Abstract: The European rabbit *Oryctolagus cuniculus* (*O. c.*) is a small game species found in several parts of the world and represents an important resource for many predators. It has been classified as a Near-Threatened species on the Red List of Italian Vertebrates even though it is also considered to be an agricultural pest species in many areas. It is a polytypic species present as two known subspecies: *O. c. cuniculus* and *O. c. algirus*. The Italian geographical distribution of the two subspecies is known, but mostly based on morphological, biogeographic, and historical literature data. In Sicily, there is no complete genetic description of the actual existing subspecies; previous studies have only reported the differences in size of the Sicilian rabbit population. In this study, we analyzed genetic data within a phylogenetic framework through mitochondrial (mt) cytochrome *b* (*cyt b*) DNA from 13 rabbit samples collected from different sites in Sicily. We reconstructed the intraspecific phylogeny by comparing *cyt b* mtDNA sequences of 13 newly isolated *O. cuniculus* haplotypes from Sicily and 7 individuals from other areas (Canada, France, Mexico, North Italy, South Africa, Spain, Sweden). Our results show that the rabbit population from Sicily has a mitochondrial type (lineage B) previously shown to be associated with *O. c. cuniculus*, which is similar to sequences from rabbits in Northeast Spain, South France, Sweden, and South Africa.

Key words: Biodiversity, rabbit taxonomy, *cyt b* mitochondrial DNA, *Oryctolagus cuniculus*

1. Introduction

The European rabbit *Oryctolagus cuniculus* (*O. c.*) is traditionally one of the most important small game species in the Mediterranean Basin. It is also considered a multifunctional keystone species for natural and cultivated Mediterranean ecosystems (Delibes-Mateos et al., 2008). It is present in Europe, North Africa, South America, Australia, and New Zealand (Ferrand, 2008). Currently, the species has been classified and given the status of Near-Threatened at the international level (<http://dx.doi.org/10.2305/IUCN.UK.2008.RLTS.T41291A10415170.en>).

In Italy, the European rabbit has been classified as a Near-Threatened species on the Red List of Italian Vertebrates (IUCN, 2014; available at www.iucnredlist.org).

The European rabbit was quite common in central and southern Europe during the late Upper Pleistocene. At the end of the last glaciation the geographical distribution

of this species was limited to the Iberian Peninsula (IP) and probably the south of France (SF) (Kaetzke et al., 2003; Lopez-Martinez, 2008), where there were likely two glacial refugia; thus, as a consequence, two divergent genetic lineages evolved. The signatures of this are evident throughout the genome and can be observed in the analysis of allozyme variation, mtDNA variation, the Y-chromosome, the X-chromosome, and autosomes (Branco et al., 2000; Geraldès et al., 2006, 2008; Ferrand and Branco, 2007; Carneiro et al., 2010, 2014a, 2014b). The European rabbit is recognized formally in two subspecies, *O. c. cuniculus* (L., 1758) and *O. c. algirus* (Loche, 1858), as described by Ferrand (2008).

The species later spread throughout almost all of the world as a result of human activity (Flux, 1994). Specifically, during the 2nd or 3rd centuries AD, the European rabbit was introduced onto the central Mediterranean islands, including Sicily (Flux and Fullagar, 1992; Flux, 1994; Kaetzke et al., 2003), probably by the Romans (Bodson,

* These authors contributed equally to this work.

** Correspondence: franco.palla@unipa.it

1978). After its introduction, the only evidence of the presence of the European rabbit in Sicily is represented by fossils found at the Brucato site during the Middle Ages (13th–14th centuries) (Barrett-Hamilton, 1912; Constable, 2003). At this site, archaeological research has revealed that about 40% of the animals hunted by humans consisted of rabbits (Bresc, 1980). Thanks to the income of “Venatio cuniculorum”, of which there are different statements, it is known that rabbits abounded in many other places in Sicily. In the Mediterranean Basin, there is indication of the presence of the European rabbit from archaeological exploration on the islands of Nisida and Capri (Naples, Italy), and Zembra (Tunisia) (Flux and Fullagar, 1992; Flux, 1994; Kaetzke et al., 2003).

