplest to apply, and studies have showed that HG is associated with sports performance (FERRAGUT et al 2011). However, a few studies have showed the power of HG to predict other physical fitness variables. Purpose To examine the power of HG to predict physical fitness in boys and girls with different sexual maturation levels. Methods A cross-sectional study from the "Longitudinal Project of Growth, Development and Physical Fitness in Children from Ilhabela", Brazil. The sample consisted of 468 youth aged 10-15 living in a low socioeconomic status island in Brazil. We measured body composition (BMI), waist circumference and adiposity with mean of 7 skinfolds), physical fitness (lower limb strength: with vertical jump test, standing long jump; curl up, flexibility, agility and speed), energy expenditure (IPAQ), HG strength (mechanical dynamometer - Takey) and Pubertal status by Tanner self-evaluated. Multiple regression analysis investigated associations of physical fitness parameters with age, sexual maturation, energy expenditure and grip strength. Statistical significance was set at  $p<0.05$  Results The prediction power of HG in total sample was: 29% for vertical jump ( $R=.54$ ,  $R^2=.29$ ;  $P=.002$ ), 46% for standing long jump ( $R=.68$ ,  $R^2=.46$ ;  $P=.0005$ ), 24% for curl up ( $R=.49$ ,  $R^2=.24$ ;  $P=.010$ ), 4% for flexibility ( $R=.21$ ,  $R^2=.04$ ;  $P=.655$ ), 25% for agility ( $R=.50$ ,  $R^2=.25$ ;  $P=.0005$ ), 38% for speed at seconds ( $R=.61$ ,  $R^2=.38$ ;  $P=.0005$ ) and 47% for speed at meters per seconds ( $R=.69$ ,  $R^2=.47$ ;  $P=.0005$ ) to 47% (speed at meters per seconds:  $R=.69$ ,  $R^2=.47$ ;  $P=.0005$ ). Discussion Studies have showed the importance of hand-grip as a predictor of some anthropometric variables (SHYAMAL K et al. 2009). Our results support that hand-grip is consistently associated with several distinct parameters of physical fitness regardless of age, gender and sexual maturation, permitting to suggest that physical fitness could be independently predicted by hand grip strength with an elevated accuracy. ### EFFECTS OF SUPINE POSITION IN WATER ON ARTERIAL STIFFNESS IN THE MIDDLE-AGED FEMALES

SAITO, T.1, TAKAHARA, T.2, TAKAGI, Y.1,3, HAYASHI, S.1, ARAKANE, K.1, SAITO, K.1,4, YAMADA, A.5, YOSHIOKA, A.6, ONODERA, S.2

1: GRADUATE SCHOOL, KUMMW, 2: KUMMW, 3: JSPS RESEARCH FELLOW, 4: THE SAKAKIBARA HEART INSTITUTE OF OKAYAMA, 5: MIYAKE MEDICAL INSTITUTE GROUP, GRACEFUL SPORTS CLUB SALAMANDER, 6: KAGAWA UNIV

Introduction: Heart rate, oxygen uptake and body temperature are influenced by the physical characteristics of water (water temperature, buoyancy, viscosity, etc). brachial-ankle pulse wave velocity (baPWV) is depended by Systolic blood pressure (SBP) and age. Previous studies demonstrated an increase of baPWV and SBP with aging. SBP was a different response to age in water. SBP of Younger decrease and the middle-aged increase. Therefore, we hypothesized that baPWV and SBP could change in water in the middle-aged. The purpose of this study was to clarify the effects of supine position in water on arterial stiffness in the middle-aged females. Methods: Six Japanese middle-aged females volunteered to participate in this study. We had informed consent prior to participate in this study. The age, body weight and body height of subjects were  $63.0 \pm 3.9$  years old,  $55.9 \pm 7.9$  kg and  $152.4 \pm 5.7$  cm respectively. This study consisted of two conditions. One was the land condition (room temperature:  $28.6 \pm 0.4$  °C), and the other was the water condition (water temperature: 30 °C). Subjects lay in supine position on the experimental steel board under the water. Whole body except for the face was submerged below the water surface. Measurement indexes were baPWV, heart rate, blood pressure and the scale of a subjective thermal sensation (STSS). Land condition was measured after supine position on land for 5 minutes. Water condition was measured after supine position in water for 5 minutes. Results: baPWV ( $1916 \pm 105$  cm/s), SBP ( $160 \pm 14$  mmHg) and STSS (2=Cool) at water condition was significantly higher than that at land condition (baPWV;  $1771 \pm 69$  cm/s, SBP;  $145 \pm 9$  mmHg, STSS; 0=Neutral,  $p < 0.05$  respectively). Discussion: STSS in water condition showed as 'cool'. SBP and age are potentially influential factors of the baPWV. SBP is determined by cardiac output and arterial elasticity. It was considered that the baPWV was influenced by SBP during supine position in water. Conclusion: Our conclusion is that supine position in water (water temperature: 30 °C) could be contributed to the constriction of a blood vessel of arterial stiffness in the middle-aged.

### EFFECTS OF A BEHAVIOR-ORIENTED EXERCISE INTERVENTION ON ACTIVITY-RELATED SELF-EFFICACY BY OBESE ADULTS

Eckert, K., Lange, M., Huber, G., Wagner, P.

University of Leipzig, University of Heidelberg

Eckert, K.1, Lange, M.1, Huber, G.2, Wagner, P.1 1: University of Leipzig, Institute of Exercise and Public Health (Germany) 2: University of Heidelberg, Institute of Exercise and Sport Science (Germany) Introduction There is enough evidence that physical activity (PA) plays an important part in regulating an un-healthy body weight, but the integration of PA in an individual's everyday life rarely succeeds. Ac-tivity related self-efficacy (SE) has determined to have a long-lasting effect on behavior change (Niermann, 2010). According to the literature SE typically differs in three SE phases: intention, recovery and planning SE (Schwarzer et al., 2008). The aim of our study was therefore to evaluate the effects of a behavior-oriented exercise program regarding the phase-specific self-efficacy by obese people. Method The study was designed as a multi-center, controlled intervention study (treatment group (IG): N=101, control group (CG): N=23) with pre-post testing (t1 and t2). The intervention took place for 10 weeks (1x/week á 90 min.) and combined functional training with elements of patient education and behavior-oriented techniques. Data of physical activity and phase-specific self-efficacy (SE) was assessed by questionnaires at first (t1) and last session (t2). Results The mean BMI of all participants was  $34,12$  kg/m<sup>2</sup> (s=4,52, Range 25,22 – 50,56) at time point t1. 84 complete datasets could be analyzed after intervention (t2). Only participants of the IG with a PA-level of 60-240 min./week at t1 showed significant improvements of their intentional SE at t2 (n=28;  $p < 0.01$ ,  $t = -2,657$ ;  $d = 0,67$ ). Furthermore participants of the IG with initially high levels of SE (in all three phases) at t1 increased their PA level significantly during the intervention (n=50;  $p < 0.001$ ,  $t = -4,145$ ;  $d = 0,67$ ). The CG showed no improvements neither to the intentional SE ( $p = 0,232$ ,  $t = 1,235$ ) nor the physical activity level (n=19;  $p = 0,461$ ,  $t = 0,798$ ). The measurements carried out did not reveal any significant changes in behavior change when comparing the groups (time:  $p = 0,167$ ,  $F = 1,950$ ; interaction time\*group:  $p = 0,182$ ,  $F = 1,851$ ). Discussion Our findings indicate that there is an interrelation between PA-level and phase-specific self-efficacy. Obviously, exercise interventions require a more behavior-oriented emphasis especially for unmotivated people. A replication of the intervention with a larger sample size and a longer, modified intervention-duration needs to be discussed. Literature Niermann C (2010). ### MENSTRUAL STATUS OF ATHLETES AND NON-ATHLETES

Atan, T., Cicek, G., İmamoglu, O.

Ondokuz Mayıs University

MENSTRUAL STATUS OF ATHLETES AND NON-ATHLETES Atan, T.1, Çiçek, G.2, İmamoglu, O.1 1 Ondokuz Mayıs University, Yaşar Doğu Physical Education and Sports High School (Turkey) 2 Hitit University, Physical Education and Sports High School (Turkey) Introduction The menstrual cycle is a complex physiological phenomenon and a major part of every woman's life (Fox et al., 1988). The aim of this study was to examine the menstrual status and feelings of athletes (in different sport branches) and non-athletes. Materials and methods A questionnaire consisting of 21 questions were prepared by researchers in order to obtain age, menarche age, menstrual status, menstrual cycle, menstrual pain, menstrual regularity and feelings throughout menstruation. Questionnaires were applied to participants by face-to-face method. Results In this study non-athletes' reached menarche age earlier than the whole athletes except wrestlers-judokas. Athletes' menstrual status was found more irregular than non-athletes. During the high intensive training, the percentage of regular menstrual cycle (29.7 %) was lower than the normal time (56.6 %). Menstrual cycle was found more irregular during high intensive training than in normal time. The prevalence of menstrual pain is higher in non-athletes. Throughout the menstruation, ratio of non-athletes to feel better about themselves were less than athletes. Discussion In the current study it has been seen that the mean menarche age for total athletes is  $13.78 \pm 1.31$  years. Athletes in certain endurance and aesthetic sports appear to be at an added risk of delayed menarche (Malina, 1979). The menarche age of non-athletes was found 13.04 years. When the status of the menstruation in normal time was examined, 56.6% of athletes and 59.1% of non-athletes had a regular menstrual cycle (once in 21-30days). This means that athletes' menstrual status is more irregular than non-athletes. As a result of a questionnaire 41.6% of athletes and 59.5% of non-athletes have pain all the time. Bayram (2007) have found frequency of dysmenorrhea 59% in athletes and 76% in sedentary women. Throughout the mens, ratio of non-athletes to feel better about themselves were less than athletes. Women who frequently exercised may be to some extent protected

from deterioration of mood before and during menstruation (Choi et al., 1995). References 1. Fox, L.E., Bowers, R.W., Foss, M.L. (1988). ## WELLNESS EDUCATION IN JAPANESE UNIVERSITIES AND COLLEGES

Mizumura, S.

*Meiji University*

Introduction "Wellness is an active process of becoming aware of and making choices toward a more successful existence."(1) It is apparent that the concept of wellness is not widely spread throughout Japan. The author believes that university and college students should be familiar with the concept before they graduate. Therefore, it is very important to clarify the degree of wellness education at Japanese universities and colleges. To obtain basic data reflecting the spread of the wellness concept among Japanese institutions of higher education, the author investigated the number of Japanese universities and colleges providing courses which address the concept of wellness. Methods According to the previous study(2), the author investigated a total of 1335 websites from 771 universities (803 websites) and 532 junior colleges (532 websites) by using an internet search engine over a two month period. The word "wellness" and a Japanese word corresponding to wellness were selected as search terms. By using "site:" syntax all web pages that contained the search terms were retrieved from each official Japanese University or College website. Three investigators, including the author, separately inspected all web pages retrieved. The obtained data inspected by the three investigators were compiled into a single spreadsheet. Results The main findings of the present study were that only 10.3 and 2.4 percents of the websites from Japanese universities and junior colleges respectively, offered courses which included the word "wellness". The percentage of universities offering the subjects was significantly higher than that of junior colleges. A total of 177 courses contained the word "wellness" in its title or syllabus. Courses were classified into eight fields as follows: Health and physical education, 70.0%; Welfare and Nursing, 9.6%; Tourism, 5.6%; Nutrition, 4.5%; Human life, 4.5%; Psychology, 2.3% and Marketing, 1.1%. An analysis from each syllabus of the 177 courses revealed that 81 courses (45.8%) clearly describe the concept of wellness. Discussion The present study is the first to show how many Japanese universities and colleges provide courses that include the concept of wellness. The results revealed that Japanese universities and colleges offered small number of courses that included the concept of wellness, and the courses consist of many fields of study. These results indicate that the concept of wellness should be more spread in Japanese universities and colleges. The author also believes that Japanese wellness researchers and educators should expand their efforts to spread the knowledge of wellness for Japanese university and college students. ## INFLUENCE OF BODY MASS AND SKINFOLDS ON SKIN TEMPERATURE THROUGH INFRARED THERMOGRAPHY

Fernández-Cuevas, I.1, Marins, J.2, Ribot Serrano, J.1, Arnaiz Lastras, J.1, Butrageno, J.1, Sillero Quintana, M.1

*Technical University of Madrid (Universidad Politécnica de Madrid)*

Introduction For a correct application of Infrared Thermography (IR) on humans several influence factors should be controlled (Ring & Ammer, 2000). Subcutaneous fat is meant to be one of the most important factors on skin temperature, due to its isolation properties, between the body core and the skin. The aim of this study was to study the relation between body mass, skinfolds and skin temperature in different body areas. Methods A total of 33 male and female were divided according to their BMI classification: being normal weight NW (n=10: 24.9±3.9 yr, BMI 22.2±1.6), overweight OW (n=11: 41.6±7.0 yr, BMI 28.4±1.1) and obese OB (n=12: 37.8±8.5 yr, BMI 32.1±2.0). Skinfold thicknesses at 5 body sites -biceps (BI), triceps (TR), subscapular (SE), abdominal (AB) and thigh (T), all in mm- were measured following the ISAK guidelines with a skinfold caliper (Slim Guide, USA) in order to assess local fat distribution. Skin temperature from participants were recorded by Infrared Thermography (T335, FLYR Systems, Sweden) in a environment-controlled room (Temperature: 22.7±1.6°C; humidity: 44.0±3.2%), following the patterns set by Gomez-Carmona et al. (2010) patent pending protocol. Skin temperatures from 72 Regions of Interest (ROI) were obtained using Termotracker® software. ANOVA test were carried out for averaged temperatures by BMI group, and Pearson correlation test between skinfold thickness and averaged skin temperatures in each body area were calculated (alpha<0.05). Results Skinfolds temperatures for normal weight subjects were NW(TR)=29.3±0.8, NW(SE)=31.7±0.6, NW(T)=29.±1.0, NW(AB)=1.8±0.7; NW(BI)=31.8±0.6; for overweight were OW(TR)=30.1±1.1, OW(SE)=30.5±1.2, OW(T)=30.4±1.4, OW(AB)=30.8±1.5, OW(BI)=31.3±1.1; and for obese were OB(TR)=30.6±1.2, OB(SE)=31.2±1.2, OB(T)=30.2±1.3, OB(AB)=31.1±1.1, OB(BI)=31.7±0.9. ANOVA results show us only significant differences between BMI groups in Triceps (F=4.01; p<0.05) and Subscapular (F=3.42; p<0.05). However, Pearson test correlation results could not establish any significant relationship between local temperature and skinfold thickness. Discussion Some studies have considered that a greater subcutaneous abdominal adipose tissue provides a significant insulation and a cooler temperature (Savastano, 2009). Nevertheless, this BMI-based study could not get that relationship, probably due to the influence of other factors as the time of data collection or aging between BMI groups (Weinert, 2010). Based on our data, we conclude that the BMI classification NW, OW and OB is not related with the thermal response at skin level. Further investigations with a larger sample and more information about adipose tissue (i.e. DXA) are required (Glickman-Weiss, 1996). References Glickman-Weiss, E. L. et al (1996). *Wilderness & Environmental Medicine*, 7(1), 19-27 Gomez-Carmona, P. M.(2010). Spain Patent Pending No. P201031080 Savastano, D. ## AN EXAMINATION OF SEDENTARY AND EATING ATTITUDES OF A SPANISH UNIVERSITY POPULATION: THE INFLUENCE OF STUDYING NURSERY ON ITS STUDENTS OWN BEHAVIOUR

Varela, V., Cancela, J.M., Ayán, C.

*Vigo University*

Introduction: Future education and health professionals will be responsible for encouraging physical activity and correct eating habits among the general population. However, it has been noted that the period of undergraduate study is often a phase of change in terms of practice of PA, often reduced<sup>1</sup>, and indeed dietary habits curb to less healthy options<sup>2</sup>, notably among females university students. The aim of this study was to discover the prevalence of physical activity and the existence of eating disorders among Nursing, Physiotherapy

and Education students. Materials and Methods: A transversal descriptive study through a combination of the International Physical Activity Questionnaire and the Eating Attitude Test 40 was directed to students that take part in the aforementioned degrees in the Pontevedra Campus at Vigo University. The data collection took place during a single day in the class with the most registered students for the selected course and academic year through an individual, anonymous and voluntary questionnaire on an "ad hoc" basis. Results: The data showed that 64% of Nursing students and 72% of Teaching students were qualified as sedentary individuals, while 19.5% and 15.3% of them respectively were likely to suffer from eating disorders. A significant association between physical activity performance and disturbed eating behaviours was observed among Education students. Discussion: The practice of PA has been identified as a risk factor linked with the existence of DEA13 among university students<sup>14</sup>, which coheres with the results of this particular study. However, this behaviour was only found to be significant among teaching students, albeit the results that showed that Nursery and Teaching students presented similar health patterns. As a result, it has been recognised that sedentary behaviour and poor dietary habits are linked to students within the vocations of health and education. References: 1. #### EFFECTS OF TRAINING ON 10MIN CYCLING TIME TRIAL PERFORMANCE AND PACING STRATEGY

Martin, D.T.1,2, Barnes, C.1, Bartram, J.1, West, N.1,3, Stephens, J.1, Michaels, S.1, Abbiss, C.2, Halson, S.L.4

1: AIS Physiology (Canberra, Australia), 2: Edith Cowan University (Perth, Australia), 3: Griffith University (Gold Coast, Australia), 4: AIS Performance Recovery (Canberra, Australia)

**Introduction** In sport, the distribution of work over a defined exercise period has been defined as a "pacing strategy." Both teleoanticipation and feedback mechanisms have been suggested to influence pacing (Abbiss and Laursen, 2008). The purpose of this study was to examine the influence of a 3-wk training camp on the pacing of cyclists that improved overall cycling time trial performance (i.e. responders) in order to gain insight into the role teleoanticipation and feedback mechanisms may play in pacing. **Methods** Male competitive cyclists (n=13; 19.9±1.3y, 71.8±5.7kg, maximal aerobic power; 370±36W) completed structured training for 5wks. Cyclists trained for 2-8 hours daily and the program included cycle ergometer sessions 3 d.wk<sup>-1</sup>. Each week participants performed a 10min cycling Time Trial (TT; Wattbike) at the end an interval session. Power was recorded at 1Hz and maximum mean power (MMP10min) was calculated. Responders were defined as cyclists that improved MMP10min 5-15% from baseline with baseline tests within 5%. The Typical Error (TE) was used to estimate reliability. A priori planned contrasts (paired t-tests) were used to compare MMP10min performance and pacing during baseline and best performances. Pacing was quantified by dividing the 10min time trial into 4, 150s segments. Results The TE for MMP10min was 1.4%. The best MMP10min produced in the camp was 8.4±2.9% (mean±90% CI) greater than baseline (362±41W vs 334±37W). The perception of effort and post TT heart rate were similar for baseline and best TT performances (~98%max and ~180-185bpm). On average, the distribution of work for each 150s of the TT10min at baseline and best performance was similar (25%, 25%, 24%, 26%). Following training, the increase in power for each of the four segments (150s) of the TT was 7±3%; 7±2%; 9±2% and 12±3%. **Discussion** Cyclists selected for this analysis produced a large and consistent increase in MMP10min (~8%) during a 3wk training study. The pacing during baseline testing and best 10min TT were similar. The dramatic increase in cycling power (~7%) during the first 150s of the 10min TT, following training supports the concept of teleoanticipation as feedback mechanisms are less likely to be involved. The improvement in power during the final 150s (~12%) with similar peak heart rates and perception of effort, indicates that peripheral feedback mechanisms may be involved in training improvements. Our data support the concept that both feed forward and feedback mechanisms contribute to training induced improvements in time trial performance. #### EFFECT OF AEROBIC FITNESS LEVEL ON THE AMPLITUDE OF MODERATE, HEAVY AND SEVERE INTENSITY DOMAINS IN CYCLING

Greco, C.1, Caritá, R.A.C.1, Caputo, F.2, Denadai, B.S.1

1: Human Performance Laboratory - UNESP, 2: UDESC

**Introduction** Exercise intensity domains have been defined based upon their distinct metabolic profiles (Gaesser and Poole, 1996). The moderate domain consists of work rates at or below the lactate threshold (i.e., the first sudden and sustained increase in blood lactate above resting concentrations - LT). The heavy domain includes work rates above LT, but at or below critical power (i.e., the asymptote of the power-duration relationship - CP). The severe domain encompasses work rates above CP in which maximal oxygen uptake (VO<sub>2</sub>max) can be elicited. Endurance training enhances LT, maximal lactate steady state (MLSS) and critical power CP. However, VO<sub>2</sub>max has shown to be less sensible to aerobic training, particularly in well-trained subjects. Thus, the objective of this study was to analyze the amplitude of the exercise intensity domains in cyclists, runners and untrained subjects during cycling. **Methods** Twelve cyclists (EC) (25±5 yr., 67±8 kg, 65±7 ml/kg/min), eleven runners (ER) (27±9 yr., 65±6 kg, 55±6 ml/min/kg) and eight untrained subjects (UT) (24±3 yr., 72±11 kg, 42±4 ml/kg/min), performed the following protocols, in different days, in a cycle ergometer: 1) incremental test to determine the LT, VO<sub>2</sub>max and the intensity associated with the achievement of VO<sub>2</sub>max (IVO<sub>2</sub>max); and (2) constant work-rate running and cycling exercises to exhaustion at 95, 100 and 110% IVO<sub>2</sub>max in order to determine the CP and the highest intensity (IHIGH) at which VO<sub>2</sub>max is reached (Caputo and Denadai, 2008). The amplitude of the exercise intensity domains (i.e., moderate < LT; LT < heavy < CP; CP < severe < IHIGH) was expressed as percentage of the difference between the VO<sub>2</sub> at LT and estimated VO<sub>2</sub> at IHIGH (i.e., %Δ). Results The IHIGH was significantly higher in EC (448.9±34.4 W) than ER (318.7±50.7 W) and UT (257.3±58.9 W). The amplitude of moderate exercise domain

in EC ( $51.7 \pm 7.9\% \Delta$ ) was similar to ER ( $46.7 \pm 4.2\% \Delta$ ) and significantly higher than UT ( $41.2 \pm 6.8\% \Delta$ ). The heavy intensity domain was significantly narrower in EC ( $17.5 \pm 3.5\% \Delta$ ) than UT ( $27.1 \pm 5.6\% \Delta$ ) and ER ( $27.5 \pm 9.1\% \Delta$ ). The amplitude of the severe domain was similar among EC ( $30.9 \pm 6.5\% \Delta$ ), ER ( $26.2 \pm 5.2\% \Delta$ ) and UT ( $31.3 \pm 7.3\% \Delta$ ). Discussion The main finding of our study was that the magnitude of the exercise intensity domains may be influenced by the aerobic status training. Basically, the moderate exercise domain seems to be more sensitive to long-term endurance training in cycling. This can be explained, at least in part, by the greater sensitivity of blood lactate response (i.e., LT) to endurance training. References Caputo F, Denadai BS. (2008). *Eur J Appl Physiol* 103: 47-57. Gaesser GA, Poole DC. (1996). *Exerc Sports Rev* 24: 35-71.

### SPECIFIC PERFORMANCE DIAGNOSTIC IN LABORATORY AND FIELD OF BMX-RACING

Meurer, R., Schmidt, A., Meyer, H., Heine, O., Nüsser, S., Loetzerich, H.

*German Sports University Cologne*

Specific performance diagnostic in laboratory and field of BMX-Racing R.Meurer<sup>1</sup>, A.Schmidt<sup>1</sup>, H.Meyer<sup>1</sup>, H.Loetzerich<sup>1</sup>, O.Heine<sup>2</sup>, S.Nüsser<sup>3</sup> GSU1: (German Sport University, Cologne, Germany), OSP2: (Olympic Base Center Rheinland, Köln, Germany), SNDC3: (Stepahn Nuesser Diagnostic Center, Burscheid, Germany) Introduction: BMX Racing is an Olympic discipline and the BMX Sport is experiencing more attention. There is not much detailed information available about the sport specific requirements and the common performance tests are mostly transferred from road and track cycling. Method: Six high level BMX riders (mean  $\pm$  SD: 16,2 yrs  $\pm$  1,2, 65,2 kg  $\pm$  5,1, 178 cm  $\pm$  0,01cm) performed a performance test in the laboratory with the individual BMX bike position (standing up). Therefore the bicycle ergometer was adjusted to transfer the individual bike setup on to the ergometer. First step was a standardised warm up, with a step-wise increase of the resistance (watt), for 15 min. The test was performed until 200 watt was reached, mean lactate levels after the warm up were 1,92 mmol/l  $\pm$  0,25. Step two was a BMX start simulation, where the riders had to sprint for 5 sec., set up and resistance of the ergometer were similar to the start on a BMX bike. Peak Power Start (PPS) was 1311 w  $\pm$  154.17. Third step of the test protocol was a 15 sec. sprint test which is similar to the active exercise time on a BMX track. The test was accomplished in a isokinetic mode with a limit of rpm to determine Peak Power (PP). After the test, lactic acid was measured, regularly over 10 min to determine peak lactic values (PL). PP was 1283,75 w  $\pm$  135,44. PL was 7,43 mmol/l  $\pm$  1,59. To compare our data's from the laboratory we measured PP and PL on a BMX track with portable power meter system. After one lap under race conditions PP was 990 w  $\pm$  178,9. Mean power over the first 5 sec at the start (MPS) was 427,90 w  $\pm$  132,65. PL was 5,81 mmol/l  $\pm$  1,12. Results: The results of the BMX performance test show very assimilable results to the data we measured on the BMX track with mobile powermeter systems. PP, LP in the laboratory was for all riders higher than on the track. The order of the measured values in the comparison of laboratory to track was significant. The order of PPS, MPS, PP, PL were identical. The rider with the highest values in the laboratory also had the highest values on the track, same structure for all riders. Discussion: The purpose of this project was to develop a test protocol for a BMX specific performance diagnostic in the laboratory. In our BMX performance test protocol we are able to investigate the rider's individual performance and requirements of BMX racing performance under standardised conditions in the laboratory. The individual structure of the riders peak power, start power and lactic acid production are reflecting very closely the individual physiological performance on the track.

### THE ACUTE EFFECT OF WHOLE-BODY VIBRATION ON CYCLING PEAK POWER OUTPUT

Hill, C.

*University of Worcester*

Introduction The application of an acute bout of whole-body vibration (WBV), whereby athletes stand on a vibrating platform prior to exercise, has been shown to increase short-term anaerobic leg power (Cardinale & Lim, 2003; Cochrane & Stannard, 2005; Torvinen et al., 2002). The use of WBV has not, for the majority of cases, been applied to a sport specific event. The purpose of this study was to determine if WBV, included as part of a warm-up, will increase peak power output during standing sprint cycling. Methods Ten experienced cyclists performed two separate performance tests comprising of a ten second standing sprint on a cycle ergometer. Preceding both performances participants performed a ten minute cycling warm-up. In one of the two warm-ups participants were also exposed to a two minute bout of WBV after the cycle specific warm-up. Results No significant difference was found for peak power ( $p = 0.17$ ), time to peak power ( $p = 0.47$ ), peak cadence ( $p = 0.46$ ) and time to peak cadence ( $p = 0.18$ ) between trials. Discussion The main finding from this study is that the use of WBV prior to maximal sprint cycling does not increase peak power output. The repeated eccentric – concentric action that skeletal muscle undergoes during WBV may not be an appropriate intervention for the predominant concentric only activity of cycling (Cochrane et al., 2008). Previous successful intervention studies have utilised exercises that incorporate the stretch-shortening cycle during eccentric – concentric activity such as a countermovement jump (Cardinale and Lim, 2003; Cochrane and Stannard, 2005; Cormie et al., 2006; Torvinen et al., 2002). The results suggest that WBV does not affect the concentric only action of cycling. References Cardinale M, Lim J. (2003). ### CHANGES IN ENDURANCE PERFORMANCE DUE TO AN ULTRA-NON-STOP CYCLING RACE – A SINGLE CASE STUDY

Wallner, D.1, Simi, H.1, Konrad, M.1, Hofmann, P.2

1: FH JOANNEUM Univ. Appl. Sci., 2: Karl-Franz.-Univ. and Med. Univ. Graz

Ultra-long distance exercises lead to changes in energy metabolism (Henrikson, 1991; Volk & Neumann, 2000) and hemodynamic variables which probably effect heart rate behavior (Pokan et al., 2011). These changes may influence endurance performance. Aim of this study was to analyze the effect of a 27 h non-stop cycling race on endurance performance. Method: One trained male cyclist ( $VO_{2max}$ : 59.1 ml/kg/min) performed an incremental exercise test before (T1) and after (T2) a 27:17 h (718 km, 8000 m difference in altitude) non-stop cycling race across Austria (Trans-Austria). During incremental test heart rate (HR) was measured continuously and blood lactate concentration (La) was measured at rest and after every load step (increments: 20 W every minute). Heart rate turn point (H RTP), first (LTP1) and

the second (LTP2) lactate turn point were defined as reported by Hofmann et al. (1997). Results: Average race speed was 26.3 km/h with an energy consumption of about 6300 kcal. Maximal power output (Pmax) was 400 W (T1) and 300 W (T2), respectively. La and HR at Pmax were 9.7 mmol/l (T1) and 2.9 mmol/l (T2), 199 min<sup>-1</sup> (T1) and 150 min<sup>-1</sup> (T2), respectively. No difference was found in the La performance curve till subjective exhaustion, whereas HF showed an increasing reduction with work load in T2. HRTP and LTP2 could not be defined in T2. Power output and La at LTP1 were unchanged (212 W (T1) and 210 W (T2), 0.7 mmol/l (T1) and 0.9 mmol/l (T2), respectively) whereas HF was reduced by 12.3% (155 min<sup>-1</sup> (T1) and 136 min<sup>-1</sup> (T2), respectively). Conclusion: Low pace aerobic endurance performance remains unchanged after ultra-non-stop cycling races whereas the corresponding HR markedly decreased. Therefore, exercise intensity regulation during ultra-long distance exercises should not be based on HR. References: Pokan et al. ## THE EFFECT OF MAXIMAL AND SUB MAXIMAL STRENGTH TRAINING ON CYCLING ENDURANCE PERFORMANCE

Smit, A.1, Hameetman, C.W.1, Peters, T.1, Bastiaans, J.J.2

1: NOC\*NSF (Arnhem, the Netherlands), 2: KNWU (Nieuwegein, the Netherlands)

**INTRODUCTION** Cyclists feel reluctance to do maximal strength training (ST) because they fear for negative effects on cycling endurance performance. However, recent studies showed positive effects of maximal ST on endurance cycling performance. Therefore, the aim of the study was to compare the effects of a maximal and sub maximal ST program on cycling performance in elite cyclists. **METHODS** Seventeen highly trained cyclists (20.0±1.6 years old) were divided in two training groups. that performed a maximal or sub maximal ST program, twice a week for two blocks of four weeks concurrent to cycling endurance training. Changes in average power at 80% and 90% of the maximal heart rate (P80% and P90%) and total work (TW) and critical power (CP) were assessed in two consecutive tests. Between-group effects were determined with inferences based on a meaningful difference of 6% and 3% for P80% and P90% respectively and a smallest worthwhile change of 1% for time trial performance and standardized changes for road races for TW and CP. A Students T-test was used to establish within-group differences. **RESULTS** There were "likely positive" between-group differences for mean changes in the P90% (6.3%; 90% confidence limits, ±6.3) in favour of the sub maximal training group, with only a significant increase in P90% for the sub maximal group (p=0.011). Between-group differences for mean changes in P80%, W and CP were "unclear". T-tests revealed significant improvements in TW (p=0.019 and 0.030) and CP (p=0.022 and p=0.028) for the sub maximal and maximal group respectively from pre- to post-test. **DISCUSSION** The findings show that sub maximal ST, when performed concurrent to cycling endurance training, results in a greater improvement in sub maximal cycling performance than maximal ST. Earlier studies showed that replacing a portion of endurance training with sub maximal ST compared to only endurance training could maintain high intensity cycling performance (Bastiaans et al., 2001), while recent studies suggest that adding heavy-resistance ST improves endurance cycling performance (Aagaard et al., 2011; Rønnestad et al., 2010). Although concurrent strength and endurance training have a negative effect on each other (Rønnestad et al., 2011), the combination increases cycling performance more than one type of training alone. Our study suggests that cycling endurance training can best be combined with sub maximal ST instead of maximal ST to increase cycling performance. **REFERENCES** Aagaard P et al. ## COMPARISON BETWEEN LOW VS HIGH CADENCE INTERVAL TRAINING SESSIONS

Bosio, A., Induni, M., Menaspà, P., Morelli, A., Tornaghi, M., Carlomagno, D., Rampinini, E.