Today, in the Sicilian region of Italy, as well as in other European countries (Millán et al., 2012), the European rabbit is at the center of serious management and conservation problems. In fact, this lagomorph is very important for the conservation of the endangered Sicilian population of raptors such as Bonelli’s eagle (*Hieraaetus fasciatus*), and also for very generalist species such as the common buzzard (*Buteo buteo*) and red fox (*Vulpes vulpes*) (Caruso and Siracusa, 2001; Moleón et al., 2012; Lopez-Lopez et al., 2012).

According to the Guidelines for the Release of Wildlife Species (INFS, 2007), the rabbit is considered to be a para-autochthonous species, as it was introduced before 1500 and is therefore now contextualized in the local fauna landscape (Lees and Bell, 2008). Nevertheless, in some areas of Sicily and on the nearest small islands, where there are no predators and in a nature reserve where hunting is prohibited, the European rabbit is a pest species inducing damage to the agroecosystem and a decrease in the plant population, and causing considerable irreversible ecological and economic damage (Lees and Bell, 2008; Cooke, 2012).

In Sicily, as well as in the rest of Europe, the reduction in the rabbit population was probably due to myxomatosis and rabbit haemorrhagic disease (reviewed by Abrantes et al., 2012) recorded in 1986. In this context, and mainly for hunting purposes, regional authorities have released about 10,000–15,000 captive-raised rabbits of uncertain origin every year. The population of European rabbit living in Sicily and on the nearest small islands seems to belong to the subspecies *O. c. huxleyi* (Haeckel 1874), which is synonymous for *O. c. algirus*, according to Toschi (1965). However, this statement is based only on the biometric analysis of the body size. Recently, Lo Valvo et al. (2014) examined 7 body variables and 23 cranial variables of 166 and 120 individuals, respectively, and compared the results with biometric data from other European populations. They showed that the European rabbit currently present

in Sicily does not have a small body size, as assumed by Toschi (1965), but rather has a medium body size as in current populations living in northern Spain and southern France, which are referred to as *O. c. cuniculus* (Callou, 2002; Ferreira et al., 2015).

It is clear that the European rabbit population in Sicily has never been carefully managed, mainly because of very poor knowledge of its biology and ecoethology in the wild, and also because of a strong uncertainty about its genetic, morphometric, and biogeographic characteristics. To start filling these gaps, we worked on a research project on the European rabbit in Sicily, studying the genetics of the Sicilian *O. c.* by means of a marker gene, namely the mitochondrial DNA (mtDNA) of the cytochrome *b* (cyt *b*) gene, which is commonly used in phylogenetics to determine evolutionary relationships between organisms due to its DNA sequence divergence. It is considered one of the most useful genes in determining relationships within families and genera as demonstrated for mammals (Castresana, 2001; Tobe et al., 2010), and within subspecies, such as *Lepus corsicanus* (Pierpaoli et al., 1999). In the mitochondrion, the cyt *b* gene encodes for an integral membrane protein of approximately 400 amino acid residues; it is a component of the respiratory chain complex III, also known as the bc1 complex, involved in the electron transport of protons (Howell, 1989; Degli Esposti et al., 1993). Since it is possible to perform genetic studies about species evolutionary history, we used the mitochondrial cyt *b* gene known as a valid marker of intra- and interspecific variation (Degli Esposti et al., 1993; Tobe et al., 2010).

mtDNA is a maternally inherited nonrecombinant molecule and therefore, in species that hybridize, only provides information on the ancestry of the female lineage. As an example, it was used to establish introgression cases for hares in the IP; in fact, a high frequency of *Lepus timidus* mtDNA is observed in individuals from native hares, but *Lepus timidus* itself no longer occurs in the IP (Melo-Ferreira et al., 2009).

In this study, we applied genetic analysis as a complement to the phenotypic descriptors of the *O. c.* Sicilian population investigated before. We present the results on Sicilian rabbit phylogeny by comparing cyt *b* mtDNA and protein sequences with homologs from European populations with the aim to better understand their taxonomic relationships and to specify which lineage (A or B) the Sicilian rabbit belongs to. The island of Sicily is at the border of the distribution of *O. c. cuniculus* in the area of the Italian Peninsula. Therefore, depending on the subspecies of the Sicilian population, the geographic ranges would be confirmed or modified.

2. Materials and methods

2.1. Tissue sample collection

Between 1997 and 2006, European rabbit tissue specimens obtained from hunters were collected from different sites in the Sicilian provinces, including some small islands (such as Ustica in the province of Palermo and Vulcano in the province of Messina). The specimens were collected as representative samples from about 50 rabbits from diverse sites in different geographically distributed Sicilian provinces. Twenty samples were then amplified and sequenced, 13 of which were found to have different DNA sequences; for this reason, they were selected for the purpose of this study. The *cyt b* mtDNA partial sequence, 954 bp in length (out of the whole coding region of 1140 bp) was analyzed. In Table 1 and Figure 1A, the Sicilian sites are described in detail, together with the relative provinces of sampling, the geographic coordinates (UTM WGS84), and the size of the isolated DNA fragments. Two samples are smaller in size, probably due to a polymerase failure, being 921 and 927 nt long, from Isola delle Femmine (Palermo) and Oasi Scala (Caltanissetta), respectively.

Animals were treated in accordance with the guidelines of the local ethics committee.

2.2. mtDNA extraction and polymerase chain reaction (PCR) of the *cyt b* gene

The mtDNA was extracted from ear and muscle samples using the genomic DNA Purification Kit (Fermentas) according to the manufacturer's guidelines. An aliquot of DNA was amplified by using conventional PCR approaches. PCR was performed with Taq (Invitrogen) polymerase in 25- μ L reactions under the following conditions: 1 cycle at 95 °C for 5 min; 30 cycles at 95 °C for 45 s (denaturation), 55 °C for 30 s (annealing), and 72 °C for 60 s (extension); and 7 min at 72 °C (final extension). Specific oligonucleotides used to amplify mtDNA were designed as follows: forward 5'-ATCCAACATCTCTGCTTGATG-3' and reverse 5'-GGTTGGCCTCCGATTCATGT-3'. The PCR reaction products were DNA fragments ranging from 921 to 954 nt that were purified by Exosap (BMR Genomics Service, Padua, Italy) and sequenced in both directions by MWG-Operon Sequencing Service (Germany). Sequences were deposited in GenBank and the comparison of sequences