*Mapei Sport Research Centre*

**COMPARISON BETWEEN LOW VS HIGH CADENCE INTERVAL TRAINING SESSIONS** Bosio A.1, Induni M.1, Menaspà P.1,3, Morelli A.1, Tornaghi M.1, Carlomagno D.1, Rampinini E.1,2 1MAPEI Sport Research Centre (Castellanza, Italy) 2Faculty of Exercise Sciences, Milan University (Milan, Italy) 3AIS, (Canberra, Australia) **Introduction** SFR (uphill pedaling at low rpm) is a type of interval training (IT). High cadence cycling achieves higher cardio-respiratory and metabolic responses than low cadence, but decreases neuromuscular properties to the same extent (Hirai et al. 2010; Lepers et al., 2001). Low compared to high cadence IT seems a better strategy to improve uphill and flat time trial performance. Aim of the study was to compare the acute effects of two IT sessions. **Methods** Low (35rpm, SFR) and high (115rpm, HC) cadence IT sessions (8x4min 2min rec) were carried out on 2 days. Workload was 64±2% of the aerobic peak power output. Heart rate (HR), oxygen uptake (VO<sub>2</sub>), blood lactate (La), and RPE were monitored. Quadriceps peak torque (PT), maximal rate of torque development and relaxation (MRTD, MRTR) were assessed by single (ST) and paired stimuli at 10 Hz (DB10) and 100 Hz (DB100). Maximal voluntary contraction (MVC) and activation (VA) were also noted. Measurements were performed at baseline (PRE), 5 and 20min after each session (POST5, POST20). Repeated measures ANOVA was used for analysis. **Results** SFR determined lower (p<0.05) HR (140±13 vs 149±7), VO<sub>2</sub> (2.664±0.297 vs 2.797±0.264), La (1.5±0.7 vs 2.4±1.1) than HC. RPE was similar (3.7±1.1 vs 3.7±1.2, p=0.734). MVC and VA decreased at POST5 (-9.5±6.7% and -3.9±5.0%; p<0.05) in SFR and HC, only VA recovered at POST20. PT ST decreased similarly at POST5 and recovered at POST20 only in HC (SFR: 49±8, 31±8, 41±8 Nm; HC: 48±7, 33±7, 46±8 Nm respectively at PRE, POST5, POST20; p=0.021). MRTD ST and DB10 (p<0.05) decreased similarly at POST5 but recovered at POST20 only in HC. MRTR DB100 decreased at POST5 and did not recover at POST20 just in SFR (1.14±0.31, 0.91±0.23, 1.03±0.19 and 1.19±0.31, 1.11±0.23, 1.19±0.24 N•m-1•ms-1 SFR, HC and PRE, POST5, POST20 respectively; p<0.05). **Discussion** The locus of exercise-induced fatigue is not central. The decreased MRTR DB100 and the non-recovery of PT and MRTD ST at POST20 support a more likely peripheral origin of fatigue during SFR, even with a lower physiological strain than HC. For each stroke, average torque is ~200% higher and applied for three times longer during SFR than HC. A greater blood flow restriction caused by a high level of muscle contraction (Lollgen et al., 1980) might be a reason for the greater peripheral fatigue induced by SFR. **References** Hirai, D. ## EFFECT OF MUSCLE SIZE ON CRANK FORCE GENERATION CAPACITY DURING CYCLING EXERCISE IN MALE.

Tanaka, S.1, Hiratsuka, K.1, Teshima, T.1, Kumagawa, D.2, Tsunoda, N.1

1: Kokushikan University. 2: Japan institute of Sports Science.

**Introduction** Anaerobic power generation capacity is important factor in athletic performance. Its power output capacity in cycling exercise affected by crank force was reported previously. Whereas, it was not cleared that the muscle thickness on lower limbs effect to the crank force during cycling exercise due to maximum efforts. Therefore, the purpose of this study was to investigate effect of muscle size on crank force generation capacity during cycling exercise in male. **Methods** The subjects were 37 varsity males. Muscle thickness in anterior, lateral and posterior of the thigh and that of anterior and posterior lower leg muscles were measured using the B-mode ultrasound method. The anaerobic power and crank force generation capacity were measured by a cycling ergometer with costume made measurement-analysis system. The all subjects performed the cycling exercise for ten seconds with maximal effort intermitted between three-step loads. The initial load was 6.0%kp, second load was 9.0%kp, third load was 12.0%kp to the body mass. **Results** Significant correlation was obtained between anaerobic power and crank force in all the cycling exercise. The ratios of anaerobic power to the crank force on initial and second loads were significantly higher than that of third load. The angular velocities of the crank were changed due to number of pedaling time in all the cycling exercise. However, changes of angular velocity due to number of pedaling time differed by the loads. The muscle thicknesses of the lower limb were closely related to the peak crank force in all the cycling exercise. In initial and second loads, muscle thickness were effect to the change ratio of crank force. **Discussion** In this study, it was cleared that characteristics of crank force generation capacity in cycling exercise. In addition, significant correlation was observed between muscle thickness and crank force. Moreover, muscle thickness was closely related to the change ratio of crank force from first pedaling to the seventh pedaling. From these results, it was suggested that muscle size of the lower limb was affect crank force generation capacity in cycling exercise. **References** Hintzy F, Belli A, Grappe F, Rouillon J. ## VO2 KINETICS DURING CYCLING AT CRITICAL POWER UNTIL EXHAUSTION BY TRAINED AND UNTRAINED SUBJECTS

Pessoa Filho, D., Caritá, R.A.C., Greco, C.C., Denadai, B.S.

São Paulo State University

**VO2 KINETICS DURING CYCLING AT CRITICAL POWER UNTIL EXHAUSTION BY TRAINED AND UNTRAINED SUBJECTS** Pessoa Filho, D.M. 2, Caritá, R. A. C. 1, Greco, C. C. 1, Denadai, B. S. 1 1: UNESP (Rio Claro-SP/Brazil), 2: UNESP (Bauru-SP/Brazil) **Introduction** The cycling intensity at critical power (PC) has been considered the upper boundary of the heavy exercise domain, which is characterized by the occurrence of an additional slow component of the VO<sub>2</sub> (CL) to the primary amplitude, without reaching its maximum rate (VO<sub>2</sub>max). Above PC (severe domain), time to exhaustion is shortening as soon as VO<sub>2</sub>max is reached by continuous increasing of the CL. Investigations outlined with untrained individuals exercising at heavy domain rarely was carried out until exhaustion takes place. Thus, the objective was to analyze the VO<sub>2</sub> kinetics in subjects with different aerobic training status, cycling at CP until volitional exhaustion. **Methods** Six trained cyclists (GT) and seven non-trained subjects (UNT) performed the following protocols in a cycle ergometer: (a) progressive test until voluntary exhaustion to determine VO<sub>2</sub>max and the intensity at VO<sub>2</sub>max (IVO<sub>2</sub>max); b) three constant workload tests until voluntary exhaustion at 95, 100 and 110% IVO<sub>2</sub>max to determine CP, and; (c) constant workload test at 100%CP until exhaustion takes place. The tests were performed in different days. The breath-by-breath VO<sub>2</sub> data was used to analyze the VO<sub>2</sub> responses to high-intensity exercise transition, which was fitted by a bi-exponential model. The initial cardiodynamic component will be ignored. Differences between groups means were analyzed by independent T-test, with significance level of 0,05. **Results** CP was significantly higher for GT (319.8+/-33.8W) than UNT (197.1+/-38.9W) when expressed as absolute value, but not when expressed as percentage of IVO<sub>2</sub>max (GT: 84.4+/-0.05%IVO<sub>2</sub>max and UNT: 83.2+/-0.03%IVO<sub>2</sub>max). The slow component VO<sub>2</sub> was significantly higher for GNT in absolute value (GT: 342.4+/-165.8ml.min<sup>-1</sup> and UNT: 571.3+/-170.1ml.min<sup>-1</sup>), as well as when expressed relatively to VO<sub>2</sub> increasing during the exercise (GT: 10.0+/-4.6% vs. UNT: 26.6+/-7.3%). The end VO<sub>2</sub> expressed as absolute value (GT: 3912.5+/-321.1ml.min<sup>-1</sup> vs. UNT: 2806.7+/-581.5ml.min<sup>-1</sup>) and relative value to VO<sub>2</sub>max (GT: 89.8+/-8.4% vs. UNT: 97.4+/-2.8%) were also significantly different between groups. **Discussion** For UNT, the end VO<sub>2</sub> was similar to VO<sub>2</sub>max, showing that the exercise for UNT group was severe, since it allowed subjects to attain VO<sub>2</sub>max. GT did not attained VO<sub>2</sub>max, but the time to exhaustion at CP was similar between groups (GT: 1177•402s vs. UNT 1400•506s). If CP had not be overestimated for UNT, it can be concluded that tolerance to exercise at CP is not modified by training status, but might determine different responses of VO<sub>2</sub>. **References** Jones AM, Grassi B, Christensen PM, Krstrup P, Bangsbo J, Poole DC. ## NEURAL ADAPTATION TO PLYOMETRIC TRAINING

Behrens, M., Mau-Moeller, A., Pohlentz, B., Bruhn, S.

University of Rostock

**Introduction** Plyometric training (PT) is a popular form of physical conditioning of healthy individuals and patients, e.g. people suffering from osteoporosis. It has been shown that PT has the ability to increase maximum voluntary contraction (MVC) and rate of force development (RFD) (Markovic et al., 2010). Although numerous studies examined the effects of PT on MVC and RFD, only a few studies focused on the possible neuromuscular mechanisms. Therefore, we investigated the contribution of neuromuscular adaptations to strength changes after PT. **Methods** Twenty subjects, including 7 controls, volunteered for the study. Data were obtained before and after PT. The experimental group trained twice a week for 8 weeks. PT included countermovement jumps (CMJ), squat jumps (SJ) and drop jumps. We measured jump height in CMJ and SJ as well as isometric maximum voluntary torque (iMVT), normalized root mean square of the EMG signal during iMVT ( $\sum$ RMS-EMGiMVT/Mmax), voluntary activation (VA) and twitch contractions (TC) of the quadriceps muscle. Furthermore, we evaluated rate of torque development (RTD), impulse (IMP) and  $\sum$ RMS-EMG/Mmax in four 50 ms time windows (0-50 ms, 50-100 ms, 100-150 ms, 150-200 ms). The measurements were performed in two knee angles, i.e. 80° and 45° (0° = full extension). Transcutaneous femoral nerve stimulation (single and doublet stimulation) was used to produce TC. VA was assessed using the interpolated twitch technique. %VA was calculated with the formula:  $(1 - (\text{superimposed twitch} \times (\text{Tb}/\text{iMVT}) / \text{control twitch})) \times 100$ . Paired t-tests were used for statistical analyses ( $p \leq 0.05$ ). **Results** Jump height in SJ (+7.3%), iMVT (+8.9%),  $\sum$ RMS-EMGiMVT/Mmax (+26.1%), VA (+3.4%) and RTD, IMP as well as  $\sum$ RMS-EMG/Mmax in the four time windows were significantly increased after PT at the knee angle of 80°. Jump height in CMJ, TC at 80° of knee flexion and all parameters at 45° of knee flexion did not change significantly. No differences in any parameter could be observed in the control group. **Discussion** The increased iMVT, RTD and IMP, in the four respective time windows, at 80° of knee

flexion could be explained by an enhanced neural drive to the quadriceps muscle, as evidenced by increases in VA,  $\Sigma$ RMS-EMGiMVT/Mmax and  $\Sigma$ RMS-EMG/Mmax. This is in line with results of other studies that reported an increased MVC and RFD after PT (Saez-Saez de Villarreal et al., 2010). Data suggest that the neural adaptation was knee angle specific because parameters at 45° of knee flexion did not change. The strength gains probably contributed to the enhanced jump height in SJ. Adaptations at the muscle level seem unlikely because the parameters of TC did not change. References Markovic G, Mikulic P (2010). *Sports Med*, 40, 859-95. ### RATE OF FORCE DEVELOPMENT DURING ISOMETRIC KNEE EXTENSION AT DIFFERENT KNEE JOINT ANGLES

Kobayashi, Y., Akagi, R., Hirayama, K., Hirano, Y.

*Japan Institute of Sports Sciences*

Introduction Measurement of the rate of force development (RFD) during maximal voluntary isometric knee extension has been performed at various knee joint angles, including 70° (Aagaard et al., 2002) and 90° (Blazevich et al., 2008) of knee flexion (full extension = 0°). However, the difference in RFD among various knee joint angles remains unclear. Therefore, the aim of the study was to determine the difference in RFD during maximal voluntary isometric knee extension between two knee joint angles. Methods Eighteen healthy adults participated in the study. Maximal voluntary isometric knee extensions of the right leg were performed at 70° or 90° knee flexion using an isokinetic dynamometer (Biodex System3, New York, NY, USA). Each subject performed three maximal isometric knee extensor contractions at each angle. Each contraction was sustained for approximately three seconds and the subjects were instructed to extend their knee "as fast and as hard as possible". For each trial, the dynamometer torque signal was sampled at 2000Hz. All torques were corrected for the effect of gravity on the lower leg. The participants were divided into a stronger (n = 9) or weaker (n = 9) group based on the mean value of the maximum torque at 70° and 90° knee flexion. Results In the stronger group, maximal torque and RFD were not significantly different between 70° and 90° knee flexion. However, in the weaker group, maximal torque and RFD at 70° were significantly greater compared with 90° knee flexion (P < 0.05). Discussion The results suggest that maximal, isometric knee extension strength and RFD at 70° are greater than at 90° knee flexion in relatively weaker individuals. Therefore, when evaluating maximum isometric strength and RFD, we should take into account differences in strength when selecting the knee joint angle that is going to be assessed. #### PERCEPTION OF EFFORT DURING LOCAL AND GENERAL EXERCISE IN JUDOKAS

Invernizzi, P.L., Michielon, G., Longo, S., Scurati, R.

*Università degli studi di Milano*

Introduction In judo combats, the physiological demand involve both the aerobic (to sustain effort for the duration of the combat) and the anaerobic systems (to provides the short, quick, all-out bursts of maximal power) (Franchini et al, 2003). The perceived exertion of the effort can be assessed, with respect to various features of effort (i.e. general, cardiopulmonary and of the lower limbs fatigue), through ratio-scales methods (Noble, 1996). This study in judokas aimed to analyze the perception of the effort during local and general exercise, at a high intensity. Methods Ten competitive judokas (19.9±4.7 years, 65.2±8.7 kg, 171.9±6.4 cm, 21.98±1.82 kg/m<sup>2</sup>) participated in the study. At a distance of 4 days, subjects performed following fatiguing tasks: i) push-up (PU), as exercise for upper limbs; ii) vertical jumps from deep squat (VJ), as exercise for lower limbs; iii) alternating push-up and vertical jump (PU-VJ) as global exercise. To ensure the raise of fatigue during the tasks, subjects performed five trials, in which the exercise stopped as the set pace was no longer held, one minute of recovery among trials. Perceived exertion of muscular and respiratory efforts were surveyed by CR10 scale and heart rate was also collected. Results Heart rate was significantly lower in PU than in VJ and PU-VJ (p<0.01, 156.4±4.7 vs. 172.0±3.0 and 179.7±1.8, respectively). VJ was lower than PU-VJ (p<0.05, 172±3.0 vs. 179.7±1.8). The perception of the muscular effort was lower in PU-VJ than in PU and VJ (p<0.05, 7.2±0.5 vs. 8.3±0.6 and 8.2±0.5, respectively) whereas no difference was found (p>0.05) between PU and VJ. The perception of the respiratory effort was lower in PU than in VJ and PU-VJ (p<0.01, 3.9±0.3 vs. 5.9±0.3 and 7.6±0.3, respectively). VJ was lower than PU-VJ (p<0.05, 5.9±0.3 vs. 7.6±0.3). Discussion The scale of the effort has been defined by heart rate variation. The heart rate during the tasks related to the volume of the muscular mass involved during each exercise, growing in this sequence: PU, VJ and PU-VJ. Muscular fatigue was highly perceived after local effort (arms or legs only) than after global exercise. This could be due to the wider recovery between the successive muscular contractions that in PU-VJ would be induced by the alternating actions of arms and legs, unlike in PU or VJ. On the contrary, the respiratory fatigue highly addressed to the volume of the muscular mass involved in the exercise, that is to the metabolic engagement. #### DIFFERENCES ANALYSIS IN SITUATIONAL EFFICIENCY OF WINNERS AND DEFEATED FIGHTERS AT THE INTERNATIONAL BOXING TOURNAMENT

Kapo, S., Fetahovic, Dz., Cutuk, H., Zoranic, J.

*Faculty of Sports and Physical Education, University of Sara*

Introduction Success in boxing is defined by the level and structure of a large number of abilities, knowledge, and characteristics which can be measured and analyzed, and then improved during the sports carrier with adequate means and methods (Kapo, 2005). Main goal is identification of parameters of situational efficiency of fighters based on the registration of events during a tournament, using a set

of technical and tactical elements applied by winners and defeated fighters at the boxing tournament "Zlaten Gong 2010" in Skopje. Methods The sample of analyzed fighters comprised of 56 representative competitors. The information was gathered based on video records of 28 fights / 18 semi-final and 10 final fights/. The collected data were processed using descriptive statistics. Results and discussion The basic descriptive parameters indicate that the total frequency of punches at this boxing tournament was 4,269, or 53.2%, for the winners, while for the defeated fighters it was 3,755, or 46.8%, of the total number of applied hand technical elements during fights. The winners were dominant in the application of direct punches to the head, with 2,682, or 63%, while the defeated fighters had only a somewhat higher frequency of applied uppercut punches to the head, namely 157, or 4%. The application of defensive techniques is on the side of defeated fighters, with a total frequency of 1,949, or 53%, while winners had a frequency of 1,665, or 47%. The winners applied a larger number of defense techniques against uppercut punches, 285 or 8%, than the defeated fighters, most probably due to the reason that the defeated fighters more frequently applied uppercut punches. The frequency of used offensive tactics and attacking techniques by the winners was 15, or 26.7%, which most probably contributed to their win, while the defeated fighters used defensive and combined tactics, which is confirmed by the fact that they applied defensive techniques more often than offensive techniques. A significant frequency of knock-downs was displayed by winners, namely 13, or 93%, while the defeated fighters only had one knock-down, or 7%, at the tournament. Conclusion The analysis of the differences in application of technical and tactical elements between the winners and defeated boxers, indicate that the winners used all hand techniques, and applied mostly offensive tactics, more than the defeated boxers. ### FEMALE OLYMPIC WRESTLING: PHYSICAL FITNESS MARKERS AND GENDER DIFFERENCES

Torres-Bonete, M.D., López-Gullón, J.M., De la Cruz-Sánchez, E., Izquierdo, M., Pallarés, J.G.

*University of Murcia*

Introduction Although female wrestling has received minor research attention, in male participants few studies examined differences in physical fitness and anthropometrical markers between successful and less successful wrestlers (García-Pallarés et al., 2010). These data have been of great importance for optimizing training programs, talent selection and weight cutting strategies for Greco-Roman and Freestyle male wrestlers (Horswill, 1992). Therefore, the first aim of this study was to investigate which anthropometric, physiological and neuromuscular factors are different between elite and amateur female wrestlers. Our second aim was to compare physical fitness markers between these elite female and those of a recent study conducted in our laboratory with elite male wrestlers. Methods Thirty five female wrestlers were assigned into 4 groups according to their body mass (light and middle weight) and their competitive level (elite and amateur): Light Weight (49-58 kg) in elite (LWE, n=6) and amateur (LWA, n=12) level; and Middle Weight (58-67 kg) in elite (MWE, n=7) and amateur (MWA, n=10) level. A binary logistic regression analysis was performed to identify which variables better predict female wrestling successes. Results Elite female wrestlers were older (8%-10%), had more training experience (27%-29%), fat free mass (FFM) (3%), maximum strength in absolute and allometrically scaled values (13%-33%), maximal muscle power (16%-34%), anaerobic capacity and power in absolute and allometrically scaled values (17%-23%) compared to amateur wrestlers ( $p < 0.05$ ). Discussion Based on the logistic regression analysis, FFM and 1RM strength were the most important factors of successful female wrestling performance. These results may suggest that the higher absolute and normalized maximum strength, muscle power and anaerobic metabolism, although explained in part by the differences in FFM, will give elite female wrestlers a clear advantage during Olympic wrestling compared to amateurs. When these results and those of a recent study performed in our laboratory with elite male wrestlers (García-Pallarés et al., 2010) were compared, elite females presented lower ( $p < 0.05$ ) physiological and neuromuscular values even when these data were normalized using allometric methods. In addition to differences in the FFM, other sex distinctions such as hormonal, enzymatic and/or neural activations patterns could be related to the physical fitness performance differences between genders (Weber et al., 2006). ### ANALYSIS OF THE DIGIT RATIO ASSOCIATION WITH SUCCESS IN OLYMPIC WRESTLING

Torres-Bonete, M., Pallarés, J.G., López-Gullón, J.M., De la Cruz-Sánchez, E.

*University of Murcia*

Introduction The second-to-fourth digit ratio (2D:4D) has been reported to be negatively correlated with sport performance in male and female athletes across a variety of endurance and team sports (Manning and Taylor, 2001), even when physical factors and effort, cognitive, and personality variables are controlled (Testern and Campbella, 2001). Therefore, the aim of this study was to analyse the contribution of the 2D:4D to success in Olympic wrestling. Methods A total of 180 wrestlers that took part in the 2011 Spanish Wrestling Championship, in one of the three Olympic wrestling styles, participated in the study: Greco-Roman Male (GRM), n = 60; Freestyle Male (FSM), n = 72; and Freestyle Female (FSF), n = 48. According to the tournament results, two different competitive levels (i.e., successful and non-successful) were established in each wrestling style and weight category for subsequent comparisons. Successful groups of wrestlers were formed from the four medal winners (i.e., 1st, 2nd, and the two 3rd classified) in each of the 7 weight categories for both male styles (GRM and FSM) and the female style (FSF). Prior to competition, wrestlers were interviewed about their years of training experience and their hands were scanned. 2D:4D was calculated using computer-assisted image analysis (Allaway et al., 2009). A multinomial logistic regression coefficient to calculate odd ratios (OR's) and 95% confidence intervals (CI's) were established to determine the contribution of 2D:4D and training experience to success in Olympic wrestling. Results We found differences between genders and we could determine that 2D:4D was greater in men than women in both hands (right hand t-test  $p=0.009$ ,  $t=-2.63$ ; left hand t-test  $p=0.015$ ,  $t=-2.45$ ). There were no differences between successful and non-successful wrestlers in 2D:4D in any wrestling style (GRS, FSM and FSF) ( $p=0.87$  for right hand, and  $p=0.46$  for left hand), whereas having high training experience supposed an increase up to 4.38 (1.70 – 11.01) times more likely to be successful. Discussion As a possible marker of prenatal testosterone exposure (which could be a key factor in strength development), 2D:4D has been proposed as an indirect measure which can discriminate an exceptional and talented genotype for sport participation (Testern and Campbella, 2001). However, the main finding of the present study was that 2D:4D is not a valid assessment to discriminate successful and non-successful wrestlers, while training experience is a good predictor of competition prowess in that kind of highly trained athletes. ## MATCH ANALYSIS OF YOUTH TAEKWONDO COMBATS

Tornello, F.

*University of Rome*

Match analysis of youth taekwondo combats Tornello F. 1,3, Minganti C.2, Chiodo S.2,3, Tessitore A.1 1Department of Human Movement and Sport Sciences, University of Rome "Foro Italico", Italy. 2 Department of Experimental and Clinical Medicine, University "Magna Graecia" of Catanzaro, Italy. 3 Italian Taekwondo Federation, Rome, Italy. Introduction To deal a systematic coaching of taekwondo athletes based on scientific principles, a clear understanding of technical and tactical combat actions is needed. To this scope, providing a match analysis of actual combats can be an important factor in developing specific training programs (Pieter and Heijmans, 2000). However, at the contrary of elite athletes (Kazemi et al., 2010) there is a paucity of studies on youth competitions. Thus, the purpose of this study was to examine technical-tactical aspects during official youth taekwondo combats. Methods Altogether, thirty combats (semifinals: n=20; finals: n=10) of 10 male weight divisions were recorded and analyzed during the 2010 Italian Championship "Cadetti A" (age: 13-14 years). The recording of combats was authorized by the Italian Taekwondo Federation (FITA). All athletes were in the black belt rank (World Taekwondo Federation), had at least 4 years of previous training consisting of four 2 hr sessions week-1. The technical-tactical analysis was applied to investigate the following parameters: a) frequency of occurrence of offensive, defensive and block actions; b) efficacy of actions (i.e. actions resulted in points). An ANOVA for repeated measure was used to test for differences in type of actions (i.e. offensive, defensive and block) in relation to combat outcome (i.e., winner vs loser). A separate ANOVA was used to test differences between winner and non-winner efficacy. Results Differences ( $p < 0.001$ ) were found between all the action typologies (offensive:  $50.9 \pm 2.9$  %; defensive:  $28.4 \pm 1.8$ %; block:  $20.6 \pm 1.8$ %). Post-hoc showed that winner ( $p=0.004$ ) performed less offensive actions (winner:  $42.6 \pm 4.1$ %; loser:  $59.2 \pm 4.1$ %) and more ( $p=0.010$ ) defensive actions (winner:  $33.4 \pm 2.6$ ; loser:  $23.4 \pm 2.6$ ) with respect to loser. Furthermore winners were more efficacy ( $24.1 \pm 2.3$ %) than losers ( $8.9 \pm 2.3$ %), ( $p < 0.001$ ). Discussion The findings of this study showed as one action on two of Cadet competitions was generally performed as offensive. This trend can be argued by the fact that at this age the technical and tactical skills previously acquired, being still in developing phase, make easier to manage an offensive rather than defensive action. This hypothesis can be supported by the profile of winners, which performed less offensive and more defensive actions, compared to the losers. Furthermore, the winners showed a higher efficacy in terms of technical and tactical skills. References Pieter W, Heijmans J. (2000). Scientific Coaching for Olympic Taekwondo. ## EXPERT ANALYSIS K-1 GP FINAL JAPAN 1993

Kapo, S., Cikatic, B.

*Faculty of Sports and Physical Education, University of Sara*

Introduction Analysis of competitions of top K-1 fighters who were finalists of the K-1 Final, aims at determining the technical and tactical elements which are dominant in K-1 based on the situational efficiency of finalists of the K-1 WGP Final, Japan, 1993. Methods The sample of analyzed fighters comprised of eight top K-1 super heavyweight fighters, who are specialists for individual martial arts (boxing, kick boxing, karate, muay thai, etc.), and who competed under K-1 rules. The analysis reviewed the technical and tactical activities of the two finalists during the tournament. The total number of variables for this research was 38, in order to review the presence of technical and tactical elements during six top fights at the GP Final, Japan, 1993, in as much detail as possible (Cikatic, 2012). The information was gathered based on video records of seven fights which were used as a basis for the analysis of the K-1 tournament. The collected data were processed using descriptive statistics. Results and discussion Winner of the K-1 tournament did not apply hand technical elements as much as the defeated finalist, but had an advanced application of leg techniques (ushiro geri and ushiro mawashi) which confirms his abilities that proved efficient in the tactical application during the fight. A higher application of technical elements of the defeated finalist is reflected in the fact that he fought a higher number of rounds during the tournament when compared to the winner, while the tournament winner ended his fights before the end of regular time in all three fights. These indicators are best confirmed by the results of the expert analysis which point to the fact that the number of knock-downs and types of wins, as well as the application of offensive tactics by the tournament winner was more successful, which, in the end, resulted in him winning the tournament. Conclusion Based on the collected data, the realization efficiency of technical and tactical elements which are greatly linked with the condition training, and the mental attitude with regards to tactical actions which is linked with a good connection and communication between the coach and the contestant, can be observed. This connection is best described with the sentence spoken by the tournament winner, who said that he only heard the voice of his coach, Tom Harrinck, and his advice from the corner, although there were around 30.000 people present in the hall. "I believe that the synthesis between the coach and fighter is the most important thing for achieving success", are the words of the winner of the first, historical, K-1 WGP Final Tournament held in 1993. ## EFFECT OF ELASTIC RESISTANCE TRAINING ON THE JAB PUNCH PERFORMANCE

Suzovic, D.1, Markovic, P.2, Planic, N.2, Jaric, S.3

*Faculty of Sport And Physical Education*

Suzovic, D.1, Markovic, P.2, Planic, N.2, Jaric, S.3 1Faculty of Sport and Physical Education, University of Belgrade, 2 Doctoral Program, Faculty of Sport and Physical Education, University of Belgrade, 3Department Kinesiology and Applied Physiology, University of Delaware, Newark, DE Introduction The elastic resistance training could be an efficient method that improves the speed performance in various movement tasks (Jakubiak, Sounders, 2008). However, very few studies have explored the effects of the elastic resistance training on the rapid arm movements. The aim of the present study was to explore the efficiency of the elastic resistance training through the performance of standard jab punch. Methods Twenty high school students (age:  $18.2 \pm 0.7$  yr, body mass:  $79.9 \pm 11.4$  kg, height:  $1.83 \pm 0.05$  m; mean  $\pm$  SD; all active in various sports through various school competition system) participated in the study. Experimental group (n=10) practiced jab with the applied elastic resistance over 6 weeks, whilst the control group (n=10) trained without the additional resistance. Both the punching peak speed and peak acceleration of selected body points were recorded by a 3D Qualisys system, while the markers placed laterally on the hand, elbow, shoulder and hip. All variables were individually tested by a mixed 2-way ANOVA with the main effects being group (elastic resistance vs. no resistance) and test (pre-test vs. post-test). Results The maximum speed of hand revealed the main effect of test ( $p < 0.01$ ), but not of group, and no interaction. Namely, the elastic resistance group was faster at the post-test, but the group x test interaction was somewhat below the significant level ( $p < 0.1$ ). However, the elastic resistance group revealed a higher gain in both the speed and acceleration of the hip and knee joint ( $p < 0.05$ ). Discussion Since the study was conducted on a relatively small sam-

ple of subjects, the observed effects suggest that the elastic training could be beneficial for improvement of rapid arm movements. Mechanisms of the improvement could be based on a higher involvement of the larger muscle groups acting in the leg and trunk joints, as we observed in the post-test of the elastic resistance group. Nevertheless, more research is needed to generalize the claims regarding the efficiency of the elastic resistance training (c.f., Jakubiak, Saunders, 2008; Stone et al. 2002) on the rapid arm movements, such as the tested jab punch. Acknowledgments The study was supported in part by a grant from Serbian Research Council (#145082) References Jakubiak, N., Saunders, H.D. (2008). ### MATCH ANALYSIS OF SPANISH FEMALE TAEKWONDO COMPETITORS

Menescardi, C., Bermejo J.L., Estevan, I., Falco, C.