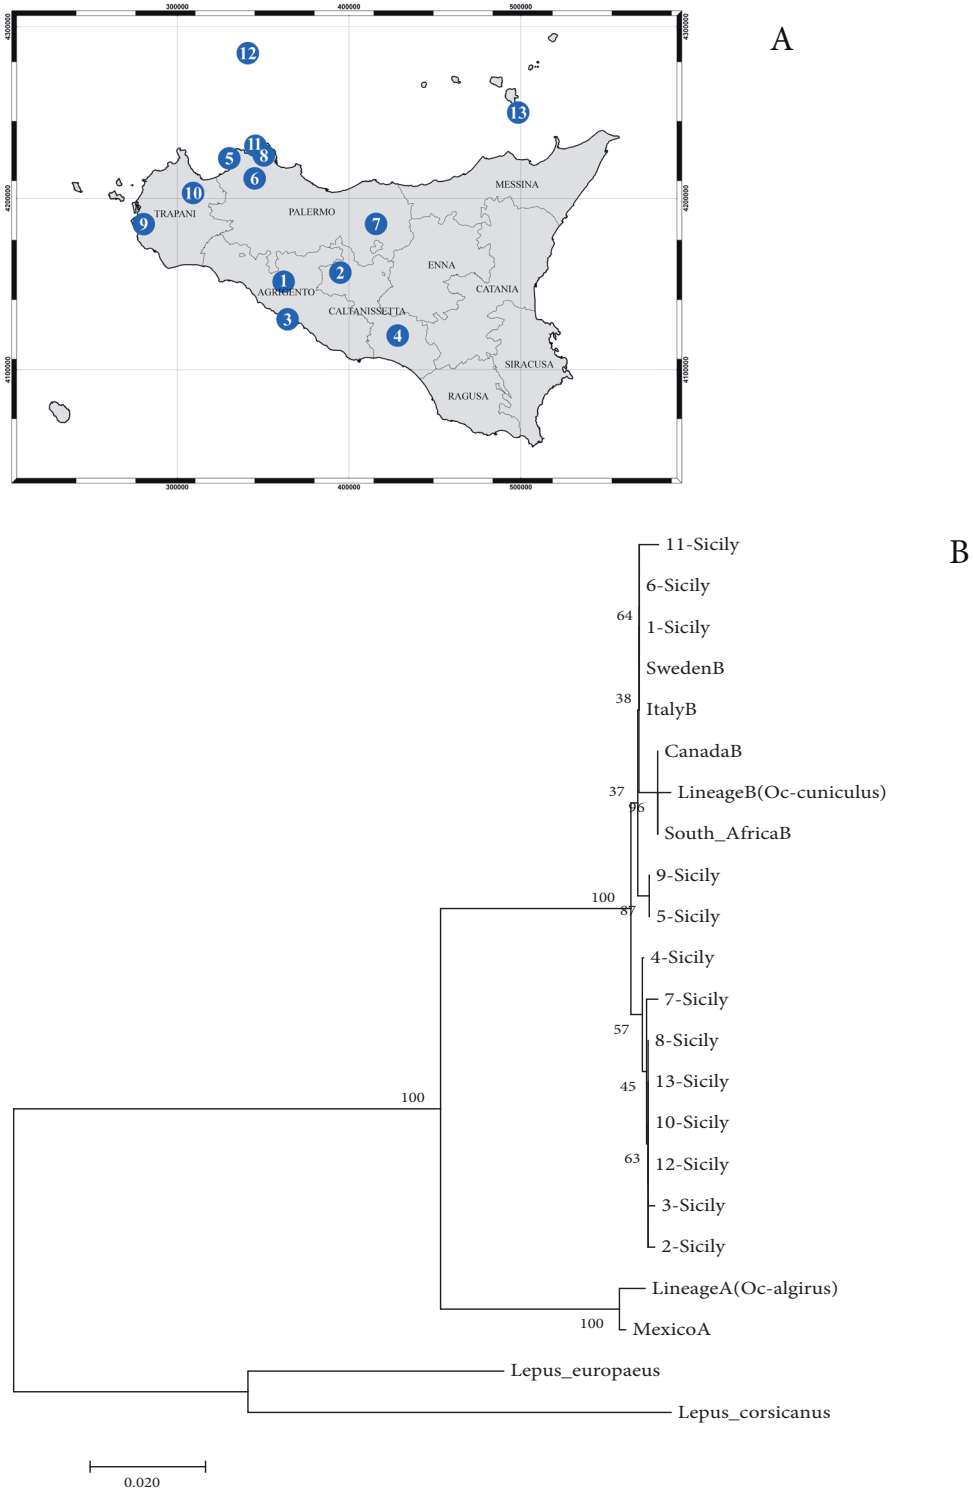

Figure 1. A) Map of sampling sites in Sicilian provinces. Numbers correspond to sampling sites described in Table 1. B) Evolutionary relationships of taxa inferred by MEGA 5 program: neighbor-joining phylogenetic tree, derived from *cyt b* mtDNA multiple alignment shown in Figure S1, of *O. cuniculus* samples derived from the sites listed in Table 1. The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown next to the branches. The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic tree. The evolutionary distances were computed using the maximum composite likelihood method (Tamura et al., 2004) and are in the units of the number of base substitutions per site. Bar = 0.02. Oc-cuniculus = *O. cuniculus cuniculus*; Oc-algirus = *O. cuniculus algirus*.

was performed using the Blast program (Altschul et al., 1990). Restriction analysis was performed with the NEB Cutter 2.0 program (Vincze et al., 2003).