*Catholic University of Valencia*

**MATCH ANALYSIS OF SPANISH FEMALE TAEKWONDO COMPETITORS** Menescardi, C.I, Bermejo J.L.I, Estevan, I.I, & Falco, C.I Catholic University of Valencia, Valencia, Spain Introduction The aim of this study was to analyze the performance of female taekwondo players in the semi-final and final contests using the eight weight divisions in the Spanish University Championship (2011), with emphasis on the type of action, type of kick and area of kick score. Methods Twenty-two female matches were analyzed. A total of eight kicking parameters were defined: total number of actions, type of action (attack or counterattack), type of kick (linear, circular or with previous spin), and the area of kick score (head or chest). Official videotapes were analyzed following standard procedures (Santos, Franchini, & Lima-Silva, 2011); a trained investigator analyzed all videos to determine the pre-defined parameters. Intraobserver measures were reliable with an ICC = .85 ( $p < 0.01$ ). Results Kruskal-Wallis test showed differences among weight divisions in total actions ( $\chi^2 = 22.74$ ,  $p = 0.01$ ), attacks ( $\chi^2 = 17.30$ ,  $p = 0.02$ ), actions to the chest ( $\chi^2 = 22.49$ ,  $p = 0.01$ ) and circular kicks ( $\chi^2 = 28.26$ ,  $p = 0.01$ ). Mann Whitney U test showed that flyweight and featherweight performed fewer total actions, attacks, circular kicks and kicks to the chest than the other weight divisions (flyweight, bantamweight, lightweight, middleweight and heavyweight). In contrast, middleweight and heavyweight performed more total actions, attacks, circular kicks and kicks to the chest than the other weight divisions (flyweight, bantamweight, featherweight and welterweight). Discussion and conclusion The results showed that attacks to the chest with circular kicks were the most commonly used actions regardless of weight division. In contrast with other studies (i.e., Santos et al., 2011), our results showed that women in higher weight divisions performed greater number of actions than lighters. This could be due to lower weight divisions perform other actions such as blocks or displacements, instead of perform attacks, while higher weight divisions do a less effective defense (Boguszewski, 2011) and therefore choose to initiate the attack. This information serves to focus taekwondo training in actions to void attacks to the chest with circular actions because it is the technical-tactical behavior undertaken by all taekwondo competitors. Moreover, in middleweight and heavyweight competitors that have had a higher frequency of actions, it could lead to a reorientation of physical training of these athletes in order to withstand in a better way the competition's demands. ### HAMSTRING INFLUENCE OF THREE POSITIONS ON FOOT IN YOYO LEG CURL

Nunez, F.J.1,2, Suárez-Arrones, L.I.2, Maldonado, R.I, Tous, J.3

*(1) VF Sport (Seville, Spain) (2) Universidad Pablo de Olavide (Seville, Spain). (3) Universidad de Barcelona (Barcelona, Spain).*

Introduction The hamstring is a muscle group that is in high risk of injury during sports activity, therefore, requires special attention in preventive training. The purpose of this study was to determine the influence of three different foot positions: neutral (PN), medial (PM) and lateral (PL) on the force (concentric-eccentric) and electromyography activity in the biceps femoris (BF) and semitendinosus (ST) in the action of leg curl when done in a iso-inertial machine. Methods 18 subjects performed in the exercise of leg curl doing 3 sets alternating different foot positions (PN, PM and PL) using the same amount of inertia, being executed at the maximum possible intensity of each subject, with a rest of 5' between series. Results Significant differences were found towards the concentric phase in the average force for each of the positions ( $p < 0.01$ ), and towards the eccentric phase regarding peak force with the exception of PN ( $p < 0.05$ ). Significant differences were observed in the ability to generate concentric strength between PN and PM ( $p < 0.05$ ) in comparing ST activation of PM-PL positions during both concentric ( $p < 0.05$ ) and eccentric ( $p < 0.01$ ) and PN-PL in both concentric phase ( $p < 0.05$ ) and eccentric ( $p < 0.05$ ). In the BF significant differences between PM-PL positions during both concentric ( $p < 0.05$ ) and eccentric ( $p < 0.01$ ), PN-PM in the eccentric phase ( $p < 0.01$ ) and PN-PL in the phase concentric ( $p < 0.05$ ). Discussion The machine iso-inertial YoYo™ Flywheel Ergometer, get great peaks of force in eccentric phases (Tous et al, 2006) and especially with the neutral foot position relative to the other two positions (medial and lateral). Given the stabilizing role that has semitendinosus and biceps femoris in the changes of direction drills (Houck, 2003), it is advisable to introduce foot rotations (internal to ST or external to BF) in the prevention or rehabilitation training programs. ### RELIABILITY OF PERFORMANCE IN 10 SEC ALL OUT SPRINTS ON A NON-MOTORIZED TREADMILL

Ribeiro, L.F.P.1,2, Sousa, F.A.B.3, dos Reis, I.G.M.3, Belli, T.2, Beck, W.R.3, Papoti, M.4, Cunha, S.A.3, Martins, L.E.B.3, Gobbato, C.A.5

*1: DCS/UESC (Ilhéus, Brasil), 2: IB/UNESP (Rio Claro, Brasil), 3: FEF/UNICAMP (Campinas, Brasil), 4: FCT/UNESP (Presidente Prudente, Brasil), 5: FCA/UNICAMP (Limeira, Brasil)*

Introduction Sprints on non-motorized treadmills (NMT) have been increasingly adopted in all-out laboratory running evaluation. Yet, limited information exists regarding the effects of familiarization and performance reliability in such tests (Lim & Chia, 2007; Hopker et al., 2009; Highton et al., 2012), particularly in fixed duration efforts. In this study we analyzed the familiarization effects as well as the reliability of performance parameters derived from 10 sec all out sprinting on a non-motorized treadmill. Methods Ten healthy active volunteers (7 men and 3 women) ( $24.7 \pm 2.4$  years,  $79.7 \pm 9.4$  Kg and  $175 \pm 6$  cm) without previous experience in NMT running underwent six sprints on an adapted treadmill (ATL, Inbrasport, Brasil). During the efforts subjects were attached by their waists to a force transducer fixed to a metal structure anchored to the wall, whereas treadmill's belt speed was accessed by means of a magnetic sensor in the front rolling

drum. Parameters retained for analysis were peak (VP) and mean (VM) velocities as well as peak (PP) and mean (PM) powers, with power measures derived from the product of horizontal force and velocity sampled at 1000 Hz. Results One way ANOVA for repeated measures showed no significant ( $P > 0.05$ ) differences between efforts for VP ( $5.4 \pm 0.7$  to  $5.5 \pm 0.8$  m/s), VM ( $4.3 \pm 0.6$  to  $4.5 \pm 0.7$  m/s) and PP ( $2347 \pm 590$  to  $2428 \pm 953$  W). On the other hand, PM increased throughout the trials ( $752 \pm 185$  to  $797 \pm 195$  W;  $P < 0.05$ ), with the highest value observed in the last effort. Coefficients of variation between consecutive trials were relatively stable and averaged 2, 3, 11 and 4.1 % for VP, VM, PP and PM, respectively. In addition, high intraclass correlation coefficients were found between trials for all studies variables (ICC = 0.98 to 0.99). Discussion The results of the present investigation suggest that familiarization has only minor effects on most performance parameters accessed in a 10 sec all out NMT sprint. In addition, in line with previous studies using fixed distance protocols (Hopker et al., 2009; Highton et al., 2012) our results indicate that reliable performance measures can also be obtained from a fixed duration sprint protocol. #### PHYSIOLOGICAL AND HORMONAL RESPONSES TO SUCCESSIVE TAEKWONDO COMBATS

Bridge, C.A.1, McNaughton, L.R.1, Close, G.L.2, Drust, B.2

1 Edge Hill University; 2 Liverpool John Moores University

**Introduction** Recent research into the physiological demands of Taekwondo has resulted in significant advances in our understanding of the energetic requirements of a single Taekwondo combat (Bridge et al. 2009; Chiodo et al. 2011). During a championship event, however, competitors may be required to compete in several combats during a single day. The aim of this study was to examine the physiological and hormonal responses to successive Taekwondo combats using an ecologically valid time structure. **Methods** Ten male international Taekwondo competitors (mean  $\pm$  SD, age  $19 \pm 3$  years, body mass  $62.3 \pm 2.6$  kg, height  $1.72 \pm 0.04$  m, competition experience  $6 \pm 1$  years) took part in a simulated championship event. During the event, the competitors performed four combats that were interspersed with different recovery intervals ( $63 \pm 4$ ,  $31 \pm 3$  and  $156 \pm 5$  minutes respectively). Each combat comprised three two-minute rounds with one-minute rest separating each round. Heart rate (HR) was recorded at 5 s intervals during the combats. Venous blood samples were obtained immediately before and after each combat to determine plasma concentrations of lactate, glucose, glycerol, NEFA, epinephrine and norepinephrine. **Results** Significant reductions in plasma lactate ( $13.9 \pm 4.2$  vs.  $10.5 \pm 3.2$  mmol.l<sup>-1</sup>;  $P < .05$ ) and a trend for diminished norepinephrine ( $21.8 \pm 12.8$  vs.  $16.1 \pm 7.7$  nmol.l<sup>-1</sup>;  $P = .06$ ) were evident between combat 1 and 4. These responses did not appear to be influenced by the different recovery intervals. In contrast, greater ( $P < .05$ ) plasma glycerol ( $202 \pm 104$  vs.  $166 \pm 92$   $\mu$ mol.l<sup>-1</sup>), NEFA ( $0.92 \pm 0.24$  vs.  $0.78 \pm 0.33$  mmol.l<sup>-1</sup>) and reduced ( $P < .05$ ) epinephrine ( $10.1 \pm 5.5$  vs.  $12.1 \pm 6.3$  nmol.l<sup>-1</sup>) concentrations were identified in combat 3 following 31 minutes of recovery compared to combat 2, which was preceded by 63 minutes of recovery. Higher ( $P < .05$ ) mean HR was also identified both before and during combat 3. In the final combat, an extended recovery period of 156 minutes was sufficient to restore plasma NEFA, glycerol and epinephrine to similar concentrations as combats 1 and 2, but higher HR was maintained. **Discussion** The metabolic adjustments associated with performing repeated Taekwondo combats in this study are suggestive of an increased shift towards aerobic metabolism and diminished anaerobic energy yield. Interestingly, brief recovery intervals appeared to augment the aerobic requirements of the combat activity and accelerate lipolysis. These findings suggest that both the number of combats and different recovery intervals may play an integral role in regulating metabolic function in Taekwondo competition. #### THE PHYSIOLOGICAL EFFECTS OF POWER ALTERNATION FREQUENCY DURING CYCLING ON SUBSEQUENT 5 KM RUNNING PERFORMANCE

Hill, C.

University of Worcester

**Introduction** Drafting behind another cyclist reduces energy expenditure and oxygen uptake compared to riding alone at the same speed (McCole et al., 1990). This leads to a significantly faster subsequent running performance in triathlon (Hausswirth et al., 2001). When cyclists alternate between a draft / non-draft position, power output also alternates, since drafting allows ~30% power reduction without a concomitant decrease in speed (Kyle, 1979). The aim of the present study was to determine if the frequency of power output alternation during cycling would affect subsequent running performance. **Methods** Eleven male triathletes completed a graded cycle test to determine power at 35% delta. Two performance tests were then conducted, each comprising of a thirty minute cycling protocol followed by a 5 km free pace run. Mean cycling power was equal for both trials; however the frequency of power alternations differed. In one trial cycling power output alternated every five minutes (CR5MIN), whereas in the other trial cycling power output alternated every one minute (CR1MIN). Power output was set to alternate 15% above and below the 35% delta value. **Results** A significant difference was observed for mean heart rate between cycle trials ( $p = 0.045$ ), however no significant difference was observed for mean oxygen uptake, minute ventilation, respiratory exchange ratio, blood lactate, rating of perceived exertion or pedal cadence ( $p > 0.05$ ). No significant difference was found between trials for the subsequent running performance time or mean heart rate ( $p > 0.05$ ). **Discussion** The present results show that when utilising a power alternation strategy in cycling, the frequency of power alternation (maximum five minutes, minimum one minute) does not significantly affect subsequent running performance. The results of this study agree with Brickley et al. (2007) who suggest that when the average PO between two protocols is similar, variations in exercise intensity do not significantly affect muscle metabolism, demonstrated by the similar overall oxygen uptake and blood lactate values for both cycle protocols. ### PHYSIOLOGICAL RESPONSES TO LOAD-INCREMENTAL AND FREQUENCY-INCREMENTAL EXERCISES DURING CYCLING

Migita, T.1, Tokui, M.2, Hirakoba, K.3

1:Kurume University, 2:Kyushu Kyoritsu University, 3:Kyushu Institute of Technology

**Introduction** Power output is recognized to generate from tension exerted by and contraction speed in exercising muscle. In cycling exercise, power output produced by exercising muscle is controlled by two factors, load added to pedal and pedal frequency. The calculation of total power output (TP) for cycling exercise is made based on external power (EP) and internal power (IP). EP is delivered to the pedal and IP is generated to overcome gravitational and inertial forces related to the movement of the exercising muscle. Then we measured physiological responses to load-incremental (LI) and frequency-incremental exercise (FI) during cycling, and re-verified the responses of the physiological variables to EP and to TP during the two modes of LI and FI. **Methods** Eight healthy male volunteers (mean  $\pm$  SD: age 20.5  $\pm$  0.5 yr, height 170.0  $\pm$  3.9 cm, body mass 64.8  $\pm$  5.7 kg) performed the two modes of cycling exercises (LI and FI). LI started 0.5 kp for 2 min, followed by an increase in 0.5 kp every 2 min until exhaustion point, at a constant pedal frequency of 60 rpm throughout LI. FI consisted of five levels of pedal frequencies of 40, 60, 80, 100 and 120 rpm and pedal frequency was increased by 20 rpm every 2 min (total exercise time = 10 min), at a constant load of 0.5 kp. TP was calculated as the sum of EP and IP. EP was obtained by multiplying by load added to pedal and pedal frequency. IP in this study was estimated according to Minetti et al. (2001). **Results** VO<sub>2</sub> at 120 rpm in FI was around 70 % of VO<sub>2</sub> peak at exhaustion in LI, whereas bold lactate accumulation in FI was only 30 % of that in LI. VO<sub>2</sub> rose linearly with increasing loads in LI and increased exponentially against increasing pedal frequencies in FI. Responses of VO<sub>2</sub>, VE, RR, RER, and HR to EP were different between LI and FI, and the changes of these variables at the same level of EP were greater in FI than in LI. On the other hand, VO<sub>2</sub> to TP revealed almost the same like other variables relationship regardless between LI and FI employed in this study. **Conclusion** These results suggested following two things: 1) an increased in pedal frequency without an increase in load to pedal could be a useful tool for adding metabolic stress to exercising muscle in unfit subjects such as older persons, 2) estimation of TP including IP is necessary to study energy demand during cycling exercise at higher pedal frequencies above 80 rpm. **Reference** Minetti AE, Pinkerton J, Zamparo P. (2001). *Proc R Soc Lond*, 268, 1351-1360.

### PEAK BODY CORE TEMPERATURE IN GRADED EXERCISE TESTING

Rakovac, M., Sentija, D., Babic, V., Marsic, T.

University of Zagreb, Faculty of Kinesiology

**Introduction** Severe increase in body core temperature (BCT) can limit duration and/or intensity of a physical activity. It is well documented that individuals with higher aerobic capacity already show thermoregulatory features that are otherwise characteristic for heat acclimatization (Gleeson, 1998; Nielsen, 1998). The aims of this study were twofold: a) to analyze peak BCT (BCT<sub>peak</sub>) during a graded treadmill exercise test; b) to determine the relationship between BCT<sub>peak</sub> and some indicators of aerobic capacity (maximal oxygen uptake (VO<sub>2</sub>max), maximum speed (v<sub>max</sub>), ventilatory anaerobic threshold (vAT), heart rate at vAT (HRAT)). **Methods** Thirty-two physically active males (age (mean $\pm$ SD) 26.5 $\pm$ 6.6 years; height 179.2 $\pm$ 5.0 cm; body mass 76.8 $\pm$ 8.1 kg) participated in the study. Graded treadmill exercise test with speed increments of 0.5 km/h each 30 seconds was performed until volitional exhaustion. The test was performed in controlled thermoneutral conditions. Ventilatory parameters, heart rate, and rectal temperature (at 8 cm from anal sphincter) were registered throughout the test. Pearson product-moment correlation coefficients were used to determine the relationship between BCT<sub>peak</sub> and indicators of aerobic capacity (VO<sub>2</sub>max, v<sub>max</sub>, vAT, HRAT). **Results** BCT<sub>peak</sub> measured during the test was (mean $\pm$ SD; range) 37.96 $\pm$ 0.37°C; 37.11–38.84°C, while the values for VO<sub>2</sub>max, v<sub>max</sub>, vAT, HRAT were, respectively, (mean $\pm$ SD) 60.4 $\pm$ 6.6 mlO<sub>2</sub>/kg/min, 17.8 $\pm$ 2.2 km/h, 13.1 $\pm$ 2.1 km/h, 170.1 $\pm$ 9.8 bpm. Moderate correlations were found between BCT<sub>peak</sub> and v<sub>max</sub> (r=0.36, p=0.043) and between BCT<sub>peak</sub> and HRAT (r=0.48, p=0.006). No significant correlation was found between BCT<sub>peak</sub> and VO<sub>2</sub>max (r=0.13, p=0.490) and between BCT<sub>peak</sub> and vAT (r=0.29, p=0.106). **Discussion** No participant reached BCT<sub>peak</sub> levels that would indicate hyperthermia, so increase in BCT was not a limiting factor in test performance. The positive correlations between BCT<sub>peak</sub> and parameters of aerobic capacity could be the combined result of: a) participants with higher aerobic capacity being able to accommodate more heat (Mora-Rodriguez et al., 2010), b) longer test duration in these participants. The relationship between the rate of temperature increase and indicators of aerobic capacity should be investigated. **References** Gleeson M (1998). *Int J Sports Med*;19:S96-9. ### POSSIBILITY OF INTRINSIC MUSCLE CONTRACTILE PROPERTIES AS AN INDEX OF MAXIMAL MUSCLE STRENGTH AND MUSCLE FATIGUE

Ohta, Y.1, Takahashi, K.2, Matsubayashi, T.2

1: Aichi Shukutoku University (Japan), 2: Japan Institute of Sports Sciences (Japan)

**Introduction** This study aimed to investigate whether the measurement of intrinsic muscle contractile properties is an index of maximal muscle strength and muscle contractile fatigue. **Methods** Seven subjects performed a fatiguing exercise involving 3 bouts of 120-s repeated right-ankle dorsiflexion at a frequency of 1 Hz with a 5-min rest period between bouts. Thirty percent of maximum voluntary dorsiflexion torque (MVC) measured at an ankle angle of 90° was used as the resistance load in the fatigue exercise. Intrinsic muscle contractile properties were defined as evoked peak torque (single stimulus, two-pulse trains, and three-pulse trains), post-activation potentiation (PAP), and ability of torque summation. The ability of torque summation was estimated by torque contribution of second stimuli of two-pulse trains (C2) and third contribution of three pulse trains (C3). The contribution of the response to the Nth stimulation was determined by subtracting the response to the N-1 stimulation from that to the N stimulation. Non-PAP-evoked torques, PAP-evoked torques, and MVC torques of dorsiflexion at isometric contractions were measured at an ankle angle of 90° in each rest period. The electrical stimulation was delivered from the common peroneal nerve near the fibular head. The responses to two-pulse trains and to three-pulse trains, which were delivered with a constant inter-pulse interval of 10 ms (100 Hz), were recorded. **Results and discussion** Regardless of with or without PAP, the peak torque evoked by a single stimulus, two-pulse trains, and three-pulse trains decreased with the increase in fatigue. Although C2 and C3 without PAP decreased with the increase in fatigue, the pattern of changes in C2 and C3 with PAP differed from that in other parameters. The percent fall was greater in the evoked torque parameters than in the MVC torque. These results suggest that the measurement of intrinsic muscle contractile properties overestimates the muscle fatigue during MVC of dorsiflex-

ion at isometric contraction. Moreover, the present study found that, with or without fatigue, the absolute value of evoked peak torque showed a significant positive correlation with MVC torque. In addition, significant relationships were found between MVC torque and magnitude of PAP and between MVC torque and magnitude of ability of torque summation by a second stimulus. Thus, the measurement of intrinsic muscle contractile properties can be used as an index of maximal muscle strength with or without fatigue.

### EVOLUTION OF HRR WITH TRAINING AND DETRAINING MEASURED WITH A NEW PROTOCOL.

Romagnoli, M.1, Alis, R.1, Basterra, J.1, Villar, J.1, Llana, S.2, Arduini, A.3

*Catholic University of Valencia*

Evolution of HRR with training and detraining measured with a new protocol. Romagnoli M.1, Alis, R.1; Basterra, J.1, Villar, J.1, Llana S.2, Arduini, A.3 1 Catholic University Valencia (Valencia, Spain). 2 University of Valencia (Valencia, Spain) 3 Harvard University (Boston, MA, USA) Introduction: The recovery of heart rate (HRR) after exercise responses to the training processes in health subjects [1]. Several test protocols and durations of the recovery period have been proposed to assess HRR. Our goal in this study is to check if a new protocol to assess HRR [2] responses to training and detraining periods. Methods: 20 healthy subjects (10 training, 10 controls) were involved in the study. The subjects on training group performed a 8 weeks aerobic training and a 8 weeks detraining periods. HRR test was performed at week 0, 4, 8 and 16 for training group and 0 and 8 for control group. Maximal tests to assess VO<sub>2</sub>max were performed at week 0 and 8 on both groups. HR recovery was assessed by 8 models, based on monoexponential kinetics or absolute recovery (recovered HR at fix time points). The protocol allows to determine HRR indexes for two submaximal exercise intensities (65% and 80% HR<sub>max</sub>) on cycle ergometer. Differences between variables were analyzed with multiple analyses of variance for related measures. Statistically significance was set at  $p < 0,05$ . All values as mean  $\pm$  sd. Results: We found no statistically differences on HRR measures between training and control subjects on Week 0 (W0) measure. VO<sub>2</sub>max was increased at week 8 (W8) (W0: 36,07  $\pm$  6,60 W8: 42,26  $\pm$  4,67 ml/min/kg,  $p < 0,05$ ) for training group. Absolute recovery of HR at fixed points were incremented significantly for both intensities and decreased to base line level after detraining except for indexes at 80% of HR<sub>max</sub>. T30 didn't decrease significantly with training but T30min did it (W0: 179,90  $\pm$  83,56 W8: 104,68  $\pm$  30,28  $p = 0,003$ ) at 65% HR<sub>max</sub>. HRR measures for control group at W8 weren't significantly different to W0 measures for the same group. Discussion Absolute indexes of HRR assessed using the proposed protocol reflects the effects of training period on the subjects. Monoexponential indexes of HRR weren't significantly improved, the effects of poor fitting data to the proposed function could explain this lack of response to the training effects. All indexes returns near to base line levels with detraining but this period seems not long enough. We conclude that HRR indexes measured with the proposed protocol are useful to determine the training status of the subjects. References 1. ### RELATIONSHIP BETWEEN OBESITY, HEART RATE VARIABILITY, AND SALIVARY ALPHA-AMYLASE IN CHILDREN

Santos-Magalhaes, A.1, Teixeira, A.M.2, Martins, C.3, Aires, L.3, Mota, J.3, Rama, L.2

1: *University Fernando Pessoa (Oporto)*, 2: *Research Centre for Sport and Physical Activity, FCDEF (Coimbra)*, 3: *Research Centre in Physical Education, Health and Leisure Time - CIAFEL, FADEUP(Oporto)*

Introduction: Obesity is characterized by changes in the activity of the autonomic nervous system (ANS), more specifically altered balance between the parasympathetic nervous system and sympathetic nervous system. Power spectral analysis of heart rate variability (HRV) allows for the characterization of sympathovagal balance. Salivary alpha-amylase (sAA) is an emerging biomarker for stress and there is evidence that might reflect changes in the ANS (Nater & Rohleder, 2009). The aim of the present study was to analyse the relationship between obesity, HRV and sAA in school children. Methods: A total of 30 school children (11 normal weight and 19 obese), 6-10 year-olds (8.33  $\pm$  1.14), of both genders (13 Males; 17 Females) were analyzed. Measurements included anthropometric variables (weight, height, waist circumference as well as BMI). Children were then categorized in obese/non-obese BMI groups (CDC Growth Charts). Maturation status was determined by Tanner's criteria. Autonomic function was evaluated by HRV short term evaluation (Task Force, 1996) and salivary alpha-amylase analysis (Salimetrics, UK). Descriptive statistics and partial correlations with gender, age and maturational stage adjustments were used to examine the relationship between the analyzed variables. Results: The HRV analysis showed that obese children presented significantly higher low frequency/high frequency ratio (LF/HF) than their normal weight counterparts. Additionally, positive correlations between obesity indicators (BMI and waist circumference) and LF/HF ( $p = .000$ ) were observed. No significant correlations were observed between sAA and obesity indicators. Conclusion: Our data support the evidence that obesity status is positively correlated with LF/HF in children, which can be an indicator of autonomic dysfunction. No other significant correlations were observed. Although we were not able to demonstrate an association between the sAA and obesity, more studies are needed to clarify this biomarker potential. ### COMPARISON OF ANAEROBIC THRESHOLD DURING GRADED EXERCISE BETWEEN IN THE MORNING AND IN THE AFTERNOON

NISHIMURA, K.

*Hiroshima Institute of Technology*

Comparison of anaerobic threshold during graded exercise between in the morning and in the afternoon Kazuki NISHIMURA1), Koji NAGASAKI1), Hidetaka YAMAGUCHI2), Akira YOSHIOKA3), Yuka NOSE4), Yutaro TAMARI5), Sho ONODERA6) Noboru TAKAMOTO1) 1) Hiroshima Institute of Technology, 2) Kibi International University, 3) Kagawa University, 4) Yasuda Women's University, 5) Graduate School of Hiroshima Institute of Technology, 6) Kawasaki University of Medical Welfare Purpose: The purpose of the present study was conducted to determine the relationships between the double product (DP) and cardiac parasympathetic nervous system (PNS) modulation during graded exercise in the morning and afternoon. Method: Volunteering to participate in this study were 10 healthy Japanese males, who gave their informed consent prior to participation. Each subjects performed graded exercise consisting of 90 seconds of exercise at pedaling rate of 60 rpm on an electrically braked cycle ergometer. The intensity of exercise was started at 10 watts and was increased 10

watts at every step of the graded exercise. The subjects were instructed to stop the exercise when the HR reached 160 bpm. Both experimental tests were performed in the morning (8-10 a.m.) and the afternoon (3-7 p.m.). Heart rate (HR), blood pressure (BP) and cardiac autonomic nervous system activity were measured at each exercise step. DP was calculated by multiplying systolic BP (SBP) and HR. A breaking point of DP (DPBP) was determined to be the point of rapid elevation of DP in relation to workload. An equation to define the relationship between each exercise workload and HF was obtained. The workload that yielded the highest absolute value for the slope was defined as the breaking point of HF, called the HFBP. The DPBP and HFBP were used as index of anaerobic threshold. Results and Discussion: At rest, HR, SBP and DP in the morning were significantly lower than in the afternoon ( $p < 0.05$ , respectively). The ln HF, index of cardiac PNS modulation, in the morning was significantly higher than in the afternoon ( $p < 0.05$ ). The DPBP and HFBP in the morning were significantly lower than in the afternoon ( $p < 0.05$ , respectively). These data suggested the possibility that an anaerobic threshold index showed a change in days. At intensity of DPBP, HR, SBP and DP in the morning were significantly lower than in the afternoon ( $p < 0.05$ , respectively). During graded exercise in the morning, the anaerobic metabolism was provided at HR, SBP and DP are low values. The maximum oxygen uptake of each subject in the morning was not observed comparison with the afternoon. This result suggests the possibility that DPBP in the morning was reached at a low at the relative intensity excise for maximum oxygen uptake. In conclusion, the anaerobic threshold in the morning was reached at a lower exercise intensity than exercise in the afternoon.

### SUITABILITY OF MODIFIED TANDEM-BICYCLE ERGOMETER

ONODERA, S.1, YOSHIOKA, A.2, YAMAGUCHI, H.3, MATUMOTO, N.4, NISHIMURA, K.5, SAITO, T.6, ARAKANE, K.6, HAYASHI, S.6, TAKAGI, Y.6, FURUMOTO, K.6, WOORAM, B.1, TAKAHARA, T.1 KATAYAMA, K.7, OGITA, F.8

1: KUMMW, 2: KAGAWA UNIV, 3: KIBI INTERNATIONAL UNIV, 4: SHUJITU JUNIOR COLLEGE, 5: HIT, 6: GRADUATE SCHOOL, KUMMW, 7: NAGOYA UNIV, 8: NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

Purpose: The tandem-bicycle ergometer we designed, has unique characteristics, which swing joint with one load and braking pist type. The aim of this study was to verify the validity of new tandem-bicycle ergometer. Methods: Fourteen Japanese healthy male volunteered to participate in this study after they signed the informed consent forms prior to participation in this study. The mean (SD) of their age, height, body weight and maximum oxygen uptake was 23 (4) years, 170 (6) cm, 69.0 (12.4) kg, and 45.4 (7.6) ml/kg/min, respectively. The experiments were performed in three different conditions: the single-bicycle ergometer (a), former saddle (b) and rear saddle (c) positions of the tandem-bicycle ergometer. The subjects were performed exercise for five minutes intervals at three loaded (1.5, 2.0 and 2.5kp). We measured heart rate, oxygen uptake and RPE. Results: Coefficient of variation (CV) of heart rate was  $6.4 \pm 3.9$ ; 1.5kp,  $4.7 \pm 4.4$ ; 2.0kp and  $4.1 \pm 3.7$ ; 2.5kp, respectively. CV of oxygen uptake was  $5.9 \pm 4.5$ ; 1.5kp,  $5.5 \pm 2.9$ ; 2.0kp and  $5.9 \pm 1.4$ ; 2.5kp, respectively. Also, CV of RPE was  $10.6 \pm 5.5$ ; 1.5kp,  $7.9 \pm 5.9$ ; 2.0kp and  $6.7 \pm 4.5$ ; 2.5kp, respectively. The correlation of heart rate among the each condition was  $r=0.848$ (a vs. b),  $r=0.929$ (a vs. c) and  $r=0.938$ (b vs. c). The correlation of oxygen uptake among the each condition was  $r=0.940$ (a vs. b),  $r=0.937$ (a vs. c) and  $r=0.948$ (b vs. c). The correlation of RPE among the each condition was  $r=0.795$ (a vs. b),  $r=0.734$ (a vs. c) and  $r=0.797$ (b vs. c). Thus high correlations among the each condition were observed. Discussion: It is known that CV of oxygen uptake whole circadian change is conceivable 3~10%, and CV whole changes of inter individual difference are conceivable about 5.5 %. Accordingly, the three conditions in our experiment did not affect the physiological parameters during the cycle exercise. Therefore, it might be that the suitability of a new tandem-bicycle ergometer was confirmed by CV.

#### INJURIES IN THE FIRST CROATIAN SOCCER DIVISION

Matkovic, B.R., Radman, I., Ruzic, L., Barisic, V.

*University of Zagreb, Faculty of Kinesiology*

Introduction Soccer players in most world leagues have very condensed schedule and these games are played at high intensity. Dupont with his coworkers (2010) showed that recovery time between two soccer matches appears to be sufficient for maintaining the level of physical performance but is not long enough to secure a low injury rate. The injuries in soccer appear to be more frequent and even more dangerous. The aim of this study was to identify the specific soccer circumstances and immediate technical and tactical causes of injuries in training process and competition of elite Croatian soccer players. Methods The study was conducted on the sample of 175 players from seven soccer clubs of the First Croatian Soccer Division at the beginning of the season 2010/2011 Croatian Championship. Soccer players were tested just before the start of regular practice through the written questionnaire. The questionnaire consisted of general questions about number of training sessions per week and their duration, number of games played in last two seasons and number and character of the injuries in the same period. Results and discussion The results show that 40% off all injuries occur during autumn competitive period. Significantly more injuries were sustained due to exposure to training load (60%). The highest percentage of injuries was recorded in the phase of defence set (26%). According to the ball possession, the highest injury risk was recorded during immediate contact with the ball or fight for her possession. In 70% of all injuries, recorded injuring mechanism was the physical contact with an opponent. The most vulnerable parts of the body were ankles and knees, and the ligaments and muscles were the most affected tissues. As prevention, implementation of training process should take place under conditions of controlled load in order to reduce the number of training caused injuries. The number of injuries caused by direct physical duel with an opponent is significantly higher than in Western European leagues, and indicates the need to raise the player body's hardiness and tactical maturity of team trainers. ## DOES RAMADAN FASTING INFLUENCE INJURY INCIDENCE AND INJURY PATTERN IN PROFESSIONAL MUSLIM FOOTBALL ATHLETES?

Farooq, A., Eirale, C.

*Aspetar-Qatar Orthopaedic and Sports Medicine Hospital*

**Introduction** Ramadan is the holy month of Islam, during which Muslims observe fasting (i.e. abstaining from eating and drinking) from sunrise to sunset. Among football players, Ramadan fasting is known to influence unhealthy dietary habits and disturbed circadian rhythms. Not being able to rehydrate during daytime in combination with lack of sleep may mediate increased susceptibility to injury during Ramadan. The aim of the present study was to investigate incidence and pattern of football injuries during Ramadan month among Muslim athletes practicing Ramadan fasting. **Methods** A total of 462 first division Muslim athletes from Qatar Stars league (QSL) were followed up for their total exposure to match as well as training sessions for three consecutive seasons that included the Ramadan month. All injuries were assessed for type, location, severity, mechanism and pattern by professional medical staff. Injury incidence was calculated as rate per 1000h of game exposure and data was compared between Ramadan and non Ramadan periods. **Results** During the three seasons, the football players sustained, on an average 5.0 injuries per 1000 hours of game (95% CI 4.6- 5.3). No differences were seen in injury incidence during Ramadan month (4.0/ 1000h) compared to non Ramadan period (4.9/ 1000h),  $p=0.266$ . Most common during Ramadan month were thigh injuries, with an injury rate of 1.4 per 1000 hours, and knee injuries, with a rate of 1.0 per 1000 hours. Muscular strains dominated in Ramadan month, with an injury rate of 1.5 per 1000 hours of activity. However, these patterns and injury severity were found to be similar with rest of the non Ramadan period. **Discussion** Ramadan fasting was not associated with increased risk of injury among Muslim athletes observing Ramadan fasting and moreover athletes presented with similar injury patterns as non Ramadan period. This study should be interpreted in light of the fact that at QSL, all training and competitions during Ramadan take place at least 4h after the break of fast. Further studies that also adjust for training intensity and sleep quality may provide better understanding of injury incidence during Ramadan.

## ACUTE AND PERSISTING FATIGUE EFFECTS IN BOW ARM MUSCULATURE IN COMPETITIVE RECURVED ARCHERY ATHLETES

Kolayis Eroglu, I., Knicker, A., Soyulu, R., Ertan, H.

*Sakarya University*

**Introduction** In an archery competition the archer is sustained to shoot in difficult conditions as stress, wind, etc. The pulling weight is approximately 20 kg. of a bow, and the archer 144 times pull his bow in a competition. If stress or weather conditions block shooting, the archer can hold down the bow but must pull again in order to shoot his arrow in a given period. When considering of the pulling weight of the bow, to shoot arrow will be difficult for the archer. Because of these conditions, the aim of this study was to analyse the effects of fatigue on bow arm muscular activity in archery. **Methods** 6 Female (Age: 16,66+3,44; Training age: 5,88+2,92) and 10 male (Age: 22,33+12,95; Training age: 4,11+2,80) subject were involved in the study. Each subject participated in double test session and each archer shot 12 arrows before and after fatigue protocol and bow arm Deltoid Posterior, Deltoid middle, Deltoid Front part, Trapezius Middle, Trapezius Upper, Triceps Brachii, Biceps Brachii, Forearm extensors and Forearm flexors EMG activities have been measured in each test. In the fatigue protocol, the subjects have repeated several sets of drawings. The subject was asked to rate his/her fatigue level according to the rating scheme of the Borg Scale. The subjects have repeated the drawing set till exhalation. The researchers has asked to archers who perform the drawing action to provide a score from 0 to 10. EMG recordings 1 s prior the fall of the clicker have been analysed and their Median Frequency values have been calculated in Matlab. Differences between two test session were analysed in paired samples t-tests. **Results** According to the results of the study, there were significant differences in DM and DF parts muscles ( $p<0,05$ ) on the basis of comparisons of the mean values of 12 arrows in test –retest condition. To estimate more acute fatigue effects only values of the first three arrows after fatigue protocol have been included into the statistical analysis. In this way there were significant differences between T.Brachii and D. middle test-retest results ( $p<0,05$ ). **Discussion** As a result, D. Middle muscle has an importance for stabilising the bow till the archer has pulled the string under his chin prior to the aiming phase and in the release phases to balance the weight of the bow. Insufficient release and instability of the bow can cause bad performance in a competition. In archery, an archer does not use his maximal strength for drawing the string. So recovery process starts after each arrow in the given time allowed. Long lasting fatigue effects were apparent for deltoid muscles and acute fatigue effects could be identified for triceps brachii muscles also. This indicates that resting periods between shots are long enough to recover from acute fatigue in some muscles but fatigue effects persist in other muscles. despite recovery periods. These results may help to design recovery strategies in archery shooting.

## THE INFLUENCE OF INJURY AND ILLNESS ON TOTAL HAEMOGLOBIN MASS

Gough, C.E.1,2, Sharpe, K.3, Garvican, L.A.1, Anson, J.4, Saunders, P.U.1,2, Gore, C.J.1,2,5

*Australian Institute of Sport*

The influence of injury and illness on total haemoglobin mass C. E. Gough<sup>1,2</sup>, K. Sharpe<sup>3</sup>, L. A. Garvican<sup>1</sup>, J. Anson<sup>4</sup>, P.U.Saunders<sup>1,2</sup>, C.J.Gore<sup>1,2,5</sup>. 1. Physiology, Australian Institute of Sport, Australia 2. Faculty of Health, University of Canberra, Australia 3. Department of Mathematics and Statistics, University of Melbourne, Melbourne, Australia 4. Faculty of Applied Science, University of Canberra, Australia 5. Exercise Physiology Laboratory, Flinders University, Adelaide, Australia Inclusion of total haemoglobin mass (Hbmass) in the Athlete Blood Passport would improve its sensitivity to acute autologous blood transfusion (1), a form of blood doping that is currently undetectable. The relative stability of Hbmass in non-doping athletes compared to doping athletes makes it potentially suitable for inclusion in the ABP (2) but reports of large (13-19%) Hbmass fluctuations in some injured athletes could compromise its reliability (3,4). This study quantified the effects of reduced training, surgery and changes in body mass on Hbmass in injured or ill athletes, and examined the dose-response effect of a decrease in training on Hbmass. Fifteen athletes (6 m, 9 f) were monitored for Hbmass a mean of 9 ( $\pm$  6; SD) times over 162 ( $\pm$  198) days, spanning a phase of their training involving a prolonged period of injury or illness. Additionally, body mass was recorded, as were details of recent altitude exposure, iron supplementation, blood donation or surgery. Details of the athletes' training (type, duration and intensity) were recorded and compared to pre-injury training load. Linear mixed models were fitted with  $\ln(\text{Hbmass})$  as response variable, Sex, Altitude, Surgery, Iron, Training and (log of) Body Mass as fixed effects and Athlete as a random effect. Detailed models of training intensity and volume, and combined models of training load were assessed for their effect on Hbmass. Using a simple dichotomous model of combined training load, a decrease from HIGH to LOW training led to a significant 2.3% (0.3 to 4.3, 95% confidence interval;  $p=0.02$ ) decrease in Hbmass. When training variables were examined in more detail, there was no significant association

for any other training model with Hbmass. Surgery was associated with a 2.7% (-5.4 to -0.1,  $p = 0.04$ ) decrease in Hbmass and a 10% decrease in body mass led to a 1.3% decrease in Hbmass. Reduced training, surgery and reduced body mass are each, separately, associated with significant Hbmass decreases in injured and ill athletes. These estimates could be used to differentiate the effects of injury-induced changes in Hbmass from doping if incorporated into the ABP. It was not possible with any real certainty to estimate the dose-response effect of training reductions on Hbmass using these data. 1. Morkeberg et al. *Scand J Med Sci Sports* 2011; 21: 235-243 2. ### MORPHOLOGICAL CHANGES OF NEUROMUSCULAR JUNCTIONS DUE TO INACTIVITY IN RAT SKELETAL MUSCLE

Nishizawa, T.1, SUZUKI, H.2, YUKI, A.2, NORIKATU, K.2

1.sigakkan junior university, 2.aichi university education

**Introduction:** The purpose of this study is to clarify the form of degenerative changes in the neuromuscular junctions (NMJs) due to inactivity. Although skeletal muscles are significantly affected by inactivity, these changes are reversible and they recover functionally when the muscles are made to work again. Muscle activity also simultaneously restores the function of motor cells which govern skeletal muscle. This suggests that the contractive activities of muscles is not only output to the exterior from the nerves, but is also necessary to maintain neuromuscular function. **Materials and methods :** Cast immobilization was performed in order to observe adaptive changes occurring on inactivity. Male Fischer 344/Jcl rats (15 weeks old) were used. All procedures in the animal experiments were performed in accordance with the guidelines. The muscles studied were the plantaris muscle (PLA), extensor digitorum longus muscle (EDL), and soleus (SOL). In a deep relaxed state under anesthesia, using bandage type gypsum (Scott cast), the knee joint and ankle joint of the hind legs were fixed to cause inactivity. Cast immobilization was performed for 1week (G1W) and for 2weeks (G2W), and another group (R2W) was prepared which was fed as usual for 2weeks after cast immobilization for 2weeks. Single muscle fibers were dissected from the EDL. The morphological observation of NMJs by optical microscope used was used for the observation cholinesterase (ChE) and silver staining. **Results:** Regarding the skeletal muscle weight of G1W, G2W, and R2W, the value for group C decreased significantly. In G2W, it decreased to 60% for SOL and PLA, and muscular atrophy due to cast immobilization was observed. R2W showed a higher value than for Group G, which suggested increase of muscle weight after resumption of activity. When the skeletal myofiber and NMJs were observed by an optical microscope, small diameter muscle fibers were observed in G1W and G2W. This suggests that muscle atrophy takes place in 1week due to inactivity. On the other hand, in the NMJs of G1W, no anomaly was found in the axon terminal morphology. In G2W, an indicator of injured muscle fibers was observed, and there was a tendency to decreased area of the NMJs. In motor-endplate observation by acetylcholinesterase dyeing, no anomaly was observed in either G1W or G2W, suggesting that denervation does not occur due to cast immobilization. In R2W where there was resumption of activity, recovery of the diameter of muscle fibers was observed, and a nuclear matrix which is an indicator of regenerated muscle fiber was observed. This suggests the possibility that muscle damage had occurred when activity was resumed after cast immobilization.

### SERUM CONCENTRATION OF CARTILAGE OLIGOMERIC MATRIX PROTEIN IS DIMINISHED DURING 5 DAYS OF HDT BED REST

Liphardt, A.M., Mündermann, A., Andriacchi, T.A., Heer, M., Koo, S., Achtzehn, S., Mester, J.

German Sport University Cologne

Serum concentration of cartilage oligomeric matrix protein is diminished during 5 days of HDT bed rest Liphardt, A.M.1, Mündermann, A.2, Andriacchi, T.A.3, Heer, M.4,6, Koo, S.5, Achtzehn, S.1, Mester, J.1 1: DSHS-Institute of Training Science and Sport Informatics, Köln Germany, 2: Sport Science, University of Konstanz, Germany, 3: Mechanical Engineering, Stanford University, Stanford, CA, US, 4: DLR-Institute of Aerospace Medicine, Köln, Germany, 5: School of Mechanical Engineering, Chung-Ang University, Seoul, South Korea, 6: Profil Institute for Metabolic Research, Neuss, Germany **INTRODUCTION** Cartilage oligomeric matrix protein (COMP) is a structural protein found primarily in cartilage which has been associated with cartilage degradation (1). Serum COMP concentration is sensitive to physiological loading (2, 3). During spaceflight or immobilization the lower limb is unloaded for prolonged periods of time. Unless exposed to regular mechanical loading, cartilage atrophies (4, 5), and COMP is sensitive to 14 days of immobilization (6). The purpose of this study was to determine the effect of unloading on serum COMP concentration during 5-days of bed rest (BR) in combination with an exercise program using vertical jump and squats. **METHODS** Ten healthy male subjects (78.0±3.7 kg; 178.8±3.7 cm, 29.63±5.9 yrs) participated in a 5-day BR study after giving their informed consent. The study was divided into three periods: 5 days adaptation, 5 days HDT BR and 6 days recovery. Seven fasting blood samples were taken throughout the study in the morning before rising. Serum COMP concentration was analyzed using COMP@ELISA (AnaMar Medical AB, Uppsala, Sweden). Statistical analysis (IBM SPSS Statistics, 19.01) was performed using paired-samples T-Test ( $p < 0.05$ ). **RESULTS** Serum COMP decreased significantly after 24h of HDT by 17% (control: baseline = 7.6±1.5; HDT2 = 6.3±1.4,  $p = .000$ ), 12% (sham: baseline = 7.2±1.3; HDT2 = 6.4±1.2,  $p = .000$ ) and 9% (exercise: baseline = 7.7±1.6; HDT2 = 7.0±1.6,  $p = .013$ ) respectively. On the first day of recovery, COMP levels recovered to baseline values with all three interventions. **DISCUSSION** These results support earlier findings that HDT results in an immediate reduction in serum COMP concentration (8). COMP levels recover to baseline immediately after the end of the disuse period. The observed reduction in serum COMP concentration may be caused by decreased diffusion of molecules from cartilage into serum or by a change in cartilage metabolism both in response to the lack of mechanical stimulus during bed rest. **REFERENCES** 1)Neidhardt et al. ### CARDIORESPIRATORY FITNESS AFFECTS RELATIONSHIP BETWEEN GHRL LEU72MET POLYMORPHISM AND CARDIOVASCULAR DISEASE RISKS.

Shumpei, F.1, Motoyuki, I.1, Haruka, M.2, Kiyoshi, S.1, Hiroshi, K.3, Yuko, G.3, Ryoko, K.2, Motohiko, M.2

1: Ritsumeikan University, 2: National Institute of Health and Nutrition, 3: Waseda University

**BACKGROUND:** The Leu72Met (214C>A) polymorphism of ghrelin (GHRL) is associated with eating disorder, obesity and diabetes. Habitual exercise brings higher cardiorespiratory fitness and results in the improvement of risk of cardiovascular disease. However, combined effects of cardiorespiratory fitness and genetic variation on the ghrelin gene on cardiovascular disease risks remain unclear. **PURPOSE:** In the present study, a cross-sectional investigation of 763 Japanese men and women (18-70 years old) was performed to clarify the effects

of cardiorespiratory fitness and GHRL Leu72Met polymorphism on risks of cardiovascular disease. METHODS: Carotid beta-stiffness, measured by ultrasonography and tonometry, and brachial blood pressure, measured by oscillometry, were assessed as risks of atherosclerosis and arteriosclerosis. As an index of cardiorespiratory fitness, we measured peak oxygen uptake (VO<sub>2</sub>peak) during an incremental cycle ergometer exercise test, and then the study subjects were divided into high-cardiorespiratory fitness (High-Fit) and low-cardiorespiratory fitness (Low-Fit) groups based on the median value of VO<sub>2</sub>peak in each sex and decade. GHRL Leu72Met polymorphism was determined by real-time PCR with Taqman probe. RESULTS: In High-Fit subjects, VO<sub>2</sub>peak and serum HDL cholesterol level were significantly higher and serum LDL cholesterol and triglycerides levels were significantly lower than that in Low-Fit subjects. Additionally, total cholesterol, LDL cholesterol and triglyceride levels were significantly lower in the Met/Met genotype of GHRL Leu72Met polymorphism compared with the Leu/Leu and Leu/Met genotype individuals. Interestingly, in the High-Fit subjects, total and LDL cholesterol levels were significantly lower in Met/Met genotype individuals than that in Leu/Leu and Leu/Met genotypes, whereas there were no such differences in Low-Fit subjects. However, carotid beta-stiffness and blood pressure were not significantly affected by the GHRL genetic variant and fitness levels. The 72Met allelic frequency of in the GHRL genetic variant was 25.2% in the High-Fit group and 25.2% in the Low-Fit group. CONCLUSION: These results suggest combined effects of and genetic variation on the ghrelin gene on cardiovascular disease risks. Thus, GHRL Leu72Met variant may affect individual difference in the effect of habitual exercise on lipid profile. ### ROLE OF THE ADRB2 GLN27GLU POLYMORPHISM ON THE EFFECT OF A WEIGHT LOSS PROGRAM

Szendrei, B.1, Cupeiro, R.1,2, Amigo, T.3, Morencos, E.1, Galindo, M.1, González-Lamuno, D.3

1:Facultad de Ciencias de la Actividad Física y del Deporte. Universidad Politécnica de Madrid, 2:Instituto de Ciencias del Deporte. Universidad Camilo José Cela, 3:IFIMAV-Universidad de Cantabria

Introduction The adrenergic system plays a role in the lipolysis, the lipid mobilization and the energy expenditure, so is associated with overweight and body composition (1). Therefore, its functionality could influence the response to an exercise-based weight loss program. Thus the aim of the present study is to analyse the effect of the Gln27Glu polymorphism of the ADRB2 gene on the response to a weight loss program for obese women. Methods 38 Caucasian obese women (39.2±7.8 yrs; 164.7±7.2 cm; 90.4±9.6 kg) followed a 24-week weight loss intervention. This consisted of a controlled training program (3 times/week, 38-60 min/session; strength, endurance and combined training) and a caloric restriction (30% of the daily energy expenditure). The Gln27Glu ADRB2 polymorphism was determined by PCR and restriction enzyme digestion. One-way ANOVA tests were used to determine differences among the genetic groups in body weight (BW) and fat percentage (F%) – initial data and the changes due to the intervention. The significant level was set at  $\alpha \leq 0.05$ . Results The Bonferroni post-hoc test showed differences between Glu/Glu and Gln/Glu for the initial BW ( $p=0.016$ ) and the initial F% ( $p=0.04$ ). Furthermore, we found significant differences between Glu/Glu and Gln/Gln for the initial BW ( $p=0.014$ ) and a borderline significant difference ( $p=0.086$ ) for the initial F%. However, we did not observe differences among groups in the BW and F% losses. Discussion Our results show that in Caucasian obese women, this polymorphism can have an influence on body weight and body composition, but not on weight or fat loss during the described intervention. The international studies have no consistent results about the exact role of this gene in obesity (2,3,4). Further studies are needed to investigate, not only isolated polymorphisms, but also haplotypes related with body composition, to show up stronger associations with the effects of weight loss programs. ### DEPENDENCE OF CARDIO-RESPIRATORY SYSTEM ADAPTATION REACTIONS OF ATHLETES TO ENDURANCE TRAINING ON COMPLEX OF GENE POLYMORPHISMS.

Drozdovska, S.1, Lysenko, O.1, Dosenko, V.2, Ilyin, V.1

NATIONAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORT OF UKRAINE

Introduction The adaptation of an athlete to systematic physical exercise has been shown to depend on an individual's inherited properties (Bouchard et al., 1999). These properties are determined by a combination of great many genes polymorphisms (Bray et al., 2009; Timmons et al., 2010). The aim of our study was to investigate the dependence of the aerobic capacity parameters in sport on the gene polymorphisms. Methods Two hundred and ninety six athletes participated in the study of genotype features of the athletes including: 109 athletes specializing in the speed and strength sports, 103 athletes specializing in the endurance sports, and 93 volunteers which are not involved into sport. The T-786→C polymorphism of the promoter of eNOS gene as well as I/D polymorphism of ACE gene, Pro/Ala polymorphism of PPARG gene, G/C polymorphism of PPARA gene, Pro582Ser polymorphism of HIF1 $\alpha$  gene, and Ala203Pro polymorphism of PPARGC1B gene were identified using the method of PCR. Adaptation to exercise was assessed using the gas analysis which was carried out by an automatic gas analyzer of the Meta Max. Stress tests were conducted using the ergometer and treadmill. Results The impact of 6 polymorphisms on the aerobic performance level was analyzed. Cumulative impact of these polymorphisms in the combination with the individual parameters (gender; qualification; kind of sport) stipulates 71% of dispersion of VO<sub>2</sub>max value. The most stable parameters of the cardio-respiratory system reactions of the athletes in the repeated testing included: HRmax (V=1,5%), VCO<sub>2</sub>/VO<sub>2</sub> (V=5,5%), VO<sub>2</sub>max·kg<sup>-1</sup> (V=5,7%), VO<sub>2</sub>max (V=5,8%), HRTh (V=5,8%), Wmax and Wmax·kg<sup>-1</sup> (V=5,9%), VEmax and VEmax·kg<sup>-1</sup> (V=7,4%), EQO<sub>2</sub> (V=7,6%), fTmax (V=7,9%). ACE gene polymorphism has a definite effect on EQO<sub>2</sub> ( $p=0,020$ ), HRmax ( $p=0,029$ ). PPARA gene polymorphism has a definite effect both on WTh ( $p=0.04$ ) and WTh·kg<sup>-1</sup> ( $p=0,009$ ). eNOS gene polymorphism has an effect on EQO<sub>2</sub> ( $p=0,046$ ). Discussion The analysis of the obtained results has shown both single and combined effect of the gene polymorphisms on the aerobic capacity in the sports with the prevailing development of endurance. Though many studies demonstrated the exceptional significance of the maximal oxygen uptake to achieve the high sport results in the endurance sports, the necessity of VO<sub>2</sub>max high level is overestimated. Competitive activity has different requirements to the level and ratio of the factors in the functional fitness structure in the different sports. Each sport should have its own criteria of the aerobic capacity evaluation. It is necessary to focus on the sport-specific molecular-genetic markers. **A SYSTEMATIC REVIEW OF S100B METHODOLOGY AND ANALYSIS – WHAT DO WE KNOW?**

Schulte, S.1,2, Podlog, L.1, Hayes, B.1, Hamson-Utley, J.3, Toth, R.1, Petron, D.1

1: University of Utah (USA), 2: German Sport University Cologne (Germany), 3: Weber State University (USA)

Introduction S100B is an astroglial protein that is released after traumatic brain injury (TBI) and enters the peripheral bloodstream in higher amounts through a dysfunctional blood-brain barrier. Elevated levels of S100B in the peripheral blood stream have been shown to be predictive of mild TBI (mTBI). Furthermore, physical activity can affect S100B levels. However, S100B values of the same individual can differ by the methodological approach used to measure it, such as the type of sample assessed, the sample processing, storage time, or the type of assay. As a consequence, the discussion about appropriate reference values in the diagnosis of concussed athletes remains unclear. The purpose of this systematic review was to evaluate the methodology of S100B analytical measures. Methods Databases: PubMed, SciVerse Scopus, SPORTDiscus, CINAHL, The Cochrane. Keywords: S100B, S100 $\beta$ , S100beta, S-100B, S-100beta, S-100 $\beta$ , biomarker, assess\*, diagnos\*. Study selection: (i) exclusively research studies on humans in which (ii) physical activity was used as an intervention or (iii) physical active individuals/ athletes were test subjects and (iv) S100B was measured as a dependent variable. Results This review identified 23 articles that met the inclusion criteria. Four different types of S100B samples (serum, plasma, saliva, CSF) have been investigated and various procedures of sample processing (time, centrifugation, temperature) have been applied. None of the articles provided a precise statement about the storage time of the frozen sample. Six different types of immunoassay techniques (e.g. ELISA) were described. Additionally, we identified more than 8 different categories of physical activity (see ii/iii). Discussion Given the non-uniformity of analytical methods utilized, data samples collected, as well as diversity in the physical activities of individuals investigated, the similarity of S100B reference measures within the literature is currently unclear. Therefore, the appropriate evaluation and assessment of S100B levels remains unresolved at present. Thus, we recommend that the interpretation of S100B values be based on congruent study designs regarding the analytical method, the nature of intervention and other possible S100B level influencing factors to ensure the reliability and validity in the assessment of S100B measurements. **EFFECTS OF ORAL APPLIANCE AND CPAP ASSOCIATED WITH PHYSICAL EXERCISE IN IMPROVING BODY COMPOSITION AND CARDIORESPIRATORY FITNESS IN PATIENTS WITH OBSTRUCTIVE SLEEP APNEA.**

Ackel-D Elia, C.1,2, Pantiga Jr, G.1, Luz, G.C.P.1, Alves, E.S.1, Schütz, T.C.B.1, Cunha, T.C.A.1, Guimaraes, T.M.1, Mansur, M.1, Tufik, S.1, Bittencourt, L.R.A.1, Mello, M.T.1,2

Universidade Federal de São Paulo

1Departamento de Psicobiologia 2Departamento de Nutrição \*Universidade Federal de São Paulo – Escola Paulista de Medicina – UNIFESP-EPM Abstract Aim: The aim of this study was to compare the effects of Oral Appliance (OA) and Continuous Positive Airway Pressure (CPAP) associated with physical exercise in improving body composition and cardiorespiratory fitness after 2 months of aerobic+resistance training in patients with obstructive sleep apnea (OSA). Methods: A total of 19 male patients with OSA were randomized in three groups: OA (n=5), CPAP (n=7) and exercise (n=7). All patients completed 2 months of physical exercise (aerobic+resistance training) alone (exercise group) or associated with OA (OA group) or CPAP (CPAP group) during the study. Polysomnography (PSG), cardiopulmonary exercise test (CPET) and body composition (BODPOD) were evaluated before and after 2 months of physical training. Results: No differences were found among groups in the baseline condition for body mass (kg), BMI (kg/m<sup>2</sup>), body fat mass (%), body lean mass (%), sleep parameters (PSG) and CPET variables. VO<sub>2</sub>max (ml/kg/min) and maximal speed (km/h) increased significantly only for OA and exercise groups (VO<sub>2</sub>max=31.87±4.97 and 37.17±4.66\*; 32.70±5.38 and 36.72±5.47; 32.94±4.55 and 38.46±3.63\*; Maximal speed=10.80±0.84 and 12.40±0.89\*; 11.43±1.90 and 12.29±2.43; 10.86±2.34 and 12.14±1.86\* before and after physical training for OA, CPAP and exercise groups, respectively). Body lean mass (%) increased only in OA and exercise groups (64.64±5.14 and 68.12±4.00\*; 71.26±7.95 and 71.66±6.80; 75.11±9.06 and 78.56±9.41\* before and after physical training for OA, CPAP and exercise groups, respectively) while body fat mass (%) decreased only in exercise group (32.76±4.99 and 31.88±4.00; 28.74±7.95 and 28.63±6.19; 24.89±9.06 and 21.44±9.41\* before and after physical training for OA, CPAP and exercise groups, respectively). No differences were found after physical training for body mass (kg), BMI (kg/m<sup>2</sup>) and sleep parameters (PSG). Conclusion: OA associated with physical exercise is more effective than CPAP in improving body composition and cardiorespiratory fitness after 2 months of aerobic+resistance training in patients with obstructive sleep apnea (OSA). **14:45 - 15:45****Poster presentations****PP-PM82 Physiology 23****HUMAN SKIN-GAS AMMONIA AFTER SPRINT CYCLE EXERCISE**

Itoh, H., Zhang, W., Inoko, N., Kimura, S., Ohkuwa, T., Yamazaki, Y., Tsuda, T.

Nagoya Institute of Technology

Introduction During short-term sprint exercise, the accumulation of ammonia in working skeletal muscles increases, and effluxes into the blood. Previously, we (Itoh & Ohkuwa 1991) have confirmed that the peak value of blood ammonia concentrations appears in sprints within 15-s. On the other hand, Nose et al. (2005) have found the existence of ammonia in human skin-gas in healthy persons and patients with hepatic disease. However, no one has confirmed changes in the skin-gas ammonia concentrations after exercise. Therefore, we examined changes in human skin-gas ammonia concentrations after the 10-s supramaximal cycle exercise. Methods Nine healthy male students (22.1 ± 1.0 years; mean ± SE) volunteered as the subjects. The subjects performed 10-s sprint cycle exercise as fast as they could. The skin-gas samples were obtained from the surface of forearm with a sampling probe which we developed. Both the skin-gas

and the blood samples were collected before exercise, after warm-up and 0, 3, 6, 9, 15 min after the 10-s sprint exercise. The skin-gas ammonia concentrations were measured by the ion chromatographic analysis. Blood ammonia concentrations were measured using the Ami-check (Arkray Co., Ltd., Japan). Results The peak power and the exercise load of the subjects were  $794.0 \pm 1.0$  watt and  $6.1 \pm 0.5$  kp, respectively. Both the skin-gas and the blood ammonia concentrations significantly increased after the exercise compared to pre-exercise values ( $p < 0.01$ ), and then returned to pre-exercise levels. The peak skin-gas concentrations of each subject appeared 3 or 6 min after the sprint exercise. Similar changes in the blood ammonia concentrations were observed, however, there was no significant relationship between the peak skin-gas and the peak blood ammonia concentrations. Discussion The ammonia that appears in the blood during short-term exercise originates from the deamination of adenosine 5'-monophosphate (AMP) to inosine 5'-monophosphate (IMP) in the muscle. This reaction occurs via the purine nucleotide cycle (PNC) and is catalyzed by AMP deaminase (Lowenstein 1972). Ammonia production via the PNC in contracting muscle depends on exercise intensity, and occurs predominantly in fast-twitch muscle fibers (Dudley et al. 1983). In this study, excessive energy demands during the sprint cycle exercise increased the blood ammonia concentrations, and these increased blood ammonia levels might reflect the ammonia concentrations in the skin-gas. Conclusions Skin-gas ammonia concentrations increased after 10-s sprint exercise, and reflected the blood ammonia concentrations. ## RELATIONSHIP OF ADIPONECTIN WITH SOME OF CARDIOVASCULAR RISK FACTORS, TESTOSTERONE, CORTISOL, AND VO<sub>2</sub>MAX IN SEDENTARY YOUNG MEN

Aminiaghdam, S., Moradi, F.

*Islamic Azad University, Saghez Branch*

**Introduction** Adiponectin is the one of adipocytokines secreted by adipose tissue that decreases with increased insulin resistance, dyslipidemia, and diabetes. The purpose of this study was to survey relationships between serum adiponectin levels and some of cardiovascular risk factors, testosterone, cortisol, and VO<sub>2</sub>max in sedentary young men. **Methods** This study conducted on 45 sedentary young men (BMI=26.3 kg/m<sup>2</sup>), between 20 and 30 years old who voluntarily participated in this study. Blood samples were collected to determine blood parameters after an overnight fasting. Also, general characteristics of subjects such as age, weight, body mass index, body fat percent, rest blood pressure, rest heart beat, and maximal oxygen uptake were measured. Pearson's correlation method was used to determine the relations of adiponectin with other variables in sedentary young men. **Results** Adiponectin levels were negatively correlated to insulin ( $r = -0.45$ ,  $p = 0.009$ ), glucose ( $r = -0.27$ ,  $p = 0.007$ ), HOMA index ( $r = -0.40$ ,  $p = 0.002$ ), LDL cholesterol ( $r = -0.25$ ,  $p = 0.008$ ), triglyceride ( $r = -0.30$ ,  $p = 0.003$ ), and testosterone ( $r = -0.41$ ,  $p = 0.002$ ), while positively correlated to HDL cholesterol ( $r = 0.26$ ,  $p = 0.005$ ) and maximal oxygen uptake ( $r = 0.31$ ,  $P = 0.09$ ). No significant correlations were observed between adiponectin levels with total cholesterol ( $r = -0.21$ ,  $p = 0.053$ ), resting blood pressure ( $r = -0.38$ ,  $p = 0.01$ ) and cortisol ( $r = 0.16$ ,  $p = 0.089$ ). Discussion The data suggest that sedentary young men with lower cardiorespiratory fitness and lower adiponectin levels may be associated with disorder in glycemic (Hansen et al, 2010) and lipid profile control (King GL, 2008) so that probability of diabetes type II and cardiovascular diseases increase in these subjects (Hamburg et al, 2007). Furthermore, serum concentrations of adiponectin are directly correlated with testosterone levels (Rolland et al, 2006); however, no correlations between adiponectin levels and cortisol concentrations and resting blood pressure were observed. In contrast, Venkatesh et al (2009) reported a significant relationship between plasma cortisol and adiponectin in critically ill patients. **References** Hansen D, Dendale P, Beelen M, Jonkers R, Mullens A, Corluy L, Meeusen R, Loon L. ## EFFECTS OF EXERCISE TRAINING WITH WHEAT GLUTEN HYDROLYSATE SUPPLEMENTATION ON LEG FORCE GENERATING CAPACITY IN MIDDLE AGED AND ELDERLY INDIVIDUALS.

Shimmura, Y.1,2, Kobayashi, K.2, Aikawa, M.2, Nakamura, M.2, Kobayashi, M.2, Kanazawa, A.2, Fujikake, H.2, Asada, K.1, Yahata, N.1,2, Yamauchi, J.2,3

*1.Nisshin Pharma Inc. 2.Tokyo Metropolitan University 3. Future Institute for Sport Sciences*

**[Introduction]** Exercise training at home without using strength training equipment becomes increasing in demands of elderly individuals. We have shown that the exercise training with only using body weight for the 10-month period successfully increased in maximum force for average 15% and power output for 13% (Yamauchi et al. 2009). Aging-related muscle loss is also known as a cause of imbalance in protein turnover. It has been suggested that increase in protein intake enhances the synthesis rate of muscle proteins in older individuals. We have demonstrated that exercise with wheat gluten hydrolysate (WGH) supplementation has a beneficial effect on the muscle size (Shimmura et al. ECSS2012). However, there is currently little data available concerning the influence of exercise training with WGH supplementation in human. Therefore, the purpose of this study was to investigate the effects of bodyweight-based exercise training with WGH supplementation on leg muscle force generating capacity in middle aged and elderly individuals. **[Methods]** Twenty-five healthy middle-aged and elderly individuals between 35 and 75 years old completed the exercise training program for 3 months. They were randomly assigned to the exercise training with WGH supplementation group (WS, n=13; 61.6 ± 7.0 years; height, 160.1 ± 7.7 cm; body weight, 58.4 ± 9.8 kg) and the exercise training only group (EXE, n=12; 57.0 ± 13.5 years; height, 159.5 ± 7.5 cm; body weight, 57.7 ± 8.9 kg). The exercise program consisted mainly of exercises for large leg muscle groups without using external weight, performing 10-50 repetitions and 1-3 sets for each exercise. Before and after the training period, body composition, maximum isometric force of knee extension and knee-hip extension movements were measured with bioelectrical impedance analysis (Inbody), the knee extensor and leg press dynamometers, respectively. The EXE was administered total 1.5g containing sugar (77.3%) as a placebo, while WS was administered total 1.5g containing wheat gluten hydrolysate (66.1%), chondroitin sulfate (10.4%), and vitamin B (0.7%). **[Results and Discussion]** Both WS and EXE groups resulted in significant decreases in body weight and body fat, and increases in knee extension and leg extension force generating capacity. EXE group showed a decrease in muscle mass, but WS groups did not. This study showed the important findings with regard to the exercise training with WGH supplementation in middle aged and elderly individuals. Our results suggest that it is possible to gain muscle strength without muscle loss after 3 months of body weight based exercise training with WGH supplementation. **[Reference]** Yamauchi J. *Geriatrics & Gerontology International* 9: 262-269, 2009.

**EFFECT A BOUT ECCENTRIC EXERCISE ON HSP70 IN TRAINED RATS**

Isanezhad, A.

*tarbiat modares university*

Effect a bout eccentric exercise on HSP70 in rat muscles Isanezhad, A1., Saraf, Z H1. Mahdavi, M2. Gharakhanlo, R1. 1 Tarbiat modares university( Iran).2 Pastour institute (Iran) Introduction Myofibrillar disorganization and membrane disruption are hallmarks of exercise-induced muscle damage (Lieber et al 1999), and the functional outcome of such muscle damage is reduced force generating capacity. To counteract harmful events and agents, skeletal muscle cells provide protective mechanisms and produce stress proteins, such as heat shock protein 70. This heat shock protein affected the immune system (Fleshner et al 2003). Methods 24 male Wistar rats (body mass  $250 \pm 9$  g) were used in this study. Rats were maintained on a 12:12-h light-dark cycle and received food and water ad libitum. Rats were randomly assigned to one of four groups: control (Con; n= 6) and exercise group (n= 18). For eccentric exercise all animals ran individually on a  $16^\circ$  decline for 90 min (5-min bouts with 2 min of rest between successive bouts). Twenty four hour after a bout of eccentric we sacrificed animals. Twenty-four hours after the acute exercise bout, all animals were anaesthetized with an intraperitoneal injection of  $200 \mu\text{l}/100$  g body weight of a solution of 40 mg/ml ketamine and 5 mg/ml xilazine and the soleus muscle quickly dissected., rapidly frozen in liquid nitrogen, and stored at  $-70^\circ\text{C}$  until further analysis. After homogenate muscle, HSP70 measured in soleus muscle we used of ELISA kit for HSP70 (R&D system). A one-way repeated-measures ANOVA test used. Result Our result showed that HSP70 significantly increased after a bout of eccentric exercise ( $p \leq 0.05$ ). There is and significant difference between trained and untrained animals in muscular HSP70 ( $p \leq 0.05$ ). Dissuasion We indicated that muscular level of HSP70 rise in soleus muscle after a bout of eccentric exercise. Relatively new area of muscle damage research has focused on the role of heat shock proteins (HSPs) in protection against eccentric contraction-induced injury (Thompson, Clarkson, Scordilis, 2002). HSPs play an important role in cell survival following various stressors, most notably thermal stress (hence the name). hsp 70 is a danger signal for immune cells (Fleshner et al 2003) and may be has effects on inflammatory cells for muscle repair after eccentric in juries. **STRUCTURED PHYSICAL EXERCISE PREVENTS THERAPY RELATED LOSS OF PHYSICAL PERFORMANCE IN THE PEDIATRIC PBSCT – PRELIMINARY DATA FROM THE BISON-STUDY**

Arndt, S., Senn, A., Rosenhagen, A., Vogt, L., Siegler, K., Jung, M., Banzer, W., Bader, P.