2.3. Phylogenetic analysis

DNA and protein alignments were performed using Clustal W2 software (Larkin et al., 2007). Shading of the multiple alignment of the selected sequences was obtained by using the Boxshade 3.21 program (http://www.ch.embnet.org/software/BOX_form.html). On the basis of the alignment in supplementary Figure S1, we constructed a phylogenetic tree. *L. corsicanus* and *L. europaeus* were used as outgroups to root the tree. The evolutionary profile was determined using the MEGA 5 program (Tamura et al., 2011) and the neighbor-joining method (Saitou and Nei, 1987). The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown next to the branches (Felsenstein, 1985). The program DnaSP (Version 5.0) (Librado and Rozas, 2009) was used to sort haplotypes and analyze the number of variable sites (S), number of haplotypes (h), and haplotype diversity (Hd).

3. Results

The genetics of the Sicilian population of *O. c.* was studied using the *cyt b* mtDNA sequence, as described in Section 2. First, we compared the 13 isolated sequences with those of GenBank by using the Blast program, and we found that all the Sicilian sequences showed a high similarity (equal to 99%) to *O. c. cuniculus* (L., 1758), called lineage B by Branco et al. (2000). From our results, the reciprocal comparison between the *cyt b* nucleotidic sequences from the two annotated lineages, A (corresponding to *O. c. algirus*) and B (corresponding to *O. c. cuniculus*), showed 93% homology. Identity decreased to 85% when both sequences were compared with the *Lepus* species. The nucleotidic comparison between *cyt b* sequences from the Sicilian population and from other populations found in GenBank showed a high sequence identity (equal to 99%) with the sequences from France and South Africa, Canada, Sweden, and North Italy, and a lower sequence identity (equal to 93%) with sequences from Andalusia (South Spain) and Mexico.

We then compared the newly sequenced clones with a selected series of sequences found in GenBank from the two subspecies, *O. c. cuniculus* (L., 1758) and *O. c. algirus* (Loche, 1858), that for Branco et al. (2000) correspond to lineage A. In particular, the *cyt b* genes pertaining to both A and B lineages from other areas of the world such as Sweden, France, southern Spain, Mexico, southern Africa, Canada, and northern Italy were considered. The ClustalW2 multiple alignment of all 22 sequences analyzed here is shown in supplementary Figure S1. The results of the shading program in supplementary Figure S2 (where

the different nucleotides of Sicilian sequences with respect to lineage A are shaded) showed that there is intraspecific divergence for the mitochondrial *cyt b* gene. This divergence was higher between all the Sicilian nucleotidic sequences and lineage A with respect to lineage B.

The graphic phylogram (Figure 1B) shows that the main branch divides into two clades: one for lineage A and one for lineage B. Lineage B divides further into two branches: one giving rise to a group of 8 Sicilian sequences and another containing 5 Sicilian sequences besides those from France, South Africa, Canada, Sweden, and northern Italy. The higher bootstrap values indicate the accuracy of the data.

Polymorphic and haplotype analyses are shown in Table 2. A total of 75 variable sites were detected out of 954 total nucleotides. A total of 10 different haplotypes out of 15 analyzed sequences was sorted, indicating that individuals 10-Sicily/12-Sicily/13-Sicily/8-Sicily, 1-Sicily/6-Sicily, and 5-Sicily/9-Sicily were identical respectively, considering the mtDNA sequence analyzed here.

A genetic analysis of mitochondrial *cyt b* nucleotidic sequences conducted by analyzing the single cutter restriction enzyme analysis supported our investigations. Figure S1 highlights, in different colors, some of the most interesting and indicative single cutter restriction enzyme sites and their positions. Among the differences, a very interesting finding was the discovery that all Sicilian sequences contained an EcoRI restriction site at the same position (nucleotide 558 of the partial sequence considered here), a feature that was shared with lineage B, northern Italy, Canada, South Africa, and Sweden, but was in contrast to the sequences of lineage A and Mexico, which had no EcoRI site, as well as *L. europaeus*. The Sicilian sequences shared other typical restriction sites (HincII 148, AluI 806, DrdI 888) in an identical position with lineage B and were dissimilar to lineage A; the latter does not possess the DrdI site, and it possesses the other restriction sites in different positions (specifically, AluI 500 and HincII 439). The same Sicilian individuals did not contain a SalI restriction site, which is present only in Mexico and lineage A (at the same position of 437 of the partial sequence considered here) (see Figure S1).