*Medical Center of the Goethe University*

\* the authors are equal contributors Introduction The hematopoietic stem cell transplantation (PBSCT) is associated with a rapid decline of physical and psychological resources. Especially children and adolescents limit their activity level during and after cancer therapy. For adults evidence suggests, that additional physical activity minimizes or even prevents the loss of cardio-respiratory functioning and therapy-reduced muscle performance (Mello, 2003). The aim of this randomized controlled trial is to evaluate structured sports-interventions in the pediatric PBSCT with regard to the physical benefit of a supportive attendance. Methods Included participants are randomized into a sports or control group after informed consent. The main aspects in the sports group are resistance, endurance and flexibility training. The control group performs a mental training as well as relaxation exercises. The structured training lasts for 40-60 min daily for each group. 6-minute-walking-test, hand grip and knee extension strength are assessed before hospital admission and the day before hospital discharge. Results Six children (2 girls, 4 boys;  $10.7 \pm 3.5$ y) served as intervention group (IG), while eight children (4 girls, 4 boys;  $10.5 \pm 4.3$ y) were randomized into the control group (CG). At discharge from hospital, the relative pre-post hand grip strength (mean [SE]: IG:  $7.0 \pm 6.5\%$ ; CG:  $-10.8 \pm 4.4\%$ ), knee extension strength (mean [SE] IG:  $2.6 \pm 7.5\%$ ; CG:  $-10.9 \pm 8.1\%$ ) and 6-minute-walking-test (mean [SE]: IG:  $-0.9 \pm 4.5\%$ ; CG:  $-11.3 \pm 6.6\%$ ) differ between groups. A positive trend is shown for all physical parameters. But only the hand grip strength represents significant changes ( $p = 0.043$ ) until now. Discussion Following the corresponding pilot study (Rosenhagen et al., 2011) the preliminary data are promising and imply that structured sports intervention can reduce the loss of physical performance during a pediatric pbsct. Current studies with children undergoing cancer therapy support these findings (Wolin, 2010). These results and the fact that activity is an important component of child development confirm the need of interventions during cancer treatment. As next steps the secondary outcomes fatigue, health related quality of life and immunological reconstitution and body composition should be evaluated. The recruitment of the study BISON continues until June 2013. Further findings about the outpatient setting (day +100 & +200) are following. **PHYSIOLOGICAL AND MECHANICAL RESPONSES AT AND ABOVE MAXIMAL LACTATE STEADY STATE IN SWIMMING**

Almeida, T., Espada, M., Reis, J., Vleck, V., Bruno, P., Alves, F.

*Faculty of Human Kinetics, Technical University of Lisbon*

Introduction In swimming, the velocity corresponding to the maximal lactate steady state (MLSSv), is the highest intensity that can be maintained over time without continuous blood lactate accumulation, defines the transition between heavy and severe domains of intensity, characterized by differences in  $\text{VO}_2$  kinetics (Reis et al., 2011) and stroke parameters (Dekerle et al., 2005). The purpose of this study was to analyze the physiological and mechanical responses at and above MLSSv in swimming. Methods Twelve competitive male swimmers completed an incremental test composed by  $5 \times 250$  and  $1 \times 200$  m front crawl for  $\text{VO}_2$ max determination. For MLSSv estimation, subjects performed, in random order and different days, 30-min at constant velocity at 87.5, 90 and 92.5% of  $\text{vVO}_2$ max. In a complementary day, two 6-min bouts were performed separated by one hour of passive rest between each repetition at 102.5% of MLSSv. Respiratory gases exchange was analyzed using a K4b2 unit with a "aquatrainer" swimming snorkel (Cosmed®). The parameters of the  $\text{VO}_2$  kinetics were modelled with two exponential functions. Best 400 and 800 m performances in a swimming competitive event were recorded (respectively, T400 and T800). Results MLSSv was achieved by all athletes at 90% of  $\text{vVO}_2$ max ( $1.30 \pm 0.04$  m.s<sup>-1</sup>). The athletes completed the two 6-min bouts at a mean swimming velocity of  $1.34 \pm 0.04$  m.s<sup>-1</sup> with seven swimmers exhibiting relevant slow compo-

ment (mean value  $41.4 \pm 21.4$  ml.min<sup>-1</sup>), 1.1% of VO<sub>2</sub>max ( $3767.67 \pm 483,86$  ml.min<sup>-1</sup>). Maximal lactate steady state ( $4.6 \pm 1.2$  mmol.L<sup>-1</sup>) was significantly lower ( $p < 0.01$ ) than at 102.5% MLSSv ( $7.4 \pm 1.4$  mmol.L<sup>-1</sup>), the same was also verified concerning the stroke rate ( $33.3 \pm 3.8$  vs  $37.8 \pm 4.1$  cycles.min<sup>-1</sup>) and rate of perceived exertion ( $5.8 \pm 0.6$  vs  $7.6 \pm 1.0$  in a 0-10 scale). Contrarily, stroke length significantly decreased above MLSSv ( $2.41 \pm 0.27$  vs  $2.17 \pm 0.20$  m.cycle<sup>-1</sup>). MLSSv was inversely correlated to VO<sub>2</sub> primary phase time constant ( $\tau_p$ ) ( $r = -0.59$ ;  $p < 0.04$ ). This last parameter was also correlated with T800 ( $r = 0.58$ ;  $p < 0.05$ ). Discussion Our results corroborate the assumption that MLSSv represents an exercise intensity above which swimmers have to adopt different strategies to deal with fatigue, decreasing stroke length and relying on higher stroke rate in order to maintain a constant velocity for a longer period of time. VO<sub>2</sub> kinetics time constant is related to exercise tolerance and performance, in line with previous results (Reis et al., 2011). ### ROLE OF POSTURE IN EXERCISE INDUCED HYPERVOLEMIA

Perissiou, M., Xirouchaki, C., Armenis, E., Geladas, N., Baltopoulos, P.

*Faculty of physical education and sport science*

Introduction The supine posture has been shown to limit exercise-induced plasma volume expansion. Differences in hydrostatic pressure gradients between the standing and supine position. Exercise in water in both positions indicates that vertical posture during exercise might promote a greater plasma volume expansion than supine posture during exercise. Methods To test this hypothesis twenty subjects divided in two teams (swimmers and non swimmers) performed intermittent high intensity exercise (4 min at 85% VO<sub>2</sub>max, 5 min at 40% VO<sub>2</sub>max repeated 4 times) on separate days in the water in vertical and supine posture. Changes in plasma volume expansion were calculated from changes in hematocrit and hemoglobin. Plasma albumin content was also measured. Results Statistical analysis of the data indicated that all participants, both swimmers, as well as non swimmers, presented plasma volume expansion and an increase to plasma albumin content 24 hours after the completion of the vertical posture protocol respect to the values of the pre-exercise measurements. Special concern should be given on the supine posture protocol cause there was no plasma volume expansion or an increase in plasma albumin content 24 hours after the completion of the protocol in both groups due to the values of pre-exercise measurements. There were no significant statistical differences between the two different groups after the vertical exercise protocol in plasma volume expansion ( $p < 0.05$ ) Discussion The results confirm that exercise in water in both positions indicates that vertical posture during exercise promotes a greater plasma volume expansion than supine posture during exercise, though increased values in plasma albumin content after vertical exercise in water were slightly reduced in compare to vertical exercise in ground according to recent relevant articles. In conclusion the mechanism of the redistribution of albumin between extra and intra-vascular stores is altered by posture remains unknown but our speculations are that factors associated with postural changes (e.g. central venous pressure) modify the increase in plasma albumin content and the plasma volume expansion after exercise. ### SUBSTANCE USE IN SPORT COACHES

Nedic, A., Matkovic, A., Matkovic, B.R.

*Faculty of Kinesiology*

Introduction The risk factors influencing health in relation with the way of life are nutrition, physical inactivity, smoking, alcohol consumption and use of drugs (WHO, 2003). Smoking, as well as alcohol consumption start is associated with the influence of friends, parents or older brother and sisters (Epstein, 2000). Sport coaches are specific population who are in contact with children as well as adults. Dealing with children very often they become idols and children try to copy their behaviour. The aim of this study was to examine alcohol and smoking habits in sport coaches. Methods Respondents of this study were active sport coaches of both genders (57 females and 152 males) and from different sport disciplines. Alcohol Use Disorders Identification Test (AUDIT), developed by the World Health Organization (WHO) was used for screening alcohol consumption and for cigarette smoking habits FTND questionnaire (Haetherton et al, 1991). The questionnaires were completed anonymously. The obtained data were analyzed by standard statistical procedures, with statistical software package SPSS 13.0. Results and discussion According to the results it is obvious that wide adopted opinion about people involved in sport having good health habits is not so truth. The percentage of athletes consuming alcohol, mostly beer and wine, is great, even 87%. There is no statistically significant difference among the genders. According to AUDIT only 3 female coaches were above the limit values of AUDIT which indicates dangerous alcohol addiction, but among males 21% was above this limit values. The good observation is that most of the points were collected on questions dealing with alcohol risky behavior and very few of coaches get points on those questions indicating that harmful consequences were already experienced. Concerning the smoking habits it was found that 25% of the female coaches and 19.7% of the males are smokers. The majority of females stated that they are smoking between 5 and 10 cigarettes per day, while among the males dominate those who are smoking from 10 to 20 cigarettes per day. Although this study is showing somewhat lower values of smokers and coaches consuming alcohol than some previous studies conducted in Croatia it is still troubling number especially in the view that coaches are, through their education, well informed about the harmful effects of smoking and alcohol and that they are appearing as authoritative figures to those seeking guidance or information. ### INFLUENCE OF TYPE OF CONTRACTION UPON TENDINOUS TISSUE DURING TRAINING: ANIMAL MODEL

Kaux, J.F., Drion, P., Croisier, J.L., Besancon, B., Libertiaux, V., Forthomme, B., Colige, A., Le Goff, C., Franzen, R., Defraigne, J.O., Cescotto, S., Rickert, M., Crielaard, J.M.

*University of Liège*

Introduction: The treatment of choice for tendinopathies is eccentric reeducation. Although the clinical results appear favourable, the biomechanical changes to the tissue are not yet clear. Materiel and methods: This study compared the effects of two methods of training (eccentric (E) training and concentric (C) training) with untrained (U) rats. The animals underwent training over a period of five weeks. The tricipital, patellar and Achilles tendons were subsequently removed to perform a traction test to the point of tendon rupture, and a histological analysis was performed. Results: There was a significant improvement in the rupture force of the patellar and tricipital tendons

between the U and E groups. The tricipital tendons in the control group presented a significantly smaller cross-section than the E- and C-trained groups. No significant difference was observed for the constraints between the three groups for all three tendons. However, a tendency towards improvement was observed between the trained and the U groups for the patellar tendon. Histological studies demonstrated the development of a greater number of blood vessels and a larger quantity of collagen in the eccentric group. Discussion and conclusion: The mechanical properties of tendons in rats improve after specific training, especially following eccentric training.

##### REBOUND HEIGHT-DEPENDENT MODULATION OF LOWER LIMB JOINTS TORQUE IN DROP JUMP

Urata, T.1, Arai, A.2, Uematsu, A.1, Yamada, K.1, Akiyama, M.1, Ishikawa, M.1, Ito, A.1

1: Osaka University of Health and Sports Science (Osaka, Japan) 2: Mukogawa Women's University (Hyogo, Japan)

**Introduction** In the previous study, the peak torque in knee and ankle joints during countermovement jump was greater with increasing jump height [Vanrenterghem et al., 2004]. However, it is not clear how joint torque control when subject was performed the different rebound height from the same drop height. The purpose of this study was to investigate how angular impulse of torque in each joint control with increasing rebound height. **Methods** Seven male subjects were dropped from a 30 cm-height box and subsequently rebounded with different rebound efforts. Rebound efforts were determined by the maximal rebound efforts (RMAX), 50% rebound efforts (R50%) and no rebound efforts (RNO). The ground reaction force (GRF) and the kinematics of each joint angle were recorded to calculate GRF impulse and angular impulse of the net joint torques (TNET), the interaction torques (TINT), the muscle torques (TMUS), and the gravity torque (TGRA) in each joint during drop jump. In addition, the components of TINT were calculated separately for TINT from other joints (TINT-J) and TINT from GRF (TINT-G) during downward (toe contact-lowest COM position) and upward phase (lowest COM position-GRF below body weight). **Results/ Discussion** The rebound height in R50% ( $17.7 \pm 3.0$  cm) was smaller than that RMAX trial ( $27.0 \pm 3.6$  cm). The GRF impulses of down and upward phases were significantly greater when the rebound height was increased. With higher rebound height, angular impulse of extension TNET in hip and knee joints, extension TINT-J in knee and ankle joints, extension TMUS in knee joint and flexion TINT-G in knee joint were increased in downward phase. In upward phase, extension TNET in ankle joint, extension TINT-J in hip joint, and extension TMUS and flexion TINT-G in knee and ankle joints were increased with higher rebound height. These results suggest human mainly increase the knee joint stiffness to increase the rebound height in downward phase. Previous study reported that human stiffen the knee joint for achieving high frequent hopping [Hobara et al., 2010]. In this condition, rebound height must be lowered. Therefore, controlling the knee joint stiffness have different roll depending on performance requirements, that is to say, performing continuous or ballistic movement. In upward phase, by contrast, increasing angular impulse of extension TNET in ankle joint may be used to elastic energy stored in Achilles tendon. **References** Vanrenterghem J, Lees A, Lenoir M, Aerts P, Clercq DD. ##### COUNTER MOVEMENT JUMP AND DEPTH JUMP: POINTING TOES STRAIGHT FORWARD OR OUTWARD?

Nemtsev, O.

PTJI-ASU (Maikop, Russia)

**Introduction** Counter movement jump and depth jump from various heights are often used in sports training, as well as in fitness training. However, such an element of the technique of counter movement and depth jumping as feet position during contact phase has not been sufficiently researched. Therefore, the aim of this study was to compare the height of jump, peak and average force and ground contact time of counter movement jump and depth jump from 17 and 34 cm heights with toes pointed straight forward and outward. **Methods** From the force plate (VISTI) recordings, the following variables were calculated: flight time; contact time; peak and average vertical force developed during the jump. Six qualified male sprinters and jumpers took part in the investigation (age  $21.3 \pm 1.6$  years; body mass  $81.5 \pm 5.5$  kg; height  $1.81 \pm 0.06$  m). Each of them performed three attempts of counter movement jump (with bilateral arm-swing technique), depth jump from the heights of 17 cm and 34 cm with toes pointed outward, and three attempts of the same jumps with straight forward toes position. A Wilcoxon signed-rank test was used to examine statistical differences of data between both jumping techniques. **Results** Qualified athletes performed counter movement jump and depth jump from 17 and 34 cm heights without showing statistically significant differences in the height of jump in either position of the toes ( $p > 0.05$ ). However, the peak vertical force was significantly bigger during the depth jump from 17 cm height when the athletes performed it with their toes pointed straight forward ( $p < 0.05$ ). The contact time in the depth jump from 17 cm height with straight forward toes position was significantly less than when the athletes' toes were positioned outward ( $p < 0.05$ ). **Discussion** The absence of significant result differences between jumps with various toes positions make this element of technique meaningless for testing jumping abilities with the help of counter movement and depth jumps. The minimum differences of jump height, peak and average force of counter movement jump with various positions of feet allow to conclude that in power training this element of technique has no essential value. It doesn't confirm the existing recommendations about the necessity to use only straight forward toes position when performing this jump [Reid, 1989; Radcliffe & Farentinos, 1999]. Depth jump with straight forward toes position allows to reach a higher value of peak force during the exercise. It confirms the recommendation to use this variety of jumping technique in force training. **References** Radcliffe, JC, Farentinos RC (1999). High-powered plyometrics: 77 advanced exercises for explosive sports training. Champaign, IL: Human Kinetics. Reid, P (1989). Plyometrics and the High Jump. New Studies in Athletics, 4 (1), 67-74.

## COMPARISON OF THREE-DIMENSIONAL SCAPULAR MOTIONS DURING ACTIVE AND PASSIVE ARM ELEVATION

Kai, Y., Takei, K., Madokoro, K., Imura, T., Murata, S.

*Technical School of Medical and Welfare Ryokuseikan*

[Introduction] The normal motions of the scapula seen during arm elevation are produced by coordinated activities of the muscles around the shoulder joint. It was previously reported that abnormal muscular activities arising from shoulder muscle/tendon diseases (e.g., cuff tear and impingement syndrome) often result in abnormal scapular motions. The present study was undertaken to compare three-dimensional scapular motions between two types of arm elevation involving different muscular activities, i.e., between active and passive arm elevation. [Subjects and Methods] The dominant shoulders of 35 healthy subjects (35 male,  $21.2 \pm 1.8$  yrs) were examined. None of the subjects had any history of shoulder pain or injuries before participation to this study. Approval for this study was obtained from the institutional review board at Kurume University (#09078). The motion tested was scapular plane elevation. Active elevation (without a load and with a 3- and 5-kg external load) was compared with passive elevation (induced with an electrical motor-driven elevating device). Three-dimensional scapular motion was determined from electromagnetic tracking sensors (3SPACE-Liberty, Polhemus) attached to the scapular, humerus and thorax during active and passive arm elevation. For each 10-degree elevation of the arm, the angles of upward rotation, posterior tilt, and external rotation of the scapula were calculated. Muscle activity during each type of arm elevation was recorded from surface and intramuscular fine-wire electrodes on each of the supraspinous, upper and lower subscapularis, infraspinatus, middle deltoid, serratus anterior, upper and lower trapezius muscle. Two-way repeated measures analysis of variance was used as statistical analysis. Differences at  $p < 0.05$  considered significant. [Results] The angles of upward rotation and external rotation of the scapula during arm elevation by up to 90 degrees were significantly larger during active than during passive elevation ( $p < 0.01$ ). None of these angles differed significantly depending on the conditions of active elevation (no load, 3 kg, and 5 kg). The angle of posterior tilt of the scapula did not differ significantly between active and passive elevation. [Discussion] The results of this study indicate that scapular motions during arm elevation by up to 90 degrees show three-dimensional differences between active elevation and passive elevation which involve different muscular activities. The results additionally show that scapular motions are preserved even when muscular activity is increased by external loading.

## DIFFERENCES IN LOWER EXTREMITY JOINT KINEMATICS AND KINETICS DURING VERTICAL JUMPS WITH AND WITHOUT A LACROSSE STICK

Sanomura, M., Sakaguchi, M., Saho, Y., Fukubayashi, T.

*Waseda University*

Introduction Non-contact anterior cruciate ligament (ACL) injury has been reported to occur during the early stance phase of landing and/or cutting (Krosshaug et al., 2007). The incidence rate of ACL injury in women lacrosse athletes is higher than those in other competitive athletes. The purpose of this study was to compare lower extremity joint kinematics and kinetics during drop vertical jumps with and without a lacrosse stick. Methods Nine female collegiate lacrosse players participated in our study (mean age,  $20.0 \pm 1.3$  years; height,  $159.6 \pm 5.8$  cm; weight,  $55.1 \pm 6.3$  kg; lacrosse experience,  $24 \pm 3.4$  months). An 8-camera motion analysis system and a force plate were used to record three-dimensional marker positions and ground reaction forces, sampled at 240 Hz and 2400 Hz, respectively. The subjects were asked to perform the double-leg drop vertical jump from a 30-cm-high box (landing on a force plate with their right foot), and raising both arms above the head when vertical jumping, and were recorded for each of the 3 conditions; not holding a lacrosse stick (NH); holding a lacrosse stick in the right hand (RH); and holding a lacrosse stick in the right hand with a target ball (RHT). The values of knee abduction and hip adduction, knee and hip flexion angles at initial foot contact, and the peak values of knee abduction and hip adduction, knee and hip flexion angles, and peak knee abduction and hip adduction moments during the first 30% of the landing phase were compared among the 3 conditions. Results The peak knee flexion angle in the RHT trial was significantly smaller than that in the RH trial during the first 30% of the landing phase ( $109.7 \pm 10.4^\circ$  vs.  $113.5 \pm 9.8^\circ$ ,  $p < 0.05$ ). No significant differences in any other parameters were observed. Discussion The extended knee position during the landing from a jump has been reported may be a risk factor for ACL injury, as assessed by video analysis of actual injury and laboratory motion analysis (Renstrom et al., 2008). With respect to the relationship between the sagittal plane of the knee flexion angle and ACL strain, a cadaveric study showed that quadriceps muscle contraction at a smaller knee flexion angle produces an anterior shear force on the tibia relative to the femur (Li et al., 1999). The results of this study suggest that the RHT trial tended to have a smaller knee flexion angle during landing than the RH trial. Therefore, the drop jump task holding a lacrosse stick with a target (e.g., a lacrosse ball) may be useful as a screening test to prevent lower extremity injuries, such as ACL injury, in female lacrosse athletes. ## FORCE DEVELOPMENT OF A TRACK START MOTION ON THE STARTING BLOCK WITH A BACK PLATE IN COMPETITIVE SWIMMING

Takeda, T.1, Sakai, S.2, Ito, S.1, Okuno, K.1, Takagi, H.2, Tsubakimoto, S.2

*1:Waseda University, 2:University of Tsukuba*

Introduction Some studies about swimming start conducted force measurement acting on the starting block during a track start (Cavanagh et al. 1975; Benjanuvatra et al. 2004). However, no study measured the forces acting on the starting block by front leg, rear leg and hands during a track start. Information about force development during a track start was useful for understanding kinetic characteristics and a good example for a swim start instruction. The purpose of this study was to clarify an application of force by a front-leg, a rear-leg and both hands on the starting block. Methods Twelve male competitive swimmers participated in this study. They performed a track start from the starting block with a back plate. Two force plates (9258B11 Kistler Inc, TF-2050-W Tecgihan Inc.) were mounted in the starting block to measure force development by front and rear legs separately during a track start motion. The metallic cylinder bar with two built in two load cells (TL3B04 Tecgihan Inc.) was used to measure force development by both hands during the motion. Track start motions were filmed using four high speed cameras (100fps). We obtained three dimensional (3D) coordinates of swimmer's body parts using 3D DLT method and then extracted 2D coordinates for 2D analysis. 5 m and 10 m head passing time were measure by filming using two cameras placed on the underground pool side deck. Results Changing in horizontal reaction forces showed that peak values appeared in order of by the hands and by the rear-leg, and by the front leg. The amounts of peak horizontal forces by the hands were small. Changing in the vertical reaction forces showed that greater negative force by hands were shown as opposed to the forces by legs. Mean horizontal velocities generated by the front leg, the rear leg and the hands were  $0.35 \pm 0.14$  m/s,  $1.18 \pm 0.26$  m/s and  $2.89 \pm$

0.26 m/s, respectively. Mean vertical velocities generated by them were  $4.98 \pm 0.58$  m/s,  $3.14 \pm 0.28$  m/s and  $-1.58 \pm 0.52$  m/s, respectively. Discussion We have tried to measure force application on the starting block with a back plate during a track start motion. Horizontal reaction force by hands was not greater than a value we expected. The force applied by hands was almost vertical direction. Swimmers pulled the bar by the hands inward at the beginning of starting motion, and they did not push the bar backward to gain the horizontal velocity. The front leg force development dominated the generation of horizontal take-off velocity. On the other hand, the front leg force development dominated the generation of vertical take-off velocity. ## ANALYSIS OF THE PLANTAR PRESSURE ON SOCCER PLAYERS AFTER THE USE OF CUSTOMIZED PLANTAR ORTHOSES

Leiras, J., Villas-Boas, J.P., Sousa, F.

*FADEUP*

ANALYSIS OF THE PLANTAR PRESSURE ON SOCCER PLAYERS AFTER THE USE OF CUSTOMIZED PLANTAR ORTHOSES. Leiras, J.I, Villas-Boas, J. P.1,2, Sousa, F.1,2 1 CIFI2D, Faculty of Sports, University of Porto, Porto, Portugal 2Porto Biomechanics Laboratory (LABIOMEPI), University of Porto, Porto, Portugal Although the use of plantar orthoses is performed in several applications, in recent years, they have led to greater attention particularly in sports. This has been done through the application of engineering expertise, technologies and materials applied. Orthoses are aimed to prevent and treat postural changes and promote a better distribution of body support and balance, which possibly is associated to a better organization of muscle tone and posture. According to Nigg (2003), specific and appropriate footwear for sports practice and the use of insoles or customized orthoses may reduce the frequency of movements that cause injuries, align the skeleton, provide better cushioning, improve comfort and correct the path of the centre of pressure. This study aimed to analyze the distribution of plantar pressure (PP) in soccer players of the Portuguese League, after the use of customized plantar orthoses. Fifteen male, aged between 18 and 35 years were submitted to a morphological and functional podiatric assessment, to better define the construction of the orthoses. Aspects like observation and palpation of the feet; classification of the foot, metatarsal and digital morphology; quantification range of motion of the feet joints; assessment of navicular drop and drift; position of the heel on load; classification of plantar support through the use of pedigráf, podoscopy and Foot Posture Index (FPI), were used. After the analysis of all the parameters, casts and the design of the insole inside the shoe of each individual were done. Orthoses were constructed respecting the anatomical structure of each foot. After testing the suitability of the individuals at the foot insoles and footwear, a comfort perception questionnaire was applied. Volunteers were instructed to wear the orthoses gradually for better adaptation. To analyze PP distribution a Footscan platform was used. Results showed a high incidence of digital and ungual changes, a predominance of hollow foot, heel varus, squared foot, with a high incidence of plantar support asymmetry. Before the use of the orthoses, the PP showed significant higher results on the left foot, and higher pressures on the forefoot area. After the customization of the orthoses, and their use for a period of two months, a redistribution of PP, by improving the bearing surface and distribution of the plantar support between the two feet was observed. Our results show that customized plantar orthoses on soccer players, improve the distribution of plantar loads, increasing the surface contact area and cushioning. It also improves comfort and adaptability of the shoe probably allowing the reduction of overload injuries. Nigg, B. et al (2003). *Medicine & Science in Sports & Exercise*, v.35, n.2, 314-319.

## THE EFFECTS OF SKI TYPE ON ACCELERATIONS AND FORCES DURING ALPINE SKIING

Seifert, J.G.1, Scheiber, P.2, Kipp, R.W.3, Müller, E.2

1: MSU (Bozeman, USA), 2: CDL - Biomechanics in Skiing (Salzburg, AUT), 3: USSA (Park City, USA)

Introduction The alpine ski industry is experiencing a shift towards wider recreational skis. There can be upwards of an additional 3cm width from the binding plate to the ski edge with a wide ski. Yet, little is known how this additional width affects acceleration and force patterns during skiing. The purpose of this study was to compare boot forces and accelerations between a narrow width ski (GS ski) and a wide width ski (powder ski). Methods Data collection began following approval from the IRB. Following a warmup run with each ski, 8 collegiate skiers (FIS GS pts: 71 (29) ) completed 1 run with a 65 mm mid-length width ski (GS; FIS GS) and 1 run with a 102 mm mid-length width ski (WIDE; K2 Coomback). The standardized run consisted of 10 gates that were set 20.5m downhill and 6m offset. The run was groomed nightly prior to data collection. Data from each of the 6 middle turns were averaged and used in analyses. Unidirectional force was measured with force insoles (100 Hz sampling frequency) and boot accelerations were measured with 3-D accelerometers (50 Hz sampling frequency). Data are listed as mean (+/-SD). Alpha level of significance was  $p < 0.05$ . Results No difference in completion time for the 6 measurement gates was observed between WIDE (8.20 (1.39) sec) and GS (8.16 (1.16) sec) skis. The relative total force (L + R legs) and relative force on the inner foot were greater for GS (1.32 (.24) N/kg BW; 0.41 (.11) N/kg BW) than WIDE (1.23 (.20) N/kg BW; 0.34 (.13) N/kg BW). No difference between skis was found for relative force for the outer foot. Co-loading for the inner foot was greater in GS (31.1 (7.8) %) than WIDE (26.7 (7.1) %). No differences between skis were observed for average acceleration in any of the 3 axes. The range in acceleration for the x and y axes were greater for WIDE (x: 64.7 (6.9); y: 66.6(12.7) m/s<sup>2</sup>) compared to GS skis (x: 55.9 (9.8); y: 54.9 (6.9) m/s<sup>2</sup>). Discussion Significant differences in forces and accelerations were found between the WIDE and GS skis. The greater load on the inner leg for the GS skis indicates an increased "two-legged skiing style", due to the self-steering mechanism of these skis. The greater range in accelerations was seen by significantly increased accelerations in the vertical and sagittal planes for WIDE. The significant differences between skis for the ranges and accelerations, within a turn, could indicate less stability for the skier using the WIDE ski on a groomed run. It may be assumed that for each change in acceleration, the body responds with some form of muscular contraction. Further research should evaluate i) force and acceleration data in a deep snow environment and ii) the physiologic effects using wider profile skis during on-piste and off-piste runs.

## HUMAN MOTOR NOISE AND VOLUNTARY MOVEMENT IMPLICATION

Miguel-Gallardo, C.

*Miguel Hernandez University*

Human motor noise and voluntary movement implication. Miguel-Gallardo, C., Barbado, D., Caballero, C, Urbán, T., Moreno, F.J. UMH (Elche, Spain) Introduction In biological systems noise is not completely random (white noise). Biological noises show deterministic patterns (Stergiou & Decker, 2011) and they come in different colours (for example, pink, brown, black) serving different functions (Davis et al,

2003). The aim of this study is to analyze how the structure of a signal changes according to the increased role of biological implication in movement control. To this purpose, we have computed and analyzed the complexity and the degree of autocorrelation of inert variability and movement variability under increased DoF implication. Methods Eight healthy young participants (30.6±8.28 yrs.) took part in the study. To measure inert variability, Polhemus Liberty sensor was placed on a stable surface (240 Hz). After that, the sensor was located on different places on the body according to increased DOF involved: a) on the hand placed on the stable surface (inert condition); b) on the hip, shoulder and on the hand, standing still; and c) on the hand during linear and circle movement. Each condition lasted 60 seconds with 1 minute rest between conditions. Time series data were analyzed through Fuzzy Entropy (FuzzyEn) and Detrended Fluctuation Analysis (DFA). Results The results showed significant higher FuzzyEn values for inert variability. Data from sensor on moving hand showed lower FuzzyEn values, mostly in the Z axis ( $F=89.205$ ,  $p<.001$ ). Results from DFA showed higher persistent correlation as movement implication increased, showing significant differences in every axis (X axis,  $F=138.614$ ,  $p<.001$ ; Y axis,  $F=215.726$   $p<.001$ ; Z axis,  $F=106.705$ ,  $p<.001$ ). Discussion Unlike inert condition which shows a random behavior (white noise), biological conditions show deterministic and random components (Riley & Turvey 2002). The degree of persistent autocorrelation change showing an inverse power-law ( $1/f$  - different colored noise) depending on the tasks (different movement implications). These results would indicate fractal process underlying in the biological behavior (Goldberger et al., 2002). References Davids, K, Shuttleworth, R, Button, C, Renshaw, I, Glazier, P. (2004). ### THE EFFECT OF SWIMSUIT ELASTICITY TO MASCLE OUTPUT -PILOT WORK FOR NEW SWIMSWIT PRODUCTION-

Gonjo, T.1,3, Tsuboi, J.2, Todoko, F.2, Tsubakimoto, S.3, Takagi, H.3

1: Centre for Aquatics Research and Education, The University of Edinburgh (Edinburgh, UK), 2: Descente LTD. (Tokyo, JAPAN), 3: Institute of Sports Science, University of Tsukuba (Ibaraki, Japan)

Introduction Nowadays, many swimsuits are composed of materials that have strong elasticity. It is advertised that this kind of swimsuit reduces drag, or enables an increase of power during swimming. Reduction of drag may be due to the elasticity of the swimsuit (Oliveira, 2009). However there are few studies that clarify the relationship between elasticity of the swimsuit and the swimmer's power output. Thus, the purpose of this study was to clarify the effect of swimsuit elasticity on muscle power output of swimmers. Methods Fourteen male swimmers participated in this study. The swimsuits used in this study were swimsuit A that has middle-strength elastic material on the back half side, swimsuit B whose back side has strong elastic material, swimsuit C, the back part of which is made by weak elastic material. In the experiment, three concentric hip extension-flexion tests at 60, 120, and 180 deg/sec respectively were performed by subjects wearing each of the three types of swimsuit. An isokinetic dynamometer (Biodex Medical System, Inc.) was used to measure isokinetic power output. Only the right hip extension-flexion was tested, and their upper body and left hip were fixed. Results There were no statistically significant correlations between elasticity of the swimsuit and isokinetic power output. However, when subjects wore swimsuit B, 11, 8, and 10 subjects showed larger isokinetic power output in 60, 120, and 180 deg/sec respectively. The mean values (mean±SD N/m) were as follows; 60deg/sec (swimsuit A: 212.0±32.4, swimsuit B: 220.4±31.4, swimsuit C: 193.9±32.8), 120deg/sec (swimsuit A: 196.9±20.5, swimsuit B: 208.9±28.9, swimsuit C: 189.1±27.3), 180deg/sec (swimsuit A: 184.01±17.86, swimsuit B: 198.60±24.35, swimsuit C: 185.08±29.84). Discussion Although there were no statistical differences, many subjects showed larger muscle output when wearing swimwear B in all three isokinetic angular velocity conditions. In a previous study (Doan et al., 2003) for compression garments, there was evidence that strong material elasticity may assist the athletes' hamstrings so that the height of vertical jumps increased. It is possible that swimsuit B also assists the hamstring power output. References Oliveira, S. (2009). ### RUBBER FULL-BODY SWIMSUIT: PASSIVE DRAG AND BODY POSITION OF GLIDE SWIMMING

Fantozzi, S., Cortesi, M., Di Michele, R., Zamparo, P., Gatta, G.

University of Bologna

RUBBER FULL-BODY SWIMSUIT: PASSIVE DRAG AND BODY POSITION OF GLIDE SWIMMING Fantozzi, S.1, Cortesi, M.2, Di Michele, R.2, Zamparo, P.3, Gatta G.2 1: DEIS (Bologna, Italy), 2: DIEBA (Bologna, Italy), 3: DNNMM (Verona, Italy) Introduction The swimmer's drag is due to the shape of the body and for a lower proportion to friction drag and to wave formation. Full-body swimsuits, initially manufactured using a textile material, reduce considerably the passive drag (Dp, Benjanuvatra et al., 2002). The introduction of rubber suits abruptly improved the swimming performances (O'Connor and Vozenilek J, 2012). The aim of this study was to analyze how the trunk and lower limbs hydrodynamic position, induced by wearing a rubber swimsuit, affects the Dp in glide swimming. Methods 14 male high-level swimmers performed six 20-m trials of passive swimming. From Dp glide position they were towed at the surface by means of an electromechanical motor (Ben-Hur, ApLap Roma) that measures the force needed to tow a swimmer (Dp) at increasing velocities (1.0, 1.2, 1.4, 1.6, 1.8 and 2.0 m/s). The whole protocol was repeated wearing a brief-traditional suit (S, Sali, Arena, Italy) and a full-body (shoulder to ankle) synthetic rubber swimsuit (Rs, X-glide Power-skin, Arena, Italy). The swimmers were filmed with an underwater camera placed perpendicular to the sagittal plane TI angle, between the horizontal and the trunk segment (anatomical landmarks of angle of scapula - greater trochanter) and LI angle, between the horizontal and the lower limbs segment (greater Trochanter - head of the Fibula) were computed. The automatic tracking was performed by an ad-hoc software. Paired Student's t-tests were used to assess the differences between TI, LI and Dp in the two considered swimsuit conditions. Significance was set at  $\alpha = 0.05$ . Results No significant differences were found for TI between S and RS, with the exception of the 1.6 m/s velocity (mean values: 174.0±3.6° vs. 171.8±4.3°, respectively). Conversely, the mean LI angle was significantly larger when the swimmers wore the rubber swimsuit at all the velocities (mean values for six velocities were 188.4±3.9° for Rs compared to 185.5±3.7° for S). The Dp values at the highest velocities (1.6 to 2.0 m/s) were significantly lower in RS. (Dp values at the six velocities were 29.3±4.7, 42.2±9.5, 56.7±6.4, 71.8±10.0, 90.0±11.6, 120.3±15.1 N (for S), and 28.8±4.9, 41.4±6.8, 54.0±9.5, 65.8±9.2, 77.9±9.6, 102.7±13.8 N (for RS). Discussion The present data showed that the RS induces an increase of legs inclination with a raising effect similar to that involved by a pull-buoy. As the drag is reduced by changing the body position during gliding [14], a modified position of the lower limbs may be a further factor contributing to the Dp reduction observed when using a full-

body swimsuit. References Benjanuvattra N, Dawson G, Blanksby BA, Elliott BC. (2002). *J Sci Med Sport*, 5(2), 115-23. O'Connor L, Vozenilek J. *J Strength Cond Res* (2012, in press).

### DO LATERALITY AND STRENGTH ASYMMETRY RELATE TO PREFERRED SIDE IN THE CROSS-COUNTRY SKIING G2 SKATE TECHNIQUE?

Thorrud, S.

*North-Troendelag University College, Levanger, Norway*

DO LATERALITY AND STRENGTH ASYMMETRY RELATE TO PREFERRED SIDE IN THE CROSS-COUNTRY SKIING G2 SKATE TECHNIQUE? Thorrud, S.1, Welde, B.1, Sandbakk, Ø.2 1 North-Troendelag University College, Levanger, Norway; 2 Norwegian University of Science and Technology, Trondheim, Norway. Introduction Laterality, or limb dominance, is well known feature in both humans and animals. In the cross-country skiing G2 skating technique, skiers use an asymmetrical loaded double pole push synchronous with one leg push (strong side), but without poling on the other leg push (weak side). Anecdotal evidence indicates that most elite skiers manage to use both sides without difficulties at low and medium exercise intensities. However, when the intensity increases, skiers show a greater bias towards one side. Therefore, the aim of this study was to examine whether this bias is found in elite skiers, if it is related to exercise intensity and the association with laterality, muscle strength and power asymmetry. Methods Fifteen male cross-country skiers were tested for upper and lower body maximal strength and power on the dominant and non-dominant side in five exercises. General laterality was assessed via the Edinburgh Handedness Inventory and the Waterloo Footedness Questionnaire- Revised. Lateral preferences in the G2 technique at five different intensities, ranging from low to maximal sprinting, were assessed by a five-point scale from always left to always right. Additionally, the subjects rated how well they coped with the G2 on the preferred and non-preferred strong side on a 10-point scale at the five different intensities. Results The degree of coping was significantly different ( $p < 0.05$ ) between the preferred and non-preferred strong side for all intensities. Lateral preference in the G2 was not related to either handedness ( $r = 0.218$ ) or footedness ( $r = 0.282$ ). Strength and power variables were not significantly different ( $p > 0.05$ ) between the preferred strong side and weak side. Coping of the non-preferred side decreased as intensity increased with significant differences ( $p < 0.05$ ) between all intensities, except for the two lowest. Discussion The current study demonstrates a greater bias towards preferring one side in G2 skating among cross-country skiers, and that this bias increase as intensity increases. The athletes' coping of the preferred strong side remains stable across all intensities, whereas coping of the non-preferred strong side decrease. There were no clear patterns of laterality, strength or power related to the preferences in G2 skating. Thus, lateral preference in the G2 is task specific and is not related to laterality in general or the athletes' strength asymmetry.

### RELIABILITY OF AN ISOKINETIC TEST TO ASSESS TRUNK MUSCULAR STRENGTH AND ENDURANCE

García-Vaquero, M.P., Barbado, D., Juan-Recio, C., Vera-García, F.J.

*Miguel Hernandez University of Elche*

Introduction Isokinetic tests are commonly used in laboratory settings to measure trunk muscular strength and endurance, as they are considered important for both athletic performance and health care (Ho et al., 2005; Mayer et al., 1995). The aim of this study was to analyze the reliability of a new flexion-extension isokinetic trunk test to measure trunk muscular strength and endurance, and to examine the effect of repetition on the measurements. Methods Forty physically active volunteers (28 men and 12 women) participated in this study. The isokinetic test (Biodex\*) consisted in performing 4 trials of 15 maximal flexion-extension exertions at 120°/s (range of motion = 50°). In order to assess the repetition effect on the measurements, the test was performed 4 times, with 7 days between sessions. Peak torque (PT) and total work (TW), and their decrease over trials, were used to assess trunk muscular strength and endurance, respectively. Results Extension and flexion PT and TW showed high ICC and low SEM values between trials (PT:  $0.87 \leq \text{ICC} \leq 0.96$ ,  $4\% \leq \text{SEM} \leq 8\%$ ; TW:  $0.73 \leq \text{ICC} \leq 0.98$ ,  $4\% \leq \text{SEM} \leq 16\%$ ) and sessions (PT:  $0.81 \leq \text{ICC} \leq 0.96$ ,  $5\% \leq \text{SEM} \leq 11\%$ ; TW:  $0.81 \leq \text{ICC} \leq 0.95$ ,  $7\% \leq \text{SEM} \leq 16\%$ ). ANOVA for extension PT didn't show significant differences between trials. On the other hand, the maximal extension TW was found in the first or second trial in all sessions. After the second trial, the extension TW decreased due to fatigue, although differences between the third and fourth trials were not statistically significant for session 1 and 4. Overall, the maximal flexion TW and PT were found in the first trial. Afterward, Flexion TW and PT decreased progressively from trial 1 to 4. ANOVA for extension and flexion PT and TW didn't show significant differences between sessions, with the exception of the comparison between sessions 1 and 2 for the first two trials of flexion TW. Discussion These results showed good absolute (SEM) and relative (ICC) isokinetic test reliability. In addition, there was no repetition effect due to learning, training and/or fatigue across sessions for most measures. Therefore, one recording session could be enough to evaluate trunk muscular strength and endurance. In order to achieve the maximal PT and TW, at least 2 trials of the isokinetic test are required. The decreases of PT and TW seem useful parameters to analyze trunk flexion endurance. However, only the decrease of TW seems suitable to assess trunk extension endurance. In general, 3 trials of the isokinetic test are needed to obtain reliable measures of trunk endurance. References Ho CW, Chen LC, Hsu HH, Chiang SL, Li MH, Jiang SH, Tsai KC. **DIFFERENT EFFECTS OF SHORT-TERM PREDNISONE TREATMENT ON BODY COMPOSITION AND ON ADIPOKINES IN HEALTHY, PHYSICALLY FIT WOMEN**

Rieth, N., Jollin, L., Thomasson, R., Amiot, V., Lasne, F., Collomp, K.

*UFR STAPS ORLEANS*

DIFFERENT EFFECTS OF SHORT-TERM PREDNISONE TREATMENT ON BODY COMPOSITION AND ON ADIPOKINES IN HEALTHY, PHYSICALLY FIT WOMEN Rieth, N.1, Jollin, L.1, Thomasson, R.1, Amiot, V.2, Lasne, F.3, Collomp, K. 1,3 1: CIAMS (Université Paris XI-Orléans, France), 2 : Service Médecine du Sport, CHR Orléans, 3: Département des Analyses, AFLD (France) Introduction Long-term glucocorticoid treatment has many known side effects, including weight gain and increased fat mass with skeletal muscle atrophy (Schakman et al., 2008) but deleterious effects of short-term (<2 weeks) systemic administration are still questioning. Methods This randomized, double-blind, cross-over study assessed the food intake of 17 female recreational athletes with and without prednisone ingestion (50 mg/day for 1 week). Body weight, body composition, leptin, adiponectin, insulin and blood glucose levels were determined before and at the end of each treatment. Results One week prednisone intake did not induce significant change in body weight, body composition or food intake. Insulin and blood glucose were not significantly altered by prednisone compared with placebo, but leptin and adiponectin concentrations were significantly increased after prednisone treatment (respectively  $P<0.01$  and  $P<0.05$ ). Discussion This study rules out any side effect of 1 week systemic administration of glucocorticoid on body composition and dietary intake in healthy, physically fit women. These results appear partly in contradiction with some studies (Udden et al., 2003) but in accordance with other works (Beard et al., 1984; Rieth et al., 2009). It can be suggested that the daily exercise habits of our subjects may have counteracted the increased dietary intake and/or the fat mass gain. Further studies are needed to understand the mechanisms behind the prednisone-induced increase in adipokines. **THE MINERAL STATUS OF YOUNG ATHLETES**

Rilova, N.1,2, Troyegubova, N.2

*1. Volga Region State Academy of Physical Culture, Sport and Tourism (Kazan, Russia) 2. Kazan State Medical University, Department of pediatrics (Kazan, Russia).*

Introduction From a physiological point of view, many minerals are of major importance for the high intensity physical activity given their role in the maintenance of muscle contraction, nerve impulse, transport of oxygen, activation of enzymes, immune function, antioxidant activity, bone health, and acid-base balance of blood (Dressendorfer et al., 2002). The aim of the study is assessment of mineral status in the hair of young athletes. Methods The content of magnesium, zinc and calcium in the hair samples of 15 young athletes (figure skaters) and 28 healthy children aged 12-16 years was investigated. We used a method of mass spectrometry with inductively coupled plasma mass spectrometer «Elan-9000», the optical emission spectrometry with inductively coupled plasma optical emission spectrometer for «Optima 2000DV». Results It was revealed that the level of magnesium, calcium and zinc was significantly lower in the hair of young athletes than in the hair of the control group: magnesium  $84,3\pm 4,8$  vs.  $171,6\pm 3,9$  ( $p<0.05$ ); zinc  $158,5\pm 7,2$  vs.  $204,5\pm 6,4$  ( $p<0.05$ ) (Micheletti, 2001); copper  $11,4\pm 0,8$  vs.  $15,4\pm 0,4$  ( $p<0.05$ ). Following the mineral screening, the athletes were given individual advice on the basis of gender, age, micronutrient deficiencies, and physical activity. Repeated hair samples were taken one month after the correction. It was shown that the correction of nutrient intake with mineral supplements led to an significant increase in the mineral content of hair samples. Conclusions Identified deficit of the minerals in the hair of athletes is probably due to two reasons: the loss of macro- and micronutrients with sweating (Maughan, 2000) and their movement into the intracellular region (in the active muscle cells). Correction changes can lead to better tolerance of stress among athletes who require special endurance (Lukaski, 2001). References Dressendorfer R. et al. **EFFECT OF HYDRATION STATUS ON THE DEVELOPMENT OF ACUTE MOUNTAIN SICKNESS**

Gatterer, H.1, Wille, M.1, Lukaski, H.2, Angelini, F.3, Faulhaber, M.1, Burtcher, M.1

*University Innsbruck*

EFFECT OF HYDRATION STATUS ON THE DEVELOPMENT OF ACUTE MOUNTAIN SICKNESS Gatterer, H.1, Wille, M.1, Lukaski, H.2, Angelini, F.3, Faulhaber, M.1, Burtcher, M.1 1:Sport Science, University Innsbruck (Austria), 2:Physical Education, Exercise Science and Wellness, University of North Dakota (USA), 3:Italian Society of Sport Nutrition and Wellness, University of Pavia (Italy) Introduction Low fluid intake and inadequate diuresis are risk factors for the development of acute mountain sickness (AMS) (Mairer et al., 2009). Therefore, the assessment of fluid balance before and during ascent to high altitude could be helpful to avoid excess dehydration and to provide recommendations on fluid intake. A noninvasive method to monitor body fluid variation is the RXc graph method (BIVA) (Piccoli et al., 1996). However, so far the accuracy of BIVA to identify fluid shifts and the impact of these shifts on the development of AMS were not investigated. Method 59 healthy participants (32 males and 27 females, age:  $26\pm 5$  years, height:  $173\pm 8$  cm, weight:  $68\pm 11$  kg) were exposed to a simulated altitude of 4500 m ( $F_{iO_2}=12.6\%$ ) for 12 h. During the 12 h period food and drinks were provided ad libitum. The Lake Louise Score was used to assess the severity of AMS. Before and after the 12 h exposure body weight measurements and bioimpedance analysis (BIA-101, Akern) were performed. BIA analyses were done according to the RXc graph method. The length of each vector was calculated as the hypotenuses of individual impedance values. Plasma osmolality (Posm) was measured by freezing point depression method

(Fiske Osmometer). Urinary volume and fluid intake were collected during the 12 h exposure. Results 43 participants spent the whole 12 h in the hypoxic chamber, 16 had to abort because of severe AMS symptoms. The mean AMS score when leaving the chamber was  $3.5 \pm 2.7$ . Participants drank  $309 \pm 125$  and urinated  $225 \pm 116$  ml/h. Body weight increased ( $68.0 \pm 11.0$  to  $68.4 \pm 11.1$  kg,  $p=0.001$ ) and Posm and the vector length decreased ( $297 \pm 4$  to  $293 \pm 7$  mOsm/kg and  $315 \pm 64$  to  $306 \pm 65$  ( $p<0.001$ )) from pre to post exposure. The ratio between fluid intake and water loss per h and the changes in Posm correlated with the AMS score ( $r=0.289$ ,  $p=0.027$ ;  $r=-0.336$ ,  $p=0.009$ ). Vector length changes correlated with weight changes, with the ratio between fluid intake and water loss and with the fluid intake per h ( $r=-0.587$ ,  $p<0.001$ ;  $r=-0.371$ ,  $p=0.004$ ;  $r=-0.442$ ,  $p<0.001$ ). Discussion The increases in body weight, the reduction in Posm, the shortening of the vector length and the lesser urine volume compared to fluid intake indicate fluid gain. AMS symptoms were more severe for participants whose plasma osmolality dropped the most and for whom the fluid intake was much in excess to the fluid loss. The correlations found for the RXc graph method indicate that vector length changes reflect fluid shifts. References Mairer K, et al. (2009). *High Alt Med Biol*, 10, 239-245. Piccoli A, et al. ### EFFECT OF CARBOHYDRATE SUPPLEMENTATION ON HORMONAL AND IMMUNE RESPONSES OF YOUNG TENNIS PLAYERS

Capitani, C.D.1, Gomes, R.V.2, Coutts, A.J.3, Moreira, A.2, Aoki, M.S.2

1 - University of Campinas, Campinas, Brazil; 2 - University of São Paulo, Sao Paulo, Brazil; 3 - University of Technology, Sydney, Australia.

Introduction: The aim of the present investigation was to assess the effect of CHO supplementation on hormonal and immune responses during prolonged tennis match play with well-trained young players ( $n=12$ ; top 50 in Brazil ranking) in an ecological setting. It was hypothesized that CHO supplementation would attenuate the physiological responses related to a match play. Methods: The study was conducted following a randomized, double-blind, placebo-controlled design in order to determine the influence of a carbohydrate versus placebo beverage ingestion on hormonal and immune responses to 3 h of tennis match. Cortisol, testosterone and immunoglobulin A (IgA) concentrations were assessed from saliva samples collected four times on each testing day (7:00, 9:00 (pre-match), 12:00 (post-match), 17:00 and on the following morning 7:00). Salivary steroid hormones and IgA concentration were determined by ELISA kits. Results: Accordingly, to the initial hypothesis, carbohydrate ingestion was associated with lower post-match salivary cortisol ( $p<0.05$ ). No influence of carbohydrate supplementation on salivary testosterone was observed ( $p>0.05$ ). IgA response was not affected during both experimental conditions ( $p>0.05$ ). Conclusion: These data indicate that carbohydrate ingestion during 3 h of competitive tennis match play attenuates salivary cortisol increase as compared to placebo feeding. Previous studies have shown that CHO ingestion during prolonged, high-intensity, intermittent exercise can protect against a decrease in plasma glucose levels that reduces the activation of the hypothalamic-pituitary-adrenal (HPA) axis and blunts cortisol release. On the basis the current findings, it is recommend that players consume CHO to assist in blood glucose regulation and minimize the stress hormones release during extended tennis match play.

### ETHNICITY AND SWEAT SODIUM IN MALE ATHLETES

McLean, D.W., Black, K., Brown, R.

University of Otago

Introduction Inappropriate replacement strategies can impair performance and health. Experts recommend customised fluid and electrolyte replacement strategies during recovery (Sawka et al., 2007). Individualisation is not always practical in a team sport setting. Therefore, identifying groups prone to large sodium losses is important for sports nutritionists. Sweat sodium loss may be influenced by ethnicity. Small field studies in the USA suggest that 'White' male athletes have higher sweat sodium losses than their 'Black' counterparts (Godek et al., 2010). The purpose of this study was to investigate sweat sodium concentrations of male team sport athletes of New Zealand European (EUR) or New Zealand Maori/Pacific Island (MPI) ethnicity. Methods A total of 23 elite rugby players ( $n=9$  EUR,  $n=14$  MPI) volunteered. Body mass was measured before and after a 60 minute pre-season spin (RPM) training session to estimate sweat rate. Sweat patches were placed on the athletes back to estimate sweat sodium concentration. Blood samples were collected and analysed pre- and post-exercise for blood sodium concentration. Results Pre-exercise body mass was not significantly different between EUR ( $100.2 \pm 9.9$ kg) and MPI ( $101.0 \pm 12.5$  kg) ( $p=0.872$ ). Sweat sodium concentration was significantly different (EUR= $42 \pm 13$ , MPI= $66 \pm 9$  mmol/L) ( $p=0.045$ ). However, there was no significant difference in sweat rate between the two groups (EUR= $0.96 \pm 0.53$  vs MPI= $1.01 \pm 0.39$  L/h) ( $p=0.789$ ), nor for post exercise blood sodium concentration (EUR = $137.7 \pm 2.2$  vs. MPI= $139.2 \pm 2.0$  mmol/L), ( $p=0.122$ ). Interestingly two of the participants recorded a blood sodium concentration below 135 mmol/L. Discussion This study indicates that ethnicity may influence sweat sodium losses. This may be due to dietary or genetic differences between the two groups (Eichner, 2008). The findings may allow for a more targeted approach to fluid and electrolyte replacement strategies amongst teams. The finding of two players with a blood sodium concentration below 135 mmol/L suggests that even when exercise duration is short inappropriate fluid intakes can lead to blood sodium dilution. ### EFFECTS OF LEUCINE SUPPLEMENTATION IN THE PROTEIN SYNTHESIS SIGNALLING PATHWAYS OF SOLEUS AND EDL MUSCLES IN YOUNG AND OLD RATS

Chaves, D., Nicastro, H., Lorenzetti, F.M., Dantas, W.S., Campos, P., Luz, C.R., Lancha Jr, A.H.

Universidade de São Paulo

Introduction Supplementation with leucine (Leu) has been used as a strategy to increase muscle protein synthesis and attenuate muscle loss in various situations. However, in old muscles, higher doses are necessary in order to achieve the same response observed in young muscles. The objective of this study was to evaluate the phosphorylation response of proteins involved in the protein synthesis translation initiation in soleus and EDL muscles of young and old rats given either low or high dose of leucine. Methodology Histological analyses were performed in order to confirm morphological differences between the young and old animals. Phosphorylation of eIF4E, 4EBP1, p70S6K was determined using a commercial Enzyme-Linked Immunoabsorbent Assay and oxidative stress was measured using the FOX-1 assay. Results In the young group, the low and high doses of Leu supplementation did not enhance eIF4E phosphorylation neither in soleus nor in EDL muscles. On the other hand, in the old group, eIF4E phosphorylation was enhanced in the high dose of Leu

only in soleus muscles when compared with the low dose. In the young group, the high dose of Leu supplementation enhanced eIF4E phosphorylation when compared to the control group. In the old group, 4EBP1 phosphorylation was not enhanced with either dose of Leu. In the young group, there was no difference in p70S6K with either dose of Leu in both muscles. However, in the old group, p70S6K phosphorylation was enhanced with the high dose of Leu when compared to the control in soleus muscles. Leu supplementation did not alter the levels of plasma hydroperoxide (determined by the FOX-1 assay) in the young group but, in the old group, Leu supplementation was able to reduce FOX-1 in a dose dependent manner. Discussion Here, we showed that the phosphorylation response of young and old animals was different, furthermore, we showed, to our knowledge for the first time that leucine may have an antioxidant/dose dependent effect. This research was supported by FAPESP, grants 2010/10852-6 and the scholarships 2009/52022-2, 2010/08329-3.

### DIETARY PRACTICES AND ANTHROPOMETRIC PROFILE OF PROFESSIONAL MALE SURFERS

Lima Ribeiro, S., Freitas, A.M.P., Pereira, B., Vilalva, R., Krinski, K., Souza-Junior, T.P.

*University of São Paulo, Federal University of Paraná*

**Introduction:** There is a lack of information concerning nutritional status of surfers. This study has the aim to identify dietary practices together with anthropometric variables of a group of professional surfers. **Methods:** The volunteers were recruited at a National Surf Championship in Brazil, and were evaluated for anthropometric measures, indexes and calculations (body mass, height, arm span, body circumferences and nine skinfold thicknesses, arm span/height ratio, waist-to-hip-ratio, conicity index and % body fat). They answered a 24h food-recall, calculated by daily intake of energy, macro-nutrients, some micro-nutrients and food groups were analyzed. The values were compared with some references and position statements and with the Brazilian Food Guide. The daily basal energy expenditure, daily total energy expenditure and energy balance were predicted by specific equations. **Results:** - The intake of carbohydrate is below the position statements, at least considering the day before competition. However, possibly the intake of supplements such as maltodextrin fulfilled the requirements of some, but not all, the athletes; - The intake of BCAA showed to be high; - The low intake of vegetables possibly contributes to the low intake of micronutrients such as folic acid; - The high intake of fried food overlapped healthy habits such as nuts consumption; - The percentage of body fat seems to be similar to swimmers (around 12% of body weight). **Discussion:** This study certainly will contribute to the understanding of body composition and feeding practices of professional surfers. Further investigation, with more sophisticated methods of evaluation, could improve our findings.

### COMPARISON OF PSYCHOLOGICAL STATUS FOR PROPER DIET AND NUTRITIONAL STATUS BETWEEN ADOLESCENT FOOTBALL PLAYERS IN DIFFERENT TEAM

SAKAI, K.1, HOSOYA, M.1, WATANABE, H.1, SUZUKI, I.2, OHTA, A.1

*1: Josai International University (Japan), 2: Utsunomiya Bunsei Junior College (Japan)*

**Introduction** It is well known that prudent nutrient intake and certain dietary constituents improve physical performance and/or maintain physical condition in youth football players. In Japan, all of adolescent football players registered into Japan Football Association belong to only one team under three different organizations: Nippon Junior High School Physical Culture Association (school-based team), Japan club youth football federation (town-based club team), and J. league (academy team). Therefore, the aim of this study is to compare the psychological status for proper diet and nutritional status in adolescent football players belonging to three different teams. **Methods** The cross-sectional study used a questionnaire consisting of decisional balance, self-efficacy, behavioral skills, social support, perceived environment and food accessibility for proper diet (Sakai et al., 2009). Twenty two U-15 footballers in school-based team (ST), fifty seven in town-based club team (TT) and thirty seven in J. league academy team (JT) completed the questionnaire and 2-day food records. **Results** Positive perception (pros) and self-efficacy in TT were higher than in ST. Perceived environment and food accessibility in ST was lower than in both groups. Most nutrient intakes including major nutrients, vitamins and minerals in JT were higher than in both groups, but there were no significant difference in nutrient densities except for vitamin A among all groups. **Discussion** Scores of psychological and social factors for proper diet in TT and JT tended to be higher than in ST. These results suggest that the players belonging to club team have higher consciousness to become good footballer. They joined club team although they were also able to join their school-based team. By the way, nutritional status, including intakes energy and most nutrients in JT was higher compare to other groups. There was not significant relationship between psychological and social factors for proper diet and nutritional status. The environment of each team may influence these results. The coach and trainer only in JT have received the education about sports nutrition to obtain the national license of coach. **Limitation** The population size in each group was small. Moreover, training intensity, duration and frequency was not investigated. It will be need for further study to elucidate the relationship between psychological factors for proper diet and nutritional intakes in adolescence football players belonging to different organizations. #### DIFFERENTIAL CONTRIBUTION OF EACH ONE OF THE THREE BASIC PSYCHOLOGICAL NEEDS ON INDICATORS OF WELL-BEING IN YOUNG FOOTBALLERS

González, L., Fabra, P., Mercé, J., Rodenas, L., Castillo, I., Balaguer, I.

*Universitat de Valencia*

**Introduction** Self-Determination Theory (SDT; Deci & Ryan, 2000) postulates that there are three basic psychological needs –competence, autonomy, and relatedness– that when satisfied yield well-being and optimal functioning (Ryan & Deci, 2000). The purpose of the present study was to analyze whether, according to SDT, footballers' satisfaction of the three basic psychological needs for autonomy, competence and relatedness, predicts indices of well-being (self-esteem, subjective vitality, and satisfaction with life), and in addition, to exam-

ine the specific contribution of each one of the basic psychological needs on the three different indicators of well-being. Methods 597 male footballers from the Valencian Community Football Federation (Spain) aged between 11 and 14 years old ( $M = 12.91 \pm 0.68$  years) completed a questionnaire package tapping the variables of interest. Three multiple regression analysis were performed using self-esteem, subjective vitality and life satisfaction as dependent variables and the three basic needs as independent predictor variables in each analysis. Subsequently, semi-partial correlation analyses (Cooley & Lohnes, 1976) were performed to examine the specific contribution of each one of the three basic psychological needs on the variance of the different indicators of well-being. Results Satisfaction of the three basic psychological needs predicted each indicator of well-being in the expected direction. Competence explained most unique variance in self-esteem ( $r = .27$ ), followed by the need of relatedness ( $r = .15$ ) and need of autonomy ( $r = .11$ ). Satisfaction of the need of autonomy ( $r = .22$ ) explained most unique variance in subjective vitality, followed by the need of relatedness ( $r = .15$ ) and need of competence ( $r = .12$ ). Finally, the contribution of each one of the basic psychological needs to the variance of satisfaction with life was very similar ( $r = .15$ ). Discussion Results confirmed predictions of the SDT, showing the basic psychological needs as positive predictors of the three indicators of well-being in young footballers. The contribution of each one of the basic psychological needs was not consistent in the case of each well-being indicator examined. ## RED SHIRT COLOUR AND THE HOME ADVANTAGE IN ENGLISH PREMIER LEAGUE FOOTBALL

Allen, M.

*London South Bank University*

Introduction The home advantage, which refers to a greater success rate in home versus away competitions, is a robust phenomenon that has been consistently demonstrated in various sports (Jamieson, 2010) There is also a growing body of research evidence that the colour red is associated with a greater incidence of victory in physical contests (Hill & Barton, 2005). Shirt colour represent one potential contributing factor to the home advantage in sport since home teams designate their shirt colour (away teams must wear a contrasting colour) and red shirts have been associated with a greater winning percentage in team sport competitions. This study explored the relationship between teams' home shirt colour and the magnitude of the home advantage. Method Data from 7340 matches played over the first 19 seasons of the English Premier League were obtained from the official website of the English Premier League. Data on home team shirt colour over the 19 seasons were obtained from official club websites and cross-checked with online encyclopaedias. The home advantage was calculated as the total points gained in home fixtures as a percentage of the total points gained in the season. The shirt colours explored were red, blue, white, and a fourth grouping of other colours. Results The data show that teams wearing red are more successful than teams wearing blue, white or other colours,  $F(3, 382) = 18.81, p < .001, \eta^2 = .13$ , and that teams are more successful in home games than in away games (home advantage index = .609) ( $t(385) = 29.52, p < .001, d = 1.34$ ). After controlling for team ability, it was found that teams opting for red shirts in their home games did not show a greater home advantage than teams opting for blue, white or other colour shirts,  $F(3, 381) = 1.73, ns, \eta^2 = .01$ . Discussion Although a "red win" effect and a home advantage effect were both observed, the main hypothesis that teams contesting their home games in red would show a greater home advantage was not supported. This finding has two possible explanations: 1) the red win shirt effect represents a type 2 error (in this sample successful teams just happen to play in red) or 2) the benefits of playing in red extend to away competitions even though teams are not playing these competitions in red shirts. It is recommended that researchers continue to explore the effect of shirt colour on athlete and team behaviour. References Hill, R. A., & Barton, R. A. (2005). Red enhances human performance in contests. *Nature*, 435, 293. Jamieson, J. P. (2010). The home field advantage in athletics: A meta-analysis. *Journal of Applied Social Psychology*, 40, 1819-1848.

## PASSION FOR OFFICIATING FOOTBALL AMONG TOP-CLASS REFEREES

Johansen, B.T.1, Bjørnstad, J.O.1, Giske, R.1,2

*University of Agder 1 & University of Stavanger 2*

Introduction Do top-class football referees see officiating as a passionate activity and thereby get highly motivated and involved despite experiencing extensive pressure and negative emotions? Vallerand and his colleagues (Vallerand et al., 2003) have defined passion as a strong inclination or desire toward an activity that one likes (or even loves), that one finds important (high valuation), and in which one invests time and energy. The aim of this study is to investigate the role of passion for officiating football among Norwegian top-class referees. Methods This cross-sectional study was conducted as a part of the "Norwegian Elite Referees in football"-study. A total of 83 from 98 (84.7 %) top-ranked referees (73 males and 10 females) from age 20 to 46 (mean age 33.3 years) completed a questionnaire using SurveyXact, a web based program for electronic questionnaires. In one of the questions the referees were asked to report randomly three main reasons or motives for officiating football. The data were analyzed using a well specified phenomenological procedure for qualitative research (Marton, 1995). Results were obtained by bracketing, intuiting, and describing the different motives reported and organized into categories of description. The different categories of description that emerged were studied and regrouped by two colleagues. Results 236 different motives for being a referee reported were bracket and grouped, and three main categories emerged; passion motives, 61 % (e.g., simply love football, enjoyment, mental fulfillment, coping of stress), social motives, 26 % (e.g., meeting with people, staying in football, competition situation, member of the team), fitness motives, 13 % (e.g., physical activity, being in good shape, body appearance). A second analysis of the category passion motives revealed two main categories of passion; activity related passion (e.g., enjoyable, leadership, incredible fun), and performance related passion (e.g., handling stressful situations, feeling of success, leadership fulfillment). Discussion Norwegian top-class referees are passionate in their refereeing and are truly motivated by just being part of the football family and playing a vital part of the game, and based on research in this field, there is little or no reason for suggesting that this is not the case for football referees in other parts of the world. One could say that Norwegian top-class referees' officiating is more or less based on the enjoyment in refereeing in itself, and their desire for an errorless performance. To handle the implementation of the laws throughout a football games gives them great satisfaction and fulfillment, and they are passionate about it! References Vallerand RJ et al. (2003). *J Pers & Soc Psy*, 85, 756-767. Marton F. (1995). *Nord Ped*, 15, 165-180.

**POMS DIFFERENCES BETWEEN SOCCER PLAYERS UNDER SIMILAR CIRCUMSTANCES.**

Pastor, D.1, Bonete, E.1, Sarabia, J.M.1, Aracil, A.1, Moya, M.1

*1: Research Group on Healthy Physical Conditioning, Centro de Investigación del Deporte, UMH (Elche, Spain).*

**Introduction** It is well known that self-perception of mood correlates with performance in several sports. Mood can be influenced by multiple types of social and psychobiological stimuli. In order to understand the role that perception of competitive status can have in collective sports, such as soccer, two soccer teams that were initially in the process to losing their competitive status were studied. **Methods** Two competitive non-professional soccer teams that were in the process of descending to a lower competitive status during the last three weeks of the tournament were included. Whilst one of them (team A) maintained its category, the other (team B) lost it. During the three weeks, players of each team completed weekly the POMS questionnaire after a training session (Filaire et al, 2001). Data were aggregated depending on the minutes played by each player during the three weeks, and compared between the two teams. Results When compared among teams, there was a tendency to reduce the POMS score over the period ( $p=0.05$ ), with the players feeling less tension ( $p=0.05$ ), depression ( $p=0.01$ ) and anger ( $p=0.05$ ) in the team A. In the team B increasing values in POMS score ( $p=0.05$ ) and especially anger ( $p=0.05$ ), were found in the players that didn't play in the last three matches ( $n=3$ ), in comparison with their colleagues that played more than 150 min ( $n=9$ ). After losing category, team B' players that played more than 150 min showed more depression ( $p=0.05$ ) and confusion ( $p=0.03$ ) than their colleagues. **Discussion** Our data suggest that game results and circumstances in soccer psychologically affect the players differentially. This should be taking into account when planning psychological interventions at high competitive situations like the one described in this report. **References** Filaire E, Bernain X, Sagnol M, Lac G. Eur J Appl Physiol. 2001 Dec;86(2):179-84.