4. Discussion

In this study, we applied genetic analysis as a complement to the previously defined phenotypic descriptors of the *O. c.* Sicilian population (Lo Valvo et al., 2014), by using the high variable region of *cyt b* mtDNA. In fact it rapidly accumulates nucleotidic substitutions, producing variants of mtDNA present in a single species, called haplotypes (Ingman et al., 2000). *Cyt b* mtDNA has been frequently used in mammals (Barome et al., 1998), including the wild rabbit from the IP (Branco et al. 2000), whereas this is the

first time it has been used for studying the taxonomy of the Sicilian *O. c.* population.

In addition to morphological data actually used to understand the phylogenetic characteristics of lagomorphs (Lo Valvo et al., 2014; Ge et al., 2015), the genetic and phylogenetic analyses have enabled variations in the genotypic traits to be identified. Here, genetics was useful to analyze the Sicilian *O. cuniculus* population and overall to distinguish which lineage this population belongs to out of the existing ones: lineage A (*O. c. algirus*) and lineage B (*O. c. cuniculus*), as described by Branco et al. (2000). Due to the possible intake of genetically different rabbits, which could cause a hybrid population with more health problems than the native Sicilian population that has evolved and already adapted itself to the environment, this new information can help to plan future strategies for the correct management and conservation of the Sicilian rabbit.

This study can also serve to stimulate further investigations of the genetic history of the rabbit in Sicily in order to reconstruct rabbit phylogeography in the Mediterranean, which has yet to be fully understood.

We conclude that the results related to the mtDNA analysis are consistent with the hypothesis that the Sicilian rabbit is more similar to *O. c. cuniculus*, in agreement with morphological data (Lo Valvo et al., 2014), and in disagreement with Toschi (1965), who ascribed the

Sicilian rabbit population to the *O. c. algirus* subspecies. Accordingly, Hardy et al. (1994) reported on rabbits from Zembra (Tunisia), a Mediterranean island near Sicily, belonging to the *O. c. cuniculus* subspecies. In a more recent study, rabbits from the island of Mallorca were identified as belonging to *O. c. cuniculus*, having origins from Iberian and French populations (Seixas et al., 2014). Instead, the IP population in the northeast was regarded as *O. c. cuniculus*, whereas populations in the southwest of the IP, North Africa, the Mediterranean islands (including Sicily), and the Portuguese Atlantic islands were considered as *O. c. algirus* (Branco et al., 2000; Esteves et al., 2004). All other introduced populations and domesticated varieties were considered to be descendants of the nominate subspecies (Monnerot et al., 1994; Branco et al., 2000; Branco and Ferrand, 2003).

Nevertheless, it is conceivable that an original form of *O. c. algirus* in Sicily has undergone a simple hybridization or a gene introgression after the introduction of *O. c. cuniculus* even if we have never found hybrids in Sicily. There has, moreover, not been sufficient time to determine whether *O. c. cuniculus* has been substituted by *O. c. algirus* because of the very recent intake of new rabbits on the island (in the 1980s). Thus, we hypothesize that the only species that has always lived in Sicily could be *O. c. cuniculus*.

Since mitochondrial DNA is inherited through the maternal line, given the large number of rabbits raised on Sicilian territory and the complex dynamics due to human-mediated introductions, only careful analysis conducted on genomic DNA can show whether the population of wild Sicilian rabbits belongs to a nominate subspecies or whether it is a hybrid population. If the second hypothesis were true, then this population would be a remarkable case study for evolutionary and conservation biology.

Furthermore, the Mediterranean-type ecosystem is characterized by hot, dry summers and mild, rainy winters. It is considered a very important center of biodiversity, after the tropics, and comprises the Italian Mediterranean Sea and the IP (Cowling et al., 1996), known as places of refuge for temperate species during past glaciations, as well as for rabbits (Taberlet et al., 1998).