**COPING MECHANISMS OF JAPANESE TEAM SPORT ATHLETES IN RESPONSE TO INJURY**

Geisler, G.1, Razavi, S.2, Kerr, G.2

*1: University of Edinburgh, 2: University of Toronto*

**Introduction** Injury in competitive sport can jeopardize an athlete's confidence, self-esteem, and sense of identity (Brown, 2005). Research into corresponding coping mechanisms has centered largely on problem-focused and emotion-focused strategies, but the integrated model of Wiese-Bjornstal, Smith, Shaffer, and Morrey (1998) also lists ethnicity and various social influences as factors in the psychological response to injury and rehabilitation. Therefore, the aim of this study was to examine the coping mechanisms of non-Western (Japanese) team sport athletes after debilitating sports injuries. **Methods** The participants were 12 Japanese intercollegiate athletes who competed in soccer, rugby, baseball, and American football. Each had sustained a serious injury and was currently involved in a physical rehabilitation program. Data were collected through semi-structured interviews and responses were transcribed verbatim. They were then analyzed via content analysis, which identified various meaning units that were categorized into higher order themes. Results All of the athletes used a near-equal share of problem-focused and emotion-focused coping strategies. The most common methods involved physical interventions and distractions, such as swinging a bat while sitting, picking up balls for the pitcher, and participating as much as possible in team warm-up and cool-down activities. To maintain spirits and a sense of accomplishment, players also tried to stay active by doing core conditioning and training uninjured parts of the body. Lastly, many players reported a total reliance on their trainers as a coping resource. **Discussion** A number of culturally-derived cognitions could be gleaned from the research data. To illustrate, beliefs that 'getting injured prevented me from contributing to the team,' 'the trainers' devotion to my recovery kept me from giving up,' and "the trainer has been working to treat me so I have to make progress" reflect the collectivistic nature of Japanese society and the hierarchical power dynamics within groups (Markus & Kitayama, 1991), including those of sports teams. Accordingly, the findings are compared and contrasted with the extant literature for Western athletes, and implications for future research and practice are addressed. **References** Brown, C. **PRE COMPETITIVE ANXIETY AND ROLE OF ACHIEVEMENT MOTIVATION ON PLAYING PERFORMANCE**

Antony, V.C., Tomar, R.

*King Fahd University of Petroleum and Minerals//PHYSICAL EDUCATION DEPARTMENT*

**PRE COMPETITIVE ANXIETY AND ROLE OF ACHIEVEMENT MOTIVATION ON PLAYING PERFORMANCE** Antony, Varghese C.1, Tomar, Rakesh.2  
1: KFUPM (Dhahran, Saudi Arabia), 2: KFUPM (Dhahran, Saudi Arabia) **Introduction** Anxiety and Motivation are important psychological variables in sports and it is needed to achieve high level of competition. Taylor (1994) treated motivation as the base of a pyramid towards success in sports. The elements of anxiety have a major influence in the athlete's performance in any sport. Authors examined relationship of sports pre-competition trait anxiety & achievement motivation on football performance. **Methods** Sixty football players (M age = 22.6 years) were selected as subjects, who played divisional football tournament at Jabalpur, India. Sports Competition Anxiety Test (Martens 1977) & Sports Achievement Motivation Test (Kamlesh 1990) were administered few hours and one day prior to the tournament respectively to collect data. As per SCAT scores, players were divided into moderate level and high level anxiety groups. Football playing performance was assessed by using a subjective evaluation chart prepared by soccer experts. Results Pearson Product Moment Correlation found significant relationship between achievement motivation & football playing performance ( $r=0.367$ ,  $p<.05$ ). A positive relationship was established between pre-competitive moderate anxiety level players & playing performance ( $r=0.348$ ,  $p<.05$ ); and negatively related with pre-competitive high anxiety level players & football playing performance ( $r=-0.139$ ,  $p<.05$ ). **Discussion** Football players showed significantly high level of achievement motivation towards playing performance ( $r=0.367$ ,  $p<.05$ ) which is supported by (Dureha et al., 2010; Unierzyski, 2003; Butt&Cox, 1992) who had noticed achievement motivation is one of the attributes of higher performance. Moderate anxiety level players shown positive relationship towards performance ( $r=0.348$ ,  $p<.05$ ) which endorses findings of (Bawa, 2001) that higher level performance group has moderate level of anxiety than the low level performance group. High anxiety level players had negative relationship with performance ( $r=-0.139$ ,  $p<.05$ ). If anxiety is not handled well or misinterpreted, athlete will lose control and their performance will decrease (Martens et al. 1990; Gualberto & Wiggins, 2008). **References** Bawa K (2001). *Journal of Sports Science*, Vol24, (3): 42-48 Butt DS, Cox DN (1992). *Int. ### LONGITUDINAL STUDY OF COACH BEHAVIORS, BASIC PSYCHOLOGICAL NEEDS AND WELL-ILL/BEING IN YOUNG FOOTBALLERS: A TEST INVARIANCE OF TWO CONSECUTIVE SEASONS

González, L., Fabra, P., Castillo, I., Tomás, I., Balaguer, I.

*Universitat de València*

**Introduction** Self-determination theory holds that autonomy supportive coaching style will promote well-being, whereas controlling coaching style will favor ill-being (Ryan & Deci, 2000). It has been also suggested that when the psychological needs are satisfied, well-being will be improved and when those needs are thwarted, well-being will be diminished and ill-being likely to result. The purpose of this study was to examine the relationship between changes in perceptions of the coach style (Autonomy supportive and Controlling) to changes in footballers' need satisfaction/need thwarting and indices of self-esteem/burnout over a two consecutive football season (four points in time) and to test season invariance. **Methods** 360 male footballers from the Valencian Community Football Federation, aged between 11 and 13 years old at Time 1 ( $M = 12.6 \pm 0.53$  years) completed a questionnaire package tapping the variables of interest. Data were gathered at two points in time during two consecutive seasons. The experience in competitive football at Time 1 was 3.59 years. **Results** Structural Equation Models were performed using LISREL 8.80 (Jöreskog and Sörbom, 2006). Results revealed that in Time 2 controlling Time 1 (first season), and in Time 4 controlling Time 3 (second season), changes in autonomy support to be a positive and significant predictor of changes in need satisfaction. Moreover, changes in coaching style (autonomy supportive and controlling) predicted (negatively and positively, respectively) changes in need thwarting. In turn, changes in need satisfaction emerged as a positive and significant predictor of changes in self-esteem. Finally, changes in need thwarting positively and significantly predicted changes in burnout and negatively predicted change in players' self-esteem levels. Only in the first season, changes in need satisfaction emerged as a negative and significant predictor of changes in burnout. **Results of the Multisample Invariance Models** also supported the invariance of the relationship across seasons. **Discussion** The relationship model was invariant across two seasons, which indicates the strong importance of promoting autonomy supportive atmospheres with young footballers and avoiding controlling styles to facilitate young athletes' well-being and to prevent ill-being. This Research was funded by Ministerio de Ciencia e Innovación (DEP2009-12748) Spain.

### ANXIETY IN OFFICIATING FOOTBALL AMONG NORWEGIAN TOP-CLASS REFEREES

Bjørnstad, J.O.1, Johansen, B.T.1, Giske, R.1,2

*1University of Agder, Norway and 2University of Stavanger, Norway*

**Introduction** According to Helsen & Bultynck (2004) the most important aspect of football refereeing is the decision-making process. Officiating can also be emotionally pressured, and referees need great communication skills and a calm attitude when explaining their decisions to players. Referees who have a high trait anxiety view more situations as more threatening than those with lower trait anxiety and so respond with a higher state anxiety. This is known as competitive trait anxiety (Spielberger 1983). The aim of this study is to measure Norwegian top-class referees' anxiety in officiating before and during a football match. **Methods** This cross-sectional study was conducted as a part of the "Norwegian Elite Referees in football"-study. A total of 83 from 98 (84.7 %) top-ranked referees (73 males and 10 females) from age 20 to 46 (mean age 33.3 years) completed a questionnaire using, SurveyXact, a web based program for electronic questionnaires. The questionnaire required referees to provide demographic information (age, gender, civil status) and details relating football playing experience, refereeing experience, and current referee status. The questionnaire also consists one of the most long-standing and frequently used measure of anxiety, State-Trait Anxiety Inventory STAI (Form Y) (Spielberger 1983). Cronbach's alpha in this study was 0.84. **Results** All the referees were former football players. Refereeing experience varied from 4 years to 33 years. The referees were also asked whether they played football in their spare time, and 81.7% said they rarely or never played football. Anxiety level among top-class referees show that all values are within 20 and 45, and this score is in line to findings in different elite sports (Hanin 2000). Mean score was 28.03 and the standard deviation was 5.44. The correlation analyses revealed only a significant inverse association between refereeing experience and level of anxiety ( $r = -.24$ ,  $p = .03$ ). **Discussion** The findings revealed that more experienced referees typically reported lower level of anxiety. This may be due to their experience in ability to 'read' the football game and thereby know to handle the different perceptual-cognitive demands. However, it should be investigated further if there are other background variables that help to reduce anxiety and tension level before and during a football match. The number of correct and incorrect decisions related to referees personality and perceived refereeing competence are probably factors that influence the trait anxiety and degree of stress officials have to cope throughout a game of football. **References** Hanin, Y.L. ### ACCURACY AND REPRODUCIBILITY OF A GPS DEVICE TO ASSESS SPRINTING PERFORMANCE

Urbano, R., Suárez-Arrones, L., Suárez, G., Núñez, F.J.

*Pablo de Olavide University*

**Introduction** The accuracy of GPS devices to measure distance covered in team sports and their use as an alternative to photocells to evaluate sprint and RSA performance, has been described previously (Barbero-Alvarez et al., 2010; Coutts and Duffield, 2010). The purpose of the present study has been to determine the validity of the GPS device model (VX300) to assess performance in sprint and to determine its reproducibility test-retest. **Methods** This study has been carried out in two parts involving 75 physically active athletes. The first test consisted in performing a lineal sprint of 50-m carrying the GPS (VX300) device, with timings taken through photocells at the distances of 30 and 50-m (N=75). The second phase consisted in repeating the same test with some of the athletes 6 hours later to measure the reproducibility (N=20). **Results** The average time of the athletes at 30-m (T30) and 50-m (T50) were 4.5 and 7 s respectively, while the average time between these distances 30\_50-m (T30\_50) was 2.4 s. The information obtained using the GPS, shows that the average maximum peak in velocity (PS) was 30.9 km/h. There were significant correlations ( $P < 0.01$ ) between the T30 y PS (-0.89), between the T50 y PS (-0.91), and between the T30-50 y PS (-0.91). The results to determine the test-retest reliability during the lineal sprint show for the T30, T50 and PS some coefficients of variation (CV) de 0.9, 0.9, y 1.8% respectively. **Discussion** The results of the study show that there exists a strong correlation between the times obtained through the photocells and the peak of speed reported by the GPS device. In spite of these high correlations, the results show a slight decrease in values found in another study however carried out with different devices and distances (Barbero-Alvarez et al., 2010). **References** Barbero-Alvarez J.C., Coutts A., Granda J., Barbero-Alvarez V., Castagna C.

### ACCURACY OF A GPS DEVICE TO ASSESS RSA

Suárez, G., Suarez-Arrones, L., Urbano, R., Núñez, F.J.

*Pablo de Olavide University*

**Introduction** The accuracy of GPS devices to measure distance covered in team sports and their use as an alternative to photocells to evaluate sprint and RSA performance, has been described previously (Barbero-Alvarez et al., 2010; Coutts and Duffield, 2010). The purpose of the present study has been to determine the validity of the GPS device model (VX300) to assess performance in repeated sprint ability none linear (Shuttle Sprint test). **Methods** This study has been 30 physically active athletes. They did a RSA test with change of direction (Shuttle Sprint Test), times obtained using photocells and carrying the GPS device. The variables obtained by RSA test have been: the best time or the highest peak of velocity (RSABest), the average time or average peaks of velocity (RSAMean) and the fatigue rate (RSAIFF). **Results** Through the "RSA Test", using fotocell, the athletes obtained an average time of 7.33 s for the RSABest, a RSAMean of 7.81 s and a RSAIFF of 6.54. Using the GPS device, the RSABest was 26.09 km•h<sup>-1</sup>, a RSAMean of 23.94 km•h<sup>-1</sup> and a RSAIFF of -8.21. The correlations found between both devices being -0.81 in the RSABest, of -0.95 in RSAMean and of -0.38 in the RSAIFF. **Discussion** The results of the study show that there exists a strong correlation between the times obtained through the photocells and the peak of speed reported by the GPS device. Similar results have been found in another study however carried out with different devices and distances (Barbero-Alvarez et al., 2010) **References** Barbero-Alvarez J.C., Coutts A., Granda J., Barbero-Alvarez V., Castagna C. (2010) The validity and reliability of a global positioning satellite system device to assess speed and repeated sprint ability (RSA) in athletes. *J Sci Med Sport* 13:232-5. Coutts A.J., Duffield R. #### QUADRICEPS MUSCLE STRENGTH IN PARKINSON DISEASE

Oliveira, R., Borges, E., Silva, M., Paulista, H., Moraes, A., Santos, T., Lunardi, C., Vidal, S.

*Universidade de Brasília - UnB*

**Introduction** Besides the classic symptoms of Parkinson's disease (PD), such as bradykinesia, shaking palsy and rigidity, recent studies using sensitive equipment, have identified decreased muscle strength in these patients compared with control subjects. A comparison of strength between the members has also been evaluated, but is still poorly documented and the results are conflicting. In order to contribute to more evidence, the objective of this study was to evaluate the strength of the member most involved with the least involved on the knee extension in patients with Parkinson's disease. **Methods** 14 Men diagnosed with PD (mean SD 1: age 64 SD 3.1, body mass index 74.8 SD 13, height 1.68 SD 0.1, BMI 26.6 SD 4) were recruited from outpatient Parkinson's Hospital de Base and the Parkinson's Association members at Distrito Federal - Brasília, the stage of disease between 1 and 3 based on the modified scale Hoehn and Yahr. The test consisted of three sets of 10 repetitions of bilateral knee extension at 90 ° S -1, using an isokinetic dynamometer. We used the paired Student t test and used p <0.05. **Results** There was no significant difference in quadriceps muscle strength between the leg most involved and least involved, p = 0.1. **Discussion** The most involved leg strength was less than the least involved. But the difference was not significant, according to other studies as Malika (2006). Previous studies have found differences between the members (Nokagi and Morimatsu, 1997) at a speed of 90 degrees per second and higher speeds. In the present study, using the speed of these, no difference was found. It is noteworthy that all subjects in the study were physically active, despite having no experience with resistance exercise, a fact not reported in other studies. More studies are needed with larger samples and clinical correlations in assessing the strength in individuals with Parkinson's Disease. **References** Malicka I, Chamela-Bilinska D, Koszewicz M. #### EFFECTS OF TWO DIFFERENT POTENTIATING PROTOCOLS ON STRENGTH PERFORMANCE AND RATE OF FORCE DEVELOPMENT OF THE KNEE EXTENSORS

Lima, L.C.R., Oliveira, F.B.D., Denadai, B.S.

*UNESP - Rio Claro*

**Effects of two different potentiating protocols on strength performance and rate of force development of the knee extensors.** Lima, L. C. R.; Oliveira, F. B. D.; Denadai, B. S. Human Performance Laboratory - UNESP (Rio Claro, Brazil) **Introduction** In the last two decades, many studies have investigated the enhancement of muscular strength and, mostly, power provided by prior maximal or submaximal contractions. This phenomenon has been described as post-activation potentiation (PAP). Usually, PAP stimuli are applied as warm-up routines in competitions or prior to training to impose a higher intensity training status, which is the concept of complex training. Most studies in the area suggest that this enhancement is better noticed when the protocols are applied on trained subjects and, specially, in resistance trained ones. Therefore, the aim of the present study was to investigate whether athletes without resistance training experience would benefit from the enhancing properties of PAP and, in that case, analyze the enhancements on the rate of force development (RFD) separated in different periods. **Methods** A group of 10 college level handball players participated in the study. Each subject visited the laboratory in 3 different occasions: 2 adaptations to the exercise protocols in the dynamometer and 1 data collection session. Their isometric peak torque (IPT), RFD Peak, RFD in 5 different periods (30, 50, 100, 150 and 200 milliseconds) and electromyographic signal (EMG) of the rectus femoris and vastus lateralis were assessed once, as a baseline contraction (BL), and after 2 different conditioning activity (CA)

protocols: a 9 seconds isometric contraction (C9) or 3 three seconds isometric contractions with 3 seconds rest intervals (C3). Results No significant differences were found between the baseline values and those after both CA protocols for any of the variables ( $p < 0.05$ ) with slight variations for IPT (BL: 295.65 N.m; C9: 294.86 N.m; C3: 298.97 N.m), RFD Peak (BL: 1571.59 N.m.s<sup>-1</sup>; C9: 1592.91 N.m.s<sup>-1</sup>; C3: 1439.33 N.m.s<sup>-1</sup>), and rectus femoris integral EMG signal (BL: 5.10 V; C9: 4.82 V; C3: 5.02 V). However, subject responses were not uniform as some responded positively, and some negatively, to the CA protocols. Discussion The experiment has led us to believe that PAP responses are not determined only by training levels, but also by other individual factors not tested in the current study, but cited in the literature, such as fiber-type distribution and the power-strength ratio (Tillin & Bishop, 2009). The findings in this study suggest that coaches should identify PAP responders prior to submitting athletes to CA in warm-ups or complex training sessions, even when all athletes have passed through the same training protocols. Our data also confirmed that the lack of resistance training experience might compromise PAP response. References Tillin NA, Bishop D. (2009). *Sports Medicine*, 39(2), 147-166.

### **EFFECT OF TRAINING SURFACE ON ACUTE PHYSIOLOGICAL RESPONSES FOLLOWING SPORT-SPECIFIC TRAINING**

Binnie, M., Peeling, P., Pinnington, H., Landers, G., Dawson, B.

*University of Western Australia*

This study compared the effect of sand and grass training surfaces during a sport-specific training session in well-trained team sport athletes ( $n=10$ ). Participants initially completed a preliminary testing session to gather baseline (BASE) performance data for vertical jump (VJ), repeated sprint ability (RSA) and 3 km running time trial (RTT). Three days subsequent to BASE, all athletes completed the first sport-specific training session, which was followed by a repeat of the BASE performance tests the following day (24 h post-exercise). Seven days later, the same training session was completed on the opposing surface, and was again followed 24 h later by the BASE performance tests. During each session, blood lactate (BLa), ratings of perceived exertion (RPE) and heart rate (HR) were recorded, with player movement patterns also monitored via global positioning system (GPS) units. Additionally, venous blood was collected pre-, post-, and 24 h post-exercise, and analysed for serum concentrations of Myoglobin (Mb), Haptoglobin (Hp) and C-Reactive Protein (CRP). Results showed significantly higher HR and RPE responses on SAND ( $p > 0.05$ ), despite significantly lower distance and velocity outputs for the training session ( $p > 0.05$ ). There were no differences in 24 h post-exercise performance ( $p > 0.05$ ), and blood markers of muscle damage, inflammation and hemolysis were also similar between the surfaces ( $p > 0.05$ ). These results suggest that performing a sport-specific training session on a sand (versus grass) surface can result in a greater physiological response, without any additional decrement to next day performance.

### **PROTEIN SUPPLEMENTATION IS REQUIRED TO GAIN MUSCLE MASS DURING PROLONGED RESISTANCE-TYPE EXERCISE TRAINING IN FRAIL ELDERLY PEOPLE**

Tieland, M., Dirks, M., van der Zwaluw, N., van de Rest, O., Verdijk, L.B., de Groot, L.C.P.M.G., van Loon, L.J.C.

*Wageningen University*

Introduction Sarcopenia is a process characterized by progressive loss of muscle mass and function (Cruz-Jentoft, 2010). Resistance-type exercise training might be a promising strategy to augment muscle mass and improve physical performance in frail elderly people. Dietary protein supplementation might enhance the benefits of a resistance-type exercise training. In frail elderly people, however, studies on the effects of protein supplementation on muscle mass and performance during exercise training are scarce and have generated inconsistent findings. Therefore, we investigated the impact of dietary protein supplementation on muscle mass, strength and physical performance during prolonged resistance type exercise training in frail elderly people. Methods Frail (Fried, 2001) elderly ( $78 \pm 1$ ) subjects ( $n = 62$ ) participated in the 24 wk intervention trial. They were all included in a progressive whole body resistance-type exercise program and randomly allocated to receive either a protein (15 g) or placebo supplement twice daily. Lean body mass (DXA), strength (1-RM) and physical performance (SPPB) were assessed at baseline, after 12, and 24 wks of intervention. Furthermore, habitual dietary intake and physical activity data were obtained and blood and muscle samples were collected. Results Lean body mass increased from  $47.2 \pm 1.8$  to  $48.5 \pm 1.8$  kg in the protein supplemented group and did not change in the placebo group (from  $45.7 \pm 1.8$  to  $45.4 \pm 1.8$  kg) following 24 wks of exercise intervention (P-value for treatment x time interaction = 0.006). Both strength and physical performance improved after 24 wks in both groups ( $P < 0.001$ ) with no differences between groups ( $P > 0.05$ ). Discussion Prolonged resistance-type exercise training is a feasible strategy to improve strength and physical performance in frail elderly people. Additional dietary protein supplementation is required, however, to gain muscle mass during resistance-type exercise training in this population. References Cruz-Jentoft et al. (2010). *Age and ageing*;39(4):412-23. Fried et al.(2001). *J Gerontol A Biol Sci Med Sci*;56(3):M146-56.

### **ACCELEROMETER-DETERMINED PHYSICAL ACTIVITY AND ITS ASSOCIATION WITH SELF-REPORTED HEALTH IN A POPULATION OF OLDER ADULTS <65-85 Y>**

Lohne-Seiler, H., Hansen, B.H., Kolle, E., Anderssen, S.A.

*University of Agder*

ACCELEROMETER-DETERMINED PHYSICAL ACTIVITY AND ITS ASSOCIATION WITH SELF-REPORTED HEALTH IN A POPULATION OF OLDER ADULTS (65-85 Y) Lohne-Seiler, H.1,2, Hansen, B.H.2, Kolle, E.2, Anderssen, S.A.2 1University of Agder, Kristiansand, Norway, 2Norwegian School of Sport Sciences, Oslo, Norway Introduction Regular physical activity (PA) in older adults is critically important to ensure healthy aging. The link between PA and prevention of disease, maintenance of independence, and improved quality of life is supported by strong evidence. However, there is a lack of data on population levels of PA among older adults using objective PA assessment methods. Therefore, the aim of this study was to assess PA level objectively and to examine its association with self-reported health in a random national sample of older adults. Methods The present study is a part of a national multicenter study involving 10 universities and university colleges in Norway. Participants for the initial study were randomly selected from the national population registry, and the current study includes those of the initial sample aged 65-85 years. The ActiGraph GTIM accelerometer was used to assess PA for seven consecutive days. Overall PA levels, adjusted for test center, are presented as counts per minute (cpm). A questionnaire was used to register self-reported health. Univariate analysis of variance with Bonferroni post-hoc tests were used for the analysis of multiple comparisons. Results A total of 560 participants fulfilled the accelerometer data inclusion criteria (at least four days or more of at least 10 hours of daily activity registration). Mean age (SD) was 71.8 (5.6) y for women ( $n=282$ ) and 71.7 (5.2) y for men ( $n=278$ ). No sex differences in overall PA were observed. Mean (SEM) overall PA levels were as follows: 65-69 y 317 (9) cpm, 70-74 y 301 (12) cpm, 75-79 y 237 (14) cpm, and 80-85 y 160 (18) cpm. This accounted for a reduction in overall PA of 5% ( $p < 0.05$ ) between the age groups 65-69 and 70-74 y, while a 32% ( $p < 0.05$ )

reduction between the age groups 75-79 and 80-85 y was observed. Self-reported health (%) and mean (SEM) overall PA levels were: "very good health" (19%) 344 (13) cpm, "good health" (54%) 300 (8) cpm, "either good or bad health" (24%) 208 (12) cpm, and "poor/very poor health" (3%) 170 (33) cpm. Significant ( $p < 0.05$ ) differences in overall PA level were observed between all groups, except between those who perceived their health as "either good or bad" and "poor/very poor". Conclusion PA level among older adults living in Norway decreased with increasing age, and the oldest (80-85 y) displayed a 50% lower activity level compared to the youngest (65-70 y). Overall PA levels were associated with self-reported health.

### IS LONG SLOW DISTANCE TRAINING SUFFICIENT TO MAINTAIN INCREASED PERFORMANCE AFTER A HIGH INTENSITY SHOCK MICROCYCLE IN JUNIOR TRIATHLETES

Zinner, C.1,2, Wahl, P.1,3, Krueger, M.1,2, Bloch, W.3, Mester, J.1,2

*German Sport University*

1 Institute of Training Science and Sport Informatics, German Sport University Cologne 2 The German Research Center of Elite Sport, Cologne 3 Department of Molecular and Cellular Sport Medicine, German Sport University Cologne, Germany Introduction: Preparation periods in endurance sports like triathlon are characterized by long slow distance training sessions. Most of the athletes add high intensity training sessions to their "classic" training regime only immediately before the competition period begins. Recent publications have shown that high intensity training also increases performance capacity for long distance athletes. The aim of this study was to investigate how two weeks of high intensity training during the preparation period affect the performance capacity of young triathletes. Methods: 13 junior triathletes took part in this study (10 male, 3 female;  $15.4 \pm 1.9$  years;  $171.0 \pm 8.3$  cm;  $58.3 \pm 8.8$  kg). They conducted two microcycles of different training regimes. In the first two week cycle exclusively high intensity interval training was performed. The second two week cycle included long slow distance training only. One week before and after each training cycle the athletes were tested with a 20 min time trial, a ramp test protocol to determine the  $VO_{2max}$ , and a Wingate Anaerobic Test. For all tests a cycle ergometer (SRM, Schoberer Rad Messtechnik, Juelich, Germany) was used. Results: Relative  $VO_{2max}$  of the athletes showed no changes during the whole preparation period. The mean power output during the time trial, as well as the peak power output during the ramp test was significantly higher after the first (high intensity) training cycle. The second (long slow distance) training cycle did not lead to a further increase of performance in both tests. Peak power output during the Wingate Anaerobic Test was unchanged after both periods. The mean power output and the fatigue index were unchanged after the high intensity training and significantly lower after the long slow distance training cycle. Discussion: The classical model of periodization suggests to perform long slow distance training for the most of the preparation period. We could show that performance in junior triathletes is significantly increased after a high intensity shock microcycle incorporated in the preparation period. A following microcycle with "classical" low intensity training does not lead to a further increase in performance in this study. Additionally we could not detect any sign of overtraining or overreaching in the young athletes as a result of the high intensity training.

### THE EFFECT OF CYCLING AND RUNNING ORDER WITH SIMILAR INTENSITY AND DURATION ON CARDIOVASCULAR VARIABLES

Van Beekvelt, M.C.P., Lovøll, S.M.

*Norwegian University of Science and Technology (NTNU)*

Introduction Triathlon is a multi-event sport that not only comprises the swim, bike and run events, but the actual transitions from one event to the next as well. The transitions are part of the race and of importance with respect to the end outcome. The aim of this study was to investigate the effect of the specific order of the cycling and running events such as occurs in triathlon and to distinguish between the effect of exercise order and the effect of exercise duration. Methods Eight healthy subjects performed four successive laboratory trials: (1) an incremental running test, (2) an incremental cycling test, (3) a cycle-run transition test (TCR), and (4) a run-cycle transition test (TRC). Cycling and running sessions within the transition tests lasted 30 min each and were done at a metabolic intensity of 75% of maximal oxygen consumption ( $VO_{2max}$ ). Oxygen consumption ( $VO_2$ ), heart rate (HR), minute ventilation (VE), respiratory exchange ratio (RER), and cycle cadence (CAD) were measured continuously during all four tests. Blood lactate concentration ( $[La]_b$ ) and loss of water were determined prior to and immediately after each work phase of the transition tests. Results No differences in  $VO_{2max}$  were found between cycling (C) and running (R) ( $P = 0.214$ ), but  $HR_{max}$  during running was slightly higher than that during cycling ( $P = 0.037$ ). For the transition tests, no differences were found in cycling distance ( $P = 0.691$ ), running distance ( $P = 0.220$ ), cycling intensity ( $P = 0.351$ ), running intensity ( $P = 1.000$ ), or CAD ( $P = 0.605$ ), comparing exercise with and without preceding exercise. Absolute work rates were identical within each discipline, but cycling intensity had to be decreased during the tests resulting in a significantly lower intensity than that during running (68.3%, CI: 64.7-71.9% and 74.3%, CI: 73.6-75.0%, respectively,  $P = 0.005$ ). There was a significant effect of exercise duration on the response of HR (C:  $P < 0.001$ , R:  $P < 0.001$ ), VE (C:  $P = 0.025$ , R:  $P = 0.027$ ), and RER (C:  $P < 0.001$ , R:  $P = 0.001$ ), but no effect was found for  $VO_2$  (C:  $P < 0.784$ , R:  $P < 0.429$ ). On average, cycling and running as second discipline occurred at a higher HR than that during the first discipline (C: 7.6%, R: 4.1%). A similar effect was seen for VE (C: 16.5%, R: 8.4%). Discussion/Conclusion The main findings of this study were 1) that exercise duration seemed to influence HR, VE and RER whereas it did not seem to affect  $VO_2$ , and 2) that the effect of exercise duration on HR, VE and RER was more pronounced in cycling than in running. These results indicate that despite the awkward transition from cycling to running, as reported frequently by triathletes, the order of cycling followed by running seems to be preferred above that of running followed by cycling as the effect of duration seems to be more pronounced in cycling as compared to running.

### WHAT IS THE METHOD TO ASSESS SKELETAL MUSCLE MASS WITH THE BEST ASSOCIATION WITH STRENGTH IN ADOLESCENTS?

Correas, L.G.1, Martin, N.S.1, Alvero-Cruz, J.R.2, Carnero, E.A.1

*University of Malaga*

Introduction The assessment of skeletal muscle mass (SM) may be an important concern to analyze the relationship between body composition, strength and performance. Regarding adolescents, there is a lack of valid models to estimate accurately SM. Considering this previous rationale, it should be pertinent to analyze if known models to estimate SM have a good association with strength performance in order to evaluate their construct validity. Our purpose was to compare one laboratory method with one field method, and their individual associations with isometric strength tests. Methods Seventy-five healthy adolescents (30 girls and 45 boys) were included in the analysis ( $15.4 \pm 1.5$  years; fat mass percentage ( $26.6 \pm 7.3$ )). Body composition was assessed by dual-energy X-ray absorptiometry (DXA)

and anthropometry (ANT). SM was estimated using DXA-based Kim's model (SM\_X) for adolescents (Tanner<5) and for adults (Tanner≥5). SM estimations ANT-based (SM\_A) were calculated with Poortmans' (<16-years) and Lee's models. Upper (right and left hands) and lower limbs muscle strength was measured with dynamometers (hand-grip and extension squat). Maturation was defined by Tanner's stages. Pearson's and Spearman's correlations were carried out to analysis associations between SM and strength values for both genders. Independent samples T-test were used to compare differences between methods. Results SM\_X and SM\_A showed significant differences for all participants (19.1±4.5 and 20.6±5.4kg respectively; p≤0.001). Positive correlations were found between SM and strength for all groups, except for SM\_A of girls (rho=0.30 for right hand, r=0.32 for left hand and r=0.23 for lower-limb strength). The best association was found between SM\_X and left handgrip (rho=0.84; p≤0.001) and the lowest was for boys between SM\_A and lower limbs strength (r=0.39; p≤0.01). The correlation between SM\_X and left handgrip was the highest either for boys (r=0.73; p≤0.001) and girls (r=0.54; p≤0.01). Different results were found for the same analysis with SM\_A (r=0.60 for boys; p≤0.001; non-significant for girls). Discussion Our results did not confirm agreement between models and the associations between SM and strength showed different magnitudes. The differences would be partially explained by reference method used to validate the models, so Kim and Poortmans assessed SM with MRI and DXA respectively. Since DXA is not considered a gold-standard to measure SM, the construct validity of Poortmans' model (SM\_A) should be lower than Kim's model (SM\_X). Further analysis must be necessary to confirm our conclusions.

### EMG SIGNAL PROCESSING DURING WHOLE-BODY VIBRATION: A PRELIMINARY STUDY

Lienhard, K.1,2, Cabasson, A.1, Meste, O.1, Colson, S.S.2

*University of Nice-Sophia Antipolis*

EMG SIGNAL PROCESSING DURING WHOLE-BODY VIBRATION: A PRELIMINARY STUDY University of Nice-Sophia Antipolis, Nice France 1:13S; 2:LAMHES, Faculty of Sports Sciences Introduction Whole-body vibration (WBV) has become one of the most popular alternative exercise modality. To investigate the mechanisms leading to increased neuromuscular performance following WBV exercises, numerous studies have examined the neuromuscular adaptations by recording surface electromyography signal (sEMG). However, sEMG during WBV is problematic since it contains sharp peaks at the vibration frequency and its multiple harmonics. So far, different approaches have been conducted to cut out the excessive sEMG bursts which consist of exclusion of a wide band-width frequency (Hazell et al. 2007) and elimination of the signal at the vibration frequency and its harmonics with the help of band-stop filters (Abercromby et al. 2007) or interpolation technique (Wakeling et al. 2002). Hence, there is no scientific consensus about the most adequate method to process sEMG during WBV. Another issue to be addressed is the sEMG analysis after the filtering process. For instance, the sEMG has been compared between sham and WBV conditions and/or normalized to the sEMG measured during a maximal voluntary contraction (MVC). However, to our knowledge, the normalization of the sEMG to the electrophysiological response (i.e., M-wave) evoked by nerve stimulation has never been done for WBV. Therefore, the aim of this study was to compare: 1) sEMG processing methods during WBV, namely band-stop filters vs. the interpolation technique and 2) sEMG normalization procedures (i.e., sEMG of a MVC vs. M-wave). Methods 15 physical education students performed isometric semi-squats during sham and WBV conditions (4 frequencies and two amplitudes) on a vertically vibrating platform while measuring the sEMG of the quadriceps femoris muscles. Femoral nerve electrical stimulation served for the assessment of M-wave responses. MVC of the knee extensor muscles were also performed. sEMGrms values were computed in the frequency domain after signal processing by using a band-stop filter or interpolation technique. These sEMGrms values were then normalized either to the sEMGrms value obtained during an MVC or to the respective muscle M-wave. Results We are currently collecting the data of this experiment. Due to the wide variability of results in the literature, it is hazardous to formulate a hypothesis. However, since the M-wave is the electrical equivalent of the recruitment of all motor units, we assumed that the normalization of the sEMG to this parameter will provide a better method and thus improve the scientific knowledge related to WBV exercise. ### MUSCLE DAMAGE AFTER A SIMULATED TENNIS MATCH IN YOUNG TENNIS PLAYERS

Santos, R.O.1, Gomes, R.V.1, Nosaka, K.2, Moreira, A.1, Aoki, M.S.1

*1 - University of São Paulo, São Paulo, Brazil; 2 - Edith Cowan University, Western Australia, Australia.*

Introduction: The present study investigated changes in indirect markers of muscle damage following a simulated tennis match using nationally ranked young (17.6 ± 1.4 years) male tennis players. Methods: Ten young tennis players played simulated matches in which each player had three one-hour matches against three players on outdoor red clay courts following the International Tennis Federation rules. Muscle soreness, plasma creatine kinase activity (CK), serum myoglobin concentration (Mb), one repetition maximum (1RM) squat strength, and squat jump (SJ) and counter movement jump (CMJ) heights were assessed before, immediately after, and 24 and 48 hours after the matches. Results: A one-way repeated measures ANOVA and post-hoc Tukey test revealed significant but small increases in muscle soreness, CK and Mb at 24-48 hours post-match, and decreases in 1RM squat strength (-35.2 ± 10.4%), SJ (-7.0 ± 6.0%) and CMJ (-10.0 ± 6.3%) heights immediately post-match (p<0.05). At 24 hours post-match, the 1RM strength and jump heights were not significantly different from the baseline values for the average, but several players showed lower values of these measures and required another day for the full recovery. Conclusion: The simulated tennis match induced mild muscle damage, but tennis players could recover in 48 hours.

### PHYSIOLOGICAL DEMANDS IN AN IRONMAN TRIATHLON

Barrero, A., Chaverri, D., Erola, P., Iglesias, X., Rodriguez, F.A.

*INEFC*

Introduction To optimize training and determine performance factors in a triathlon, we need to know the bioenergetic requirements and physiological response during competition. However, the physiological demands for an entire triathlon in relation to the individual metabolic capacities of triathletes have not been characterized yet. Here we aimed to provide the first comprehensive description of the physiological demands of an entire ultra-endurance triathlon. Methods Ten well-trained ultra-endurance triathletes (mean ± SD: age 37.1 ± 5.3 years, mass 74.9 ± 6.4 kg, height 1.74 ± 0.06 m, BMI 24.7 ± 1.8 kg/m<sup>2</sup>, VO<sub>2</sub>peak = 4.92 ± 0.5 l•min<sup>-1</sup>) participated in the study. To investigate exercise intensity, heart rate (HR) was recorded during a competition using portable monitors. Before the ultra-endurance triathlon, subjects performed graded exercise tests involving cycle ergometry, treadmill running and swimming to determine peak oxygen uptake (VO<sub>2</sub>peak) and heart rate corresponding to the first and second ventilatory thresholds (VT1 and VT2). Results The HR in the swimming stage was closely related to the HR at VT1 (r = 0.77, P = 0.01) and related to the HR at VT2 (r = 0.68, P = 0.03). The HR in the cycling stage

was not related to the HR at VT1 and VT2. The HR in the running stage was related to the HR at VT2 ( $r = 0.64$ ,  $P = 0.048$ ) but not to the HR at VT1. The HR during the swimming stage was significantly higher than the HR at VT1 ( $P = 0.00$ ), but there were no differences between the HR during the swimming stage and the HR at VT2. The HR in the cycling and running stages were significantly lower than the HR corresponding to VT1 ( $P = 0.01$  and  $P = 0.01$ , respectively) and VT2 ( $P = 0.00$  and  $P = 0.00$ , respectively). Discussion This study is the first to characterise the relative intensity (HR related to ventilatory thresholds) during the race of the three stages of a triathlon. The differences in HR between the swimming and cycling stages correlate with the marathon time and the overall time. The triathletes with the greatest difference in HR in the swimming stage and HR during the cycling stage had the worst cycling times. As stated in Laursen et al. (2005), working beyond capacity in one stage makes recovery difficult, leading to worse performance in the next stage. This correlation can also be seen in HR differences for the swimming and running stages, as a large difference in values is associated with a reduction in the marathon time. References Laursen, P., Knez, W., Shing, C., Langill, R., Rhodes, E., & Jenkins, D. (2005). Relationship between laboratory-measured variables and heart rate during an ultra-endurance triathlon. *J Sports Sci*, 23(10), 1111-1120.

### OBSERVATION OF AGE-RELATED DECLINE IN TRANSVERSE ABDOMINIS MUSCLE

Davies, P.1, Sculthorpe, N.1, Ferguson, R.A.2, Lewis, M.P.

*University of Bedfordshire*

Observation of age-related decline in Transverse Abdominis muscle P. Davies 1, N. Sculthorpe 1, R. A. Ferguson 2, M. P. Lewis 1,2,3,4. 1Institute of Sport and Physical Activity Research (ISPAR), University of Bedfordshire, UK 2Musculoskeletal Biology Research Group, School of Sport, Exercise and Health Sciences, Loughborough University, UK 3School of Life and Medical Sciences, University College London, UK 4Cranfield Health, Cranfield University, UK Background Ageing is associated with a decline in muscle performance (Reynolds, 1991) however the degree of decline in deep lying postural muscles has received limited attention. The core abdominal muscles provide support to the low back (Hodges et al, 2003) with weakness and poor coordination having been associated with low back pain (Hodges and Richardson, 1996). The aim of the present study was to assess the response time of the Transverse Abdominis (TA) between younger and older adults. Additionally comparisons were made between these in vivo measures and the gene expression of old and young muscle cells in vitro. Method 18 young adults ( $27 \pm 7$  yrs) and 8 older adults ( $58 \pm 3$  yrs) were tested in a side lying position during a weighted shoulder abduction. Synchronised ultrasound images of the TA and EMG trace of the deltoid were acquired. The duration (D) between the onset of shoulder EMG and the activation of TA movement was assessed between groups. In vitro, C2C12 mouse myoblasts of low and high passage number were used to stimulate ageing.  $1.15 \times 10^7$  cells were used to create collagen-based, tissue engineered skeletal muscles (TESM). TESM were assessed throughout culture for the degree of bowing as a surrogate for contraction. Following this, collagen gels were cut in half and fixed for histology or had RNA extracted for PCR analysis. Gene expression analysis was measured on matrix degrading enzyme MMP9. Results In vivo: There was no significant difference between groups with respect to D ( $-0.023 \pm 0.031$  ms versus  $-0.006 \pm 0.025$  ms for old and young respectively  $p=0.099$ ). In vitro: The age of the cells was shown to have an effect on gel performance with the younger cells being more contractile over a 14 day period. The results for gene expression showed that MMP9 was expressed early in the culture, but declined afterwards. Discussion The results of the in vivo experiment suggest that deep lying postural muscles (and the TA specifically) appear resistant to age-related decline. However methodological advances to reduce the large standard deviations may warrant further investigation. In order to determine the mechanisms underpinning this observation, robust in vitro models are required. Initial observations indicate that this is feasible although work is required to validate the in vitro data against the in vivo data. References Hodges, P. et al. ### THE EFFECT OF ACUTE AEROBIC EXERCISE ON TASK SWITCHING IN UNDERGRADUATES WITH DIFFERENT LEVELS OF PHYSICAL ACTIVITY

Tsai, C.L.1, Chou, F.Y.1,2, Chen, T.C.1

*1: National Cheng Kung University (Tainan, Taiwan), 2: Chi Mei Medical Center (Tainan, Taiwan)*

Introduction Although a few numbers of studies have assessed the effect of acute exercise on executive control function, the results are somewhat inconclusive in individuals with different levels of physical activity (PA). The present study was thus carried out to examine the influence of an acute bout of moderate aerobic exercise on executive control function engendered by a task switching paradigm in undergraduates with different levels of PA by comparing behavioral and electrophysiological performance. Methods Thirty-two male college students, aged between 19 to 23, were divided into two groups, low and high, according their level of general physical activity using the International Physical Activity Questionnaire. Before and after a 30-min session of acute aerobic exercise on a treadmill with a carefully controlled workload intensity (60%  $VO_{2max}$ ), each student performed a task switching paradigm which consisted of two conditions, a pure task condition with a repeated single task (e.g., 111111...), and a mixed-task condition with different tasks using an alternating-runs paradigm (e.g., 112211...), while the behavioral and event-related potential (ERP) indices were collected. Behavioral performance (reaction times and accuracy) and ERP measures (P3 latency and P3 amplitude) were separately submitted to a mixed-model analysis of variance (ANOVA). Results Before acute exercise, the low PA group had significantly longer reaction time (RT) and smaller P3 amplitude than the high PA group. After acute exercise, only the high PA group showed significantly smaller switching cost on RTs and significantly larger P3 amplitude in the mixed-task condition when compared to the pre-exercise session. Additionally, the P3 amplitude was significantly larger for the high PA group relative to the low PA group after the acute exercise. Discussion Physical activity and acute moderate aerobic exercise have been promoted as two factors that have beneficial effects on executive control of cognitive function (Pontifex et al., 2009). In the current study, the male college students with a high PA level exhibited a more efficient executive function than the ones with low PA level before and after acute exercise based on the behavioral and ERP performance when performing the task switching paradigm. The potential mechanism was that the individuals with high PA level may efficiently allocate more attentional resources in the

mixed-task condition, not only during the pre-exercise sessions, but also during the post-exercise ones (Kamijo and Takeda, 2010). References Kamijo K, Takeda, Y. (2010). *Int J Psychophysiol*, 75, 304-311. Pontifex MB, Hillman CH, Fernhall B., Thompson KM, Valentini. (2009). *Med Sci Sports Exerc*, 41(4), 927-934.

### PREDICTION OF MAXIMAL OXYGEN OF NORMAL ADULT MAN WITHOUT EXERCISE TESTING

Jeon, Y.J.1, Ryu, J.Y.2, Lee, B.K.3, Kim, C.H.4, Kim, B.W.5, Im, J.H.6

1,2,6 : KAIST(Daejeon, S.Korea), 3 : SangMyung U.(Seoul, S.Korea), 4,5 : Daejeon U.(Daejeon, S.korea)

**Introduction** There are two methods to estimate maximal oxygen, direct and indirect methods. Predicting maximal oxygen through sub-maximal exercise or non-exercise is more convenient for modern people because it needs less time and effort than measuring maximal oxygen directly. Therefore, aim of this study is to make the equation which can predict maximal oxygen of adult man (age from 35 to 54) without any exercising. We analyzed parameters such as age, BMI, heart rate at rest in multiple regression analysis to estimate maximal oxygen of adult man. This study may be helpful for designing therapeutic exercise and exercising program due to predicting maximal oxygen scientifically and securely. **Method** The subjects were consisted of 175 Korean adult male aging from 35 to 54. Each of maximal oxygen was measured with metabolic test system. Multiple regression analysis was applied with enter method to draw the equation of maximal oxygen. Especially, we regulated non-exercise parameters with SPSS PASW Statics 18 program. After finding the equation, we compared predicted maximal oxygen with measured maximal oxygen in scatter plot. **Result** We established the model which could estimate VO<sub>2</sub> max of adult man. Multiple correlation coefficient of this model was 0.642, and square of multiple correlation was 0.412. Standard error of estimate was 5.60ml/kg/min and coefficient of variability was 14.42% (p<0.01). The equation we made was VO<sub>2</sub> max =101.522-0.267\*(age) -0.241\*(heart rate at rest) -1.222\*(BMI). **Discussion** Many researchers studied predicting maximal oxygen without exercise (Heil, 1995, Jackson, 1990, Sanada, 2007). Heil found predicted VO<sub>2</sub>max model whose multiple R of total variable model was 0.88 and standard error of estimate was 4.90 ml/kg/min(p<.01). Jackson's also established the model whose multiple R was 0.81 and SEE was 5.35 ml/kg/min(p<.01). Compared to our study whose multiple R was 0.642 and SEE was 5.60ml/kg/min(p<.01), they have slightly higher multiple R and lower SEE. However, the equations from western countries can't exactly estimate maximal oxygen of Koreans, because Koreans have different body features(Lee Byung-keun, 1992). According to Lee's study, maximal oxygen of western people was different from Koreans about 5~14 ml/kg/min. As we used only Korean data, our study will be a greatly helpful tool for estimating maximal oxygen and designing exercising model for Koreans. In addition, because non-exercising model doesn't need any effort or time, our equation will be exclusively helpful for patients who can't walk or have serious diseases. **Reference** Heil DP, Freedson PS, Ahlquist LE, Price J, and Rippe JM. ### NMES IS NOT EFFECTIVE AS A RECOVERY INTERVENTION BETWEEN TWO BOUTS OF MAXIMAL AEROBIC EXERCISE

Malone, J.K., Blake, C., Caulfield, B.

*University College Dublin*

**NMES IS NOT EFFECTIVE AS A RECOVERY INTERVENTION BETWEEN TWO BOUTS OF MAXIMAL AEROBIC EXERCISE** Malone, J.K.1, Blake, C.2, Caulfield, B.1 1: Stim XDP Research Group, Institute for Sport & Health; 2: School of Public Health, Physiotherapy and Population Science, University College Dublin (Dublin 4, Ireland). **Introduction** There are many situations in sport, where inadequate recovery can limit performance (Higgins et al. 2011). Previous studies investigating the effectiveness of neuromuscular electrical stimulation (NMES) as a short-term (< 1 h) recovery intervention have been inconclusive (Heyman et al. 2009; Malone et al. 2011). The aim of this study was to compare NMES to traditional methods during short-term (30 min) recovery between 2 bouts of maximal aerobic exercise. **Methods** On 3 separate days, 19 trained male cyclists performed a 3 min maximal aerobic exercise bout @ 105% VO<sub>2</sub>max on a cycle ergometer, prior to a 30 min randomly assigned recovery intervention of either: i) passive (PASS), ii) active (ACT - cycling @ 30% VO<sub>2</sub>max) or iii) NMES (5 Hz / 4 pulses @ 620 μs). Immediately after, a second bout @ 95% VO<sub>2</sub>max to exhaustion (TLim) was performed. Heart rate (HR) and blood lactate (BLa) were recorded at designated time-points throughout. Data were analyzed using repeated measures ANOVA with Tukey's HSD post hoc test. **Results** TLim was significantly longer for ACT compared to NMES (P < 0.05), but not PASS. TLim was not significantly different between NMES and PASS. BLa was significantly lower, and HR significantly higher during the recovery intervention period for ACT compared to NMES and PASS (P < 0.001), with no significant differences between NMES and PASS. **Discussion** The findings for NMES in this study differ to our previous study (Malone et al. 2011), which found no significant performance differences compared to ACT and PASS, when used as a short-term recovery intervention (30 min) between two sessions of multiple supra-maximal anaerobic exercise bouts. The reasons for these findings are unknown but are likely to be multifactorial. In conclusion, NMES is less effective than active recovery when used during short-term recovery between 2 bouts of maximal aerobic cycle bouts in trained male cyclists. **References** Heyman E, B DEG, Mertens I, Meeusen R (2009) Effects of four recovery methods on repeated maximal rock climbing performance. *Med Sci Sports Exerc* 41:1303-1310 Higgins TR, Heazlewood IT, Climstein M (2011) A Random Control Trial of Contrast Baths and Ice Baths for Recovery during Competition in U/20 Rugby Union. *J Strength Cond Res* 25:1046-1051 Malone JK, Coughlan GF, Crowe L, Gissane GC, Caulfield B (2011) The physiological effects of low-intensity neuromuscular electrical stimulation (NMES) on short-term recovery from supra-maximal exercise bouts in male triathletes. *European Journal of Applied Physiology* doi: 10.1007/s00421-011-2212-9.

### CENTRAL AND PERIPHERAL VISUAL ACUITY WITH TILTED PRESCRIPTION LENSES IN CURVED SPORTS-FRAMES IN COMPARISON TO CONTACT LENSES COMBINED WITH PLANE SPORTS GLASSES

Hobé, M.1, Jendrusch, G.2, Lingelbach, B.3

1: *Vision Science and Business-Optometry, Aalen University (Aalen, Germany)*, 2: *Dep. of Sports Medicine, Ruhr-Universität Bochum (Bochum, Germany)*, 3: *Inst. of Optometry Aalen (Leinroden, Germany)*

**Introduction** In the currently used curved frames for sports glasses prescription lenses are often optimized to suit the curved shape of the spectacle. A particular calculation is needed to produce glasses with optimized aberration characteristics looking through peripheral parts of the lens. But do these glasses work well? The aim of the study was to analyze in which way visual performance changes looking sideways through the optimized curved lens (in comparison to changes wearing contact lenses combined with plane sports glasses). **Methods** The central visual acuity and peripheral visual performance (gaze angles: 0°, 15°, 25° and 35°) was measured with optimized sports eyeglasses. In a second step the same subjects were corrected with contact lenses and were then tested centrally and peripheral-

ly with sports glasses without refractive power. Finally 40 subjects completed the entire clinical study. The average age of the participants was  $39.6 \pm 9.5$  years (age range: 17 - 51 years). On average men ( $n = 21$ ;  $43.8 \pm 7.8$  years) were significantly older than women ( $n = 19$ ;  $35.0 \pm 9.3$  years;  $2p = 0.002$ ). In all tests visual acuity was examined using „Landolt-rings“. Results The mean visual acuity while wearing contact lenses and looking straight at the optotypes (gaze angle =  $0^\circ$ ) was  $1.20$  ( $- = 0.33$ ;  $+ = 0.45$ ). At the extreme peripheral visual gaze angle of  $35^\circ$  sideways the subjects attained a similar visual acuity of  $1.17$  ( $- = 0.35$ ;  $+ = 0.49$ ). The results with modern prescription sports glasses were similar. Visual acuity was hardly noticeable reduced from  $1.38$  ( $- = 0.40$ ;  $+ = 0.55$ ) at a visual angle of  $0^\circ$  to  $1.36$  ( $- = 0.34$ ;  $+ = 0.44$ ) on the periphery of  $35^\circ$ . Visual acuity kept constant without significant variation in different gaze angles ( $0^\circ$ ,  $15^\circ$ ,  $25^\circ$  and  $35^\circ$ ), independent from the kind of visual aid (sports glasses vs. contact lenses;  $p = 0.331$ ). Discussion In both conditions, optimized eyeglasses and contact lenses, there was no significant change of visual performance in relation to different peripheral gaze angles. But the visual performance was significantly better when using optimized sports eyeglasses ( $p = 0.008$ ) than it was when contact lenses were used.

## BESPOKE SODIUM SUPPLEMENTATION INCREASES PHYSICAL PERFORMANCE

WEATHERALL, L., JUTLEY, R.S., BLOW, A., NANJIAH, P., VOYSEY, V.

### PRECISION HYDRATION

Bespoke Sodium Supplementation Increases Physical Performance Weatherall, L., Jutley, R., Blow, A. et al. Introduction The loss of sodium during exercise has significant effects on performance ranging from mild cognitive impairment to fatal hyponatraemia. Sodium losses in human sweat vary 9-fold(1, 2) which when considering the high variation in sweat losses can lead to massive net sodium losses as high as 13-fold between athletes in the same session(3). In this study we evaluate the influence of replacing sweat sodium losses using a bespoke sodium electrolyte solution based on individual sweat sodium levels on physical performance under controlled conditions. Methods Randomised crossover study comparing H2ProHydrate (500, 1000 or 1500 mg/l sodium) to Evian water (5mg/L sodium) in 7 elite male athletes. Pre-trial all underwent VO<sub>2</sub> max testing and the Precision Hydration pilocarpine-induced sweat sodium analysis. Randomisation was to water or H2ProHydrate allowing ad libitum drinking for 72 hrs pre-trial. Cross-over was undertaken 2 weeks later. Athletes maintained 70% VO<sub>2</sub> max in a climate chamber at 28C, 55% humidity for 60 min followed by a 15-min blinded performance time trial (TT). End points included power output during chamber exposure and TT, RPE (Borg Scale), heart rate (HR), core body temperature (CBT) and lactate levels. Results Mean sweat sodium concentration was 1043mg/L (range 430-1640). One athlete failed to complete the trial while on water due to nausea and dizziness and was therefore excluded from analysis. Chamber Exposure The athletes were expected to maintain an output of 70% VO<sub>2</sub> max equating to 233 W. On H2Pro the group maintained 215 W and on water alone, 206 W (a 4.4% performance gain). The mean RPE was similar in both groups(16.27 on water, 16.03 on H2Pro). Mean heart rates were 4.3% lower with H2Pro compared to water (162/min vs. 169/min) as was mean CBT (38.4C vs. 38.6C). Mean lactate levels were similar; 4.8 mmol/L H2Pro, 4.7 mmol/L water Performance Time Trial During the blinded TT, athletes on H2Pro demonstrated a 7.3% performance gain compared to water (235 W vs. 219 W) Conclusion Compared to water, appropriate sodium supplementation increases performance during severe sustained exercise in the heat and during blinded performance time trials by 4.4% and 7.3% respectively. During sustained exercise the gains are seen while maintaining a lower heart rate and core body temperature and the equivalent lactate and RPE. Our study indicates that appropriate sodium supplementation maintains a more physiological state during extreme exercise. References 1. Riedi et al. ## ASSOCIATIONS BETWEEN VITAMIN D STATUS, PREDOMINANT TRAINING ENVIRONMENT, MEDICAL HISTORY AND SUN PROTECTION PRACTICES.

Peeling, P.1,2, Fulton, S.1, Binnie, M.1,2, Goodman, C.1

1: *Western Australian Institute of Sport*, 2: *The University of Western Australia*.

Introduction Vitamin D plays an important role in immune function, bone health, and potentially athletic performance. This study assessed the influence of gender, body composition and predominant training environment on the Vitamin D status of Western Australian athletes. Additionally, associations between Vitamin D status and recent injury / health status, or sun protection practices were investigated. Method Seventy-two athletes were recruited to participate in this study. Athletes underwent an anthropometric assessment, provided a venous blood sample for the assessment of Vitamin D (25(OH)D) status, and filled out a questionnaire relating to their recent training and injury history, and their routine sun protection practices. The athlete cohort were then divided by predominant training environment as either indoor, outdoor, or mixed training environment athletes. Results The average 25(OH)D levels of the group were  $111 \pm 37$  nmol/L. There were no differences between genders; however, it was noted that the levels of the indoor training group were significantly lower than those of the outdoor, and the mixed training groups ( $p < 0.05$ ). Despite these differences, the 25(OH)D levels of all groups was within a range considered healthy, with only 4.2% of the entire population ( $n=3$ ) presenting a Vitamin D deficiency. Further analysis showed that all 3 deficient athletes were members of the indoor training group (8.3% of this population). Significant correlations suggested that older, heavier and taller athletes had higher 25(OH)D levels. Furthermore, higher 25(OH)D levels were associated with a greater body composition; however, lower 25(OH)D levels were associated with a greater number of daily training hours. Finally, there were no associations between the 25(OH)D levels and the incidence of injury, illness or sun protection practice. Discussion The results of this investigation show that the Vitamin D status of Western Australian athletes may not be an issue over the summer months. The significant correlations between the anthropometric markers and the higher 25(OH)D levels are likely due to the outdoor athletes (i.e. rowers and kayakers) encountering more sun exposure, whilst being significantly taller, heavier and older than their indoor counterparts (i.e. gymnasts and divers). Although within a healthy range, the significant differences in 25(OH)D levels between outdoor and indoor trained athletes should be considered, and as such coaches or medical practitioners working with indoor trained athletes may wish to monitor their Vitamin D levels at regular intervals throughout the year (i.e. with the change in season), to avoid any possibilities of a deficiency.

### UNDERESTIMATION OF ENERGY EXPENDITURE WITH THE SENSEWEAR ARMBAND DURING UPHILL AND LEVEL TREADMILL EXERCISE.

Koehler, K.1,2, Olivar, R.1, Wallmann, B.1, Sperlich, B.3, Mester, J.1,2

1. German Sport University (Cologne, Germany) 2. German Research Centre of Elite Sport (Cologne, Germany) 3. University of Wuppertal (Wuppertal, Germany)

Purpose: The correct assessment of energy expenditure (EE) in young adults is important to ensure that physical activity (PA) requirements are met to ensure health and wellness. Accurate measurement devices can give people self awareness in the amount of energy they are expending to meet PA recommendations. The Sensewear Pro3 armband (SWA) is a multisensor device used for the individual assessment of EE. Previous studies have shown that the SWA is valid at moderate exercise intensities but may underestimate EE at higher intensities. So far, there is only little data on the validity during inclined/graded/uphill locomotion. The aim of this study was to validate the SWA for the assessment of EE in uphill and level treadmill exercise. Methods: The SWA was worn by 30 male and female volunteers from the German Sport University Cologne's faculty and student body. In average, the participants were 24.2 +/- 3.1 years of age. Each participant had to perform a treadmill exercise, which consisted of eleven five minute exercise intervals. Between each interval the participants had roughly 1 to 2 minutes before starting the next interval. Following each interval, treadmill speed and or treadmill inclination were altered in order to obtain an incremental pattern of exercise intensity. Treadmill speed ranged from 0.9 to 3.5 m/s, inclination was altered between 0, 9, and 20% and for speeds greater or equal 2.5 m/s, participants were asked to run. EE was measured with the SWA and in parallel with indirect calorimetry (IC) as reference. Results: When measured with IC, EE increased significantly between all speed intervals and at inclinations of 9 and 20%. When compared with level exercise, inclinations of 9 and 20% resulted in a significant elevation of EE. Maximum EE was recorded at 3.5 m/s and 0% inclination (16.3+- 3.0 METs). When EE was recorded with the SWA, EE increased significantly only between treadmill speeds of 0.9 and 2.5 m/s but reached a plateau between 2.5 to 3.5 m/s (9.8 +/-2.4 METs to 11.0 +/- 2.3 METs). At an inclination of 9% the increase in Sensewear EE was only marginal and not statistically significant when compared to level walking. At an inclination of 20% Sensewear EE was only significantly higher at 1.3 m/s when compared to level exercise (6.0+- 1.7 (20%) vs. 5.1 +/- 1.0 (0%) METs). The difference between IC and SWA grew with increased treadmill speed and inclination Conclusion: When the SWA is used for assessment of PA and EE during walking and running, customers, practitioners, and researchers should be aware of the limitations, especially during higher workloads and intensities. The SWA potentially underestimates EE during running (2.5-3.5 m/s) as well as uphill walking.

### EFFECT OF ACUPUNCTURE ON SALIVARY HUMAN BETA DEFENSIN 2 AFTER A BOUT OF INTENSE EXERCISE

Hanaoka, Y., Shimizu, K., Matsubara, Y., Tanimura, Y., Kimura, F., Akama, T., Kono, I., Miyamoto, T.

University of Tsukuba, Kyoto Prefectural University, Waseda University

Introduction Acupuncture has been used for treatment of injury, reduction of fatigue and management of physical condition in athletic fields. Additionally, acupuncture has been reported to modulate immune function. Intense training induces impairment of immune function, leading to increased susceptibility to infection in athletes. Human  $\beta$ -defensin2 (HBD-2) plays a crucial role in anti-viral and anti-bacterial activity. However, there is no information on relationship between HBD-2 secretion and acupuncture treatment. The aim of this study was to examine the effect of acupuncture treatment on the mucosal immune function after a single period of intense exercise by measuring salivary HBD-2. Methods Ten young sedentary males ( $23.6 \pm 1.1$  years) participated in this study with a crossover design. They subjects exercised on bicycle ergometers for 60 min at 75% of their  $VO_{2max}$ . Acupuncture treatment (ACP) was applied to meridian points (LU6, LU4, ST36 and ST6), for 30 min after the exercise session. The control treatment (CON) was rest without acupuncture and that the order of the treatment was randomized. Saliva samples were collected before (Pre) and after (P0) the exercise, and at 1 h (P1), 3 h (P3), and 24 h (P24) after the exercise session. Samples were measured for the HBD-2 concentrations by using ELISA. HBD-2 secretion rate (pg/2min) was calculated by multiplying absolute HBD-2 concentration (pg/ml) by saliva flow rate (ml/2min). Result Saliva flow rate showed significant group  $\times$  time interaction ( $p < 0.05$ ). Saliva flow rate in ACP was significant higher at P1 and P24 than that at Pre ( $p < 0.05$ ), while the rate in CON did not show significant change. Although there was no significant group  $\times$  time interaction in HBD-2 concentration, the values in both APT and CON were significant higher at P24 than that at P3 ( $p < 0.05$ ). In CON, HBD-2 concentration was significant lower P3 than that at Pre ( $p < 0.05$ ). HBD-2 secretion rate did not show significant group  $\times$  time interaction. Although HBD-2 secretion rate in CON was lower at P3 than that at Pre ( $p < 0.05$ ), ACP did not show significant change during the study period. Conclusion Acupuncture treatment might inhibit the decrease in HBD-2 secretion induced by intense exercise, leading to low susceptibility to infection in athletes. ### INFLUENCE OF L-CARNOSINE ON PRO-ANTIOXIDANT STATUS IN ELITE KAYAKERS AND CANOEISTS

Slowinska-Lisowska, M.

University of Physical Education

INFLUENCE OF L-CARNOSINE ON PRO-ANTIOXIDANT STATUS IN ELITE KAYAKERS AND CANOEISTS Slowinska-Lisowska, M.1, Zembron-Lacny, A.2, Kopec, W.3, Kasperska, A.2, Rynkiewicz, M.2, Rynkiewicz, T.2 1:USPE(Wroclaw, Poland), 2:USPE (Poznan, Poland) 3:UELS (Wroclaw, Poland) Introduction Carnosine ( $\beta$ -alanyl-L-histidine) occurs in high concentration in skeletal muscle with the highest concentrations in type II fibers. Carnosine is synthesised in muscle and CNS tissue from histidine and the non-proteogenic amino acid,  $\beta$ -alanine. It has a number of biochemical functions in vertebrate species including a role as an antioxidant and in  $Ca^{2+}$  sensitization. Carnosine may play a significant role in attenuating the decline in intracellular pH during intense exercise and consequently any increase in skeletal muscle could potentially improve performance in exercise where pH decline is a major contributor to fatigue (Kendrick, 2008). The study was designed to investigate the influence of carnosine intake on pro-antioxidant status in athletes performed intensive physical exercise. Methods Fourteen male athletes participated in a placebo-controlled, double-blind study and were supplemented orally for 2 wk with either 4 g.day<sup>-1</sup> carnosine or placebo. Blood samples were collected before and at 30 min, 24 h and 48 h after 2000-m exercise trial on canoe ergometer. In blood were measure: nitric oxide (NO), myoglobin (Mb), C-reactive Protein (CRP), hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), 8-Izoprostane, nitrotyrosine (3 Nitro-L-Tyrosine), total Antioxidant Potential (AOP-450), superoxidase dismutase (SOD), Thiol Redox Status (GSH/GSSG) and lactate. Results The effort test influence on levels : NO, Mb, CRP, H<sub>2</sub>O<sub>2</sub>, 8- Izoprostane, Nitrotyrosine, AOP-450, SOD, Thiol Redox Status and Lactate. No statistically significant different between supplementation (carnosine vs placebo) groups were found. The obtained results may suggest the 4 g.day<sup>-1</sup> carnosine supplementation for 2 weeks does not influence on antioxidant activity. Dis-

discussion Contrary to the previously published (Decker 2000) results we did not confirm statistically significant influences carnosine supplementation on reduction of the oxidation stress after the effort. References Kendrick IP, Harris RC, Kim HJ et al (2008) Amino acids 34: 547-54. Boldyrev AA. (2000) Biochem 65,751-756 This study was supported by a grant N R12 004006 from the Ministry of Science and Higher Education, Poland. We are grateful for successful cooperation with polish canoe federation in Gorzów Wlkp .
